Peritoneal fluid can be noted on radiographs for up to 1–2 weeks, especially if the fluid is proteinaceous such as serum, blood, and lymph, which are absorbed more slowly. Solutions containing water and electrolytes are absorbed more rapidly by the peritoneal membrane and

might not be visualized after 24 hours on abdominal radiographs.

Depending on the surgical intervention, radiographic changes may or may not be present. Usually no changes are noted if a partial gastrectomy or gastric biopsies have been performed. Additionally, no displacement of the stomach would be expected with these procedures. If a gastropexy was performed to reduce the risk of a gastric dilation volvulus in the future, or to inhibit cranial movement of the stomach, it is expected that the pylorus will be near the right lateroventral abdominal wall. Commonly, the pyloric antrum will be displaced caudoventrally and will be noted caudal to the last rib. If an enterotomy or intestinal biopsy has been performed, usually no radiographic changes are expected. Radiographic changes are only expected if the surgery has led to adhesions or if an extensive intestinal resection has been performed.

Ultrasound can aid in visualizing the gastropexy or enterotomy site to evaluate healing of the suture site and for the presence of adhesions. The most common ultrasound features noted are alterations or loss of wall layering. An increase in wall thickness is commonly noted at the site of the gastropexy or enterotomy. An increased echogenicity of the mesenteric fat adjacent to the surgical site and variable amounts of peritoneal fluid containing hyperechoic particles may be noted. It is expected that the increased echogenicity of the mesenteric fat and the peritoneal fluid resolves in the majority of cases within approximately 10 days post surgery.

Large Intestine

The large intestine consists of the cecum, colon, and rectum. The cecum is a S-shaped blind-ending tube located usually in the right cranial abdomen at the junction of the ileum and colon. The colon is divided into three distinct anatomic areas: the ascending, transverse, and descending colon. The colon is attached by a short mesentery, which gives the colon a semifixed position in the abdomen. The ascending colon continues from the ileum at the ileocecocolic junction and runs in a cranial direction. The ascending colon is usually positioned caudal to the stomach and is frequently noted to the right of midline; the ascending colon continues into the transverse colon. The transverse colon is located caudal of the stomach and runs from right to left in the abdomen. The descending colon continues from the transverse colon and runs caudally along the left lateral aspect of the abdomen. Once the descending colon enters the pelvic canal, it is called the rectum, which continues to the anus.

Radiographic Examination of the Large Intestine

The cecum is located to the right of midline on ventrodorsal and centrally in the abdomen on lateral radiographic views. In the dog, usually a characteristic gas pattern of the cecum is noted (corkscrew- or C- or S-shaped appearance). In the cat, the cecum is not commonly seen. The colon is usually localized by its content. The ascending colon can be identified when filled with gas or fecal matter in the right cranial abdomen. The transverse colon can be noted caudal to the stomach and can be displaced caudally with enlargement of the stomach or pancreas. The descending colon is usually located left of midline, but if filled with a large amount of fecal matter and the patient has been held in a right lateral position, the descending colon may also be seen to the right of midline in normal patients. The rectum is the most caudal extension of the descending colon, starting at the pelvic canal and ending at the anus.

Radiographic evaluation of the colon includes evaluation of the content as well as the size of the colon. Most of the feces should be seen in the colon with only a small quantity present in the rectum. The normal diameter of the colon can be quite variable and depends on defecation habits and time since last defecation. However, radiographically, the normal colon diameter should be less than the length of the fifth or seventh lumbar vertebral body. The seventh lumbar vertebra is often more variable in length than the fifth and therefore using the fifth lumbar vertebra might be a more reliable tool in the decision-making process. Additionally, the colon diameter should be less than three times the diameter of the small intestine.

Ultrasound Examination of the Large Intestine

The ileocecocolic junction is usually noted in the right cranial abdomen, but it can be quite mobile. Orad to the ileocecocolic junction, the terminal portion of the ileum can be noted, which can easily be followed orad. The ileum has a distinct appearance, characterized by a prominent submucosal layer and often folded appearance of the luminal mucosa (see Figure 48.11). Adjacent to the ileum, the cecum can be seen, which is a blind-ending sac on one side and can be followed to the ileocecocolic junction on the other side. The cecum is often difficult to examine using ultrasound, especially in the dog, where the presence of gas in its lumen may limit its evaluation. In the cat, the cecum usually does not contain gas and therefore it is easier to evaluate. The cecal wall tends to be more hypoechoic than the colon wall and has an irregular luminal mucosal surface. From the ileocecocolic junction, the ascending colon can be followed cranially into the transverse colon, which then can

be followed caudally into the descending colon. The descending colon can also be seen caudally in the abdomen, dorsal to the urinary bladder. Ultrasonographic assessment of the rectum is limited due to its location within the pelvic canal and therefore it is not accessible with ultrasound. The cranial aspect of the rectum may be visualized by tilting the ultrasound probe caudally from cranioventral to the pelvic floor. Positioning the ultrasound probe from caudal in the anus area and tilting it cranially can visualize the caudal aspect of the rectum.

Due to the typically hyperechoic content (fecal material and gas) in the colon, the colon wall close to the ultrasound probe may be the only aspect of the wall that is easily seen. The colon wall has a characteristic ultrasound appearance and is usually hyperechoic relative to the small intestine. All five layers of the colon wall are of equal thickness and are thinner than in the small intestine (see Figure 48.11). The colon wall in the dog and cat is usually very thin and only measures 1–2 mm in thickness, rarely exceeding 3 mm in normal dogs. If the colon is very empty, luminal folding of the colon wall can be noted and the wall might subjectively appear thickened. It is a common finding that no peristalsis is noted in the colon.

Barium Examination of the Large Intestine

Indications for performing a contrast study of the colon include evaluation of the position and appearance of the colon, the presence of strictures, suspected intussusception, masses associated with the colon, congenital abnormalities, or colitis. Patient preparation should include fasting for 24 hours if no preexisting clinical contraindication is present. If only positional information of the colon is needed, a pneumocolonography might provide sufficient information. It is important to remember that an upper gastrointestinal contrast radiographic study is often insufficient for evaluation of the colon as the colon is incompletely distended with contrast material and as fecal material often creates intraluminal contrast filling defects, which can be misinterpreted as mural or intraluminal lesions. Therefore, if a contrast study is performed to evaluate the colon wall, a more extensive preparation of the patient is required to ensure that the colon is empty.

Patient preparation should include a laxative 24 hours prior to cleansing enemas of the colon. For the contrast radiographic procedure, sedation or anesthesia is preferred as it limits straining by the patient. Barium enemas are best performed by placing a soft-tipped catheter with an inflatable cuff within the anal sphincter. The cuff should be gently expanded to avoid overextension of the rectum or anal sphincter. In unsedated patients, expansion of the cuff or placement of a catheter into the rectum might not be tolerated. Barium sulfate suspension (5%) at 7–14 mL/kg bodyweight should be slowly infused (over 5–7 min) to allow contrast to extend to the ileocolic junction. If available, fluoroscopy can be used to monitor the advancement of the contrast agent within the colon and especially to ensure that contrast is not infused beyond the ileocolic junction. Once the contrast agent is infused, the catheter should be closed off and the patient should be gently rolled to allow for uniform coating of the colon. Ventrodorsal and right lateral radiographic views should be obtained and additional views should be added as needed to fully evaluate the colon.

Double contrast radiography of the colon (double contrast colonogram) can be performed by slowly and carefully insufflating air into the colon after a barium enema has been performed. Double contrast colonography can improve evaluation of colon wall lesions, help identify strictures, and improve evaluation of the ileocecocolic junction.

The mucosal surface of the colon should be smooth, continuous, and well defined when the colon is filled with barium contrast agent. In the colon of the dog, small lymph follicles can be found and this might present radiographically as small focal areas of thickening of the colon wall or spicules similar to very small ulcers. These areas should become less apparent once the large intestine is distended. In the cat, the largest aggregate of lymph follicles can be noted in the ileal area and apex of the cecum; however, this is usually not discernible on radiographs.

Pneumocolonography

The most common reason pneumocolonography is performed is to gain positional information about the colon, allowing differentiation between small and large intestines. Pneumocolonography provides a quick, safe, and easy way to outline the entire colon but provides only limited information about involvement of the mucosa, wall thickness and areas of the colon which cannot be distended. In cases where a wall lesion is suspected, a barium enema should be performed. Pneumocolonography is most easily performed by using either a soft-tipped catheter or catheter-tipped syringe placed within the anal sphincter. In general, 1–3 mL of air/kg bodyweight should result in sufficient filling of the colon. It is important to ensure that the entire colon, including the cecum, is filled and distended with air. It is important to close off the catheter or syringe once the colon is insufflated to ensure that the air does not escape. Ventrodorsal and right lateral radiographic views should be obtained and additional views should be added as needed to fully evaluate the colon.

Computed Tomography of the Large Intestine

Computed tomography can be an excellent technique for evaluating the large intestine. Similarly to radiography, contrast is often needed to distend the colon and evaluate all aspects of the intestinal wall. When the colon is empty and the intestinal walls are collapsed, intestinal wall lesions are very difficult or impossible to identify. Additionally, if large amounts of fecal matter are present in the colon, artifacts created by this might limit visualization of the colon wall. Therefore, similar to radiography, optimal patient preparation, including cleansing enemas, should be performed before a contrast CT study of the abdomen is performed to evaluate the colon. The normal anatomy of the colon and regional lymph nodes is easily evaluated using CT and the ability to perform dorsal and sagittal reconstructions of the CT images helps to gain a better three-dimensional understanding of normal anatomy or pathologies. The colon wall is thin and measures 1–2 mm in thickness.

Virtual endoscopy using CT images can be performed. However, currently its use and clinical value are limited as CT does not allow assessment of the color of the colon wall or to obtain biopsies at the same time and evaluation of the wall is limited (Figure 48.30).

Inflammatory Disorders of the Large Intestine

In the acute phase of colitis there may be no abnormality present on survey or contrast radiographic studies. Infrequently, in cases of mild colitis, contrast radiographic studies show a mild thickening of the intestinal wall. Small areas of focal thickening, consistent with ulceration, may be noted. In more severe forms of colitis, more extensive thickening of the colon wall with larger areas of ulceration may be noted on contrast radiographic studies. With increasing disease severity, spasm of the colon might be present. With chronic colitis, decreased width, shortening and enlargement of the colon have all been described.

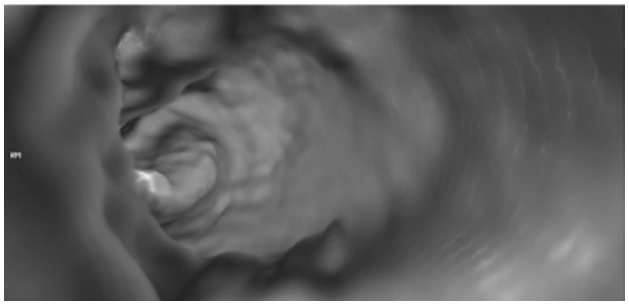

Figure 48.30 Virtual colonoscopy. Three-dimensional reconstruction virtual colonoscopy image of a normal colon. Several colonic folds are visible.

On ultrasound examination, increased thickness of the colon wall with loss of wall layering and decrease of echogenicity of the colon wall may be noted. Mild regional lymph node enlargement may be present.

Typhlitis can be challenging to diagnose clinically as well as via imaging techniques. In mild to moderate typhlitis, no radiographic changes are often noted; in severe typhlitis on contrast radiographic studies, similar changes as seen in colitis can be noted. On ultrasound, thickening of the cecum wall with a decrease of echogenicity of the wall layers might be noted (Figure 48.31).

Tumors of the Large Intestine

Tumors of the large intestine account in dogs for more than 60% of the gastrointestinal tumors diagnosed; however, it is important to remember that the prevalence of gastrointestinal neoplasms in dogs is still only 3–10% of all tumors diagnosed. Some benign tumors, especially when polypoid, might not require extensive imaging. Survey radiographs are often negative and do not provide additional information. Contrast radiography using a barium enema or double contrast colonography may allow localization of the colon wall thickening. However, colonography only allows limited evaluation of regional lymph nodes and other abdominal organs, such as the liver. Therefore, if a malignant lesion is suspected, contrast-enhanced CT or ultrasound (Figure 48.32) are preferred. These techniques allow not only visualization of the colon wall mass, but also staging of regional lymph nodes, the peritoneum, and parenchymatous organs. If a colon wall mass is suspected, CT may be preferred over ultrasound, as lesions within the pelvic canal show only limited accessibility using ultrasound due to the lack of penetration of the ultrasound wave through the osseous structures of the pelvic canal.

Megacolon

Megacolon is a broad descriptive term indicating enlargement of the colon, which can be due to lack of innervation or abnormal innervation of the colon wall, mechanical obstruction (e.g. malunited pelvic fractures, neoplasia, rectal stricture) or dietary or psychogenic causes. Idiopathic megacolon is the most common reason reported in the cat for enlargement of the colon. Patients with megacolon often have a history of constipation, painful or difficult defecation or tenesmus.

Classic radiographic findings in dogs and cats include a marked increase in the diameter of the colon (Figure 48.33). If the colon measures more than 1.5 times the length of the fifth or seventh lumbar vertebra, or more than three times the diameter of the small intestine, this is suggestive of a megacolon.

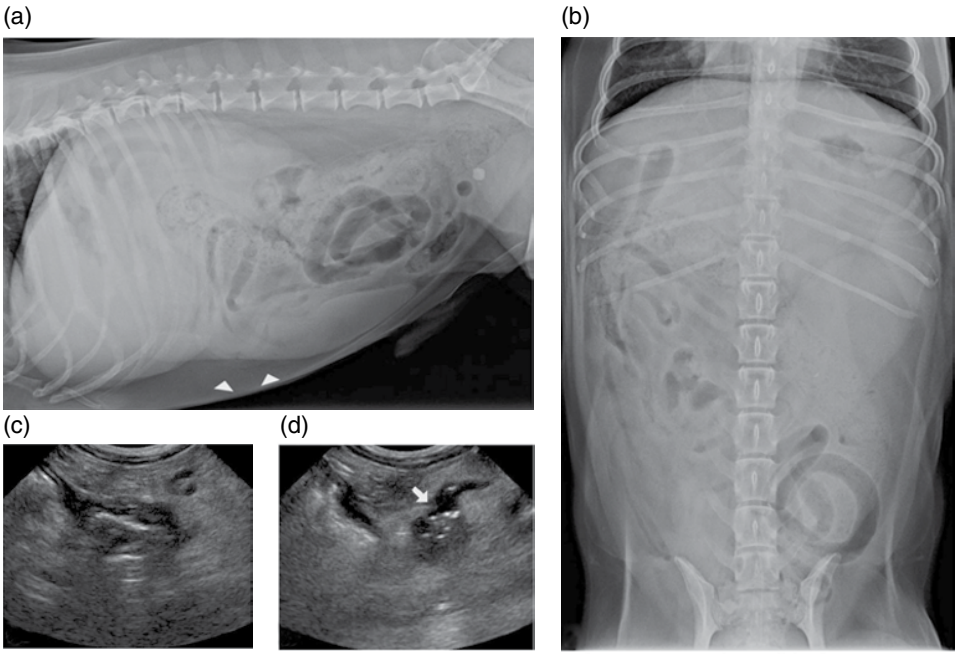

Figure 48.31 Cecal perforation secondary to typhlitis. Right lateral (a) and ventrodorsal (b) radiographs of the abdomen demonstrated a loss of serosal detail and a small amount of peritoneal free gas. The origin of the gas was not identified on radiographs; however, an intestinal perforation was suspected. A urinary bladder stone was noted. Longitudinal ultrasound images of the cecum (c) and ileocecocolic area (d) illustrating thickening of the cecum wall with loss of wall layering and decrease in echogenicity. A small amount of peritoneal fluid with hyperechoic specular reflectors, characteristic of gas, is noted adjacent to the cecum. In surgery, a perforation of the cecum was noted. The cecum was removed and histopathology confirmed typhlitis.

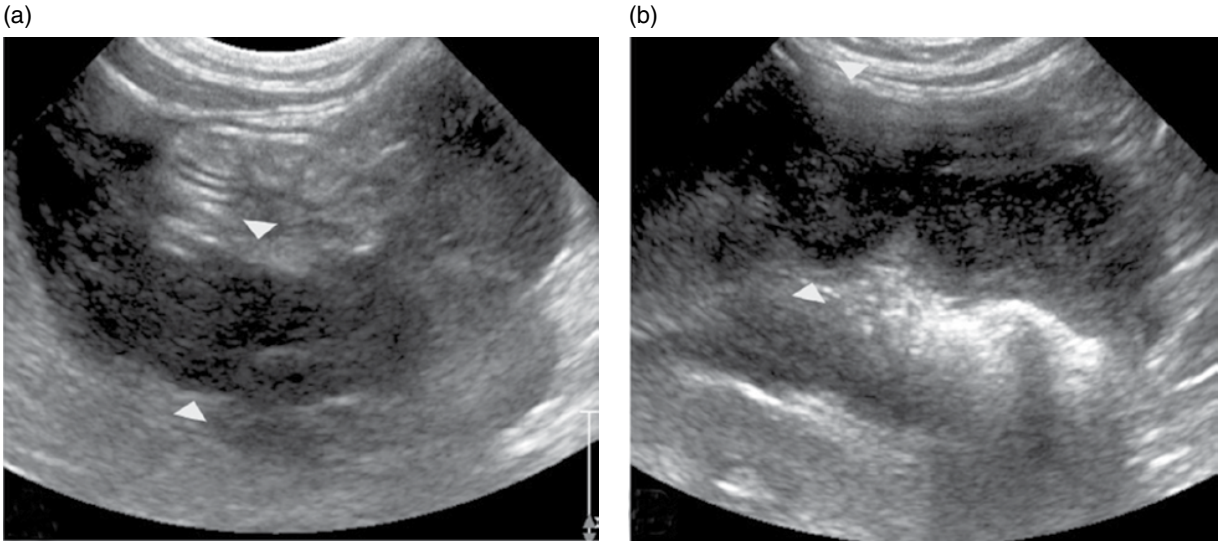

Figure 48.32 Lymphoma of the colon wall in a cat. Transverse (a) and longitudinal (b) ultrasound images of the descending colon. The colon wall is severely thickened (*arrowheads*) with a loss of wall layering and a decrease in echogenicity.

Megacolon Secondary to Abnormal Innervation or Smooth Muscle Function

Several diseases such as cauda equina syndrome, sacral spinal cord deformity in Manx cats (sacrococcygeal agenesis), aganglionosis or hypoganglionosis of the colon wall can lead to megacolon.

Radiographically, patients with abnormal innervation or smooth muscle functional abnormality of the colon wall may present with various degrees of enlargement of the colon (Figure 48.34). With aganglionosis or hypoganglionosis of the colon, a severe dilation of the colon is noted. This dilation often abruptly narrows towards the

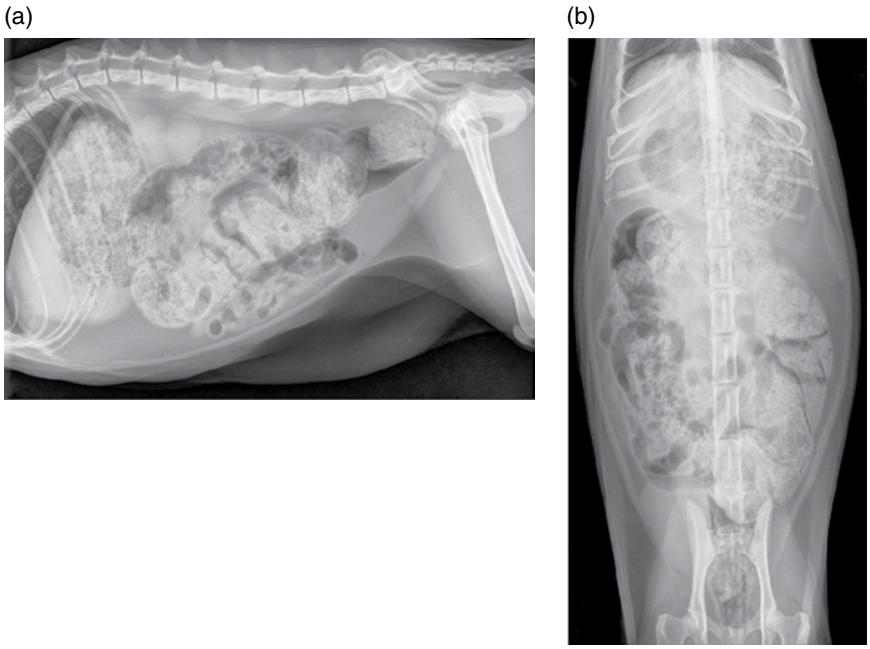

Figure 48.33 Megacolon in an obstipated cat. Right lateral (a) and ventrodorsal (b) radiographs illustrating a severely enlarged colon. The fecal material is mineral attenuating and large desiccated fecal balls, which cannot be emptied, are noted in the descending colon to rectum.

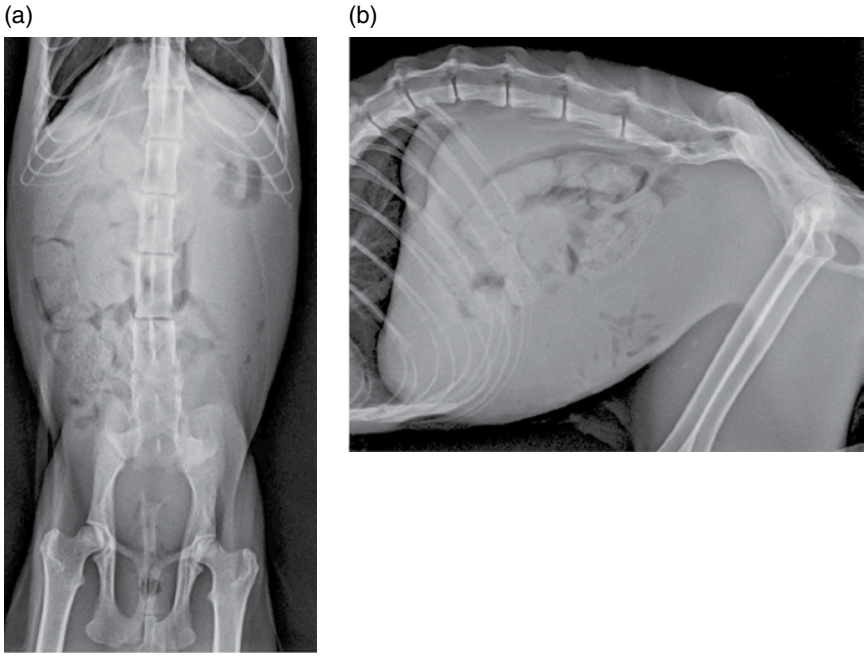

Figure 48.34 Lumbosacral malformation in a Manx cat with secondary megacolon. Ventrodorsal (a) and lateral (b) radiographs of the abdomen illustrating a fusion of the last lumbar vertebra and sacrum. The colon is filled with fecal matter and dilated. A reduced serosal detail is noted in the abdomen. The cat is emaciated.

rectum and anus, as these segments of the intestinal tract are frequently not involved in the disease process (Figure 48.35).

Large Intestinal Mechanical Obstruction

Large intestinal mechanical obstruction can lead to megacolon. Radiographically, in contrast to patients who have a lack of nerve or muscle function of the colon wall, dilation of the colon and rectum can be noted. In these cases, the osseous and soft tissue structures of the pelvis and lumbosacral spine should be carefully evaluated for the presence of pathologies causing obstruction of the large intestine. Radiopaque foreign material such as stones (Figure 48.36) or metallic objects can easily be identified on survey radiographs. Once a foreign object has made it through the small intestinal tract into the colon, it is usually expected that it will pass unhindered through the colon.

In dogs with prostatic enlargement or neoplasia, with or without secondary sublumbar lymphadenopathy, a

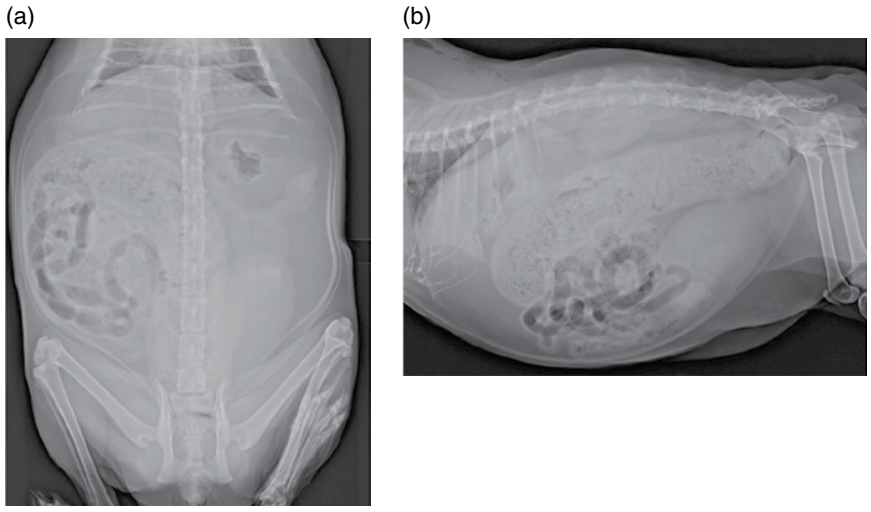

Figure 48.35 Severe megacolon in a Manx cat. Ventrodorsal (a) and lateral (b) radiographs of the abdomen illustrating severe distension of the colon with fecal matter. The colon narrows abruptly towards the rectum. A small amount of urinary bladder sediment is noted. A small amount of subcutaneous emphysema from a subcutaneous fluid injection is present.

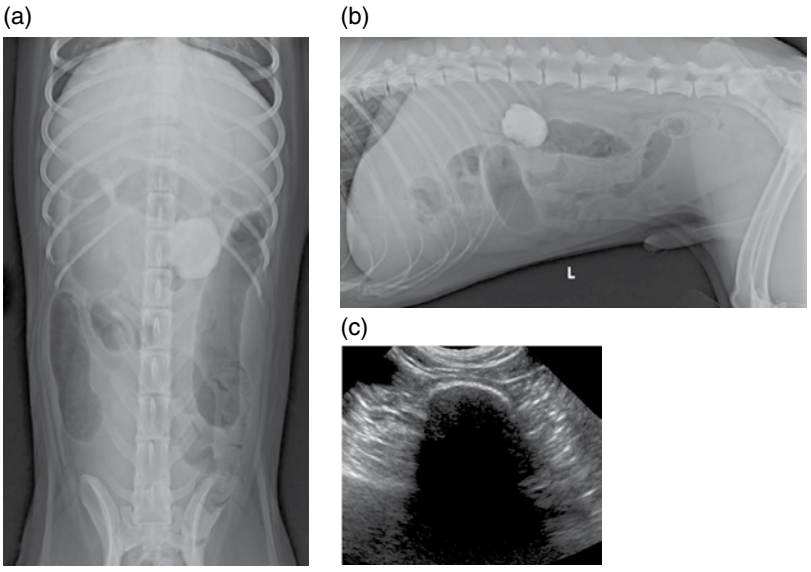

Figure 48.36 Stone in colon. Ventrodorsal (a) and left lateral (b) radiographs of the abdomen of a dog. A mineral attenuating structure (stone) is noted summating with a gas-filled loop of intestine on the lateral radiograph. On the VD radiograph, the stone is summating with the descending colon. The small intestines are in part fluid filled and in part gas dilated, which was concerning for a mechanical ileus. Transverse ultrasound image (c) illustrating a hyperechoic, distally shadowing structure representing the stone within the colon. No small intestinal obstructive disease was noted.

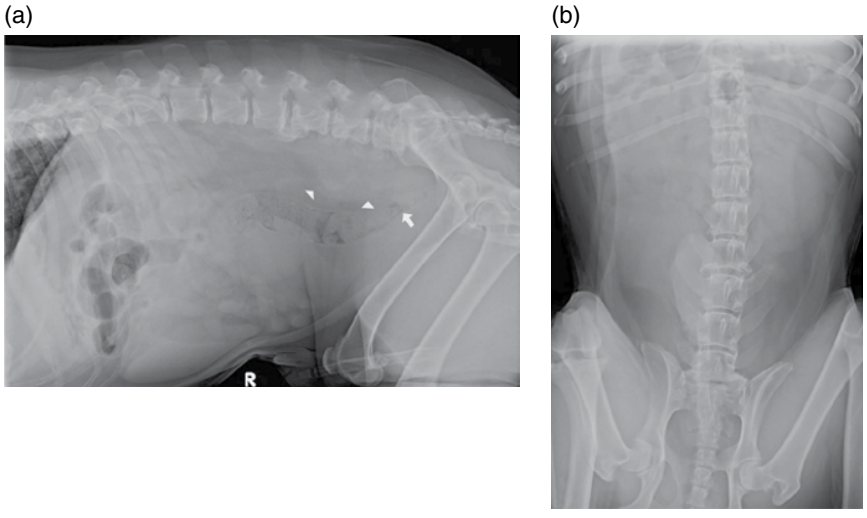

Figure 48.37 Severe sublumbar lymphadenopathy secondary to prostate neoplasia. Right lateral radiograph of the abdomen illustrating ventral displacement and compression of the descending colon (*arrowheads*) secondary to severe sublumbar lymph node enlargement due to prostate neoplasia and metastases to the lymph nodes.

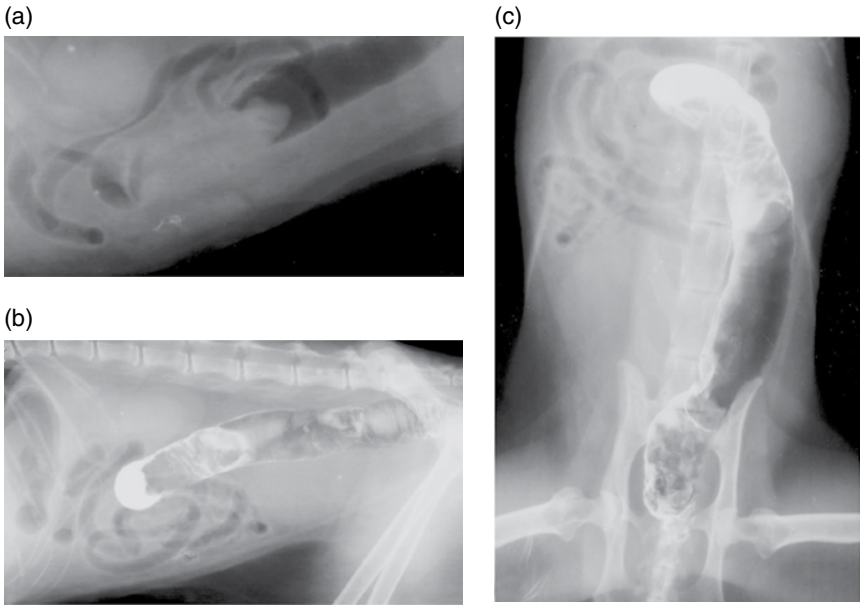

Figure 48.38 Colonocolic intussusception. On survey radiographs (a), a soft tissue attenuating mass with rounded borders is noted in the cranial aspect of the descending colon. After a barium enema was performed (b,c), a contrast-sparing filling defect is noted in the colon. This study was followed by an upper gastrointestinal contrast study to evaluate the position of the ileum. A colonocolic intussusception was confirmed at surgery.

dorsal displacement and compression of the colon is commonly noted. Additionally, if sublumbar lymphadenopathy is present, the descending colon ventral to the caudal lumbar to cranial sacral spine is ventrally displaced (Figure 48.37).

Cecal or Colonic Intussusception

The most common intussusceptions seen in the colon are ileocolic, cecocolic, and colonocolic. The intussusception might be seen as a soft tissue attenuating mass with round borders within the colon on survey radiographs, especially when the colon is gas filled (Figure 48.38).

In ileocolic intussusception, the cecum and ascending colon are not filled with gas, whereas in normal dogs some degree of gas filling is normally seen in the cecum. In cecocolic intussusception, the cecum can be seen as a radiolucent filling defect in the colon on a barium enema. The ileocolic junction and ileum are persistently normally seen (Figure 48.39).

Colonic Torsion and Volvulus

Colonic torsion and volvulus is a rare disease that has a high mortality, similar to gastric and small intestinal torsion and volvulus. A moderately to severely distended colon can be noted and the colon can be abnormally positioned. Frequently the colon is displaced cranially (Figure 48.40). However, radiographic findings in colonic torsion or volvulus may also be nonspecific and early exploration might be necessary to correctly diagnose and correct a colonic torsion or volvulus.

Figure 48.39 Cecocolic intussusception (cecal inversion) in a dog. Ventrodorsal radiograph post barium enema demonstrating an irregular-shaped radiolucent filling defect in the ascending colon, which is representing the cecum intussuscepted into the colon. The ileum and ileocolic junction are normal and contrast filled. No normal positioned cecum is identified.

Congenital Abnormalities of the Colon

A variety of congenital abnormalities have been described for the colon in the dog and cat including a short colon, atresia ani or rectum, double colon, diverticula, and fistula.

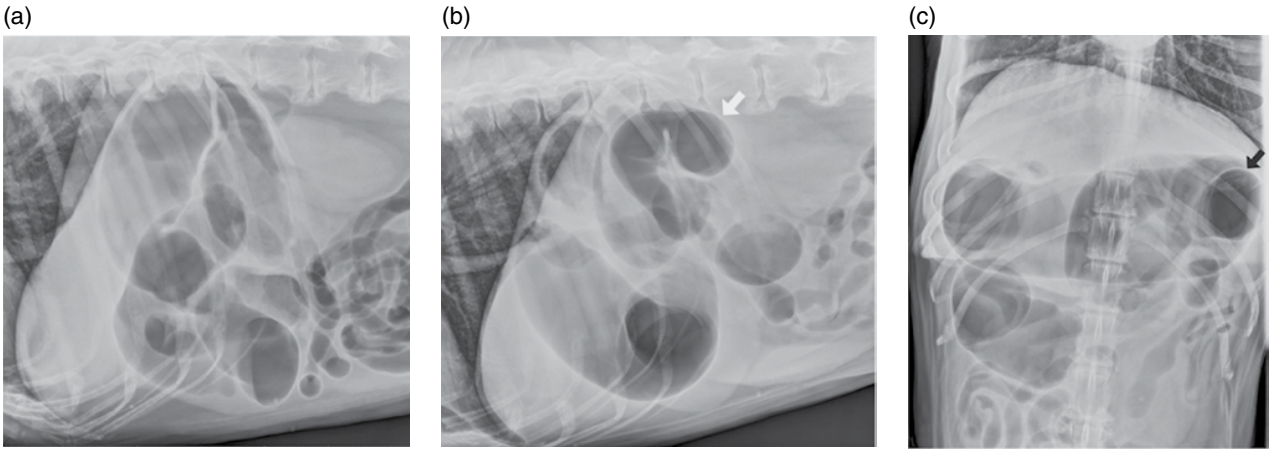

Figure 48.40 Colon torsion. Left lateral (a), right lateral (b), and ventrodorsal (c) radiographs of the abdomen of a dog. The colon is severely gas distended and cranially displaced. The cecum is dorsally and left laterally displaced (*arrows*). Most of the small intestinal segments are gas filled.

In patients with a short colon, the ileocecocolic junction is often positioned left lateral of midline at the cranial aspect of the descending colon. The clinical importance of this finding is unclear. Most congenital colon abnormalities require a contrast-enhanced study, either using radiography or CT, to fully evaluate the extent of the lesion. Especially when fistulae are present, a combination of an iodine enema and the use of intravenous iodinated contrast agents using CT might provide the best anatomic information. In diverticulae, a herniation of the mucosal layer through the muscular wall occurs. If a diverticulum is present in the rectum, it might be confused with sacculation on physical examination. Rarely, a diverticulum can rupture, which can lead to a significant retroperitonitis and peritonitis, which can be recognized radiographically by free peritoneal and retroperitoneal gas.

Displacement of the Colon

The most common displacement of the colon and/or rectum is into the perianal area, which occurs secondary to weakening or rupture of the pelvic diaphragm (perineal hernia). In addition to the displacement of the colon and/or rectum, retroflexion of the urinary bladder can occur, which causes obstruction of the urethra. On radiographs, usually a soft tissue attenuating mass can be seen in the perianal area usually ventral and lateral to the tail. This is often best seen on lateral radiographs. On ventrodorsal radiographs, lateral or caudal deviation of fecal matter in the colon and rectum may be noted. Sometimes a sigmoid shape of the colon and rectum can be seen.

Gastrointestinal Endoscopy

Craig Ruaux, BVSc (Hons), PhD, MACVSc, DACVIM (SAIM)

School of Veterinary Science, Massey University, Palmerston North, New Zealand

Gastrointestinal endoscopy is an attractive diagnostic tool for many gastrointestinal disease cases presenting to companion animal practitioners. This technique can allow direct visualization of the gastrointestinal mucosa in the esophagus, stomach, upper part of the small intestine, colon, and distal ileum. While some of these procedures are straightforward, entry into the upper part of the small intestine and the distal ileum can be quite challenging in some patients.

Endoscopy is often viewed as a much less invasive method of obtaining gastrointestinal mucosal biopsy samples than can be achieved with either exploratory laparotomy/celiotomy or laparoscopy-assisted full-thickness biopsies. While endoscopic biopsy has an advantage of lower risk and less perioperative morbidity, the quality of endoscopic biopsy samples is often found wanting. This is particularly the case with the use of smaller endoscopes with very narrow biopsy channels that limit the size of the biopsy instruments that can be passed.

With refurbished flexible endoscopy systems becoming more readily available on the market, and at reasonable prices, there is increasing utilization of these instruments and procedures in generalist practices. Competence in flexible gastrointestinal endoscopy requires meaningful amounts of hands-on practice, and guidance from an experienced operator in a hands-on training environment is the best way to achieve competence in a short period of time. The purpose of this chapter is to provide an overview of flexible endoscopic equipment types, correct handling and manipulation of the endoscope, methods for obtaining biopsies, a general overview of the steps for several endoscopic procedures, and the use of flexible endoscopy for some minimally invasive therapeutic procedures such as feeding tube placement and foreign body retrieval.

Endoscopy Equipment Options

All visual light endoscopes operate by channeling light from an external source, via fiberoptic light guides, to the area of interest. This light then illuminates the area being examined, and an image is formed. The actual mechanism leading to image formation is typically from one of two options: either the use of additional fiberoptic elements to return the light via an objective lens at the operating end of the scope (these are commonly called fiberscopes), or via direct capture of a digital image using an imaging chip at the distal, patient end of the instrument (videoendoscopes) (Figure 49.1). Fiberscopes represent an older technology, and are usually cheaper than equivalent-sized videoendoscopes, but they do have significant shortcomings. Fiberscopes are more affected by fiber breakage, as the image depends on light successfully traveling in both directions. The image is often quite dim, as there are more light losses involved with transit along the length of the scope and back. The generation of medical records with these endoscopes is also more difficult, requiring an accessory camera attached to the eyepiece, representing another potential point of failure. While fiberscopes were long the mainstay of flexible endoscopy in veterinary medicine, videoendoscopes are preferable due to superior image quality, greater ease of use, and greater ease of generation for permanent medical records.

Endoscopes used for gastrointestinal procedures should feature four-way tip deflection, allowing the deviation of the tip left or right of center and up or down. Tip deviation is defined relative to the midline of the control handle, with the control cluster in the operating hand. Some smaller scopes, designed for airway examination rather than gastrointestinal endoscopy, have only up and down deflection controls while left to right turns are made by turning the entire endoscope.

Figure 49.1 A typical flexible videoendoscopy "tower" as used for most gastrointestinal endoscopic procedures in companion animal medicine. In this particular system, the light generator and image processor are in the same unit, with separate vacuum pump and image printer. In other systems the light source and image-processing functions may be separate components. Note the large monitor and scope rack at the top of the tower. While the scope rack is a safe place to rest the scope during the procedure, it is not recommended to transport the scope (particularly longer and heavier colonoscopes) on this rack when moving the tower.

Flexible endoscopes are available in a variety of sizes, with variations in both diameter and length. Greater diameter endoscopes will typically have larger working channels, allowing the use of larger biopsy instruments, snares or foreign body retrieval devices. Larger diameter endoscopes also have greater intrinsic stiffness, which can be both beneficial (passing through restrictions such as the antrum and pylorus is easier with a stiffer endoscope) and a complicating factor (it is difficult to make very tight turns in very small animals). Generally, a flexible endoscope of around 7–9 mm diameter overall, and working length of 120–150 cm, will be adequate for gastrointestinal procedures in most companion animal practices. This length may be limiting, however, for full upper gastrointestinal examinations or colonoscopy in very large-breed dogs.

Bronchoscopes are not recommended for gastrointestinal endoscopy, as simultaneous up/down and left/right tip deflections are important for successful navigation of the upper gastrointestinal tract; it is almost impossible to achieve this when the endoscope has already made several turns to reach the gastric antrum and pylorus.

Most operators hold the control cluster in the left hand while holding and advancing the body of the endoscope with the right hand. Operators with large hands may be able to manipulate the control wheels using the fingers and thumb of the left hand, while operators with small hands will need to operate the control wheels with the right hand while supporting the control cluster with the left hand. The tension control levers (Figure 49.2) are very useful for operators who must alternate between right hand control manipulations and endoscope advancement. With very long endoscopes, longer than those typically used in companion animal practice, two operators may be necessary to control endoscope advancement and tip deflection separately.

Record Keeping for Endoscopy Procedures

Endoscopic examination findings are a critical part of the medical record in patients undergoing these procedures. Generation of a report will typically involve image capture from the endoscope and a written report detailing findings and observations. Image captures should contain sufficient information to identify the patient, along with the date of examination.

The actual content of the written component of the report will obviously vary depending upon the area being examined. The World Small Animal Veterinary Association (WSAVA) has produced template documents encapsulating the essentials for endoscopy reports for upper and lower gastrointestinal tract endoscopy procedures; these files are available to download from www.wsava.org/guidelines/gastrointestinal-guidelines. These forms include a section for recording the other documentation modalities used, but the guidelines do not make any particular recommendations regarding the best choice of image capture modality.

Image capture systems are very variable, and all have strengths and weaknesses. For quite some time, the use of video printers, which capture images from the processing unit and print to photographic paper, was the standard method. While some systems and practices continue to use these printers, the specific printer technology used (dye sublimation) is rarely used in

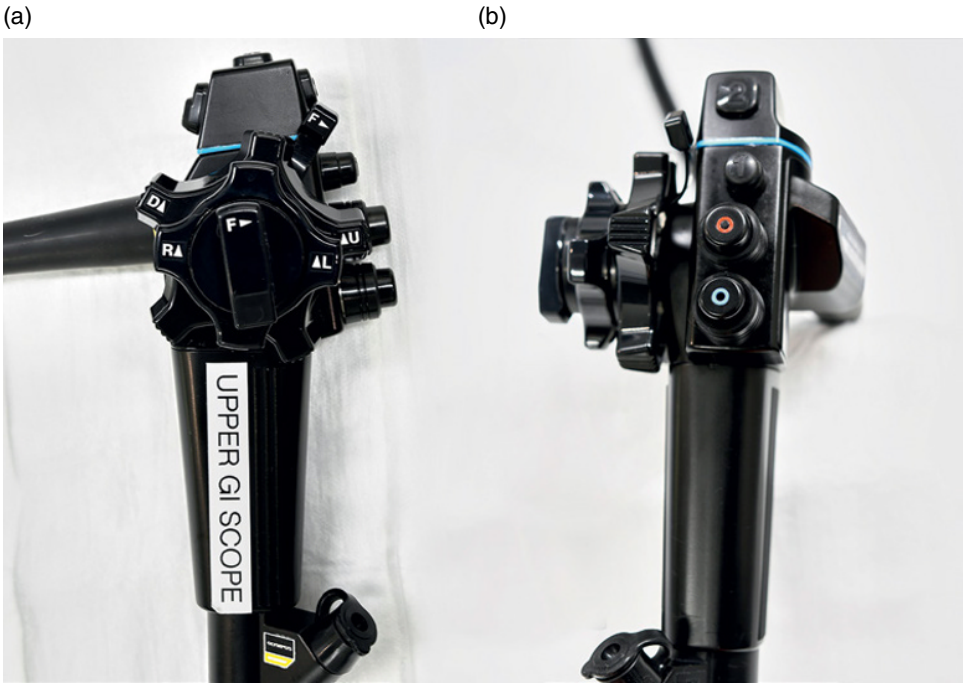

Figure 49.2 Control cluster of a typical flexible videoendoscope, in this case a gastroduodenoscope. (a) The control wheels, labeled U^ D^ and L^ R^, control tip deflection up/down and left/right, respectively. The direction of tip deflection is in reference to the center line and upper surface of the control cluster. Outside the U-D wheel, and in the center of the L-R wheel are a lever and wheel, respectively, marked F>; these are tension controls (labeling indicates the direction to give greater freedom of movement) that can be used to reduce tip deviation freedom. (b) A selection of buttons on this particular endoscope pause video capture and trigger still image capture; these are not present in this position in all endoscopes of this type. Below the two image capture buttons, a press button with a red outer rim operates suction. The bottom button, with a blue rim and small hole in the center, is a combined air/water insufflation control. Placing the operator's finger over the central hole without depressing the button will cause air insufflation, while pressing down the button causes water to be delivered from the end of the scope, washing across the distal lens. While other endoscopes from other manufacturers may have different colored or shaped buttons, the positioning of vacuum above air/water insufflation is standard across all manufacturers. Below the control buttons, a black rubber cuff is apparent; this is the seal for the working channel.

commercially available printers, thus these printers and their disposables (ink ribbons, specific papers) are expensive and increasingly difficult to source. These printer systems are hard to recommend for integration into modern veterinary practice workflows.

At the opposite extreme from the traditional dye sublimation printer, some modern endoscopy systems are able to record digital video or digital still image captures from the endoscope in real time, and then export the resulting files to either a hospital-wide DICOM system or directly into a hospital electronic record system. These capabilities are very useful for streamlining record management in busy practices, and also provide the ability to show captures to clients and generate multiple copies that can be saved to removable media or transferred digitally via email. The specific hospital management systems and DICOM products that endoscopy systems can interface with vary by manufacturer, and should be considered if a practice is planning to purchase a newer system. Aftermarket image capture and DICOM export hardware are also available from some vendors, again these systems can require significant configuration and software support, which should be clarified during the purchasing process.

A final option that is commonly used with refurbished but older endoscopy systems is to attach some form of recording device (commonly a CD or DVD recorder) to a video output from the endoscope processor. In some cases, it is possible to configure these systems to trigger capture using either a foot pedal or the capture button on the endoscope, but again as technology progresses and changes, this is becoming increasingly difficult. The simplest, but most risky, option is to simply collect and record all video from the video output and record it as a continuous stream. If doing this, it is important to consider the length and size of the recording, as many upper and lower gastrointestinal tract endoscopy procedures will last for 1.5 hours or more. Use of CD/DVD recorder systems also requires the endoscope operator or assisting technical staff to remember to start and stop recording, and finalize the recording to allow burning the final disk. The disks themselves have variable, and often short,

useful lives after burning, and may not survive for the duration necessary to meet legal requirements for record keeping in some localities.

Given the combination of workflow advantages, archivability, and integration with other hospital systems, systems that can achieve digital capture and archiving are generally the best option currently available, and will have the greatest future proofing.

Endoscope Handling

General Manipulations

The endoscope is a fragile instrument and needs to be handled carefully and appropriately to avoid damage to the scope and minimize risk to the patient. Gastrointestinal endoscopy requires an adequate plane of anesthesia. Mouth blocks or gags should be used to keep the mouth open while carrying out upper gastrointestinal tract endoscopy. These both make entry of the endoscope into the upper gastrointestinal tract easier, and provide a degree of protection against the endoscope body being bitten if patient anesthesia is inadequate.

Operation of the endoscope relies on fine control wires that extend from the control cluster to the tip of the scope, while light transmission and image formation rely on the fine fiberoptic strands within the scope body. Both of these components can be damaged if placed under excess stress. To minimize stress on the endoscope components, it is best to make fine adjustments of the operating tip that allow general visualization of a target area, while larger deviations and turns are made by turning the whole endoscope body rather than applying significant strain to the endoscope tip. A fine adjustment is made using the control wheels, the scope is advanced and turned using the entire scope body, then additional adjustments are made to gradually bring the endoscope into the desired position.

Visualization of some areas of the gastrointestinal tract, particularly the gastric cardia and aboral surface of the esophageal sphincter, requires more stressful maneuvers. Visualization of the cardia and lower oesophageal sphincter usually requires a "J-maneuver" where the tip of the endoscope is placed into maximal upwards deflection (Figure 49.3). This position is particularly stressful on the mechanical components of the endoscope, and should only be used for as long as needed to adequately visualize the anatomy in this region.

Passage of the endoscope through the pylorus into the proximal duodenum is mildly stressful on the endoscope, as in many dogs it requires a simultaneous downwards and right tip deflection while pushing against some resistance. Once the pylorus has been traversed, however, there is little to no stress applied to the endoscope as it is advanced along the duodenum.

Figure 49.3 Maximal upwards flexion of a flexible videoendoscope, necessary for visualization of the gastric cardia, aboral surface of the lower esophageal sphincter, and distal rectal lumen. This position is highly stressful on the endoscope control structures and fiberoptic elements, and should be held for as short a period as possible. Do not introduce the endoscope into a lumen (for instance, in an attempt to visualize the distal palate or rectum) while holding the endoscope in this position, as the additional compression on the distal end of the endoscope can cause severe damage.

The endoscope tip and body should be lubricated with a water-based lubricant before introduction into the gastrointestinal tract. In the initial stages of the upper gastrointestinal examination, particularly with smaller dogs and cats, there is a risk that the endoscope may slip out of the esophagus and, if not being held by the operator, the tip may fall and hit the floor or other hard surfaces, risking damage to the imaging system or the fiberoptics. This can be particularly problematic for operators with smaller hands who need to take their right hand off the endoscope body to make tip deflections. Having an assistant hold and advance the endoscope body independently from the main operator can minimize the risk of scope dislodgment and damage.

Biopsy Instruments and Working Channel Use

The biopsy and vacuum channel of the endoscope are lined with a thin, rubberized material to allow adequate flexibility while keeping the fiberoptics, control wires, and imaging electronics sealed against water ingress. Damage to the inner lining of the biopsy/vacuum channel can result in scope flooding and costly repairs, as the entire endoscope must be disassembled to repair and replace these parts.

It is imperative that biopsy instruments and retrieval snares/baskets are held closed or within their protective outer sheath when passing through the endoscope. Open biopsy jaws or exteriorized retrieval instruments can puncture or otherwise damage the internal lining of the endoscope.

Occasionally, it is necessary to biopsy lesions that require significant tip deflection for adequate visualization. A mass on the aboral surface of the esophageal sphincter, for instance, will require a J-maneuver for adequate visualization (see earlier). Attempting to pass a biopsy instrument through the endoscope while it is in this position is risky as the instrument is directly pushing against the channel lining. It is less risky to retract the endoscope slightly to allow the tip to relax, pass the instrument until it is visualized leaving the endoscope and within the gastric lumen, then return to the maximally flexed position to obtain the biopsy. Obtaining an adequate biopsy from masses in this region can be quite difficult, as the severe turns of the endoscope restrict the ability of the biopsy instrument to move within the channel.

After a biopsy is obtained, the biopsy instrument should be kept completely closed until it has been entirely removed from the biopsy channel. Foreign bodies are retracted with the retrieval instrument until they are close to the operating end of the endoscope, then removed by retracting the entire endoscope.

Endoscope Cleaning and Maintenance

Care and maintenance of endoscopes require attention to detail, care with handling of the instrument, and the use of appropriate cleaning products and equipment. These are expensive and fragile pieces of equipment, and repair costs are high. Generally speaking, it will be best for only one or two specific individuals (practitioner or technician) to be tasked with cleaning and maintenance of flexible endoscopes to ensure consistency of handling and adequate knowledge of the necessary steps. While some general observations are given here, manufacturer's guidelines should be followed. This is particularly important with respect to cleaning fluid selection, as different manufacturers use differing materials in their endoscopes that may be damaged by inappropriate cleaning solution use.

Endoscopes must be thoroughly and effectively cleaned, on both external surfaces and within the biopsy/vacuum and air/water channels, after use and before storage. On completion of an examination, it is good practice to suction plain or distilled water (not saline) through the endoscope to clear material that may have lodged within the working channel. The exterior body of the endoscope should be wiped down with water-moistened wet gauze or toweling to remove grossly contaminating material.

Complete cleaning of the endoscope requires several steps and use of different cleaning products to achieve both physical cleaning and sterilization.

The first step of cleaning is typically achieved with an enzymatic detergent solution. The endoscope is soaked in this solution, then the outer surfaces gently wiped down. The detergent solution is also pumped through the biopsy and air/water channels using a manifold (Figure 49.4) that attaches in place of the removable buttons. If manually cleaning the endoscope, these channels are then further cleaned by passing specific cleaning brushes.

After lower level cleaning with the enzymatic/detergent solution, higher level sterilization can be achieved using specific sterilization fluids. These fluids are often corrosive and toxic, and can produce toxic fumes. The operator cleaning and sterilizing the endoscope must wear adequate personal protective equipment, including facemask and eye protection. After exposure to the sterilization solution is complete, the endoscope is thoroughly rinsed with sterile water, both externally and through the internal channels. The sterilization solutions

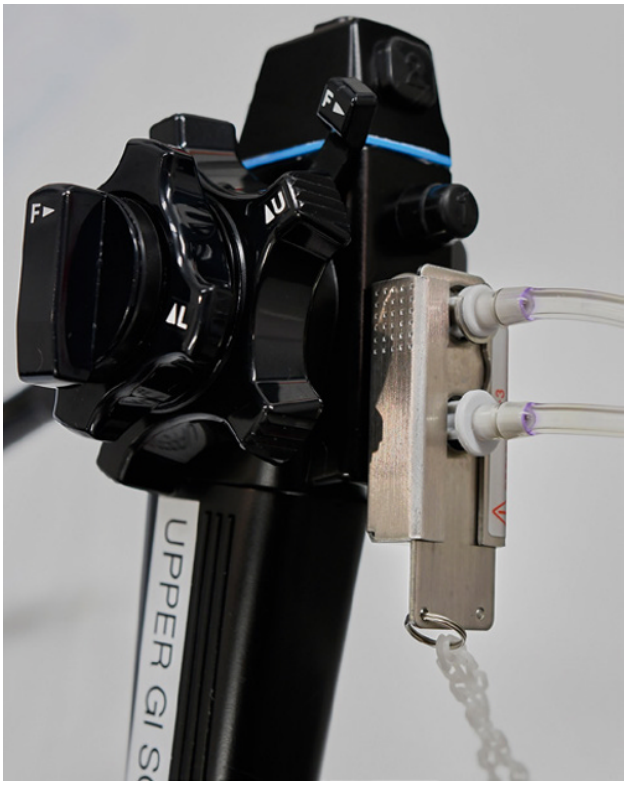

Figure 49.4 Attachment of a specialized manifold in place of the air/water and vacuum buttons allows administration of cleaning and sterilizing solutions to the inner working channels of the endoscope.

are irritating to mucosal tissue, so it is important to ensure that residues of the cleaning solution have been removed before use on a patient.

Endoscopes should be stored dry, following effective cleaning (Figure 49.5). If space is available, they can be stored in specially constructed rack systems in a dedicated cabinet. Other items unrelated to endoscopy should not be stored in the same cabinet to minimize the risk of endoscope damage. If a dedicated cabinet is not used, the cleaned and dried endoscope should be stored in the original shipping/packing case to provide adequate protection. Obviously, if transporting endoscopes in the field or between hospital sites, they are best carried in their specific transport case.

Effective complete cleaning and sterilization of an endoscope can be quite time-consuming. In practices that carry out several procedures in a day, investment in an automated scope cleaning and reprocessing system can be cost-effective, freeing up technician resources for other tasks. These systems can automatically carry out both the low-and high-level cleaning steps, final rinsing of the endoscope and pressure testing without further manual input, typically in less than one hour. These systems may also generate a record for each endoscope of cleaning solution exposure times and pressure test results, and monitor the age and use of the cleaning solutions. An additional advantage is that the operator is protected from the cleaning and sterilization fluids during endoscope reprocessing.

Figure 49.5 Clean and dry flexible endoscopes stored in a dedicated storage cabinet. An effective and sturdy retention system should be used to minimize the risk of endoscopes being dropped and damaged.

Endoscopic Terminology

Endoscopic evaluation of the gastrointestinal tract provides an opportunity to assess the gross appearance of the gastrointestinal mucosa. Findings with gastrointestinal endoscopy therefore are usually descriptions of the mucosa and attempt to define the ways, if any, in which the mucosa differs from normal. Standardization of the language used to describe endoscopy findings is useful to maintain consistency in interpretations and comparison across patients. The terms recommended for the description of the mucosa, most of which are also incorporated into the WSAVA recommended reporting forms for gastrointestinal endoscopy procedures, are summarized in Table 49.1 and discussed in greater detail below.

Friability

Friability refers to the susceptibility of the mucosa to superficial damage and hemorrhage on contact with either the endoscope tip/body or biopsy instruments.

Table 49.1 Terminology used for the description of endoscopically visualizable abnormalities of the gastrointestinal mucosa

Parameter	Definition
Normal mucosa	No macroscopic lesions are observed
Friability	Occurrence and degree of bleeding on contact of the endoscope or biopsy instrument with the mucosal surface
Granularity	Perceptible alterations in the visible texture of the mucosa
Erosion(s)	The presence of superficial linear to patchy mucosal defects, usually with bleeding present
Hyperemia	Subjective perception of the redness (pale to markedly reddened) of the mucosa
Lymphatic dilation*	The presence and degree of white foci (punctate to diffuse) within the mucosa
Mass present	Detection of abnormal tissue protruding into the intestinal lumen

Source: Modified from Slovak et al. (2015). Reproduced with permission of Elsevier.

* Lymphatic dilation is assessed and scored only in the small intestine.

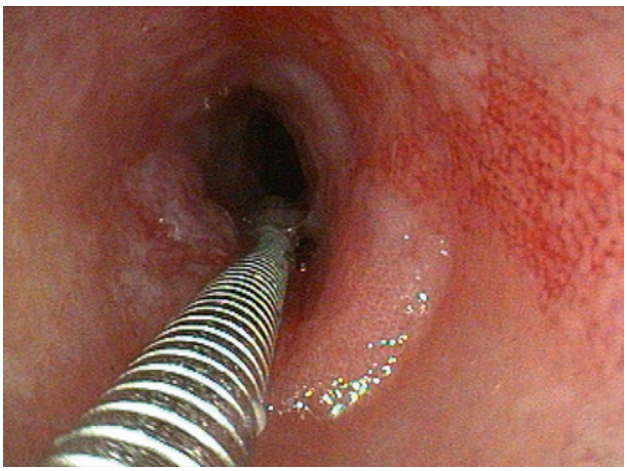

Figure 49.6 Increased friability and iatrogenic mucosal compromise of the small intestinal mucosa. There is noticeable "stripping" of the superficial mucosa visible to the right of the image; the stripped mucosa is visible piled close to the right side of the endoscopic biopsy forceps. This degree of mucosal damage from contact with the endoscope is abnormal, even within the small intestine.

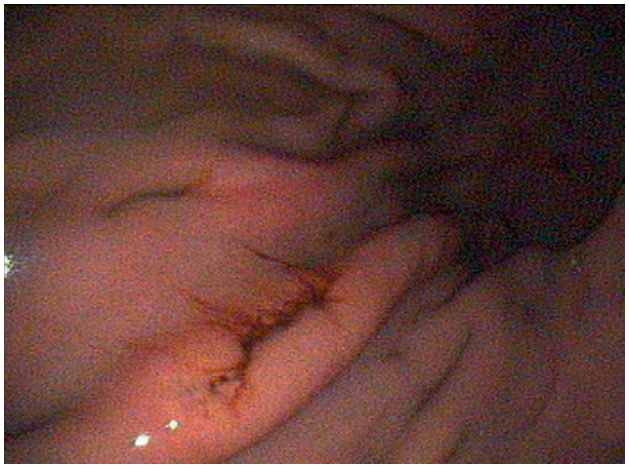
Figure 49.7 Increased mucosal granularity in the small intestine. The endoscope is approaching the end of the descending duodenum, the caudal duodenal flexure is visible in the distance. Note also the sporadic areas of lymphatic blebbing, particularly in the lower right quadrant of the mucosa. This patient was diagnosed with mild to moderate lymphoplasmacytic duodenal inflammatory disease.

The natural friability of the mucosa varies with the anatomy of the gastrointestinal tract, and this must be considered in the context of the examination findings. The esophageal and gastric mucosae, for instance, are robust and the normal mucosa should show little to no change or damage from contact with the endoscope. This is particularly true of the esophagus, antral mucosa, and pylorus. Compared to the stomach, the small intestinal mucosa is more fragile, and even normal patients will show some degree of superficial mucosal damage following contact with the endoscope, but there should not be grossly visible "stripping" of the mucosa from the submucosa, and any bleeding following contact should be minor (Figure 49.6). The large intestinal mucosa is more robust than the small intestine, but is not as resistant to impact damage as the gastric mucosa, thus contact with a colonoscope will usually produce some visible change in the mucosa, but this is less pronounced than in the small intestine.

Granularity

Granularity refers to the visual texture of the mucosa. Again, the normal texture of the mucosa varies across the gastrointestinal tract. In the small intestine, both increased and decreased granularity may be observed, while villus blunting due to infiltration or mucosal denudation may result in an abnormally smooth appearance of the small intestinal wall, or a "cobble stone" appearance caused by a patchy distribution of blunted villi. Mucosal thickening and swelling secondary to cellular infiltration or lymphatic drainage disorders can lead to an increase in granularity and a perceptible "piling" of mucosa into more prominent folds that do not dissipate with insufflation (Figure 49.7).



Erosion(s)

Erosion(s) are preexisting, generally superficial, linear to irregularly shaped mucosal defects, often marked by mild intra- or submucosal hemorrhage. These must be distinguished from lesions due to abnormalities in friability. Erosions represent an area of change in the gastrointestinal mucosa, but there should still be mucosa present (Figure 49.8). Visible loss of the mucosa with crater formation and visible submucosa is more consistent with ulceration than erosion. Erosions likely progress to ulceration in some individuals; animals with nonsteroidal antiinflammatory drug (NSAID)-induced gastritis, for instance, commonly show numerous erosions. Many erosions are linear or elongated oval shapes, oriented along the longitudinal axis of the intestinal tract, likely due to damage resulting from the passage of ingesta over the diseased mucosa.

Lymphatic Dilation

Lymphatic vessels are usually only visible in the small intestinal mucosa, and become more prominent in deeper parts of the small intestine, such as the jejunum. Lymphatic visibility is greater in the small intestine due to the role of the intestinal lymphatics in fat absorption,

(a)

(b)

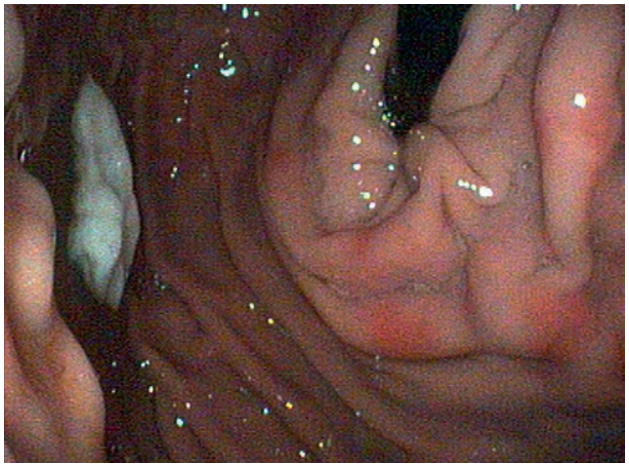


Figure 49.8 Erosions in the gastric mucosa. In the lower left of image (a), a larger erosive lesion is visible; just above this the mucosa is hyperemic and shows very superficial erosion. Note that the erosions follow the longitudinal direction of the rugae. In (b) several superficial erosions without hemorrhage are visible surrounding the lower esophageal sphincter and in the gastric cardia. This patient's histologic diagnosis was of multifocal, chronic erosive gastritis, likely secondary to chronic NSAID usage.

resulting in the presence of milky white lymph within the lacteals. Visible lymphatics within the villi are not necessarily abnormal, particularly when the lymphatics are obviously consistent in appearance and form well-circumscribed linear structures within each villus. This is a normal finding, and is more readily visible in animals that have had shorter fasting periods before the procedure. The use of milk or ice cream mixed with polyethylene glycol solutions for colonoscopy preparation (see later) is often associated with a dramatic increase in visibility of the lacteals, even in normal dogs. This should not be overinterpreted in patients having both upper and lower gastrointestinal (GI) tract procedures.

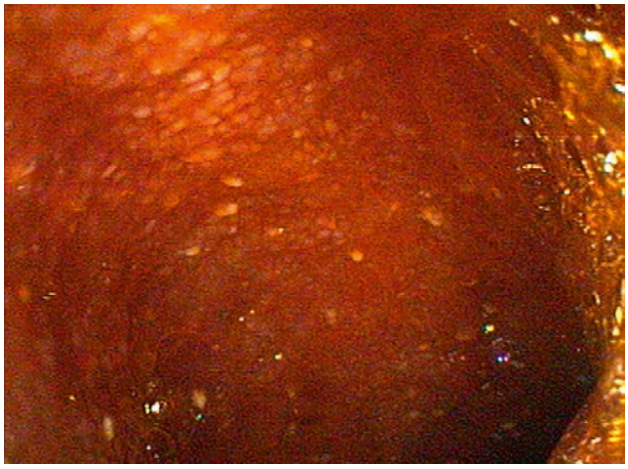

Figure 49.9 Diffuse lymphatic drainage abnormality in a dog with marked protein-losing enteropathy. Note the presence of markedly engorged lacteals within the villi in the upper left quadrant of the image, and scattered throughout.

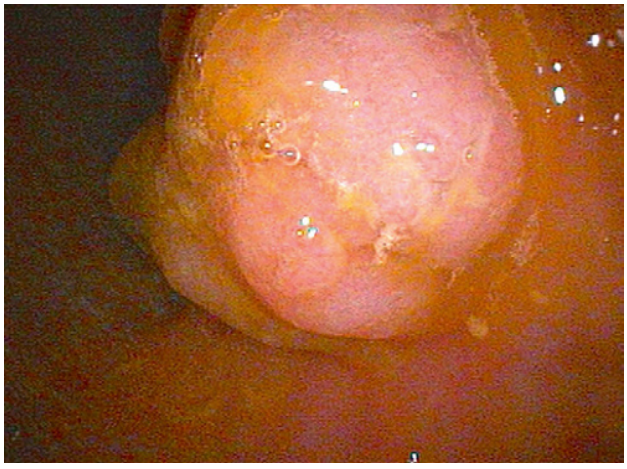

Figure 49.10 Luminal mass effect, a benign rectal polyp in a dog. The mucosa shows a "cauliflower" appearance but is not ulcerated. Histopathology was consistent with a chronic inflammatory process.

Abnormal lymphatic drainage is associated with "blebbing" and diffuse spread of lymph into the villi and the submucosa. There may be solitary punctate lesions spread diffusely throughout the small intestine, or larger areas of contiguous leakage may be perceived (Figure 49.9).

Mass Effects

Abnormal tissue entering the lumen of the gastrointestinal tract may arise from the mucosa or the submucosal layers. Mucosal masses are usually readily identified due to the obviously dysplastic appearance of the epithelium (Figure 49.10). In some cases, the mucosa will be eroded

and ulcerated, and will bleed easily (i.e., highly friable) on contact with the endoscope. Submucosal masses are recognized in areas where the lumen shows obvious architectural distortion that does not resolve with insufflation. Submucosal masses are relatively easy to recognize endoscopically, but the diagnostic yield from endoscopic biopsy of these lesions is poor. Full-thickness biopsy is usually required for accurate diagnostic assessment of submucosal or mural masses.

Hyperemia

The color of the intestinal mucosa can be assessed, and perceptible alterations from normal (again, bearing in mind that the mucosal coloration varies along the gastrointestinal tract) may be noticeable during an examination. While superficially attractive as a readily perceivable abnormality, hyperemia is actually a poor indicator of abnormalities within the mucosa. Many variables influence mucosal redness, including the hemodynamic state of the patient, circulating red blood cell mass, local changes in perfusion, and the overall color balance of the imaging system being used. Some, but by no means all, endoscopy imaging systems can have their color balance (white balance) calibrated against a white background material, which will improve the ability of the operator to define changes in redness on that specific system, but not all systems are readily calibrated, and calibration must be carried out regularly. Due to these shortcomings, diffuse hyperemia and other changes in mucosal coloration are not usually considered useful diagnostic findings during gastrointestinal endoscopy.

Upper Gastrointestinal Endoscopy Procedures

Esophagoscopy

Indications

Common indications for esophagoscopy in companion animals include assessment of patients with dysphagia, regurgitation, poor appetite, and hematemesis. Esophagoscopy is also frequently useful in the diagnosis and management of esophageal foreign bodies, strictures, and diverticulae. The esophagus is also, obviously, traversed in the process of all other upper gastrointestinal examinations and should be thoroughly examined during these procedures.

Patient Positioning

As esophagoscopy is commonly performed during other upper gastrointestinal tract procedures, the patient is typically placed in left lateral recumbence (the positioning of choice for gastroduodenoscopy). If the planned procedure is only involving the esophagus (foreign body removal or stricture ballooning, for example), sternal or right lateral positioning can be used, but there are no specific advantages of these positions over left lateral recumbence.

Equipment Choice

Both flexible and rigid endoscopes may have some utility in examination of the esophagus, but in most patients there is insufficient working length with rigid endoscopes to examine the entire esophagus. Flexible endoscopes with four-way tip deflection and a working channel are preferable, particularly if removal of a foreign body using flexible retrieval instruments is anticipated. Four-way tip deflection gives the operator a greater ability to manipulate the positions of grasping forceps or basket snares. Air and water insufflation is important, particularly for adequate examination of the cranial esophagus.

General Technique and Landmarks

The neck is extended dorsally, and the endoscope passed dorsally over the endotracheal tube to the retropharynx. Gentle pressure against the retropharynx will result in the passage of the endoscope through the upper esophageal sphincter and into the cervical esophagus.

The cervical esophagus is usually flacid and collapsed. After passage through the upper esophageal sphincter, air is insufflated to visualize the esophageal lumen. Once fully insufflated, passage of the endoscope is usually straightforward. Landmarks during the examination are the thoracic inlet (where the esophagus changes direction slightly), heart base (where there is a slight narrowing of the esophageal lumen; usually the wall will show motion due to cardiac movement), and the lower esophageal sphincter. The three landmark locations also represent areas of esophageal narrowing, and are the most common sites to encounter obstructing foreign bodies.

Ideally, as much of the esophageal lumen as possible should be visualized before advancing the endoscope over large distances. In regurgitating patients, look closely for wall defects or outpouchings that may represent esophageal diverticula, or areas of esophageal lumen that do not insufflate fully (indicating possible strictures).

Normal Findings

The cervical esophagus is normally flacid and collapsed on entry. Insufflation reveals longitudinal mucosal folds, which are flattened by air insufflation. Within the thoracic cavity, the esophagus is usually flaccid and shows a patent lumen without need for further insufflation. The normal esophagus will drape over the large vessels in a

normal animal; visualization of a strong pulsatile motion from these vessels is not necessarily suggestive of a megaesophagus.

The esophageal wall in dogs is usually smooth, or very slightly corrugated, on full insufflation. The cat has a series of mucosal folds in the distal third of the esophagus that give the normal esophageal lumen a "herring bone" appearance in this species.

The lower esophageal sphincter is readily visualized in most animals, assuming that there are no impeding foreign bodies. The lower esophageal sphincter is usually closed on examination, but a relaxed and open sphincter is not necessarily abnormal. Often, a small amount of stable white foam (aerated saliva) is adherent on the distal esophageal mucosa, which is also normal.

Potential Abnormalities Observed in Esophagoscopy Procedures

Esophagitis

Esophageal inflammation is a common finding in dogs with gastrointestinal disease, particularly if there is gastroesophageal reflux or chronic vomiting. Changes in the esophageal mucosa with esophagitis are highly variable, and often do not correlate closely with the perceived clinical severity of signs. The most common changes seen with esophagitis are increased granularity of the esophageal mucosa, hyperemia or erythema, and mucosal erosions. Often, these changes are most pronounced in the distal esophagus, particularly if they are secondary to gastroesophageal reflux (Figure 49.11).

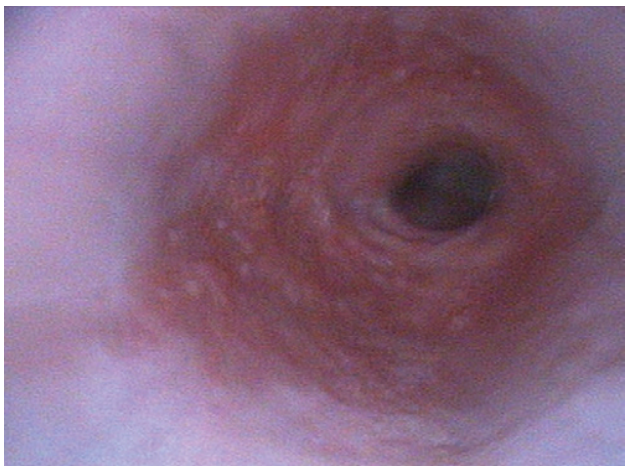

Figure 49.11 Esophagitis, likely due to recurrent gastroesophageal reflux, in a canine patient. There is increased granularity and hyperemia of the distal esophageal mucosa, and the lower esophageal sphincter is dilated. Some mild erosions are also visible in the more proximal aspect of the esophageal mucosa, particularly to the left of the image.

In humans, chronic gastroesophageal reflux can lead to squamous differentiation of the distal esophageal mucosa, which is considered a preneoplastic change. Similar changes are occasionally seen in dogs with chronic gastroesophageal reflux, but the potential for neoplastic transformation is unknown.

While a relaxed, partially dilated lower esophageal sphincter is not necessarily an abnormal finding in dogs and cats, the prolapse of gastric mucosa into the esophageal lumen is abnormal. This may occur as a result of severe, chronic reflux esophagitis, hiatal hernias, or be due to the presence of mass lesions on or just below the lower esophageal sphincter (see Gastric Tumors, later).

Esophageal Foreign Bodies

Esophageal foreign bodies are a significant medical emergency, and delays in detection and definitive treatment should be avoided as much as possible. Large obstructing foreign bodies, such as bones, swallowed chew toys, etc., are readily visualized. Common locations for foreign body entrapment are at the thoracic inlet, cranial to the heart base, and cranial to the lower esophageal sphincter, with the lower esophageal location being the most common. Sharp, more linear objects such as needles, fish hooks, etc. may lodge at any point in the esophageal lumen, but again are most commonly encountered at the thoracic inlet and cranial to the lower esophageal sphincter. Sharp linear foreign bodies often accumulate additional material such as hair, grass, and food fragments that can complicate assessment and removal.

Before endoscopy to assess and possibly attempt removal of an esophageal foreign body, it is important to have recent (ideally same day) thoracic radiographs with at least two orthogonal views. These should be carefully assessed for evidence of preexisting esophageal perforation (pneumomediastinum, mediastinitis, pneumo- or pyothorax), as these indicate a need for earlier surgical intervention. In addition, it is important to document that the foreign body is still present, and apparently within the lumen, before proceeding to esophagoscopy. Strategies for foreign body removal are discussed further later.

Esophageal Diverticulae

Esophageal diverticulae are outpouchings of the esophageal mucosa through defects in the mural musculature. On endoscopic examination, these lesions may appear as obvious outpouchings of the mucosa, they may look like an additional lumen, or they may appear to be large accumulations of hair and/or fermenting food material entrapped within the diverticulum. Large diverticulae are usually detected on plain radiographic examination of the thorax as part of the work-up for esophageal disease.

Esophageal Neoplasia

Primary esophageal neoplasia is uncommon to rare in both dogs and cats, with cats most frequently diagnosed. Squamous cell carcinoma is occasionally diagnosed within the thoracic esophagus, visualized as an eroded, proliferative mass in the distal esophagus. This diagnosis is most commonly made in elderly cats, and carries a poor to grave prognosis. Preendoscopy work-up including plain and contrast-enhanced esophograms will often reveal the soft tissue mass, which may initially be mistaken for a foreign body.

Gastroscopy

Indications

Common indications for gastroscopy include assessment of recurrent vomiting, poor appetite, weight loss (assuming other significant co-morbidities have been ruled out), hematemesis (particularly if "coffee ground" vomiting is present), and attempts at removal of gastric foreign bodies. Gastroscopic technique is also used for some minimally invasive feeding tube placements (percutaneous endoscopic gastrostomy [PEG] and percutaneous endoscopic gastrostomy-jejunostomy [PEG-J]; see later). The stomach must be traversed as part of the approach to the small intestine for duodenoscopy, and should be assessed thoroughly, including the collection of biopsies from each area of the stomach, in any patient being worked up for possible inflammatory disease of the gastrointestinal tract.

Patient Positioning

For most procedures involving gastroscopy, the patient should be placed in left lateral recumbence. As the pylorus is in the right side of the abdominal cavity in both dogs and cats, left lateral recumbence will position the antrum and pylorus dorsally, thus allowing gas to fill these parts of the stomach. This is important for clear visualization of a number of significant landmarks, and greatly simplifies the process of transiting the antrum, through the pylorus to the small intestine. Left lateral recumbence will also typically cause foreign bodies that are obstructing the pylorus to fall into the gastric body under the influence of gravity. There is much greater room to maneuver and less complex scope deviations necessary to retrieve foreign bodies from the gastric body than from within the antrum

One exception from the typical left lateral placement for gastroscopy is made when the patient is having a minimally invasive feeding assistance device placed, such as a PEG or PEG-J tube. These devices are placed through the greater curvature of the stomach, exiting at the left paranephric fossa, and thus placing the patient in right lateral recumbence is necessary to improve visualization of this region of the gastric wall. If the sole reason for the gastroscopic procedure is PEG/PEG-J tube placement, the entire process is carried out in right lateral recumbence. If the feeding device is to be placed at the end of a diagnostic upper gastrointestinal examination, it is best to start in left lateral recumbence and then reposition the patient after completion of the examination.

Equipment Choice

Gastroscopy requires the use of a flexible endoscope with four-way tip deflection. If the primary reason for the procedure is foreign body retrieval from the stomach, a relatively large endoscope (7–9 mm diameter) can be useful even in cats and very small dogs. For full visualization of all areas of the stomach and potential entry into the duodenum via the pylorus, a smaller endoscope might be advantageous with very small patients (for instance, a 5–6 mm pediatric gastroscope), but with care even a 7–9 mm endoscope can be advanced through the pylorus of many smaller dogs and larger cats.

General Technique and Landmarks

Landmarks for visualization during gastroscopy include the greater and lesser curvatures of the stomach, the cardia and aboral surface of the lower esophageal sphincter, the incisura angularis, antrum, and pyloric sphincter. All these areas and structures are readily accessible to examination in the majority of veterinary patients, assuming careful and thorough technique is applied.

The stomach is entered via the lower esophageal sphincter, which is straightforward with gentle application of pressure in the vast majority of veterinary patients. One notable exception to this would be dogs with severe megaesophagus, for any reason, where the dilated and flaccid esophagus drapes into the thoracic cavity, resulting in outpouchings that tend to capture the endoscope, and significant elevation changes are necessary to reach the lower esophageal sphincter.

After entering the stomach via the lower esophageal sphincter, a reduction in resistance to passage is felt. At this point, with the working end of the endoscope just entering into the cardia of the stomach, air insufflation is started to moderately inflate the gastric lumen. During insufflation, the gastric rugae should be closely observed for areas that are not flattening out or show marked apparent changes in rugal fold directions, as these can indicate areas of wall infiltration and pathology. Directly ahead of the endoscope from this position will be the greater curvature of the stomach and the gastric body. From this position, left and right deviations of the endoscope can be used to get a general overview of the gastric lumen.

Rightwards deviation of the endoscope tip will provide a view of the greater curvature descending to the antral

wall. Usually, the pyloric sphincter and inner antral lumen are not visible from the lower esophageal sphincter, but the incisura angularis is easily identified and is an important landmark for further manipulations. Leftwards deviation of the endoscope tip from the lower esophageal sphincter reveals the oral aspect of the fundus and greater curvature, but the cardia is not visible from this position.

The endoscope tip is advanced into the gastric lumen following insufflation, and the endoscope placed into a J shape by maximal upwards deviation using the control wheels. This will typically provide a view back towards the face of the incisura and into the antrum, and should allow visualization of the pyloric area. Applying rotational torque to the endoscope will provide a view of the cardia and the lower esophageal sphincter. The visualization of the endoscope body entering via the lower esophageal sphincter provides obvious confirmation that the cardia and lower esophageal sphincter are being visualized.

Relaxing the strain on the upwards deviation control and gently pushing the endoscope forwards will typically result in the body of the endoscope contacting the greater curvature of the stomach, and minor torqueing of the endoscope towards the right (relative to the control cluster) will usually result in a view along the greater curvature into the antral lumen towards the pylorus. Gentle forwards pressure is then applied to enter the antrum and approach the pyloric sphincter.

Entry into the antrum and visualization of the pyloric sphincter can become very difficult if the gastric body is aggressively insufflated. Introducing more and more air is tempting as it allows a larger field of view, but the resulting compression of the antrum, and greater distance of greater curvature wall that must be traversed, make entry to the antrum much more challenging. This is particularly true with very large dogs, where the entire 120–150 cm working length of the endoscopes commonly used in veterinary practice will be taken up by transit of the esophagus and around the greater curvature.

After visualization of all areas of the stomach, the endoscope may then be advanced to and through the pylorus to enter the duodenum if duodenoscopy is planned. This technique is discussed in greater depth later.

Normal Findings

The mucosa of the gastric body is generally light pink to red, and prominent rugal folds are apparent on first entry to the stomach and early in the insufflation process. The majority of the rugae run longitudinally around the greater curvature of the stomach, which can be a useful guide for orientation. Rugae should disappear as the stomach becomes distended during insufflation, but prolonged periods of aggressive insufflation should be avoided due to the risk of respiratory and circulatory compromise, and the greater difficulty of continued examination. The mucosa should be smooth in appearance. The mucosa within the antrum is a lighter color than in the main gastric body, and rugae are either absent or greatly reduced. Patchy erythematous regions, particularly on the greater curvature, are normal. The pylorus is usually not directly visible on first entry to the antrum, but instead is surrounded by a number of mucosal folds in the distal antrum. Careful observation will usually allow visualization of small amounts of bile reflux or transient opening of the pylorus.

Fluid, residual food particles, and foreign bodies will tend to pool in the left fundus when the patient is in left lateral recumbence. In normal animals, there will be scant fluid or mucus present, while those with gastrointestinal disease can exhibit large pools of fluid, mucus, and food particles. Excessive fluid will obscure visualization of the gastric mucosa in this region, and may camouflage foreign bodies. Ideally, as much fluid as possible should be suctioned from the fundus during the examination. This will improve visualization, and also decreases the risk of vomiting or regurgitation and aspiration on recovery.

Potential Abnormalities Observed in Gastroscopy Procedures

Gastritis

Gastritis is commonly encountered during gastroscopy. Gross changes that may be visible include marked reddening of the mucosa, thickening of the mucosa, increased prominence and extent of mucosal erythema, and thickening of the rugae resulting in slower and less complete flattening of the rugae during insufflation. While any or all of these changes should increase suspicion for the presence of gastritis, it is important to remember that some patients may show histologic evidence of gastric inflammation with relatively mild to nonexistent grossly visible changes. Biopsy collection is crucial to allow accurate assessment. In many animals with gastritis, the gastric mucosa is perceptibly "easier" to biopsy, requiring less avulsion force to remove tissue. Biopsy sites from animals with gastritis will often bleed more freely. As greater volumes of bleeding can be seen in animals with gastric inflammation, it is wise to biopsy the stomach at the end of the gastroduodenoscopy procedure otherwise bleeding can result in obstruction of the view.

Gastric Ulceration

Common causes of gastric ulceration include inappropriate or prolonged NSAID use and local neoplastic processes (particularly gastric carcinoma). Ulceration can also be seen due to paraneoplastic effects from mast cell

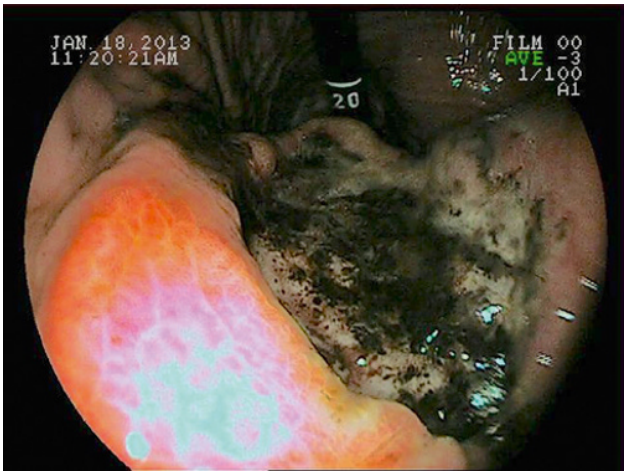

Figure 49.12 Severe ulceration on the wall of the gastric lesser curvature in a canine patient presenting with severe recurrent vomiting. In the lower left quadrant of the image, close to the endoscope, the upper edge of the incisura angularis is visible and is also dramatically abnormal. This patient was diagnosed with mucinous gastric carcinoma via endoscopic biopsy.

neoplasms and gastrinomas. Paraneoplastic ulceration secondary to severe and persistent gastric hyperacidity is often profound and severe.

Ulceration is usually seen in the secretory compartment of the stomach. The incisura angularis is also very commonly affected, and is a particularly common site to encounter NSAID-induced ulcers. Large ulcers are typically visible as dark, depressed areas of necrotic tissue, surrounded by an elevated rim of markedly reddened and thickened mucosa (Figure 49.12). Biopsy of the center of an ulcerated lesion is usually of little diagnostic value as the tissues are necrotic; this is also associated with risk for perforation of the ulcer. Biopsies for assessment should be taken from the rim at the periphery of the ulcer, as well as several biopsies from nearby apparently normal tissue to screen for infiltrative processes. Gastric ulceration due to NSAIDs cannot be differentiated from ulceration due to neoplasia, and as both NSAID and neoplastic processes are more common in older dogs, biopsy to rule out neoplasia is mandatory even in patients receiving NSAIDs.

Mural Masses

Mass lesions affecting the gastric wall may be visualized in any part of the stomach. Some potential causes of gastric mural lesions include chronic inflammatory change (polyps), lymphosarcoma, granulomatous lesions due to foreign body penetration, and tumors arising from smooth muscle (leiomyoma, leiomyosarcoma) or mesenchymal cells (gastrointestinal stromal tumor [GIST], fibrosarcomas). In areas with high regional prevalence of fungal or oomycete-induced disease, these infections may also result in intraluminal granuloma formation. Leiomyoma and leiomyosarcoma are rare in the gastrointestinal tract but when seen, are most commonly associated with the lower esophageal sphincter, and are most frequently identified in older, female dogs.

As mural mass lesions may primarily affect the deeper layers of the gastric wall, endoscopic biopsy samples are often nondiagnostic. Obtaining multiple biopsy "bites" from the same site, to allow sampling of the submucosa and muscularis layers, increases the utility of endoscopic biopsy samples for mural masses.

Gastric Parasites

Occasionally, gastric parasites, such as *Physaloptera* spp., are observed during gastroscopy, typically in patients being assessed for chronic vomiting. These are small parasites, being around 3–4 cm long and very slender. If the clinician does not suspect that they may be present, it is easy to overlook them. As these worms are susceptible to both pyrantel pamoate and most of the macrocylic lactone parasiticides (ivermectin, selamectin, etc.), this has become an uncommon diagnosis in client-owned animals.

Gastric Foreign Bodies

Gastric foreign body removal is a common indication for gastroscopy in companion animals. Foreign bodies may lodge in the antrum/pylorus or remain freely mobile within the gastric lumen. Freely mobile foreign bodies will usually be found in the left gastric body when the patient is in left lateral recumbence, due to the effect of gravity. Often, foreign bodies are associated with or surrounded by large aggregations of hair, grass, and other consumed materials, which can complicate assessment and accurate deployment of foreign body snares.

Foreign bodies lodged within the antrum/pylorus will be visualized during the approach along the greater curvature. Patients with foreign bodies in this location, particularly if they are thought to be fabric based (carpet, bedding material, wool, etc.), should be carefully assessed for evidence of linear foreign body entrapment in the small intestine before proceeding to gastroscopy, as patients with linear entrapment within the small intestine are best assessed at exploratory surgery.

Assuming successful removal of a foreign body from the stomach via endoscopy, it is strongly recommended to obtain biopsies of the gastric (and, if possible, small intestinal) mucosa before recovering the patient from anesthesia. Particularly in middle-aged to older animals, pica may be the only sign of significant inflammatory disease of the gastrointestinal tract.

Duodenoscopy

Indications

Duodenoscopy is commonly indicated for the assessment of small intestinal disease in companion animals. Mucosal assessment and biopsy are of value in cases with unexplained weight loss, poor appetite, vomiting, and diarrhea. Duodenoscopy may also yield useful information in patients with hematemesis or hematochezia, but this is less commonly the case and these clinical signs are not a primary indication for duodenoscopy. It is important to consider that the actual area of small intestine accessible via endoscopy is limited in most patients. It is unusual to be able to reach the jejunum in most veterinary patients, and thus large areas of the small intestine are inaccessible for routine endoscopy. Consequently, endoscopy is a poor choice for attempted assessment of small intestinal diseases that are discrete in nature, such as solitary ulcerative lesions or mural mass lesions.

Patient Positioning

Duodenoscopy procedures are almost invariably conducted with the patient in left lateral recumbence, as this places the pyloric sphincter and gastric wall in the optimum position for passage into the duodenum.

Equipment Choice

Standard 7–9 mm diameter, 125–150 cm flexible endoscopes with four-way tip deflection, air and water insufflation and an adequate working channel are useful in the vast majority of veterinary patients. Remanufactured/refurbished pediatric gastroscopes work well for cats and smaller dogs. In larger dogs (30 kg+), 9–11 mm 160 cm+ colonoscopes tend to have better reach into the duodenum.

General Technique and Landmarks

Navigation of the antrum and pylorus to enter the duodenum is one of the more challenging procedures in companion animal gastroduodenoscopy. Traversal of the stomach to the greater curvature, around to the entry to the antrum and the approach to the pylorus will often consume a large proportion of the working length of the endoscope, and multiple turns can result in the endoscope tip moving in directions that are counterintuitive relative to the control cluster and the operator's hands. Excessive insufflation of the stomach tends to increase the difficulty of this procedure, as it changes the anatomy of the antral opening, increases the distance of gastric wall that will be traversed, and tends to increase pyloric sphincter tone. If difficulty is experienced with this procedure, particularly if the endoscope is unable to pass the incisura angularis, gas should be removed from the stomach via suctioning.

The typical approach to the pylorus occurs by directing the endoscope towards the greater curvature, then deflecting the endoscope tip using a J-maneuver and torquing the endoscope to allow visualization of the incisura angularis. The endoscope is then advanced slightly (sliding along the greater curvature) and the upwards deflection is relaxed, allowing the end of the endoscope to relax onto the antral wall. Once the tip of the endoscope has entered the antrum, gentle forwards pressure on the body of the endoscope will usually result in forward motion of the working end of the endoscope into the antral lumen towards the pylorus. If the endoscope is repeatedly "flipping" out of the antrum, or shows paradoxical motion (the pylorus moving away as forwards pressure is applied), it is likely that there is excessive length of endoscope body within the gastric lumen due to excess insufflation. The endoscope is retracted into the gastric body, air is removed until the stomach is perceptibly deflating (rugae should be readily visible, at a minimum), and then the approach to the antrum can be repeated.

The pylorus is identified by careful examination of the center of the distal antral wall. In most animals, the circumferential muscle structure of the sphincter is easy to appreciate, in others there may be mucosal folds or more complex sphincter anatomy present, but most animals will show at least one fold or sulcus of the mucosa that is obviously deeper and more motile; this is the most likely point to find the pyloric sphincter. Entry to the sphincter typically involves incremental advancement of the endoscope body, while using progressive subtle tip deflections with the control wheels to maintain the pyloric sphincter within the center of view. As the endoscope tip impacts the mucosa, it is normal to have a complete loss of vision; gentle pressure is continually applied and the tip of the endoscope deviated slightly to the right and downwards. The endoscope operator should feel a forward motion and the mucosa "glides by" the end of the scope, the operator watches for a change in color of the mucosa from a light red (antral mucosa) to a darker red to yellow tinged color (duodenal mucosa and bile). When the mucosal color changes, the endoscope is advanced for several centimeters, then air is insufflated and the tip of the scope gently diverted in several directions to obtain a view of the lumen. Once the lumen is visible, the endoscope can be *slowly* retracted to allow examination of the very cranial aspect of the duodenum.

If the endoscope is carefully positioned in the very cranial duodenum, it is usually possible to identify the duodenal papillae. There are two papillae in dogs; the more cranial, larger papilla is the major duodenal papilla and drains both biliary and pancreatic secretions, while the smaller minor papilla drains only pancreatic secretions. In the cat, only one papilla is visualized, and drains both

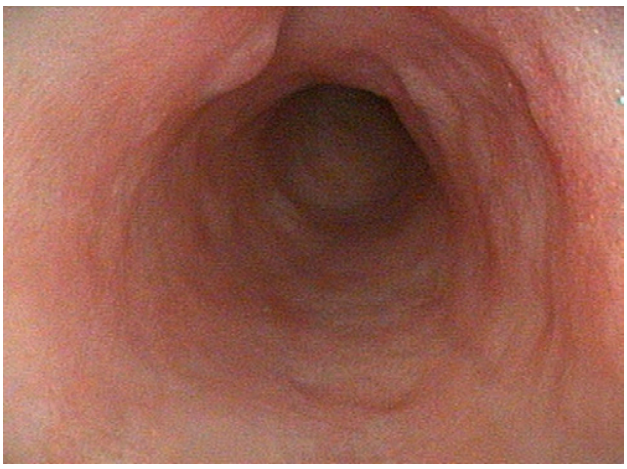

Figure 49.13 View of a normal descending duodenum from just distal to the pylorus, on initial entry to the duodenal lumen. The major duodenal papilla is visible to the upper left as a blunted protrusion into the lumen; this is a useful landmark for the upper duodenum.

Figure 49.14 Normal villi in the distal descending duodenum. This is the same patient as shown in Figure 49.13. Note that the villi are easily appreciated due to the clearly defined narrow lymph vessels circumscribing each villus. This is a normal finding (compare to Figures 49.9 and 49.15), but is usually only readily appreciated with high-resolution videoendoscopy equipment.

biliary and pancreatic secretions. The papilla(e) are a useful landmark indicating that the working tip of the endoscope is placed very close to the pyloric sphincter (Figure 49.13).

As the endoscope is advanced along the duodenum, a clear lumen is readily appreciated; this is the descending duodenum. As the end of this lumen is approached, the mucosa can be seen deviating to the left (assuming routine patient and endoscope orientation); this is the caudal duodenal flexure. If the endoscope can be coaxed around this corner (which depends heavily on the working length available and the size of the patient), it is possible to enter the transverse duodenum, and after a short distance another turn marks the beginning of the jejunum. It is relatively uncommon that this depth is reached in veterinary patients.

The leftward deviating mucosa at the caudal duodenal flexure is typically an easy site to biopsy. Biopsies are obtained from this wall, and then the endoscope is slowly withdrawn, 1–2 cm at a time, to allow biopsy of the descending duodenal mucosa. Biopsy samples are collected progressively as the endoscope retracts, until the working end falls back through the pylorus into the gastric antrum. At this point, the biopsy sample container should be changed and a new container used for gastric biopsy samples.

Normal Findings

As indicated above, observation of the duodenal papilla(e) is a normal finding, particularly in dogs. The duodenal mucosa should be pink to red, and show a fine granular to almost velvety appearance (representing the tips of the villi). Small amounts of bile and bile-stained mucus may also be observed and are normal. The duodenal mucosa is relatively delicate, and becomes more fragile in the presence of inflammatory disease, thus minor erosions and abrasions are commonly seen in areas where the endoscope has impacted the mucosa. These can be quite prominent, but are not a significant complication and require no further action. Occasionally, depending on the fasting state of the patient, the lacteals within the villi are apparent. Well-circumscribed, clean-edged lacteals visibly curving at the ends of the villus tips are not abnormal (Figure 49.14); visible lacteals in normal villi will often give the duodenal mucosa a "reptile skin," apparently scaly appearance.

Peyer's patches may be observed on the antimesenteric border of the duodenal mucosa. Peyer's patches are lighter than the surrounding mucosa, and are slightly depressed relative to the local mucosa. These represent aggregations of lymphoid tissue and are not abnormal.

Potential Abnormalities Observed in Duodenoscopy Procedures

Most of the abnormalities noted in endoscopic examinations of the duodenum relate to changes in the appearance or character of the mucosal surface. These changes are not specific to any particular disease process, but generally reflect changes in the cellularity and cellular makeup of the mucosa.

The characters most commonly assessed for evidence of abnormalities in the duodenum are granularity, friability, presence of erosions, and abnormalities in lymphatic drainage.

Increasing granularity results in a "heaped" appearance of the mucosa; with severe change, there may be apparent folds in the duodenal mucosa that do not dissipate with insufflation, while more subtle changes lead to a "cobble stone" appearance of the mucosa (see Figure 49.7).

Increasing friability is noted when impact with the endoscope leads to excessive mucosal stripping and bleeding from contact points. The mucosa is inherently somewhat friable, but contact of the endoscope with a normal mucosa should result in very minor to no loss of mucosal surface (see Figure 49.8).

Erosions are preexisting areas of loss or compromise of the mucosal surface. As some degree of mucosal contact is inevitable as the endoscope proceeds along the duodenal lumen, it is important to assess for the presence of erosions as the endoscope is advanced, not on withdrawal. Dramatic mucosal damage visible on withdrawal of the endoscope is more compatible with a change in friability than a diagnosis of erosions, as it represents greater iatrogenic damage rather than preexisting mucosal pathology.

Lymphatic drainage of the villi occurs via the lacteals, which normally contain milky white lymph due to the presence of fat micelles. This makes visualization of lacteals remarkably easy in many patients. Simply observing lacteals within the villi, even in animals that have had an overnight fast, is not evidence of a lymph drainage abnormality. Mucosal blebbing, representing rupture of the lacteals and infiltration of lymph into the interstitium, is an important finding. In patients with lymphangiectasia, the lymphatics become dramatically engorged and may occupy >80% of the volume of the villi. This degree of change is usually seen in patients with marked protein-losing enteropathies (Figure 49.15), either secondary to significant mucosal inflammatory disease or due to the presence of a primary lymphatic vessel abnormality.

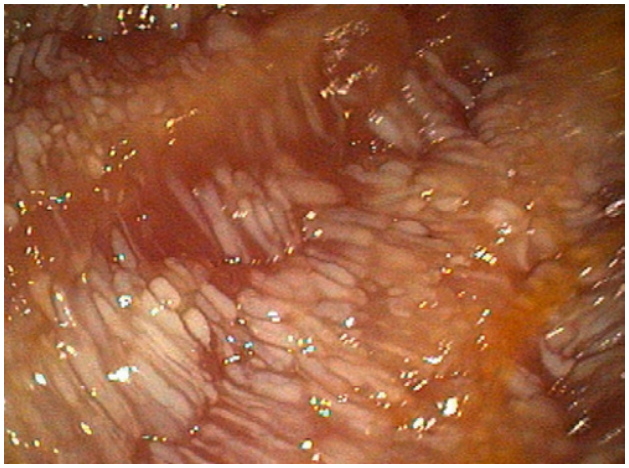

Figure 49.15 Severe lymphangiectasia in the very cranial aspect of the jejunum in a dog with severe protein-losing enteropathy. This is a more distal view of the small intestine of the same patient as in Figure 49.9. The great majority of the villi are dramatically engorged with milky white lymph. On histologic examination, >80% of the villus diameter was occupied by dilated lymph vessels.

None of the mucosal changes described above can be reliably detected in all cases of small intestinal disease, and the agreement between observation of these abnormalities and the presence of histologically important mucosal changes is poor at best. Small intestinal mucosal biopsy samples should always be obtained during duodenoscopy procedures.

Large Intestinal and Distal Small Intestinal Procedures

Patient Preparation

Adequate patient preparation is critical before colonoscopy and ileoscopy procedures. The esophagus, stomach, and upper small intestine will usually be emptied of ingesta with a 12–18-hour fast. The large intestine, however, normally contains a large amount of fecal material, mucus, and fluid that is not removed or resolved with fasting alone. Other procedures, including oral preparation solutions and enema treatments in concert with fasting, are necessary to allow adequate preparation for this procedure.

Failure to remove fecal material adequately is a major cause of incomplete or diagnostically misleading colonoscopy procedures. Visualization of the mucosa is often severely hampered (potentially resulting in failure to observe discrete lesions), and the time taken to complete the examination is markedly extended.

A number of different approaches to colonoscopy preparation have been described. Some practitioners use only warm water enemas (along with 24–48 hours of preprocedure fasting), or warm soapy water enemas. Care must be taken with enema solutions that they are not irritating (as can be the case with some solutions marketed mainly for relief of constipation in humans) and do not cause severe fluid or electrolyte shifts (phosphate-based enemas are notorious for this effect in cats).

The author's preferred approach is to use a combination of fasting with polyethylene glycol-based oral preparation solutions (GoLYTELY® or similar) combined with periprocedural enemas. The oral preparation solutions produce dramatic osmotic diarrhea, so it is often beneficial to hospitalize the patient for easier maintenance and cleaning. The solution is administered at a dose of approximately 20–25 mL/kg via orogastric intubation,

starting the evening before the procedure is planned. The solution is dosed three times (each at 20–25 mL/kg) at 2–3-hour intervals, starting approximately 18 hours before the procedure is planned (early afternoon the day before a planned morning procedure). The solution is administered via either intermittent orogastric intubation or by mixing it with plain vanilla ice-cream (one part ice-cream to two parts solution) and allowing the patient to drink it. Many dogs will readily consume the resulting solution. If oral intubation is used, the author considers nasogastric intubation and trickle infusion to be strongly contraindicated, as this is associated with increased risk of aspiration pneumonia, which can be severe and life threatening.

As the last of the evening doses of oral preparation solution is given, a warm water enema (also 20–30 mL/kg) is administered. The warm water enema is repeated early in the morning on the day of the planned procedure (around 7am for a 9am procedure), which should result in passage of clear fluid with little to no fecal material or mucus. If the morning enema continues to produce solid fecal material, ideally the procedure will be delayed by 1–2 hours to allow a second morning enema, followed by at least an hour of resting time to allow fluid absorption and resolution of transient irritation of the colonic mucosa.

An adequately prepared colon will allow easy and relatively unimpeded observation of the colonic mucosa over the length of the large intestine. Minor adherent material and mucus can usually be lavaged and flushed from the colon using endoscope suction. Specific colonoscope irrigation and washing pump systems are available and routinely used in human patients, and may be worth consideration in veterinary practices that carry out a large number of large intestinal procedures. While these pumps and washing systems can assist with final cleaning and visualization of the colonic mucosa, they are not a replacement for adequate preprocedural preparation.

Proctoscopy

Indications

Proctoscopy is a useful technique for the assessment of patients with predominantly or exclusively large intestinal symptoms, such as tenesmus, excess fecal mucus, fecal urge incontinence, hematochezia, dyschezia, and visible or palpable anorectal masses. As many of the mucosal diseases affecting the large intestine tend to be diffuse throughout the large intestinal lumen, and anorectal diseases are by definition limited to the distal large intestine and anal canal, proctoscopy may be all that is necessary to establish a useful working diagnosis in a large intestinal disease case.

Patient Positioning

Typically, the patient is placed in right lateral recumbence for isolated proctoscopy procedures without assessment of the transverse or descending colon and ileocolic junction. Right lateral recumbence causes any residual fluid from patient preparation to pool into the transverse colon (which is oriented vertically when the animal is in lateral recumbence), aiding in mucosal visualization.

Equipment Choice

Proctoscopy can be achieved with either flexible or rigid endoscopes. Refurbished human flexible colonoscopes, up to 11 mm diameter, can be effectively used in most dogs and cats, although some endoscope manipulations such a J-maneuvers (necessary for effective visualization of some very distal rectoanal lesions) can be challenging or impossible with this size endoscope in smaller dogs and most cats.

Rigid proctoscopes can be very valuable for these procedures, as they usually feature large endoscope lumens that allow passage of larger instruments, biopsy and cautery snares, and rigid forceps.

General Technique and Landmarks

The rigid proctoscope is lubricated well and introduced through the anal sphincter gently, while an obturator is in place. When resistance to passage of the proctoscope reduces, marking entry of the proctoscope into the rectum, the obturator device is removed and the lighting and visualization system (typically a rigid fiberoptic telescope and accessory camera) are attached. The proctoscope is then gently introduced into the colon lumen, while the operator closely observes the mucosa. Air insufflation is used as necessary to inflate and maintain the colonic lumen. Rigid proctoscopes should not be advanced if the lumen is not visible, as this increases the risk of colon wall perforation, which is a major and potentially life-threatening complication.

With the larger lumen of the proctoscope, there is the potential to use larger, rigid biopsy forceps and instruments to collect more substantial pieces of tissue than with typical biopsy instruments used in flexible endoscopes. Some rigid biopsy instruments feature angled biopsy cups, which make the process of sampling the mucosa through the rigid lumen somewhat easier. Rigid instruments with straight biopsy cups are still useful, but may require removal of a small amount of insufflated air to allow the mucosa to "drape" over the front of the endoscope lumen.

Normal Findings and Potential Abnormalities

Normal findings and potential abnormalities encountered during proctoscopy are identical to those seen

during flexible colonoscopy procedures, and are described in the flexible colonoscopy section below.

Colonoscopy

Indications

Colonoscopy is commonly indicated for the assessment of patients with predominantly or exclusively large intestinal symptoms, such as tenesmus, excess fecal mucus, fecal urge incontinence, hematochezia, dyschezia, and visible or palpable masses. Colonoscopy is also increasingly viewed as an important part of the overall approach to any chronic gastrointestinal disease case, a means of both assessing large intestinal involvement and collecting distal small intestinal biopsy samples via ileoscopy.

Patient Positioning

For most colonoscopy procedures, the patient should be placed in left lateral recumbence. As well as being convenient for combination upper and lower gastrointestinal tract procedures performed sequentially under the one anesthetic procedure, left lateral recumbence results in residual fluid pooling in the descending colon; this fluid is more readily suctioned from this position than if in the transverse or ascending arms of the colon. Colonoscopy procedures can also be carried out in sternal recumbence, which has the advantage that the anatomy of the colon is oriented in a "normal" position relative to the endoscope operator. However, scrupulous preparation is necessary to obtain optimum visualization if this position is used.

Equipment Choice

Navigation of the entire large intestine to the ileocolic junction requires the use of a flexible endoscope with four-way tip deflection, water and air insufflation, and a good sized working channel. Refurbished human colonoscopes with working lengths of 150–175 cm and 9–11 mm diameter are appropriate for many small animal patients and usually feature 2.8 mm working channels, allowing the use of larger biopsy instruments. In very small dogs and some cats, the use of these endoscopes may be more difficult, primarily due to the minimum turning radius of the endoscope tip rather than the endoscope diameter. In these smaller patients, a pediatric gastroscope may be a better choice.

General Technique and Landmarks

The lubricated endoscope tip is gently introduced via the anal sphincter. When a reduction in insertion pressure is noted, indicating that the tip of the endoscope has traversed the anal sphincter and is sitting within the distal rectum, the endoscopist should stop and insufflate while moving the tip controls gently in order to visualize a lumen. Unlike in the small intestine, where mucosal "fly by" procedures are common, in the large intestine it is generally best only to proceed forwards when there is a visible lumen. As air insufflation proceeds, the pressure of the accumulating gas may lead to leakage around the endoscope at the anal sphincter. This can be overcome by having an assistant apply gentle circumferential pressure around the anus; the same assistant can also advance the main endoscope body while the main operator utilizes the tip deflection controls and air/water insufflation to maintain visualization.

The distal rectum is assessed as soon as the lumen is insufflated, examining for preexisting erosions and the presence of mucosal masses. To obtain complete visualization of the distal rectum and the oral surface of the anal sphincter requires a maximally flexed J-maneuver, which may not be feasible in smaller patients.

As the endoscope is advanced, the descending colon wall is examined for changes in mucosal friability, granularity, and the presence of masses. If the patient is in left lateral recumbence, some fluid pooling is to be expected along the lumen of the descending colon; this fluid should be aspirated as much as possible to optimize mucosal visibility.

At the end of the descending colon, the lumen will make a marked deviation into the transverse colon. Ideally, this turn should be made with a target lumen visible, although this is not always feasible. Carefully assess what mucosa is visible from the descending colon before proceeding into the transverse colon; if severe ulceration or erosions are present, it may be more prudent to limit the examination to reduce the risk of perforation.

The transverse colon crosses the abdomen to reveal the short ascending colon and the ileocolic junction. This region is readily identified by the presence of a proud, intraluminal button of mucosa surrounding the ileocolic sphincter, while the nearby cecum is usually visible as a blind pouch close to the ileocolic sphincter. The cecal mucosa is usually arrayed in longitudinal folds similar to the rugae of the stomach. Lymphatic follicles can be quite prominent within the cecal mucosa.

Normal Findings

The normal colonic mucosa is smooth, a light pink in color and readily distensible with air insufflation. The ileocolic junction can be quite variable in appearance (Figure 49.16). Depending upon the trajectory of the endoscope approaching this region, the ileocolic sphincter may be visualized to the left or right, and the opening of the cecum is also quite variable, in some cases showing a prominent "ridge" of tissue around the opening, while in others the cecal opening is hard to distinguish from the colon lumen and is appreciated only as a blind sac near to the ileocolic sphincter.

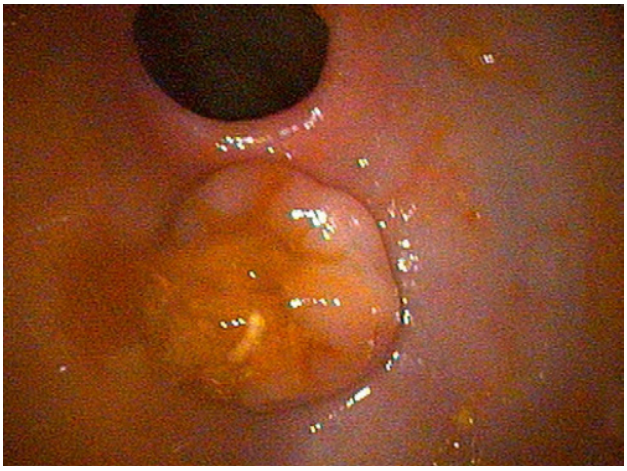

Figure 49.16 Colonic view of the normal ileocolic junction in a dog. The ileocolic sphincter, visible as a mushroom-like protrusion into the colonic lumen, occupies the lower half of the image. Above the ileocolic sphincter, the entry to the cecum is visible, surrounded by a "ridge" of normal colonic mucosa. The anatomy of this region, particularly the transition from colonic to cecal lumen, is highly variable in normal dogs.

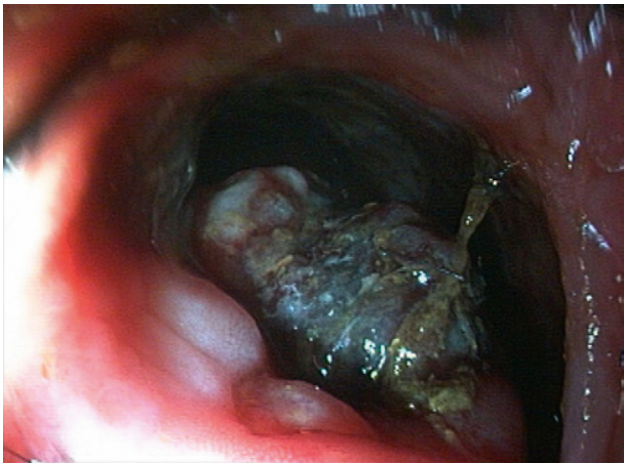

Figure 49.17 A large, severely ulcerated mass lesion in the descending colon of a canine patient. A marked increase in colonic mucosal granularity is also visible. Endoscopic biopsy of this lesion and the granular regions of colonic mucosa revealed lymphosarcoma.

Potential Abnormalities Observed during Colonoscopy Procedures

After careful assessment of the mucosa for consistency in appearance, texture, the presence of masses or erosions and ulcerations as the endoscope is advanced, biopsy samples should be obtained from areas of interest and several areas that are apparently normal as the endoscope is withdrawn. Mass lesions may also be biopsied but care must be taken to minimize the risk of colonic wall perforation. Mass lesions or ulcerative lesions with severe mucosal distortions (Figure 49.17) or deep mucosal defects are best assessed by collecting biopsies from the adjacent, more normal-appearing mucosa rather than the center of the mass, as biopsies from this region are usually of poor diagnostic quality due to tissue necrosis, and the risk of perforation is increased substantially.

Ileoscopy

Indications

Ileoscopy, while technically more challenging than many other gastrointestinal endoscopy procedures, is strongly recommended when endoscopic examination is being conducted as part of the approach to patients with gastrointestinal disease, regardless of whether the primary complaint is predominantly arising from upper or lower gastrointestinal tract signs. It is not unusual to document substantial histological disagreement between duodenal and ileal mucosal biopsy specimens, with the ileal mucosa often presenting with more severe changes. This holds true with both dogs and cats.

Patient Positioning and Preparation

As ileoscopy requires a transcolonic approach, ideally the patient will be placed in left lateral recumbence. This is consistent with the positioning for upper gastrointestinal procedures. Ideally, the patient will receive preprocedural preparation for colonoscopy. If there is no plan to fully assess the colonic mucosa and the sole reason for the procedure is to attempt to biopsy the ileal mucosa, a more abbreviated preparation protocol can be used, essentially several warm water enemas administered the evening before and once on the morning of the procedure (assuming a morning procedure time). This may provide sufficient space and visualization to allow traversal of the colon to the ileocolic junction, but there is a greater risk that the lower intensity preparation will result in inadequate visualization and failure of the procedure.

Equipment Choice

Ileoscopy requires a flexible colonoscope with four-way tip deflection, air/water insufflation and a large working channel, as used for colonoscopy procedures. Extra length will be necessary to allow navigation into and along the ileum, which may become limiting with larger canine patients.

General Technique and Landmarks

The ileocolic junction is approached at the end of the routine colonoscopy procedure, as described earlier. The endoscope tip is brought into contact with the center of the ileocolic sphincter, similarly to the antral approach to the pylorus. As with the pyloric approach, excessive air

insufflation can compromise attempts to traverse the sphincter. As there is little in the way of colonic wall close to the sphincter, due to the disparity in ileal versus colonic lumen diameters, full insufflation deprives the endoscopist of support from the colon walls.

If the endoscope can be successfully maneuvered into contact with the sphincter, gentle forwards pressure will usually result in entry to the ileum. If the ileum cannot be entered in this manner due to ileocolic anatomy, a flexible biopsy instrument can be threaded through the working channel and ileocolic sphincter to act as a guide wire. The instrument is advanced, cups closed, until it has penetrated the ileal lumen for 2–3 cm. The biopsy instrument is then held in place and the endoscope advanced over it. It is not recommended to simply follow the biopsy instrument with the endoscope, as this may result in significant trauma to the ileal mucosa (which has not been visualized).

Normal Findings

The normal ileal mucosa is grossly similar in appearance to the duodenal and jejunal mucosa. The normal villus structure results in a "velvet" appearance. The mucosa is more friable than the duodenum, even in normal individuals. Villus lymphatics are not readily appreciated.

Potential Abnormalities Observed during Ileoscopy Procedures

The ileal mucosa is assessed for changes in granularity, friability, the existence of preexisting erosions or ulcerative lesions and mass effects, and these changes documented if seen. Mucosal biopsy specimens should always be obtained from the ileum. If the endoscopist is unable to traverse the ileocolic sphincter, it is possible to obtain mucosal biopsy samples blindly by advancing a biopsy instrument through the sphincter, although this should be approached with caution as the risk of perforation is higher without the ability to visualize preexisting lesions.

Endoscopic Biopsy Technique

Endoscopic biopsies are an attractive option for more complete diagnostic assessment of the gastrointestinal tract, but are not without significant potential pitfalls. Correct biopsy technique, careful sample handling, and the collection of adequate sample numbers are all important to obtain the best diagnostic yield from these samples.

Flexible endoscopic biopsy instruments are available in several different types, including serrated or smooth jaws, and with or without central needles. Theoretically the central needle types are easier to lodge in the mucosa but in practice there seems to be little advantage to these types, and removal of the sample from the central needle can be difficult. The biopsies are inherently fragile and repeated "scraping" to remove the sample from the central needle can result in severe crush artifact distortion.

Endoscopic biopsy samples obtained using flexible instruments are unavoidably small. Even the largest of the flexible biopsy instruments that will fit in the endoscopes used most commonly in companion animal practice will typically only yield a 2.5–3 mm^3 tissue sample under most conditions. Most samples obtained endoscopically will have relatively little submucosal tissue present, and in many cases small intestinal biopsies may only yield villus tips. Correct technique is necessary to avoid excessive crush artifacts or villus degloving.

Because of the extreme wide-angle view and deep depth of focus of the endoscope lens, and lack of depth cues due to monocular vision, the distance between the end of the endoscope, the biopsy instrument, and the lesion to be biopsied can be difficult to judge. Once a site for biopsy is identified, the biopsy instrument is carefully deployed through the working channel until it is visible to the operator. Fine tip adjustments can then be made to align the instrument with the area to be biopsied, and then the instrument is advanced to make contact with the tissue. The flexible shaft of the biopsy instrument will start to bend slightly as the instrument is pushed up against the tissue. This bending is a good indicator that an appropriate amount of pressure is being applied to the tissue to provide the best chance of an adequate biopsy.

The biopsy instrument emerges from the distal face of the endoscope (Figure 49.18), which will usually result in the instrument running parallel to the gastrointestinal lumen. If the endoscope is maneuvered close to a naturally occurring fold or corner in the lumen, it is possible to directly sample tissue perpendicular to the distal scope face. For biopsies from the wall in an area that does not have a naturally occurring fold or local corner (such as in the descending duodenum), a number of strategies are available. Gently suctioning some of the insufflating gas may result in formation of rugal folds. After minor suction is applied, the endoscope tip is diverted towards the mural surface using the tip deflection controls, then the biopsy instrument is advanced out until just in view and close to, but not touching, the mucosa. The biopsy jaws should be open at this point. Full suction is then applied, which will cause the lumen to collapse and the mucosa to "drape" over the end of the scope. The biopsy instrument is advanced very slightly and then the jaws are closed. The biopsy is then collected.

The necessary action to collect an endoscopic biopsy is with a sharp "snapping" pull on the instrument at the control end of the scope. The aim is to avulse the mucosal sample by breaking the submucosal tissue. If the tissue is collected with a slower "drag" motion, it is not

Figure 49.18 A hemispherical jaw biopsy instrument exits the distal end of a videoendoscope perpendicular to the imaging components and parallel to the long axis of the gastrointestinal tract. Manipulation of the tip of the endoscope is typically necessary to bring the biopsy instrument into correct apposition against the mucosa to obtain adequate biopsies.

uncommon to yield only mucus, or to deglove the villi and retrieve only mucosal fragments. These samples are usually not of diagnostic quality, as the loss of architectural context limits the ability of the pathologist to accurately assess the mucosa.

After collection, the biopsy instrument is removed while leaving the endoscope in place. The instrument should be kept closed until the instrument has been fully removed from the endoscope and an assistant has restrained the end of the instrument. The instrument is then opened, and the tissue sample retrieved from within the biopsy cups. Often, the tissue will be adherent to the biopsy cups, and the tissue may need to be removed by *gentle* manipulation with a fine hypodermic needle (typically 25 ga). "Stickiness" of the biopsy to the instrument is more pronounced with smaller biopsy instruments and in samples from the small intestinal mucosa.

Given that each individual sample is very small, and may not be representative of the total of the pathologic changes present in the patient, it is important to obtain multiple biopsy samples from each organ sampled. Assuming adequate biopsy technique and handling, at least seven samples per site (i.e., seven each from upper and lower small intestine, stomach) in dogs and 10 in cats are necessary to achieve acceptable correlation with full-thickness biopsy results. If inadequate technique is used, particularly in cats, there is a very real chance that samples will have no diagnostic utility.

Biopsy of the gastric mucosa is somewhat more straightforward than in the small intestine as the stomach is more readily distensible and the greater space within the organ allows easier manipulation of the endoscope to a position perpendicular to the mucosa. The gastric mucosa is more robust than the small intestinal mucosa, and good-quality biopsies are easier to obtain from most areas of the stomach.

The esophageal mucosa is predominantly squamous epithelium, and difficult to adequately biopsy unless severe pathology is present.

Tissues from different sources (small intestine vs large intestine vs stomach) should be handled and submitted separately.

Postbiopsy handling of the tissues is also important for maximum diagnostic utility. Different pathology services may have differing requirements for sample submission but generally speaking, it is best to organize biopsy samples in a manner that will maintain consistent orientation as the samples are paraffin embedded and sectioned. If feasible, samples can be directly placed into sample handling cassettes, oriented with the mucosa perpendicular to the base of the cassette. It is important to use cassettes that are compatible with the sample handling systems of the pathology laboratory. The whole cassette can then be submerged in buffered formalin for histologic assessment. This will result in samples that are as close to parallel to the microtome blade as possible, yielding a greater proportion of longitudinal sections of the villi. This is important to allow the pathologist to assess characters such as villus blunting and the presence of inflammatory infiltrates within the crypts.

Endoscopic Interventions

PEG Tube Placement

Percutaneous endoscopic gastrostomy tubes are useful for providing long-term nutritional support to veterinary patients with severe esophageal or oral pathology, and also for those with poor appetite due other co-morbid

conditions. Placement of these devices is relatively simple, but care must be taken to minimize the risk of complications.

Indications and Patient Choice

Percutaneous endoscopic gastrostomy tube placement should be considered in patients with significant dysphagia, anorexia, esophageal or oral pathology with an anticipated need for nutritional support beyond 3–5 days. PEG tubes may be placed in both canine and feline patients, but are of particular use in dogs (particularly larger breeds) where the placement of esophagostomy tubes is more difficult due to the anatomy of the neck and cervical esophagus. PEG tubes have the advantage of larger lumens than are typically used in nasoesophageal or esophageal feeding, and are generally well tolerated such that they can be maintained for weeks to months. After formation of a stable adhesion of the gastric wall to the peritoneum and abdominal wall (generally after 10–14 days), it is feasible to convert PEG tubes to lower profile gastrostomy tubes that are somewhat easier for clients to maintain and do not feature extraabdominal tubing that must be restrained and maintained.

Placement of PEG tubes is straightforward in most patients. Difficulty can be encountered in patients with megaesophagus, due primarily to negotiating the lower esophageal sphincter in these patients. Large, deep-chested dogs can also be more difficult as the normal gastric position in these patients is high under the thoracic cage, these patients can require substantial insufflation of the stomach to allow access, and the resulting ostium and adhesions are under tension after the stomach is deflated. Larger breed, debilitated dogs have a greater risk of tube failure and peritonitis so in these patients it may be more prudent to place gastrostomy tubes surgically.

While the procedure is relatively easy to describe, and manufactured kits designed to make tube insertion simple are available, it is still prudent to have at least some guidance from an experienced endoscopist when first learning to place these tubes.

General Procedure

Percutaneous endoscopic gastrostomy tubes are placed exiting the flank on the left side, so the patient should be placed in right lateral recumbence. The left paracostal region is clipped and surgically prepared. The endoscope is passed into the stomach, and air insufflated to distend the stomach against the abdominal wall. While the endoscope operator is visualizing the gastric wall, an assistant wearing sterile gloves palpates and presses on the region of maximum distension, to allow the endoscopist to establish where the tube will eventually be placed. The endoscope is then manipulated to the point of compression and the gastric wall transilluminated to ensure that there are no major structures (particularly the spleen) present between the gastric and abdominal walls.

The description given below assumes that a manufactured PEG tube kit is being used, which are provided with the tube mechanically bonded to a loop of wire at the proximal end, and a guide wire that features a loop at the distal end. Techniques for the assembly of PEG tubes using sterile pipette tips and standard suture materials have been described, but with the ready availability of commercial PEG kits in the veterinary market, the manufacture of tubes from a miscellany of materials is no longer recommended.

Once the point of insertion is established, the sterile-gloved assistant passes a large hypodermic needle (typically 18–16 ga, 2+ inches) through the skin and gastric wall, typically placed just ventral and slightly caudal to rib 13. The endoscope operator monitors the hypodermic needle entry. Once the hypodermic needle is placed, a guide wire with a terminal loop is threaded through the lumen of the needle by the assistant, and captured by the endoscopist using either flexible alligator or cup biopsy forceps. Once the guide wire loop is captured, it is carefully pulled through the stomach, esophagus, and oral cavity by withdrawing the endoscope. The assistant should feed the guide wire via the needle, while monitoring closely to ensure that the full length of the guide wire is not pulled into the stomach lumen.

After the loop of guide wire is withdrawn via the mouth, it is attached to the proximal end of the tube by passing the tube mushroom tip through the guide wire loop, then through the tube's own bonded wire loop, resulting in the tube proximal end being attached to the guide wire via linked loops.

The guide wire and linked tube, bonded tip first, are withdrawn into the oral cavity, through the esophagus and into the stomach lumen by the sterile-gloved assistant. As the guide wire and linked proximal tube end encounter the gastric wall, the wall is pulled up against the flank. The bonded sharp tip of the tube is drawn through the abdominal wall by continuous gentle traction. A small stab incision will usually be necessary at the point of tube exit.

As the tube is withdrawn through the abdominal wall, the endoscopist replaces the endoscope into the gastric lumen and monitors the positioning of the distal mushroom tip against the gastric wall. The mushroom tip should be placed with sufficient tension to hold the gastric wall against the abdominal wall, but excessive tension should be avoided as this may lead to gastric wall necrosis below the mushroom tip and failure of the gastrostomy site. The mushroom tip should gently flatten the gastric mucosa, but blanching of the mucosa should not be visible on examination. If the mucosa is blanched,

the distracting tension on the tube must be loosened to reduce the risk of gastric wall compromise.

When the operator is satisfied that the tube is correctly positioned, the bonded sharp end is removed with heavy bandage scissors and the tube retained against the external flank using a retaining anchor system. The gastrostomy site is bandaged and the tube trimmed to length before assembly of a catheter tip closure to allow administration of food. The remaining tube should be loosely restrained against the body using stockinet tubing and/or an old t-shirt, and an Elizabethan collar applied for at least the first 4–5 days while a stable adhesion is being formed.

Assuming no complications in placement of the PEG tube, administration of fluids (water initially) and then liquid or blenderized diets can commence approximately eight hours after the patient recovers from anesthesia.

PEG-J Tube Placement

Percutaneous endoscopic gastrostomy-jejunostomy tubes are a refinement and addition to the PEG tube systems described above, with additional placement of a tube into the jejunum. A PEG tube is placed as described above, then a narrow feeding tube with a loop of suture material at the distal end is threaded into the gastric lumen via the gastrostomy tube. This second tube is captured at the loop of suture material, then the tube is carried through the pylorus and into the duodenum by the endoscope. The second tube is carried as far as possible distally by the endoscope, then gently threaded further to reach the jejunum. The PEG and J-tubes are then trimmed and retained as previously described. The addition of the J-tube allows the delivery of liquid diets into the jejunum, completely bypassing the duodenum. While nutrition is being delivered to the jejunum, gastric secretions and fluid can be suctioned via the PEG tube, which may help to control vomiting in patients with severe gastric or pancreatic inflammation. As the patient recovers and the stomach is more amenable to diet input, the J-tube can be removed and use of the PEG tube instituted.

While there are some theoretical benefits to the use of PEG-J tubes in animals with very severe pancreatic disease, the author rarely uses these tubes in these patients. Instead, a multimodal antiemetic protocol is used along with gastric tube or esophagostomy tube feeding. There is no evidence to support the contention that "pancreatic rest" is important for patients with pancreatitis, which is the main imperative behind J-tube feeding in most patients.

Foreign Body Removal

The use of endoscopy, either rigid (within the esophagus) or flexible (esophagus and stomach), is an attractive first-line option for management of this problem. The potential for removal without surgery allows more rapid recovery of the patient and reduces the risk of gastrointestinal perforation and/or wound dehiscence. This potential must be tempered by the reality that often the endoscopic removal of foreign bodies, particularly "slippery" gastric foreign bodies that can be quite fragile, can take long periods of time and may not be feasible. It is good practice to define an upper time limit for the endoscopic procedure before transitioning to surgical management.

A variety of retrieval devices is available, with varying strengths and indications (Figure 49.19). For esophageal foreign bodies, it is often possible to use long, rigid forceps to grasp the foreign body. This is particularly helpful if using a rigid endoscope for the esophagoscopy, but can also be carried out with flexible endoscopy equipment by carefully introducing the retrieval instrument beside or above the endoscope that is viewing the foreign body. Other retrieval instrument options include flexible alligator forceps, deployable wire cages, three-pronged graspers, Foley catheters, wire loops and snares, and old endoscopy biopsy forceps. The use of biopsy forceps for foreign body retrieval will usually result in dulling of the edges and loss of effective biopsy function so older forceps should be used.

There is no one technique or device that reliably succeeds in grasping and removal of all foreign bodies of any specific type. While some general observations can be made, such as alligator forceps have no utility with rounded, smooth-surfaced objects, most foreign body retrievals will require the use of several different types of instrument. For instance, flexible alligator or old biopsy forceps may be used to reposition an object within the gastric lumen, allowing application of a wire basket for the actual retrieval process. Some foreign bodies will require reorientation several times to allow a graspable surface to be visualized. As wide a selection of retrieval instruments as possible should be available to the endoscopist. Foley catheters can be used to manipulate and reposition some objects by threading them past the obstruction, then inflating the balloon before applying gentle distracting pressure.

It is particularly attractive to attempt esophageal foreign body removal endoscopically wherever possible, as removal of foreign bodies from the thoracic esophagus via thoracotomy and esophagotomy is technically difficult and has a high risk of wound dehiscence and subsequent development of pneumomediastinum, pneumothorax, and pyothorax. As a general observation, endoscopic removal of esophageal foreign bodies becomes increasingly difficult as the time since obstruction increases. Esophageal mucosal swelling and erosion/ulceration can occur rapidly, and these changes result in the foreign body becoming more and more

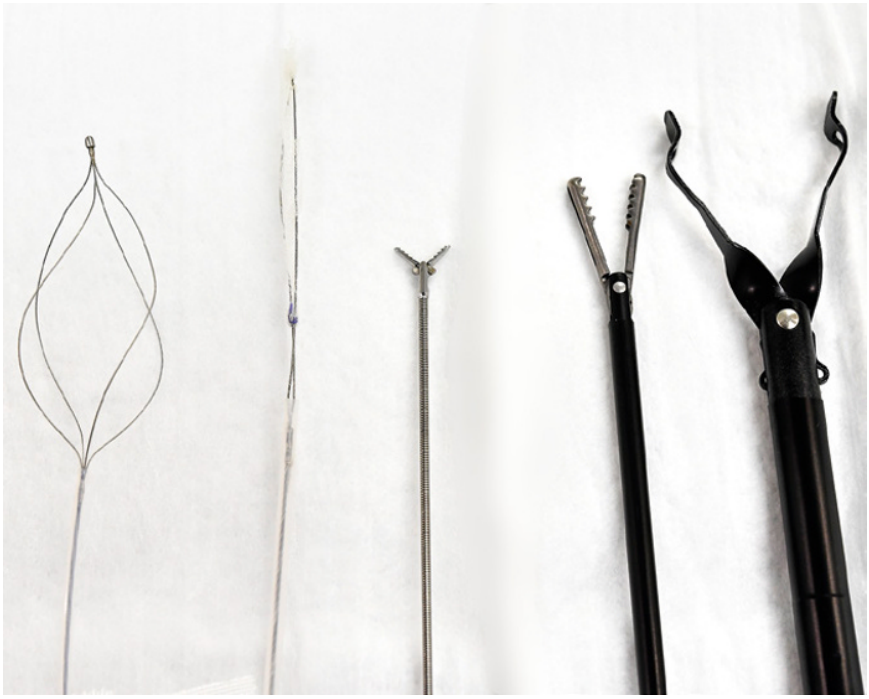

Figure 49.19 A selection of manipulating and retrieval instruments, which may be useful in retrieval of foreign bodies within the esophagus and/or gastric lumen. The rightmost two instruments are repurposed laparoscopic surgery graspers. From left to right, a four-wire basket forceps, a netting loop snare, and flexible alligator forceps. The flexible instruments are appropriate for use through the working channel of a larger endoscope, and can be utilized in the esophagus and stomach, but lack significant grasping power. The repurposed laparoscopic instruments have much larger working graspers and better grasping power. These rigid instruments are introduced to the esophagus either through a large rigid endoscope or along the side of a flexible endoscope. They are not appropriate for use in the gastric lumen.

firmly wedged. If the foreign body can be solidly grasped, a number of attempts to remove it via the oral cavity can be made, but if the object is not mobilized by moderate traction and the esophageal mucosa is showing increasing evidence of trauma/hemorrhage, a new strategy should be followed. If the foreign body can be pushed aborally into the stomach, this is often a preferable option. Many bone foreign bodies or impacted dog chews will dissipate once within the gastric lumen, while indigestible foreign bodies can be removed via celiotomy and gastrotomy with much lower risk of complications than arise from a transthoracic route.

When attempting to retrieve foreign bodies, great care should be taken that the gastrointestinal tract wall is not compromised, either by excessive force application or inadvertent perforation by sharp objects (bone fragments, needles, etc.) as they are withdrawn. It is also critical to assess the site of impaction after withdrawal for evidence of mucosal ulceration and abrasion. Within the gastric lumen, it is usually possible to visualize the site of impaction after initial grasping of the object, but with esophageal foreign bodies it will be necessary to reintroduce the endoscope to assess the mucosa. Severe circumferential mucosal damage, particularly if there is exposure of the submucosa, leaves the patient with a high risk for esophageal stricture formation. It is also recommended to obtain thoracic radiographs following removal of esophageal foreign bodies to assess for early signs of esophageal perforation such as pneumomediastinum or pneumothorax. If the patient has evidence of severe esophagitis and mucosal ulceration/abrasion, placement of a PEG tube for postoperative nutritional support is strongly recommended.

Esophageal Stricture Management

Esophageal stricture recognition and management via either bougienage or balloon dilation are discussed in detail in Chapter 52.

Future Directions of Gastrointestinal Endoscopy

After the unavoidably small size of biopsies achievable using flexible endoscopy, probably the greatest limitation of endoscopy in the gastrointestinal tract of veterinary patients is the lack of ability to assess the entire gastrointestinal tract. While many diseases that affect the gastrointestinal tract are diffuse, and thus duodenoscopy and distal ileoscopy will commonly result in meaningful diagnostic findings, solitary lesions in the deeper jejunum and proximal ileum are not unknown.

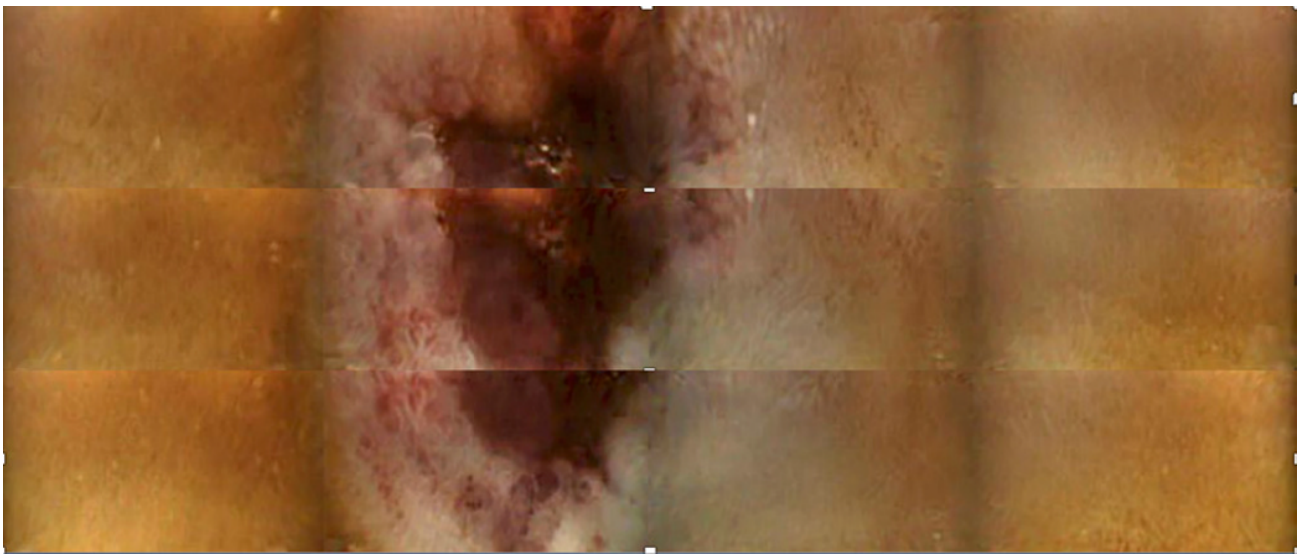

Figure 49.21 Composite image showing several captures from a capsule endoscopy system as it transits the small intestine of a canine patient. Marked mucosal erosion and ulceration are apparent. *Source:* Image courtesy of Infiniti Medical, LLC. www.Infinitimedical.com

A number of newer systems and strategies have been described that have the potential to allow direct visualization of much larger proportions of the gastrointestinal tract. The two most promising are double balloon push and pull enteroscopy and the use of capsule endoscopy systems.

Double Balloon Enteroscopy

Double balloon push and pull enteroscopy is carried out using an endoscope with an inflatable balloon, similar to a Foley catheter balloon, incorporated into the distal endoscope tip, and an additional balloon on a mobile

cuff that surrounds the distal endoscope. These balloons are sequentially inflated and deflated, and the endoscope advanced, as the small intestinal loops fold up behind the outer cuff. This technique has been described in a limited number of canine patients at the time of writing, and has some limitations due to the overall diameter of the specific endoscope/cuff combination (13.2 mm) and the increased stiffness and turning radius of the endoscope. The full exploration of the gastrointestinal tract using this endoscope is also a longer procedure than is typical for upper gastrointestinal endoscopy. An advantage of this approach is that biopsy samples can be obtained from a greater proportion of the gastrointestinal tract, and discrete lesions within the jejunum may be able to be sampled.

Capsule Endoscopy

Complete assessment of the entire gastrointestinal tract of dogs can be obtained in a minimally invasive manner through use of self-contained capsule endoscopes. These devices include cameras with 360° field of view, light sources, and digital storage space within a plastic enclosure that is similar in size and shape to a large capsule (Figure 49.20). The capsule is administered to the patient orally, and after transit through the entire gastrointestinal tract is recovered to allow downloading of digital image files. These systems have advantages in avoiding the need for anesthesia and postprocedural recovery, and arguably allow assessment of the gastrointestinal tract in a more natural state as the vascular changes induced by patient preparation and anesthesia are avoided.

An obvious limitation of the capsule endoscopy systems is that they are unable to retrieve biopsies, and the actual location where a lesion is observed cannot be determined with great accuracy as the images are typically not accessible until after complete transit through the gastrointestinal tract. This approach is very useful, however, for a complete assessment of the gastrointestinal tract for focal lesions, bleeding ulcers, discrete mucosal pathology changes, etc. (Figure 49.21). Anatomic landmarks, such as the pylorus, major duodenal flexure, and ileocolic junction, are usually easily identified, allowing some degree of certainty of the specific section of the gastrointestinal tract that can be observed.

Diseases of the Oral Cavity and Salivary Glands

Maria M. Soltero-Rivera, DVM, DAVDC[1] and Alexander M. Reiter, Dipl.Tzt., Dr.Med. Vet., DAVDC, DEVDC[2]

[1] *VCA San Francisco Veterinary Specialists, San Francisco, CA, USA*
[2] *School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA, USA*

A history of ptyalism or drooling saliva, perioral +/– oculonasal discharge, anorexia, weight loss, unkempt hair coat, vocalizing when eating, pawing at the mouth, rubbing the face on the furniture or carpeting, bruxism, chattering, and/or hesitation to have the head or face touched should prompt the clinician to perform a thorough intraoral and extraoral examination. Oral and salivary gland diseases can have various presentations, and often the duration of clinical signs along with the distribution of the lesions can aid in determining the etiology of the condition (Table 50.1). Histologically, oral lesions can range in appearance from areas of ulceration to vesicles to even proliferation of tissues, whether it is through hyperplasia, neoplasia or granulation tissue formation, to areas of necrosis. Salivary gland enlargement follows a spectrum, with the noninflamed form, known as sialadenosis, followed by sialadenitis and finally necrotizing sialometaplasia. Neoplasia can also occur in the salivary glands. It is important to keep in mind that some systemic diseases can manifest with oral lesions. Additionally, some systemic diseases that lead to immunosuppression can predispose patients to oral disease.

Healthy Oral Tissues and Salivary Glands

The masticatory and lining mucosa are the primary tissues affected by oral inflammation. The epithelium of the masticatory mucosa is moderately thick and frequently ortho-keratinized. It is inextensible and well adapted to withstanding abrasion. The epithelium of the lining mucosa is thicker than that of masticatory mucosa and is nonkeratinized. The surface is flexible and the submucosa is elastic, allowing it to stretch. Taste buds, gingival crevicular fluid, and normal bacterial flora play a role in protecting the oral cavity from insults. Taste buds reject potentially toxic materials. The gingival crevicular fluid is believed to cleanse the gingival sulcus, improve adhesion of the epithelium to the tooth via plasma proteins, possess antimicrobial properties, and exert antibody activity to protect the gingiva. The normal bacterial flora of the oral cavity plays a role in the innate resistance by preventing colonization and growth of foreign microbes.

There are four major pairs of salivary glands: mandibular, sublingual, parotid, and zygomatic. Minor salivary glands can be found on the palate, alveolar, labial and buccal mucosa, tongue, and along some of the ducts of the major salivary glands. Cats have an additional pair of mixed salivary glands found on the lingual aspect of the mandibular first molar tooth, known as the linguomolar gland. Secretory cells can be predominantly serous, predominantly mucous, or mixed. The secretory cells of the salivary glands form acini, surrounding a central draining space that empties into the intercalated, striated, and excretory ducts, successively. These ducts play a major role in determining the composition of saliva. Saliva cleanses the mouth, maintains tooth integrity, dilutes noxious materials, contains antibodies and antimicrobials, maintains the pH in the oral cavity, and plays a role in the formation of the bolus of food and initial digestion, depending on the species. The ducts and acini are surrounded by connective tissue carrying blood vessels and nerves.

Gingivitis and Periodontitis

Periodontal disease is commonly seen in dogs and cats characterized by inflammation of the supporting structures of the tooth. Ninety-six percent of 109 adult cats, with a mean age of 6.2 +/– 5.2 years, showed evidence of gingival inflammation in one study. A recent study

Table 50.1 Nomenclature of oral and oropharyngeal inflammation according to the American Veterinary Dental College (AVDC)

Location	Term	Definition
Gingiva	Gingivitis	Inflammation of gingiva
Periodontal ligament, alveolar bone and cementum	Periodontitis	Inflammation of nongingival periodontal tissues
Bone and bone marrow	Osteomyelitis	Inflammation of the bone and bone marrow
Alveolar mucosa	Alveolar mucositis	Inflammation of alveolar mucosa (i.e., mucosa overlying the alveolar process and extending from the mucogingival junction without obvious demarcation to the vestibular sulcus and to the floor of the mouth)
Sublingual mucosa	Sublingual mucositis	Inflammation of mucosa on the floor of the mouth
Labial/buccal mucosa	Labial/buccal mucositis	Inflammation of the lip/cheek mucosa
Mucosa of the caudal oral cavity	Caudal mucositis	Inflammation of mucosa of the caudal oral cavity, bordered medially by the palatoglossal folds and fauces, dorsally by the hard and soft palate, and rostrally by alveolar and buccal mucosa
Palatal mucosa	Palatitis	Inflammation of mucosa covering the hard and/or soft palate
Lingual mucosa	Glossitis	Inflammation of mucosa of the dorsal, lateral and/or ventral tongue surface
Lip	Cheilitis	Inflammation of the lip (including the mucocutaneous junction area and skin of the lip)
Mouth	Stomatitis	Inflammation of the mucous lining of any of the structures in the mouth; in clinical use the term should be reserved to describe widespread oral inflammation (beyond gingivitis and periodontitis) that may also extend into submucosal tissues (e.g., marked caudal mucositis extending into submucosal tissues may be termed caudal stomatitis)
Palatine tonsil	Tonsillitis	Inflammation of the palatine tonsil
Pharynx	Pharyngitis	Inflammation of the pharynx

looking at the prevalence of disorders recorded in dogs in attending primary care veterinary practices in England revealed periodontal disease to be the second most frequently identified disorder. Gingivitis is inflammation of the gingiva, which may remain stable throughout the life of the animal. However, with the aid of additional factors and in a cyclical fashion, it may progress to periodontitis. Periodontitis is inflammation of the periodontal ligament, cementum and alveolar bone, resulting in pocket formation, gingival recession, and alveolar bone loss (Figure 50.1).

Histologically, the pulp tissue of teeth with advanced periodontitis may undergo changes including acute and chronic pulpitis, vascular congestion, and pulp necrosis. These changes may be the result of occlusion of the vascular channel by secondary or tertiary dentinal deposition, increased mobility of teeth with severe attachment loss, or, less likely, the centripetal spread of infection or inflammation into the pulp.

Up to 13% of cats suffering from periodontal disease may have evidence of aggressive periodontitis. There is also a strong association between periodontal disease and type I tooth resorption. In one study, up to 72% of teeth with type I resorption showed periodontitis, as opposed to approximately 16% of teeth with type II resorption. Tooth resorption has also been reported in dogs but not necessarily in association to periodontitis. It can occur in association to endodontic disease or with oral neoplasia at tumor sites and at sites distant from tumors.

A strong suspicion for a genetic predisposition towards dental disease exists in cats and dogs. Pure-bred cats are said to develop dental calculus more commonly than domestic shorthair cats. Additionally, rapidly progressive and refractory periodontitis has been reported to occur more commonly in young Somali and Abyssinian cats exhibiting stomatitis or feline immunodeficiency virus (FIV) involvement. A condition known as juvenile hyperplastic gingivitis has been described in cats younger than 2 years of age (Figure 50.2).

In dogs, a familial predisposition to gingival hyperplasia has been found in the boxer. Smaller breeds and brachycephalic pets can have crowding of their teeth and malocclusion that can predispose them to periodontal

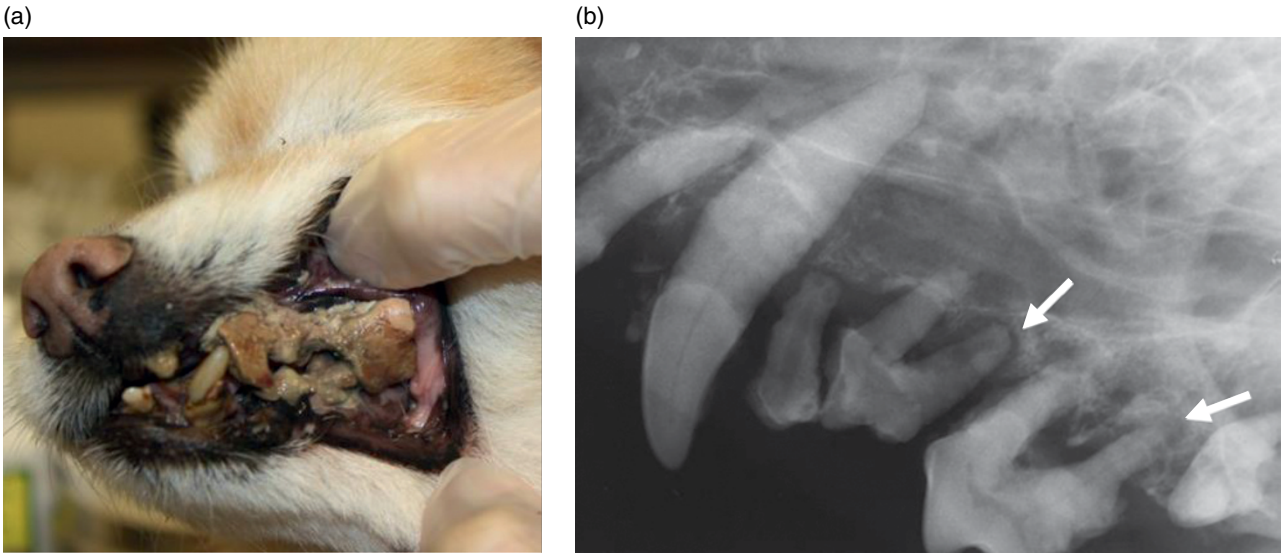

Figure 50.1 (a) Photograph of a 15-year-old Pomeranian, showing severe calculus and plaque accumulation along with multiple missing teeth. disease. Miniature schnauzers and greyhounds have a propensity to localized juvenile periodontitis and refractory rapidly progressing periodontitis.

In humans, periodontitis has been associated with abnormal phagocytic activity as well as immunosuppressive states. Hypoplasia of root cementum has also been implicated as a cause specifically in human cases of juvenile periodontitis. Single amino acid variations because of mutation in interleukin (IL)-6, IL-10, and lactoferrin genes may result in a change in their functionality which could play a role in the development of disease. However, this has yet to be confirmed in pets.

Periodontal disease treatment has the goal of cleaning and eliminating deep pockets with closed or open

techniques, restoring a normal gingival contour via careful gingivectomy and gingivoplasty, extracting teeth with severe attachment loss, and instituting rigorous home oral hygiene until elimination of potential causes of the disease.

Medical management with antibiotic treatment may occasionally be considered as an adjunct to definitive treatment, in preparation for the procedure or in patients where anesthesia is not an option. Amoxicillin-clavulanic acid (Clavamox®, Pfizer) has the highest *in vitro* susceptibility against all isolates and all anaerobes isolated from the subgingival spaces of cats. Additionally, enrofloxacin (Baytril®, Bayer) shows high *in vitro* susceptibility for the anaerobes isolated in cats. In dogs, amoxicillin-clavulanic acid has the highest *in vitro* susceptibility against all isolates, all aerobes, and all anaerobes. For dogs, enrofloxacin showed the highest *in vitro* susceptibility for gram-negative aerobes. Anaerobic bacteria oral bacteria in dogs appear to be susceptible to amoxicillin-clavulanic acid, doxycycline, and erythromycin, while aerobic bacteria are often also susceptible to sulfa-trimethoprim.

Despite the slight differences in susceptibility, no major differences are found between the subgingival floras of dogs and cats with gingivitis. Evaluation of the effects of systemic doxycycline use in dogs has shown a significant improvement in gingival attachment and bleeding with oral subantimicrobial doses of 2 mg/kg per day. A short-term (42 days) study evaluating the efficacy of control of gingivitis with use of cefovecin sodium (Convenia®, Pfizer) after a professional dental cleaning showed no significant difference when compared to oral administration of clindamycin.

In feline cases where professional dental cleaning and extraction of severely affected teeth do not resolve periodontal inflammation, patients should be tested for feline immunodeficiency virus (FIV)/feline leukemia virus (FeLV) seropositivity. A greater prevalence and increased severity of oral inflammation were noted in cats infected with FIV. The disease was worse in those with co-infection of FIV with feline calicivirus (FCV), or with FCV and FeLV.

When evaluating the systemic effects of periodontal disease in dogs, a strong association has been found between increasing severity of attachment loss with changes in systemic inflammatory variables and renal indices. Additionally, in dogs with advanced periodontal disease, increases in systemic nitric oxide levels two weeks after periodontal treatment have been reported, but the response is idiosyncratic. In cats, the severity of periodontitis has been associated with increases in globulins, alanine aminotransferase, and IgG blood levels, suggesting that periodontal disease is not simply a localized disease but may also affect patients systemically.

Stomatitis

Stomatitis is a complex, chronic, and destructive inflammatory process affecting the epithelium and lamina propria, with frequent extension into the submucosal tissues. This more widespread inflammation of the oral mucosa is estimated to affect 0.7% of cats presented to veterinary practices.

The etiology of stomatitis is not fully understood, but it is suspected to be multifactorial and a response to chronic stimulation by a still unidentified antigen. This contrasts with the contact stomatitis or contact mucosal ulceration that results from mucosal contact with an irritant, allergen or antigen most often in areas of heavy plaque burden. This condition is known as canine chronic ulcerative stomatitis and chronic ulcerative paradental stomatitis. However, the lesions are commonly referred to as "kissing ulcers" or "contact ulcers." Two cases of concurrent osteomyelitis and paradental stomatitis have been reported. Epitheliotropic T cell lymphoma and erythema multiforme have also been reported as causes of an ulcerative stomatitis with minor to no significant abnormalities in complete blood counts and blood biochemical profiles of affected dogs. Whereas cats are likely affected by the idiopathic form of this disease, in dogs the oral inflammation is often associated with a systemic disease. Vesiculobullous autoimmune disease, although sometimes confined to dermal tissues, can present as oral lesions in up to 90% of patients with pemphigus vulgaris and 50% of those with bullous pemphigoid.

A similar type of lesion, called pyogenic granuloma, that is proliferative rather than ulcerative in nature develops in the alveolar or buccal mucosa distobuccal to the mandibular first molar tooth in cats (Figure 50.3). The lesions may result from continued trauma secondary to a tight caudal occlusion between the maxillary fourth premolar and the mandibular first molar, or due to continued trauma from the maxillary fourth premolar on an area of inflammation on the distobuccal aspect of the mandibular first molar. Surgical excision of the mass and blunting or extraction of the involved tooth or teeth have been reported to be 100% effective.

Some of the common bacterial isolates in cats with stomatitis include *Pasteurella pneumotropica*, *Pasteurella multocida*, and *Capnocytophaga canimorsus*. Prior exposure to viral diseases such as FCV, feline herpesvirus (FHV), FeLV, and FIV is thought to be a risk factor for developing stomatitis. This is likely due to the progressive decline in immune functions caused by infection with FIV and FeLV. On the other hand, FCV does seem to play a more direct role as shown by persistent shedding of this virus in all cats with chronic ulceroproliferative stomatitis compared to only about 20% in normal cats.

Figure 50.3 Photograph of a pyogenic granuloma in a 5-year-old domestic shorthair. Copyright 2015 Alexander M. Reiter.

Ulcers on the tongue, philtrum, and palate can be seen in cases of FHV, but they are infrequent compared to FCV infection. Infection with FIV, FeLV, and FCV may also influence disease severity. The role of infection with *Bartonella* remains controversial. Infection with feline panleukopenia virus, feline syncytium-forming virus, feline infectious peritonitis, and *Candida albicans* have also been implicated as causes of stomatitis.

In cats with stomatitis, immunohistochemistry (IHC) has shown that the number of CD79a+ cells, L1+ cells and CD3+ T cells and the level of MHC class II expression tend to correlate with disease severity. Additionally, CD8+ T cells are more numerous than CD4+ T cells, and most of the plasma cells are of the IgG isotype. The number of cells labeled for CD3, CD4, CD8, CD79a, IgG, IgA or L1 and the number of mast cells within the lamina propria and submucosa are significantly increased in affected patients. The epithelial compartment also has more CD3+ T cells compared to healthy cats. Mast cell density is also significantly increased in gingival tissues adjacent to areas affected by stomatitis. IHC has proven value in reaching a definitive diagnosis in dogs with stomatitis due to erythema multiforme and epitheliotrophic T cell lymphoma. Immunohistochemistry, clonality testing, repeated biopsies, and close follow-up are recommended in such difficult cases.

Animals affected by stomatitis will often show signs of oral discomfort when eating, grooming, or when manipulating their mouths. In addition to the often symmetric, bright, ulcerated or proliferative lesions of the area lateral to the palatoglossal folds, multiple areas can be affected by inflammation including the gingiva, alveolar mucosa, labial and buccal mucosa, the lateral margins of the tongue and the areas of the hard palate that are in contact with the teeth (Figure 50.4).

Physical examination findings may include a poor hair coat and decreased body condition. Of cats with stomatitis, 49–61% show radiographic evidence of resorption of multiple teeth. Periodontal disease is seen in all cases, and retained tooth roots can be found in 56% of cases. Differentiation into squamous cell carcinoma has been reported in some cats.

Acutely, treatment for cats consists of controlling the inflammation via immunosuppression or immune modulation along with symptomatic control. In dogs, treatment of the underlying cause is extremely important. Glucocorticoids such as prednisone or prednisolone are typically used at a dose of 0.5–1 mg/kg by mouth once daily and can be effective in 73–86% of cases. Antibiotics may also be used. However, only 30% of cases respond, and the response is only transient. Amoxicillin-clavulanic acid (13.75 mg/kg q12h, PO) or clindamycin (5–11 mg/kg q12h, PO) are most commonly used. Nutritional support is sometimes necessary, especially in chronic cases with severe weight loss and evidence of dehydration. Otherwise, the patient should only be offered soft food. If symptoms resolve or the patient improves significantly, plaque control measures, namely daily tooth brushing, should be instituted. However, many pets are too painful to allow this. Pain control with sublingual buprenorphine (0.01 mg/kg q8–12h, PO) or a transdermal fentanyl patch should also be considered.

Chronically, treatment with glucocorticoids is not recommended due to the undesirable long-term side-effects that may develop, including diabetes mellitus, polyuria, and polydipsia. Full-mouth extraction is recommended in cats which has achieved a nearly 80% success rate with either a complete cure in 60% of cases or a clinical cure in 20% of cases. In severe cases, transient treatment with glucocorticoids (0.5–1 mg/kg q24h, PO) immediately after full-mouth extraction may be necessary. A recent study comparing full-mouth versus partial-mouth extraction in cats showed the extent of extractions not to be associated with the overall response of treatment. Additionally, the 68.8% of symptomatically or clinically cured cats required extended medical management for a finite period to achieve a positive outcome. In dogs, a staged approach by removing severely diseased teeth is recommended, and extraction of teeth directly in contact with the areas of inflammation can be considered. A professional dental cleaning should also be performed until the underlying disease process is controlled.

When cases are refractory, treatment with interferon omega may be considered. Daily use of this medication (0.1 mU q24h, PO) in cats has resulted in significant improvement of pain scores at 60 and 90 days post

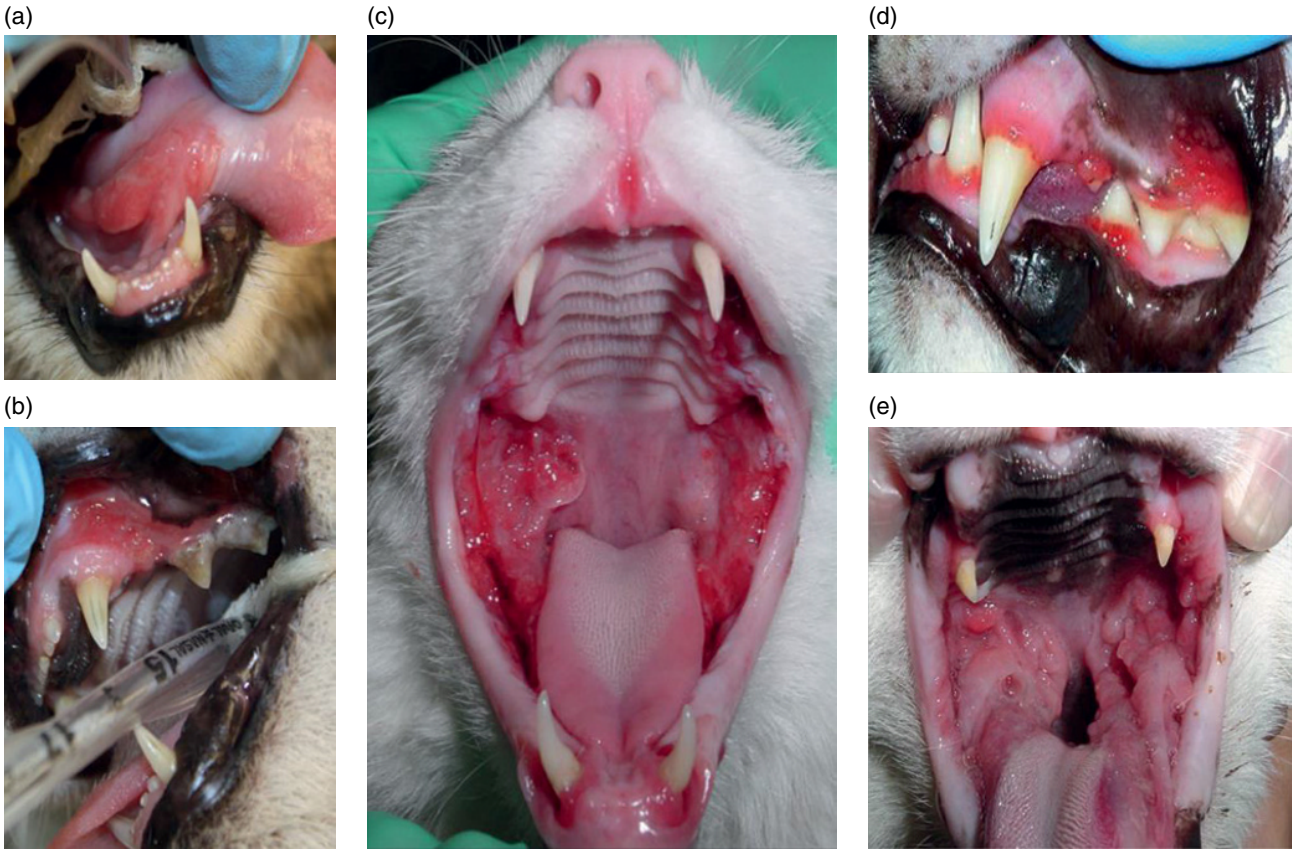

Figure 50.4 Photographs of multiple patients showing varying presentations of feline stomatitis. (a) Sublingual. (b) Diffuse alveolar. (c) Ulcerative, caudal and lateral to the palatoglossal folds. (d) Focal alveolar. (e) Proliferative, caudal and involving the palatoglossal folds. Note that the hard and soft palate are usually not involved in this classic type of stomatitis. Copyright 2015 Alexander M. Reiter.

treatment. Intralesional injections with interferon omega can be considered prior to oral administration. Finally, ablation of inflamed tissues in cats using CO_2 laser has been reported to promote fibrosis after repeated treatments in a refractory case. When treating with interferon omega or CO_2 laser, the owners need to understand that repeated treatments are often necessary before even slight improvements are seen.

Autologous mesenchymal stem cell therapy has also been used for treatment of refractory stomatitis, with success being seen in five out of seven cats that completed the study. Cats that responded to treatment also exhibited systemic immunomodulation demonstrated by decreased numbers of circulating CD8+ T cells, a normalization of the CD4:CD8 ratio, decreased neutrophil counts, and interferon gamma and IL-1-beta concentration, and a temporary increase in serum IL-6 and tumor necrosis factor-alpha concentration.

Stomatitis can be a frustrating condition for the pet, the owner, and the veterinarian. Retroviral status should be assessed prior to therapy, as this may affect prognosis. In dogs, prognosis is largely dependent on the underlying systemic disease process.

Odontogenic Tumors and Cysts

Odontogenic tumors are more common in dogs than cats. Acanthomatous ameloblastomas are more commonly seen, followed closely by peripheral odontogenic fibromas and focal fibrous hyperplasia. Acanthomatous ameloblastoma commonly arises in the rostral lower jaw whereas peripheral odontogenic fibromas and focal fibrous hyperplasia tend to be more commonly seen in the rostral upper jaw. A breed predisposition for development of acanthomatous ameloblastoma has been suggested, with golden retrievers, Akitas, Shetland sheepdogs, and cocker spaniels being more commonly reported. Peripheral odontogenic fibromas may also have a predilection for castrated male dogs.

Azithromycin in systemic and toothpaste forms has been used in the management of gingival hyperplasia secondary to ciclosporin treatment in dogs. In this report, there was a significant decrease in gingival sulcus depth for the capsule group at week 8 and for the toothpaste group at weeks 2, 4, and 8. Gastrointestinal adverse events occurred in all groups, but more frequently in the patients treated systemically. Gingival recontouring to

reduce the pseudopockets created by hyperplastic gingiva along with periodontal treatment can also be recommended.

Extent of resection required to prevent tumor recurrence depends on the tumor type. A study describing the clinical behavior of acanthomatous ameloblastoma revealed 0% of patients had incomplete histopathologic margins when 2 cm intended surgical margins were utilized compared to 33% when 1 cm intended surgical margins were utilized. However, it was found that regardless of postsurgical neoplasia-free margin, no gross local recurrence was noted in the oral cavity for a minimum follow-up of 12 months after surgery.

Odontogenic cysts are also commonly seen, with more than half arising from unerupted teeth, mainly the mandibular first premolar teeth. This type of cyst is known as a dentigerous (or tooth-containing) cyst, and brachycephalic dogs appear to have a predisposition to development of these lesions. Dentigerous cysts are thought to arise from the proliferation of basal cells in the lining epithelium or the epithelium of the tooth crown but may also arise from cell rests of Malassez. If the tooth fails to erupt, the follicle remains and produces the sac lined by stratified mucus or cutaneous epithelium. Cysts can be very expansile, causing weakening of the bone involved and root resorption of neighboring teeth. A potential for pathologic fractures and tooth loss arises if these cysts are not treated. Even though radiographic findings are virtually pathognomonic, biopsy is always recommended to confirm the clinical diagnosis and rule out any malignancies that have been reported to arise in long-standing cases. In a survey of epithelial odontogenic tumors and cysts in dogs and cats, six cystic lesions gave rise to basisquamous cell carcinoma. This is thought to be associated with the deregulation of cell death in the lining epithelium derived from odontogenic origin as shown by immunoreaction for amelogenin and ssDNA.

Four other types of cysts have been described including the lateral periodontal, radicular, gingival inclusion, and odontogenic keratocyst. Thorough removal of the cyst lining, extraction of the unerupted tooth, and extraction of teeth affected by cyst expansion should be performed. In cases of extensive lesions and those in which complete removal of the cyst lining is challenging, sclerotherapy with tetracyclines can be considered.

Malignant Melanoma

Melanoma is the most common malignant neoplasia in the canine oral cavity. In a retrospective study of 338 canine oral melanomas, chow chows, golden retrievers, and Pekingese/poodle mixes were overrepresented, and the gingiva and labial mucosa were the most commonly affected sites. Melanomas can be amelanotic in some cases, posing a diagnostic challenge. However, Melan A is a specific and sensitive marker for canine melanoma. Dogs with melanomas of the labial mucosa may have an increased survival time (310 days) compared to those with oral melanomas at other sites (123 days). This difference was, however, not statistically significant. In this same study, postsurgical survival time was 173 days. Survival was significantly associated with the presence of KIT anywhere in the section of a melanoma. This also becomes important when considering the use of c-kit inhibitors such as toceranib phosphate (Palladia®, Pfizer Animal Health) in the treatment of oral melanomas. When evaluating the effects of multimodal therapy with adjuvant treatment with carboplatin, the median overall survival for all dogs was 440 days. In a study evaluating the use of radiation therapy with an alternate-day schedule of 4 Gy/fraction for a total of 48 Gy over four weeks, 8% of dogs had acute reactions, and 7.6% of dogs showed chronic effects including osteonecrosis and the development of fistulae. Local efficacy was determined by tumor size, and systemic metastasis influenced long-term survival in patients with tumor recurrence.

Antiangiogenic therapies have also been evaluated after the discovery of higher vascular endothelial growth factor (VEGF) levels in the plasma and serum of dogs with malignant melanomas than in a control population. In a study describing the effect of radiation on the expression of VEGF and VEGF receptor in the canine melanoma cell line TLM 1, radiation induced significantly higher VEGF production in the 8 and 10 Gy group, which may have contributed to tumor resistance. The enhanced secretion of VEGF may increase survival by decreasing apoptosis, stimulating proliferation, and increasing angiogenic potential.

When evaluating the efficacy of a xenogenic vaccine targeting tyrosinase as an adjuvant treatment, results have been contradictory. One study found no difference between progression-free survival, disease-free interval or median survival time in dogs that received this treatment. A study evaluating the safety of administration of this vaccine in cats revealed side-effects of grade 1–2 in 11.4% of cats, suggesting a minimal risk of adverse effects.

Oral melanoma is highly metastatic and recurrent, with age, size, site, and stage being reliable prognostic indicators. A subset of well-differentiated melanocytic neoplasms in dogs has been described, and these tumors have shown a mean survival of 23.4 months and a median survival of 34 months after local excision without adjuvant therapy.

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is the most common oral tumor in domestic cats and the second most

common oral tumor in dogs. This tumor can vary in appearance and may present as an ulcerated area or a mass. In cats, sometimes the ulcerated area appreciated on oral examination may represent the "tip of the iceberg" (Figure 50.5).

Although historically, the sublingual/lingual region has been reported to be the most commonly affected site, recent reports show the gingiva on the mandible and maxilla to be most often involved. Metastasis to mandibular lymph nodes in these cases, as evaluated by fine needle aspiration cytology, has been documented to be as high as 31–36%. A significant association between mandibular lymph node metastasis and survival time has not been found. Evidence of pulmonary metastasis, which had been evaluated by three-view thoracic radiography or necropsy, was present in 10% of cases but was not a significant negative prognostic factor. Interestingly, tumor volume appeared not to be a predictor for regional and distant metastasis, as no significant association was seen between tumor size and metastasis.

Feline oral SCC is generally considered to carry a poor prognosis, and outcome has been largely dependent on the degree of primary tumor invasion at diagnosis. Most cats with oral SCC succumb to the effects of progressive local disease and treatment failure. The prognostic impact of completeness of surgical margins is unclear, and studies evaluating multimodal treatment have shown improved survival times compared to monotherapy. A study evaluating multimodal therapy for nonresectable tumors found survival times with complete remission of up to 759 days. Twenty-one cats treated with 10, once-daily fractions of 4.8-Gy showed a median overall survival of 174 days.

Squamous cell carcinoma in dogs commonly arises in dentate areas, although well-differentiated tumors have been reported to arise more commonly in edentulous areas and the tongue. A retrospective study evaluating 84 dogs with a diagnosis of oral and oropharyngeal SCC reported different subtypes, including conventional (well differentiated, moderately differentiated, and poorly differentiated), papillary, basaloid, adenosquamous, and spindle cell carcinoma. Neutered female dogs, dogs aged 10–15 years, English springer spaniels and Shetland sheepdogs were overrepresented in this retrospective study.

Papillary SCC is the term used for a well-differentiated variant of this tumor that grossly as well as microscopically shows papillae or fronds on the surface. Papillary SCC appears to carry the best prognosis. Thought to be a tumor of young dogs, papillary SCC has recently been shown to be a tumor of adult dogs as well, with a retrospective study revealing that more than 75% of the affected canine population was older than 6 years of age. In this study, two distinct histologic presentations were described that correlated with the appearance on imaging studies: the cavitating and noncavitating patterns.

Predominance of large breeds and the rostral maxilla as the most common location in dogs with papillary SCC have also been reported. In this study, surgical excision with 1–2 cm margins allowed for a mean tumor-free interval of 12.1 months. Neither study found regional or distant metastasis. A hemangiosarcoma-like mass composed of numerous vascular clefts and variable numbers of keratinizing epithelial cells was described in a case report of an 8-year-old female mixed breed with a caudal maxillary mass. The mass was characterized as a pseudoangiomatous SCC, a well-recognized human variant of acanthomatous SCC that shares histopathologic similarities with canine gingival hemangiosarcoma. A study evaluating risk factors for nontonsillar SCC in dogs showed that surgical treatment can decrease the risk of death for these patients by 91.4%. Perineural, lymphatic and vascular invasion, as well as peritumoral inflammation, may play a role as a prognostic indicator when looked at together as a combined score. In a study evaluating the effects of combining cisplatin with piroxicam in dogs with oral melanoma and SCC, about 50% of dogs

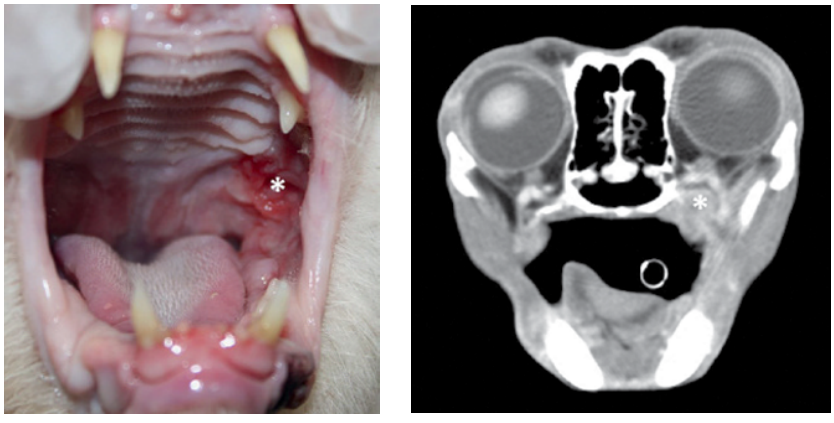

Figure 50.5 Photograph (a) and transverse computed tomographic image in soft tissue algorithm obtained after IV administration of contrast medium (b) of a 12-year-old Persian with squamous cell carcinoma (*white asterisks*) of the left caudal upper jaw. Note orbital invasion of the tumor. Copyright 2015 Alexander M. Reiter.

with SCC responded to treatment versus 18% of patients with oral melanoma. The most commonly reported side-effect for this combination of treatment was renal toxicosis, so close monitoring of renal values is recommended.

A protocol of accelerated chemoradiotherapy using 14 fractions of 3.5 Gy over nine days, combined with carboplatin as a radiosensitizer (total dose 180 mg/m^2 in feline and 300 mg/m^2 in canine cases) resulted in a complete tumor response in most cases (4/5 feline and 3/3 canine) with acceptable acute and long-term side-effects. Overall response rate in both dogs and cats treated with bleomycin enhanced with electroporation (ECT) was 89%, with 21 showing a complete response (CR) and two a partial response (PR) whereas controls had a response rate of 33% (4 CR and 3 PR). Median time to progression in the ECT group was 30.5 months, whereas in controls (bleomycin alone) it was 3.9 months (P <0.0001). Median time to progression for ECT cohorts was 24.2 months for the periocular cohort and 20.6 in the advanced head SCC cohort, respectively.

Eosinophilic Granuloma

Eosinophilic granuloma is a disease that results from underlying antigenic stimulation. The eosinophil is one of the players in type I inflammatory reactions. The most commonly identified underlying causes in cats include ectoparasites and other insects, environmental allergens (i.e., atopic dermatitis), and food hypersensitivity. Eosinophilic granulomas are exfoliative, and thus diagnosis can be reached through fine needle aspiration or impression smears. However, histopathologic examination is useful to rule out other differential diagnoses such as neoplasia or infection. Distinctive histopathologic features of eosinophilic granuloma are small foci of collagen degeneration in which degenerated collagen fibers are surrounded by degranulated eosinophils, resulting in flame figures. Clinically, these lesions are characterized by a proliferative or ulcerative component with yellow pinpoint areas consistent with sulfur granules. Granulomatous nodules can be seen in the tongue, palate and/or glossopharyngeal arches (Figure 50.6).

Indolent ulcers, also known as rodent ulcers, another presentation for this type of inflammatory process, are commonly seen near the midline of the (usually) upper lip but can also be seen on the lower lip. A puffy lip or a diffuse, firm sublingual swelling are rare manifestations of this disease. Some cats are asymptomatic, and in some the disease may be self-limiting.

Ulcerative eosinophilic palatitis has been described in Cavalier King Charles spaniels. Some can have full or near resolution of lesions with glucocorticoid therapy whereas others may resolve spontaneously. Eosinophilic granuloma has also been reported in the Siberian husky in which a hereditary cause has been proposed. Treatment involves removing the underlying cause by recommending flea prevention, a hypoallergenic diet, and switching to stainless steel bowls. Additionally, immunosuppressive therapy with prednisone or prednisolone at 0.5–1 mg/kg q24h PO may be necessary. Recently, a study evaluating the efficacy of treatment with amoxicillin-clavulanic acid in cats for 21 days showed a 42.6% reduction in mean lesion size for lip ulcers and a 96.2% reduction in skin plaques. If the area shows evidence of chewing trauma or exposure to foreign objects, debulking may be considered as well as intralesional glucocorticoid injections (e.g., triamcinolone). Treatment with palmitoylethanolamide (PLR120), a downregulator of mast cell degranulation, showed clinical improvement in 67% of affected cats. For cats with severe ulcerative cutaneous or oral lesions that are unresponsive to glucocorticoid treatment, FHV-1

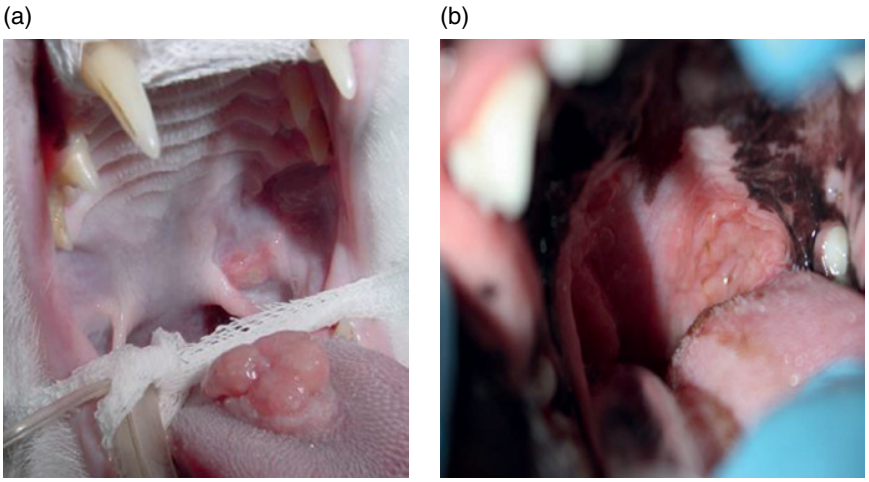

Figure 50.6 Photographs of eosinophilic granuloma involving the dorsal tongue surface and left caudal oral cavity in a 9-year-old domestic shorthair (a) and eosinophilic palatitis in a 3-year-old Cavalier King Charles Spaniel (b). Copyright 2015 Alexander M. Reiter.

infection should be considered, and the diagnosis can be achieved via immunohistochemistry or polymerase chain reaction. Eosinophilic vasculitis, which is a rare disease seen in dogs and cats in association with arthropod and insect-induced lesions and occasionally in mast cell tumors, can also be present along with cutaneous eosinophilic granulomas and plaques in the absence of cutaneous vasculitis.

Foreign Body

A retrospective study evaluating gastrointestinal foreign bodies in dogs and cats showed that 63% of linear foreign bodies originated from the base of the tongue in cats as opposed to 3% in dogs. English bull terriers and springer spaniels were overrepresented in this study. The most common types of foreign object recovered from cats were string, rope, or fishing lines. Burdock and fox tails can also become entrapped in the oral mucosa, and in dogs they have been reported to elicit a type of granular stomatitis. These oral lesions most often occur on the tip and lateral edges of the tongue and the rostral portions of the gingiva, usually at the mucogingival junction and the labial mucosa of the upper lip. Occasionally, the philtrum is involved. Initially, they appear as small papules that can then coalesce, and eventually a necrotic center may develop. Removal of the foreign body along with thorough debridement and flushing of the wound is the treatment of choice. Oral antibiotics and soft food may also be considered.

Oropharyngeal and esophageal stick penetration injuries in dogs can pose a challenge, as studies have shown that foreign bodies can be found in only about half or less of the affected patients. Surgical exploration, local debridement, and thorough lavage, however, have shown a favorable outcome in both studies. Esophageal penetration injuries carry the worst prognosis, and thus a ventral medial surgical approach has been recommended in cases where cervical emphysema is seen radiographically. Advanced diagnostic imaging with magnetic resonance imaging and/or computed tomography may improve the rate of recovery of patients with such foreign bodies.

Immune-Mediated and Autoimmune Diseases

Failure of desmosomal adhesion can result from genetic, autoimmune, or infectious causes. Pemphigus represents the most common autoimmune blistering dermatosis in domestic animals. Pemphigus vulgaris (PV) is a deep, acantholytic dermatosis. It is rare in cats, with an estimated incidence of one per 10 000 veterinary dermatology cases per year. It is more commonly seen in mature cats. This condition is also rare in dogs, with no age predisposition but a predilection for certain breeds such as German shepherds and collies, and a predisposition for males. PV can have mucosal and mucocutaneous manifestations. In most dogs, lesions first develop in the oral cavity or mucocutaneous junctions. Lesions on haired skin predominate over pressure points. Presentation can be acute or chronic, and the direct Nikolsky sign is usually positive. Lesions can present as erythemas, erosions, ulcerations, scales, and crusts. Light microscopy shows suprabasal acantholysis and cleft formation. Erosive lesions are preferentially located in the oral cavity and mucocutaneous junctions. Oral involvement may also include gingivitis, stomatitis, or glossitis. Most patients with PV show signs of systemic disease such as anorexia, lethargy, weight loss, and fever. Spontaneous resolution of cases has been reported. However, 40% of dogs were reported to have a fatal outcome due to either their local disease or systemic manifestations.

Of the autoimmune subepidermal blistering dermatoses, 80% of patients with bullous pemphigoid develop oral lesions at the initial onset of disease or later during its course. Bullous pemphigoid represents 50% of subepidermal autoimmune blistering dermatoses in cats and 26% in dogs. As opposed to PV, this disease can afflict animals of any age, even before puberty. Lesions consist primarily of turgid vesicles, erosions, ulcers, and crusts. Oral lesions can be seen in 60% of dogs, but in cats few lesions are present. In cats as well as in horses, subepithelial vesicles exhibit fewer inflammatory cells, and special stains are needed to visualize degranulating eosinophils. Long-term remission of bullous pemphigoid has been seen in one cat treated with corticosteroids.

Mucous membrane pemphigoid, although uncommon, has been reported in at least two cats, and the authors have witnessed one additional case. Laminin 5 and 6, collagen XVII, and integrin alpha-6/beta-4 have been implicated as autoantigens in both humans and dogs. However, only laminin-5 has been recognized in the feline homologue of this disease.

Canine systemic lupus erythematosus (SLE) occurs mainly in pure-breds including spaniels, pointers, retrievers, German shepherd dogs, and Doberman pinschers ranging from 2 to 6 years of age. SLE has been reported in at least two cats with palatine and glossal ulceration. Behavioral changes, nonerosive polyarthritis, fever, lymphadenomegaly, weight loss, and leukopenia are primarily seen with this condition, and dogs tend to have one or two systemic signs. The oral ulceration is likely a complication of the systemic vasculitis that occurs.

Erythema multiforme (Figure 50.7) accounts for 0.11% of dermatology cases seen in the feline population at an academic institution. In this report, only 38% of dogs showed oral lesions, and no oral lesions were reported in the only cat described. In a case report of erythema multiforme in a cat, lesions first developed on the face and head, but there were no visible lesions in the oral cavity. This patient did not respond to withdrawal of current medications, but a significant improvement was noted approximately one week after treatment with human immunoglobulin. Toxic epidermal necrolysis and idiopathic vasculitis have also been reported to occur in a small number of cats and dogs.

The diagnosis of these disorders is based on both morphologic and immunologic criteria. Proper site selection, biopsy technique, and sample handling are extremely important to reach a definitive diagnosis. Biopsy of the leading edge of a lesion when an intact blister is not found may be sufficient. Preserving the samples in Michel's solution is also preferred by some pathologists. This is a transport medium that preserves tissue antigenicity at ambient temperatures.

Treatment for these conditions should be considered life-long, and owner commitment for periodic monitoring is imperative. Animals must be routinely monitored with complete blood counts and serum chemistry panels. Although glucocorticoids have been reported to be successful in treating most of these conditions, some cases require other forms of immunosuppressive or immune-modulating therapy. Some immune-mediated skin diseases have also been treated with tetracycline, niacinamide and pentoxifylline which together can have

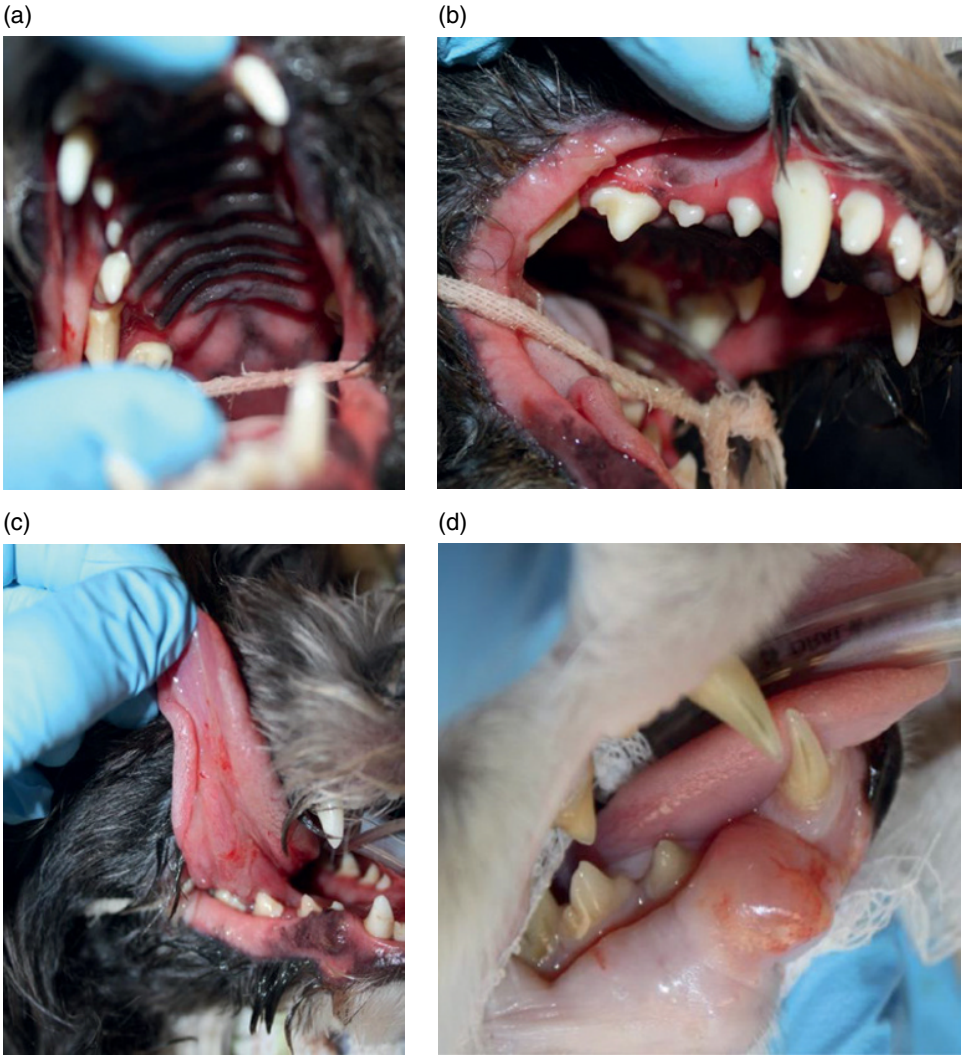

Figure 50.7 Photographs of a 6-month-old mixed breed with erythema multiforme manifesting on the hard palate (a), gingiva and lips (b), as well as the sublingual area (c). Photograph of a 9-year-old domestic shorthair with mucous membrane pemphigoid on the right lateral lip frenulum (d). Copyright 2015 Alexander M. Reiter.

immune-modulating and antiinflammatory effects. Antibiotics should be prescribed in cases with a secondary infection. Symptomatic treatment is required acutely, including nutritional support and pain control until long-term therapy takes effect. Idiopathic vasculitis can also cause oral ulcerations.

Metabolic Disease

Nutritional deficiencies, although uncommon, can have oral manifestations. In the acute setting, tacky mucus membranes can indicate dehydration or hypovolemia, and pale mucus membranes can indicate shock or anemia. Oral manifestations of metabolic disease may resurface with the recent increase of owners opting to feed their pets home-cooked diets. Protein deficits can cause ulceration of the dorsal surface of the tongue. Severe niacin deficiency can cause hyperemia and ulceration of mucosal surfaces, especially the tongue. Severe biotin deficiency causes salivation and scaling of the lips. Hypervitaminosis A can lead to gingival enlargement and delayed development and early exfoliation of incisor teeth. Primary or secondary hyperparathyroidism can lead to a condition known as "rubber jaw" which is characterized by a diffuse decreased radiographic density in the bones, primarily of the lower jaw.

Acute uremia is defined as a rapid decline in renal function leading to retention of uremic wastes. The incidence of acute uremia in animals is unknown, but in humans it accounts for 1% of hospital admissions. Uremic halitosis and oral ulcerations are common findings on physical examination of severely affected patients. This occurs especially at the labial and buccal mucosa, lateral margins of the tongue, sublingual mucosa, lateral lip frenula, and lip commissures. Uremic vasculitis and thrombosis lead to necrosis and sloughing of the mucosa. Hypothyroidism can also lead to vasculitis and petechiation on the gingiva and tongue. Halitosis is often a feature of this syndrome, as the lesions become secondarily infected. In severe cases, there may be extensive necrosis that leads to sloughing of the tip of the tongue. The lesions are often very painful and contribute to the anorexia often observed in animals with kidney disease. Any condition that can produce a hypercoagulable state may lead to thrombi formation and subsequent sloughing of the affected areas.

Treatment for these conditions is symptomatic until the inciting cause can be removed or resolved. Symptomatic treatment includes pain management (buprenorphine 0.01 mg/kg q8–12h, IV), bypassing the mouth with supplemental enteral or parenteral nutrition, and use of gastric protectants (sucralfate 0.5–1 g q4–6h, PO). Topical mouthwashes such as a mixture of diphenhydramine, sucralfate or aluminum and magnesium hydroxide (Maalox®, Novartis), and lidocaine may provide some local pain control. Dilute (0.12%) chlorhexidine rinses also play a role in preventing secondary infection of the necrotic areas. Other metabolic disease such as diabetes mellitus, liver failure, and respiratory disease as well as immunosuppressive medications have also been reported to lead to oral ulceration and necrosis.

Burns

Burns can be caused by electricity, chemicals, heat, friction or radiation (Figure 50.8).

Chewing on household power cords is the most common cause of electric burns in dogs and cats, and these are likely low-voltage injuries. The electrical current can cause damage through its direct effect as well as via transformation of electric energy into heat. The pet should be evaluated for cardiac arrhythmias and neurogenic pulmonary edema prior to evaluating the oral cavity under sedation or anesthesia. Edema and necrosis are typically seen in the tongue, palate, and lip commissures. Discoloration of adjacent teeth secondary to pulpitis can also be seen. Some of the long-term effects of electric burns include development of an oronasal fistula and sloughing of necrotic portions of the tongue. Patients should be treated symptomatically for at least 7–10 days or until the tissues fully claim themselves. Until definitive surgery can be performed, antibiotics and pain medication should be instituted. Nutritional supplementation should be considered when patients refuse to eat soft food. Definitive therapy consists of debridement of the lesions unless these are superficial enough to heal by contraction and reepithelialization.

Chemical burns can result from exposure to household cleaning products, phenolic compounds, essential oils, heavy metal (thallium) or plant toxins (i.e., *Diffenbachia*). The rostral and dorsal aspects of the tongue and the palate are usually affected. The poison control center should be contacted in these cases for treatment of any ingested substances. Similar to electric cord injuries, treatment should be symptomatic, but debridement is less often necessary. Patients should be evaluated for esophagitis and gastritis and treated accordingly. The hair of affected patients should be clipped or washed with dish detergent if grooming caused the chemical to contact oral mucosa. Thermal injuries can be encountered in animals that are fed home-prepared diets or heated milk. Injuries are like those seen with chemical burns, with the lips and nasal plane also being affected. With both chemical and electric burn injuries, symptomatic treatment and client education are necessary.

Salivary Gland Disease

The prevalence of salivary gland disease in dogs and cats in a retrospective study was 0.3% , with dogs accounting for two-thirds of the population studied. Salivary gland neoplasia accounted for 30% of the cases seen, followed by, in order of decreasing frequency, sialadenitis (26%), degenerative or fibrotic lesions (11%), sialoceles (9%), and infarction (8%).

Salivary gland neoplasia appears to have different behaviors in the dog and cat. Cats tend to have more advanced disease at the time of diagnosis. A possible familial predisposition in Siamese cats has also been reported. Despite this, survival times in dogs and cats appear to be similar, at 500–550 days. Masses are usually detected by owners, although halitosis, dysphagia, and exophthalmia have been reported. Adenocarcinoma is the most common histologic type of tumor seen. A sialolipoma of a minor salivary gland and lymphosarcoma of major salivary glands have also been reported.

Sialadenosis typically is a bilateral and painless enlargement of the salivary glands. Although the exact cause of this disease is unknown, concurrent gastrointestinal disease, certain medications, hormonal disorders or primary disorders affecting the sympathetic innervation to the glands have been implicated. Retching and gulping are the most common clinical signs seen with this condition. Differential diagnoses for this disease include inflammatory variants including necrotizing sialometaplasia, granulomatous giant cell sialadenosis, and spirocercosis. Both sialadenosis and necrotizing sialometaplasia have shown response to treatment with phenobarbital at an anticonvulsant dose (starting at 2 mg/kg, PO BID). Cases of spirocercosis also respond to phenobarbital treatment, but this is in addition to macrocyclic lactones used to eliminate the microorganism. Granulomatous disease has responded to treatment with glucocorticoids at an anti-inflammatory dose. Necrotizing sialometaplasia has been reported in a few cats. In contrast to dogs, excision of the affected salivary glands in cats provided resolution of signs with no recurrence reported.

Salivary mucoceles, also known as sialoceles, are swellings created by the extravasation of saliva from the ducts or salivary glands themselves. Extravasation of saliva can not only cause a localized swelling, but also the inflammation that results can lead to signs of discomfort. Although trauma, foreign bodies, sialoliths, aberrant parasite migration, and neoplasia have been reported to lead to sialocele formation, sometimes the exact cause for these swellings cannot be determined. With these differentials in mind, advanced diagnostic imaging such as CT or ultrasound should be considered for evaluation. A difference in the imaging characteristics of these lesions can be found when comparing acute with chronic cases, and dystrophic mineralization can occur in very long-standing cases. In dogs, sialoceles arise more commonly in the cervical and sublingual regions. However, the sublingual area seems to be more commonly affected in cats. Sialoceles in the cervical, sublingual, and pharyngeal regions can all lead to difficulty swallowing and breathing. Surgical removal of the glands involved is the treatment of choice, and different approaches have been described for the resection of mandibular/sublingual and zygomatic glands to increase exposure and also decrease the morbidity that can be associated with these surgeries.

Conclusion

Examination of the oral tissues and dental structures is an essential component of physical examination. Dental and oral disease is very commonly seen in our pets. The systemic health of the patient should be thoroughly assessed before attributing a presenting complaint of anorexia to dental and oral disease alone. The anamnesis will also prove to be helpful in guiding your treatment approach when dealing with patients with concurrent conditions. Staging treatment and triaging are at times favorable for these patients to prevent very prolonged anesthetic episodes that may endanger the health of our compromised patients.

Gastritis and Gastric Ulceration in Dogs and Cats

Katie Tolbert, DVM, PhD, ADCVIM (SAIM) and Emily Gould, DVM, MS

College of Veterinary Medicine, Texas A&M University, College Station, TX, USA

Normal Gastric Mucosal Barrier Function

The gastric mucosal barrier is provided by the luminal production and secretion of protective factors, an intact epithelial lining, and a rich mucosal blood supply. Mucosal secretions including bicarbonate, mucus, immunoglobulins, and anti-bacterial substances promote the integrity of the mucosa and protect the underlying epithelium from noxious insults. Potential insults to the gastric mucosa include diffusion of luminal acid and pepsin, fluctuations in temperature and osmolality, and translocation of ingested bacteria. The gastric mucosal barrier is bolstered by a single layer of epithelial cells which is capable of rapid repair following injury. The local production of prostaglandins acts to stimulate bicarbonate and mucus secretion, decrease gastric acid secretion, and promote a healthy gastrointestinal mucosa. The total flow of blood through the gastric mucosa can be increased to clear noxious substances produced during the inflammatory response and deliver oxygen and bicarbonate to injured epithelium. Breakdown of the gastric mucosal barrier is a primary source or consequence of nearly all causes of gastritis and gastric ulceration.

Etiology and Pathophysiology of Gastritis

Canine and feline gastritis is defined as inflammation of the stomach and occurs in response to many stimuli. Gastritis can be classified by duration of clinical signs (acute or chronic) and by histopathologic changes (e.g., lymphoplasmacytic, eosinophilic, fibrosis, atrophy). The release of a variety of inflammatory mediators, including pro-inflammatory cytokines and chemokines, eicosanoids (prostaglandins, leukotrienes, and thromboxanes), neuropeptides, nitric oxide, peroxidases, and proteinases, perpetuate gastritis through increasing exposure of the denuded epithelium and underlying mucosa to toxic insults (e.g., gastric acid, bile acids, pepsin). As well as exerting direct effects on the gastric mucosal cells, many of these mediators act to alter mucosal permeability and blood flow.

Gastric ulceration, which can be a sequel of severe or prolonged gastric inflammation and ischemia, is defined as a defect in the gastric mucosa extending to the muscularis mucosa or through the muscularis propria. Ulcers can be full thickness (perforating) or partial thickness. Perforating ulcers can be associated with hemorrhage and septic peritonitis and therefore are considered life threatening when left untreated. Gastric ulceration is more frequently reported in the dog than the cat, but as observed with gastritis, toxic agents, drug-induced reactions, neoplasia, severe systemic illness, and infectious organisms can be injurious to the gastric mucosa in both species.

A variety of etiologies have been implicated in the development of canine and feline gastritis and gastric ulceration (Tables 51.1 and 51.2). These include mechanical irritants, drugs, systemic illness, infections, breed-associated diseases, motility disorders, and occupational and exercise-related stressors.

Gastric foreign bodies and dietary indiscretion are common causes of acute gastritis in dogs and cats. Although the stomach is not the primary site of protein absorption, dietary protein intolerance and food responsive disease can also be linked with gastritis in both dogs and cats, albeit less frequently. The presentation of food antigens to the gut-associated lymphoid tissue in the small intestine can initiate immediate or delayed hypersensitivity reactions capable of inducing vomiting with

Table 51.1 Causes of gastritis in dogs and cats

Category	Dogs	Cats
Primary gastric	Dietary indiscretion, foreign body, IBD, food allergic, gastric neoplasia (carcinoma, leiomyoma, leiomyosarcoma, mast cell tumor)	IBD, alimentary small cell lymphoma, foreign body, gastric neoplasia (lymphoma, carcinoma, leiomyoma, leiomyosarcoma, mast cell tumor)
Systemic	Acute or end-stage organ (hepatic, renal) dysfunction, anaphylactoid reaction, hypoadrenocorticism, pancreatitis, sepsis, hypercoagulable states (Cushing disease, PLE, PLN), portosystemic shunts	Acute or end-stage organ (renal) dysfunction, pancreatitis, sepsis, hypereosinophilic syndrome, eosinophilic fibrosing gastritis
Infectious	Viral (distemper, parvo, corona), bacterial (*Helicobacter*, *Clostridium*, *Salmonella*, *Campylobacter*, *E. coli*), fungal (*Histoplasma*), helminth (*Gnathostoma binucleatum*, *Physaloptera* spp., *Toxocara canis*), oomycete (*Pythium*)	Bacterial (*Helicobacter*), helminth (*Aonchotheca putorii*, *Ollulanus tricuspis*, *Gnathostoma binucleatum*, *Toxocara cati*), feline dirofilariasis
Medication related	NSAIDs, antibiotics (penicillins, tetracyclines, chloramphenicol, lincosamides), chemotherapeutics	Same as dogs
Hyperacidity	Pancreatic gastrinomas, mastocytosis	Same as dogs
Stress, exercise induced	Surgery, Alaskan sled dogs (exercise induced)	Surgery, prolonged hospitalization
Breed related	Basenjis (immunoproliferative enteropathy), Norwegian lundehund (atrophic gastritis, lymphangiectasia), Rottweilers (eosinophilic enteropathy)	None known
Miscellaneous	Benign gastric hypertrophy, bilious vomiting syndrome	

IBD, inflammatory bowel disease; NSAID, nonsteroidal antiinflammatory drug; PLE, protein-losing enteropathy; PLN, protein-losing nephropathy.

Table 51.2 Causes of gastric ulceration in dogs and cats

Category	Specific causes
Ulcerogenic drugs	NSAIDs (selective and nonselective), steroids (in combination with NSAID or additional risk factor)
Primary gastric	Neoplasia (carcinoma, lymphoma, mast cell tumor, leiomyosarcoma), IBD, gastric foreign body
Systemic disease	Hepatic dysfunction, hypoadrenocorticism, GDV, pancreatitis, sepsis, hypercoagulability (DIC, PLE, PLN), hyperacidity (gastrinoma, mastocytosis)
Stress	Surgery, severe critical illness
Infectious	Helminths (*Aonchotheca putorii*, *Ollulanus tricuspis*, *Gnathostoma binucleatum*, *Toxocara cati*), fungal (histoplasmosis), oomycete (pythiosis)
Miscellaneous	Toxic/caustic substances, ingestion of sharp/perforating objects, thermal injury secondary to foodstuffs, occupation related (Alaskan sled dogs), iatrogenic (perforation during gastroscopy)

DIC, disseminated intravascular coagulation; GDV, gastric dilation-volvulus; IBD, inflammatory bowel disease; NSAID, nonsteroidal antiinflammatory drug; PLE, protein-losing enteropathy; PLN, protein-losing nephropathy.

secondary gastritis. Inflammatory bowel disease (IBD) is considered to be a predisposing factor for gastric ulceration, but this is a relatively uncommon complication of IBD.

Invasive gastric and nongastric tumors resulting in gastric hyperacidity cause physical damage to the gastric mucosal barrier that can incite the development of secondary gastritis and gastric ulceration. Primary gastric neoplasms represent 1% of all cancers diagnosed in companion animals. Gastric carcinoma (most common in the dog), lymphoma (most common in the cat), leiomyomas, leiomyosarcomas, and mast cell tumors are the most frequently reported in association with gastritis. Mast cell tumors, systemic mastocytosis, and pancreatic gastrinomas increase the risk of ulceration due to the overproduction of histamine and gastrin, respectively. Mast cell tumors and gastrinomas were overrepresented in one large literature review of cats with gastroduodenal ulceration.

Nonneoplastic, proliferative masses associated with gastritis include gastric polyps and benign gastric hypertrophy or hyperplasia with accompanying gastritis.

Chronic hypertrophic pyloric gastropathy has been documented in many breeds and usually manifests with clinical signs of pyloric outflow obstruction.

Drugs, household chemicals, and plants are also a frequent cause of gastritis in dogs and cats. A list of common plants and household chemicals associated with gastritis may be found in an excellent review by Webb and Twedt (see Further Reading list).

Nonsteroidal antiinflammatory drugs (NSAIDs), a leading cause of gastritis and gastric ulceration in companion animals, are both directly and indirectly injurious to the gastric epithelium as a result of being weak acids and via their inhibitory effect on prostaglandin production, respectively. Aspirin, flunixin meglumine, indomethacin, ibuprofen, acetaminophen, ketorolac, deracoxib, and carprofen have all been associated with the development of gastric lesions. Nonselective COX NSAIDs (e.g., aspirin) are the most ulcerogenic and should be used with caution. NSAID-induced ulcers are often localized to the pyloric antrum and pylorus. COX-2 selective NSAIDs (e.g., meloxicam) are considered less ulcerogenic than nonselective inhibitors, but careful monitoring is still advised as all NSAIDs can be ulcerogenic as well as delay healing of epithelial injury. NSAIDs should be considered contraindicated and used sparingly in companion animals that have concurrent diseases with ulcer-inducing potential.

Corticosteroids at high doses can cause gastritis, but they are unlikely to be the sole cause of gastric ulceration except when given concurrently with an NSAID or in the presence of other risk factors. Other drugs commonly associated with gastritis in either species include some antibiotics (e.g., penicillins, chloramphenicol, lincosamides, tetracyclines) and chemotherapeutic agents. Ingestion of noxious chemicals (e.g., phenols/alcohols), toxic substances (e.g., lead, *Dieffenbachia*), foodstuffs capable of producing thermal damage and foreign bodies has also been reported to cause gastritis and ulceration. Systemic illness (e.g., hepatic, renal, neurologic or endocrine disease) and/or conditions causing poor gastrointestinal (GI) perfusion (e.g., hypoadrenocorticism, gastric dilation-volvulus, thromboembolic disease) can trigger gastric inflammation and/or gastric ulceration. Ulcer development in animals with hepatic dysfunction most commonly results from compromised hemodynamics. Although severe renal dysfunction results in decreased elimination of uremic toxins and gastrin, gastric ulcers are uncommonly documented in dogs and cats with end-stage renal failure.

Infectious causes of gastritis include a variety of bacterial species, helminths, oomycetes, fungi, and viruses. Most infectious agents rarely cause gastric signs alone, however, and therefore are not discussed in detail in this chapter. Although uncommon, infectious and parasitic etiologies (e.g., pythiosis, gnathostomiasis, *Aonchotheca putorii*, *Toxocara cati*) have also been associated with gastric ulceration. In cats, heartworm infection may cause vomiting and gastritis, while this is uncommon in dogs.

Bilious vomiting syndrome, a frequently encountered yet poorly understood gastric motility disorder in dogs, can induce gastritis through reflux of injurious bile salts into the stomach. Affected dogs generally vomit early in the morning following an overnight fast.

Other less commonly encountered causes of gastritis and gastric ulceration include occupational stress (e.g., racing Alaskan sled dogs) and breed-related gastropathies, including atrophic gastritis in the Norwegian lundehund and immunoproliferative enteropathy in basenjis. Hypereosinophilic syndrome, particularly in Rottweilers, and both hypereosinophilic syndrome and feline gastrointestinal eosinophilic sclerosing fibroplasia (FGESF) in cats can cause severe gastritis and gastric ulceration. Hospitalization and postoperative stress may be a more common cause of ulceration in cats than in dogs.

Helicobacter pylori and Related Organisms

The relationship between colonization with *Helicobacter* spp. in canine and feline patients and the occurrence of gastritis and gastric ulceration is unclear. *Helicobacter pylori* is an important cause of gastritis and ulceration in humans but not in companion animals, and the role of other *Helicobacter* species as gastric pathogens in dogs and cats is less well defined. Multiple *Helicobacter* spp. (*H. heilmannii*, *H. pylori*, *H. felis*, *H. bizzozeronii*) have been isolated in both dogs and cats with varying degrees of gastritis. Thus, *Helicobacter* infection should only be considered as a cause of clinical signs in dogs and cats when associated with histopathologic evidence of gastric inflammation, and after other causes have been excluded.

Epidemiology of Gastric Disease

Consideration of the animal's signalment aids in the prioritization of differentials for gastritis and gastric ulceration. For example, foreign body ingestion, dietary indiscretion, and infectious causes of gastritis are more commonly identified in younger animals. Dachshunds and other chondrodystrophic breeds predisposed to intervertebral disc disease might be at higher risk for subclinical gastric ulceration with concurrent steroid and/or NSAID therapy. German shepherd dogs have been reported to be at greater risk for gastric ulceration following ibuprofen administration.

Gastritis resulting from inflammatory bowel disease, systemic disorders, and neoplasia is more common in middle-aged to older companion animals. Breed-related gastritis, however (seen in Norwegian lundehunds, Rottweilers, and basenjis) can occur at any age.

Adenocarcinomas develop in middle-aged dogs (<10 years) more frequently than other gastric neoplasms, and are usually located in the pyloric antrum or gastric body (greater curvature). Collies, German shepherd dogs, Staffordshire terriers, Bouviers des Flandres, Norwegian elkhounds, and Belgian shepherds have been identified as breeds at higher risk for developing gastric carcinoma. Male dogs are overrepresented among dogs with gastric neoplasms in some reports, although a sex predisposition is not yet widely recognized. The Norwegian lundehund is at higher risk for development of neuroendocrine carcinoma secondary to chronic, severe atrophic gastritis. Lymphoma is more prevalent in older cats, while middle-aged cats are more likely to be diagnosed with inflammatory bowel disease. No breed predispositions are recognized for primary gastric cancer in cats, but one report exists of two related Persians with confirmed gastritis and adenocarcinoma.

Large-breed, deep-chested and working dogs (Great Danes, standard poodles, Irish wolfhound, Newfoundland, Weimaraner, mastiff and hound breeds, German shepherd dogs) are at higher risk for gastric dilation-volvulus (GDV) and secondary ulceration.

Young to middle-aged, spayed female dogs are more likely to develop hypoadrenocorticism and gastritis secondary to vomiting. Breeds such as the standard poodle, Novia Scotia duck tolling retriever, Rottweiler, Great Dane and Portuguese water dog are overrepresented.

Geographic location influences the risk of development of fungal gastritis. *Histoplasma capsulatum* is one of the most common canine mycotic pathogens in the United States and manifests primarily with signs of gastrointestinal disease in young to middle-aged dogs. *Histoplasma* spp. infection should be ruled out in dogs displaying signs of gastrointestinal disease that are living in endemic regions such as the mid-western, southern, and Gulf Coast regions of the US, as well as Central America. There is a higher prevalence of histoplasmosis in males compared to females, with pointers, Weimeraners, and Brittany spaniels identified as predisposed breeds. *Pythium insidiosum* has been documented in dogs with a travel history to or residing in tropical regions, the Gulf Coast and mid-western states, and northern California. Male Labrador retrievers and German shepherd dogs are overrepresented. Dogs infected with parvovirus, distemper virus, and coronavirus are often younger (less than 3 years of age), unvaccinated and from multidog environments (kennels, shelters).

Environmental history may also give clues towards identification of uncommon causes of feline gastritis. The nematode *Ollulanus tricuspis* is found in cats throughout the US, whereas *Aonchotheca putorii* is more common in tropical, temperate areas worldwide. Feline dirofilariasis occurs more commonly in the mid-west and south-east, with a higher prevalence also reported in northern California and Florida.

History and Clinical Signs of Gastritis

The duration (acute versus chronic) and severity of signs in dogs and cats with gastritis and gastric ulceration vary depending on the underlying etiology. Clinical signs can range from overt gastrointestinal signs to only weight loss. For animals with "garbage gut" or those that have ingested caustic substances, toxins, ulcerogenic medications or foreign bodies, the onset of clinical signs is often rapid (usually within a few hours). Clinical signs in patients with gastric foreign body obstruction often include lethargy, inappetence, vomiting, and antisocial or "hiding" behavior. Owners should be questioned regarding the possibility of exposure to yarn, string, tinsel, needles or hair ties accessible in the house. Intoxications secondary to chocolate (theobromine), macadamia nuts, mycotoxins (e.g., mushrooms, sago palms, blue-green algae, molds), and marijuana should be considered in dogs exhibiting vomiting in association with an acute onset of neurologic abnormalities.

Viral etiologies should be suspected when there is an outbreak of gastrointestinal signs in multiple dogs from the same shelter or household. Viral gastroenteritis can cause inappetence, fever, lethargy, vomiting, and small bowel diarrhea. Distemper is known to cause severe neurologic signs, but manifests as gastrointestinal (inappetence, vomiting, diarrhea) and respiratory signs early in the course of infection.

As the vast majority of episodes of drug-induced gastritis and GI ulceration in the dog are caused by NSAID use (with or without steroids), a full drug history should be obtained for any dog (or cat) presenting with signs of gastric disease. Dogs receiving chronic NSAID therapy with gastrointestinal signs should be regularly evaluated for gastritis. A change as subtle as hyporexia should raise concern. A recent history of antibiotic administration preceding development of clinical signs should raise suspicion for an adverse reaction to medication.

Infectious gastritis should be suspected if there is travel history to an endemic area or there has been ingestion of uncooked or raw foods. Vomiting in animals with pythiosis or histoplasmosis is often accompanied by other clinical signs including diarrhea, cutaneous lesions, lymphadenopathy, and ocular abnormalities

(uveitis, retinal lesions). Dogs suffering from fungal mycosis may also exhibit anorexia and rapid weight loss, and succumb quickly to their disease. Puppies or younger dogs, especially those that have not received a broad-spectrum anthelminthic, are at higher risk for parasitic disease.

Animals with neoplasia-induced gastric disease may have a more chronic history, with progressive signs of gastrointestinal disease (e.g., weight loss, lethargy, anorexia, ptyalism, vomiting, diarrhea). Clinical signs of lymphoma in cats are often protracted and mimic those of inflammatory bowel disease, although cats with lymphoblastic lymphoma often exhibit a more rapid deterioration. Some gastric neoplasms can lead to gastroesophageal reflux, thus these animals can present with signs of esophagitis including regurgitation or ptyalism following meals (see Chapter 52). Animals with mastocytosis or gastrinomas can have evidence of hematemesis, depending on the severity of gastric lesions. Cutaneous lesions can also accompany systemic mastocytosis and fungal disease.

Inflammatory bowel disease and food responsive gastroenteritis are two of the most common causes of gastritis in young and middle-aged dogs. Common clinical signs in animals with IBD can include weight loss (with or without good appetite), lethargy, hyporexia or anorexia, intermittent vomiting and either large or small bowel diarrhea with large bowel diarrhea being more common. Beef, wheat, lamb, egg, chicken, soy, and wheat are common dietary allergens, but any protein or carbohydrate source is capable of eliciting an immune reaction. Younger dogs that are presented with mild clinical signs and predominantly diarrhea of large bowel origin are more likely to have food-responsive disease. Cats with inflammatory bowel disease often exhibit weight loss, hyporexia, anorexia, ptyalism, vomiting, and diarrhea.

Cutaneous lesions, lower airway abnormalities (coughing, tachypnea) and palpably thickened intestinal loops on exam should increase the clinical suspicion for eosinophilic gastroenteritis or hypereosinophilic syndrome in cats.

Dogs and cats that develop gastritis secondary to systemic disease often have other clinical signs related to the primary system involved. Hepatic dysfunction can result in polyuria and polydipsia (PU/PD), petechiae or ecchymosis secondary to coagulopathy, and neurologic signs indicative of encephalopathy in severely affected cases. Portosystemic vascular anomalies should be ruled out in younger dogs with chronic or intermittent gastrointestinal and neurologic signs and inability to gain weight. Suspicion of a shunt is particularly high if the animal's owners report a history of worsening neurologic signs following ingestion of a meal. Vomiting secondary to advanced kidney disease should be suspected in dogs with PU/PD, weight loss, and a poor hair coat. Dogs with hypoadrenocorticism commonly present for waxing and waning lethargy, hyporexia, vomiting and soft stools or small bowel diarrhea.

Cats with secondary causes of gastritis (e.g., hyperthyroidism, chronic kidney disease [CKD] or liver disease) also typically display extragastrointestinal clinical signs. Owners might note hyperactivity, weight loss, dull hair coat, alopecia, and occasionally aggression in hyperthyroid cats. Clinical signs of renal and liver disease mimic those seen in dogs, although uremic ulceration of the tongue and palate might be noted more frequently in cats. Uremic gastropathy, characterized by erosive or ulcerative gastritis, has been a previously reported sequel of renal dysfunction. Recent studies, however, suggest this is not a common finding in cats with CKD.

Physical exam findings in companion animals with gastritis or gastric ulceration are variable and depend on the underlying etiology. Slightly thickened or "ropey" small intestinal loops are often appreciated in both dogs and cats with inflammatory bowel disease. Many of these patients are moderately to severely underweight. Abdominal lymphadenomegaly might be noted on abdominal palpation in cats with IBD or GI lymphoma. Pruritus and/or signs compatible with allergic dermatitis might be noted in patients with food-responsive gastritis. Cranial abdominal pain might be appreciated on physical examination in cases of foreign body ingestion, pancreatitis, gastric neoplasia, and/or severe GI ulceration. These animals might also be febrile. Linear foreign bodies may become anchored to the base of a cat's tongue, so careful inspection of this area on physical examination is critical. Depending on the severity and chronicity of disease, patients can exhibit signs of dehydration, hyperthermia, and/or hypovolemic or septic shock. Cardiac arrhythmias can also be noted secondary to hypovolemia and ischemia. Frank blood or tarry stools may be identified on rectal examination, but the absence of these signs does not rule out gastric bleeding. Severe or prolonged blood loss is often associated with pale mucous membranes.

Neurologic abnormalities (e.g., myoclonus, nystagmus, tremors, seizures or inappropriate mentation, head pressing, star gazing) are often observed in animals with distemper virus, intoxications or hepatic dysfunction. Pyrexia, cutaneous lesions, lymphadenopathy, and ocular lesions (uveitis, tapetal hyper- or hyporeflectivity, fundic lesions) can occur with fungal infections. Tapetal hemorrhage or a detached retina might be visible (secondary to systemic hypertension) during the fundic exam of patients with renal dysfunction.

Cutaneous lesions such as edema, ulceration, and abscessation are often found in dogs with systemic mastocytosis and fungal disease.

Diagnostic Approach to Suspected Gastritis

Clinicopathologic Examination of the Gastritis Patient

A minimum database of clinicopathologic testing, including a complete blood count, serum chemistry, urinalysis, and total thyroxine (in middle-aged to older cats), is typically recommended for dogs and cats being presented with moderate to severe signs and/or a chronic history of disease, prior to more invasive testing. Clinicopathologic abnormalities vary depending on the underlying etiology, duration, and severity of disease. Patients with peracute causes of gastric inflammation or ulceration (e.g., foreign body ingestion, intoxication or GDV) can lack bloodwork abnormalities in the early stages of the disease. However, baseline bloodwork and imaging are recommended as they can demonstrate evidence of GI bleeding or other co-morbidities or reveal an underlying predisposing cause. Anemia is the most common laboratory finding in dogs and cats with gastroduodenal ulceration. Depending on the severity and chronicity of gastric bleeding, the anemia can vary from regenerative to nonregenerative with clinicopathologic features of iron deficiency (e.g., microcytosis, hypochromasia). Peripheral eosinophilia may be observed in dogs or cats with infectious causes of gastritis or gastric ulceration, hypoadrenocorticism or the eosinophilic enteropathies such as hypereosinophilic syndrome or eosinophilic IBD. Neutrophilic leukocytosis can be observed in patients with hyperadrenocorticism, IBD or infectious diseases.

An elevated blood urea nitrogen:creatinine ratio in the presence of anemia strongly argues for further assessment of possible GI bleeding. Electrolyte derangements may be present as a result of gastrointestinal losses (vomiting, diarrhea). The absence of a stress leukogram, with or without altered serum sodium and potassium ratios (<27:1) and/or hypoglycemia, hypocholesterolemia, and hypoalbuminemia would support pursuit of additional testing for hypoadrenocorticism.

Coagulation testing should be included as part of the minimum database in patients with unidentified causes of GI bleeding. Common causes of prolonged clotting times in dogs with clinical signs of gastric disease include septicemia, hepatic failure, and rodenticide intoxication.

Fecal flotation, examination of vomitus, and empirical anthelminthic treatment are recommended in animals where parasitic disease is likely or before pursuing more invasive diagnostic testing such as gastroscopy or exploratory laparotomy.

Diagnostic Imaging in Gastric Disease

Survey radiographs and abdominal ultrasonography (AUS) can have variable results in patients with gastritis and gastric ulceration. Neither condition should be excluded on the basis of normal abdominal imaging. Abdominal radiographs performed in patients with signs of gastric disease can reveal radiopaque foreign bodies, gastric and extragastric neoplasms (if large enough to distort normal anatomy) and/or other causes of inflammation and ulceration (e.g., pancreatitis, GDV). Gastric neoplasms in both cats and dogs are rarely identified with radiographs alone, except in cases of calcified (radiopaque) carcinomas. Abdominal effusion and pneumoperitoneum are not specific for gastric perforation, but signal the need for urgent exploration with additional imaging modalities or exploratory surgery in a patient with compatible clinical signs. Mediastinal and esophageal masses can be observed in dogs with pythiosis, so thoracic radiographs are recommended for dogs with compatible clinical signs. Ultrasonographic abnormalities observed in some patients with gastric disease, particularly gastric ulceration, include disruption of normal wall layering and/or focal gastric wall thickening. Hepatomegaly, splenomegaly, and abdominal lymphadenopathy can be present in dogs with neoplastic and/or infectious causes of gastric disease. Gastric masses are often visible on AUS, but the absence of a mass does not rule out infiltrative neoplasia. Most commonly, changes on abdominal ultrasound are nonspecific with abnormalities suggestive of, but not diagnostic for, gastritis or gastrointestinal disease.

Gastric Histopathology

Histopathologic evaluation of biopsies (endoscopic or full thickness) is required for the definitive diagnosis of gastritis while diagnosis of ulceration is generally made by visualization of the ulcerated mucosa and acquisition of biopsies with endoscopy or exploratory surgery. However, the underlying cause is often not identified on evaluation of gastric tissue, thus correct diagnosis often requires consideration of the patient's signalment, history, clinical signs, bloodwork, and imaging.

Gastroscopy or abdominal exploratory surgery are the only antemortem methods for obtaining a definitive diagnosis of gastric ulceration and gastric mucosal biopsy specimens for histopathologic examination. Animals with very diseased, friable tissue or preexisting ulceration are at greater risk for endoscopic-induced perforation, so caution is warranted with gastroscopy in patients where there is a suspicion of gastric ulceration. Ulceration secondary to NSAID administration is found more often in the pyloric antrum than other sites of the stomach. Mastocytosis typically causes multiple diffuse

ulcerative lesions in dogs. Gastrointestinal disease secondary to infectious etiologies often requires histopathologic or immunohistochemical identification of the organism. *Helicobacter*-associated gastritis in cats and dogs is definitively diagnosed by identification of the organism in gastric biopsies using fluorescence *in situ* hybridization (FISH) or polymerase chain reaction (PCR). Increased tissue urease activity and positive urea breath tests have been correlated with the presence of *Helicobacter*, but are also identified in the presence of other urease-producing bacteria and thus lack specificity. Special staining methods (Steiner staining) and immunohistochemistry methods can aid in species differentiation.

Gastritis and/or gastric ulceration secondary to gastric neoplasms (carcinomas, lymphoma, mast cell tumors) or gastrinomas can be identified via histopathologic examination of tissue (e.g., stomach, pancreas) biopsies. Serum gastrin measurement provides a noninvasive test when gastrinoma is suspected. Marked hypergastrinemia in the presence of gastroduodenal ulceration is suggestive of a pancreatic gastrinoma. Thus, a serum gastrin measurement should be performed in any patient presenting for chronic gastritis and gastroduodenal ulceration where other systemic diseases are eliminated as causes. Serum gastrin concentration should be interpreted cautiously in the face of acid suppressant treatment, which can result in increased serum gastrin concentrations.

Ancillary Diagnostic Testing in Gastric Disease Patients

Testing for the presence of bacterial enteropathogens such as *E. coli*, *Clostridium*, *Campylobacter* and *Salmonella* spp. might be considered as an ancillary diagnostic test for dogs presenting with fever, acute hemorrhagic diarrhea, and vomiting. However, results should be interpreted with caution, as these organisms have been isolated from the feces of healthy dogs and cats.

In cases where there is a high suspicion of gastrointestinal mycosis or oomycete disease, multiple diagnostics are available for antemortem diagnosis. Pythium testing includes serology, enzyme-linked immunosorbent assay (ELISA), PCR or immunohistochemistry (IHC) of infected tissues or blood. A quantitative urine antigen enzyme immunoassay is available for *Histoplasma* detection. Pyogranulomatous lesions and visualization of fungal organisms can be noted in biopsies obtained from dogs with fungal gastritis within the liver, spleen, lymph nodes, or gastrointestinal tract. If present, biopsies of cutaneous lesions should be submitted for histopathology and fungal culture. Gastritis in the Norwegian lundehund is often secondary to lymphangiectasia (diagnosed by endoscopic visualization and histopathology). Evidence of protein-losing enteropathy is variably present on bloodwork. It has been hypothesized that this syndrome can also lead to development of gastric carcinoma as a result of chronic, severe gastritis.

Treatment of Gastritis and Gastric Ulceration

The best course of therapy for animals with gastritis or gastric ulceration is removal of the offending agent, if possible, and amelioration of mucosal injury. Specific therapies will depend on the identified cause (e.g., azole treatment for *Histoplasma* infection, chemotherapy/surgery for neoplasia).

Nonspecific, supportive treatment for animals with gastritis and vomiting should begin with restoration of fluid deficits and normalization of electrolyte imbalances, if present. A list of commonly used medications for gastritis and gastric ulceration is provided in Table 51.3.

Acid suppressants (e.g., histamine-2 receptor antagonists [H_2RAs] and proton pump inhibitors [PPIs]) are recommended in vomiting animals with clinical signs of vomiting-induced esophagitis but should not be used prophylactically. H_2RAs are competitive inhibitors for the interaction of histamine with its receptor on the gastric parietal cell but differ in potency (famotidine > ranitidine > cimetidine). In contrast, PPIs (e.g., omeprazole, pantoprazole, esomeprazole) are inactivators of the proton pump and are more effective than H_2RAs in raising both feline and canine intragastric pH. Thus, PPIs, administered twice-daily, are considered the treatment of choice when concern for acid-induced tissue injury exists. Preliminary evidence suggests that PPIs are more effective when given alone than in combination with H_2RAs in dogs for the treatment of upper GI ulceration. Antiemetics (e.g., 5-HT_3 and neurokinin receptor antagonists) may be administered to vomiting animals once mechanical obstruction has been ruled out as a cause of the clinical signs.

Cytoprotective agents (e.g., sucralfate) can be given, once vomiting is controlled, if there is evidence or suspicion of gastrointestinal bleeding. Sucralfate is most effective at an acidic pH and can interfere with appropriate absorption of pH-dependent drugs. Thus, sucralfate should be administered as a slurry at least 1–2 hours before or after administration of meals and other medications. The PGE_1 analog misoprostol is indicated for use in NSAID-induced toxicoses but does not promote healing in non-NSAID-induced causes of GI ulceration.

Table 51.3 Commonly used medications for canine and feline gastritis

Drug	Mechanism of action	Formulations	Doses
Omeprazole; Esomeprazole	Proton pump inhibitor (PPI): inactivator of parietal cell H+ - K+ - ATPase pumps; inhibits acid production	Tablet, capsule (Prilosec Over the Counter®) Omeprazole reformulated paste (Gastrogard®; Nexium®)	1 mg/kg PO BID (canine, feline) 1 mg/kg IV BID (canine)
Pantoprazole	Same as above (PPI)	Injectable (Protonix®)	1 mg/kg slow IV BID (canine)
Famotidine	Histamine-2 receptor antagonist: competitive inhibitor of histamine receptors on gastric parietal cell, decreases acid production; tolerance with repeated dosing	Tablet (Pepcid AC®) Injectable	1 mg/kg PO BID (canine, feline) 1 mg/kg IV BID (canine, feline)
Ranitidine	Same as above although less efficacious; prokinetic activity	Tablet	1.5–2.0 mg/kg PO BID (canine, feline)
Sucralfate	Cytoprotective agent: sucrose-sulfate-aluminum complex that cross-links with acid to form protective barrier	Tablet (administered as liquid slurry) Oral liquid suspension (Carafate)	250 mg PO TID (small dogs, cats) 500 mg PO TID (small to medium dogs) 1 g PO TID (large dogs)
Misoprostol	Prostaglandin $(PGE)_1$ agonist: used for prevention of NSAID-induced gastrointestinal injury	Tablet (Cytotec)	3 µg/kg PO BID (canine)
Metoclopramide	Antiemetic (dogs only): dopamine receptor antagonist which acts to decrease nausea and vomiting; prokinetic activity	Tablet (Reglan) Injectable (Reglan)	0.2–1 mg/kg PO, SC QID (canine) CRI: 1 mg/kg/day (canine)
Chlorpromazine	Antiemetic (dogs only): same mechanism of action as metoclopramide	Tablet (Thorazine) Injectable	4–8 mg/per dog (do not exceed 0.5 mg/kg) PO BID (canine) 0.2–0.4 mg/kg SC, IM TID (canine)
Maropitant	Antiemetic: neurokinin (NK1) receptor antagonist that works at the chemoreceptor trigger zone (CRTZ) to decrease nausea and vomiting	Tablet (Cerenia®) Injectable	1 mg/kg SC q24h (canine, feline) 2 mg/kg PO q24h (canine, feline)
Ondansetron	Antiemetic (canine, feline): serotonin 5-HT3 receptor antagonist, no effect on dopamine receptors	Tablet (Zofran®) Injectable (Zofran®)	0.1–0.2 mg/kg IV BID (canine) 0.1–1 mg/kg PO q24h BID (canine) 0.5 mg/kg IV, PO BID (feline)
Cisapride	Prokinetic: increases lower esophageal peristalsis and increases gastric emptying. Also effective colonic prokinetic	Compounded tablet or suspension	0.1–0.5 mg/kg PO BID-TID (canine) 2.5 mg PO TID (felines <10 lb), 5 mg PO TID (felines >10 lb)

ATP, adenosine triphosphate; BID, twice a day (*bis in die*); CRI, constant rate infusion; IM, intramuscular; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug; PO, by mouth (*per os*); QID, four times a day (*quater in die*); SC, subcutaneous; TID, three times a day (*ter in die*).

Prokinetic drugs (e.g., cisapride, ranitidine, erythromycin, metoclopramide) canbe used for the treatment of gastric motility disorders (e.g., bilious vomiting syndrome) when mechanical obstruction has been ruled out.

Dietary restriction (<24 hours with access to water at all times) can be considered for dogs with nonobstructive acute gastritis but should be used with caution in cats as they are predisposed to hepatic lipidosis with even short periods of dietary rest. Dietary modification (hydrolyzed, limited ingredient, and/or low fat) is necessary for animals with chronic gastritis where diet is suspected to be the cause of gastric signs.

Broad-spectrum anthelminthic drugs are recommended in animals when an underlying cause of gastritis cannot be identified and/or prior to pursuit of invasive diagnostics (e.g., endoscopy, surgery). Triple antimicrobial therapy with amoxicillin, metronidazole, and bismuth subsalicylate has been used in dogs to treat *Helicobacter*-associated gastritis, but this course of therapy might not eradicate infection.

Prognosis

The prognosis for patients with gastritis and/or gastric ulceration ranges from excellent to guarded depending on the underlying etiology, severity of disease at presentation, and individual response to therapy. Uncomplicated, acute disease in younger, otherwise healthy animals without significant co-morbidities is usually associated with a good prognosis. In contrast, onset of significant gastric disease and ulceration in older animals with chronic histories of gastrointestinal disease or other co-morbidities is often associated with progression of an underlying disease process and can carry a more guarded prognosis.

Normal Esophageal Anatomy and Physiology

The esophagus is a readily distensible, muscular tube that transports ingested material from the oropharynx to the stomach. It is divided into three sections –the cervical, thoracic and abdominal segments – and enclosed at each end by a muscular sphincter (the upper and lower esophageal sphincters).

The esophageal wall has four distinct layers: adventitia, muscularis, submucosa, and mucosa. The entire muscularis layer in the canine esophagus is composed of skeletal muscle, whereas the distal one-third of the feline esophagus consists of smooth muscle. This difference in muscular structure may partly explain the differing prevalence of esophageal disease in dogs and cats, with cats relatively rarely presenting with esophageal diseases other than foreign bodies or squamous cell carcinoma. The upper esophageal sphincter is composed of fibers from the cricopharyngeus muscle and thyropharyngeus muscle. In dogs, the lower esophageal sphincter is composed of an outer layer of striated muscle and an inner layer of smooth muscle, while in cats the lower esophageal sphincter consists of smooth muscle only.

Swallowing is a complex motor reflex requiring coordinated action of the tongue, oropharynx, upper esophageal sphincter, and esophagus to ensure that food enters the gastrointestinal tract and not the upper airways. When swallowing is not occurring, the upper and lower esophageal sphincters are tightly closed and the esophagus is relaxed. During swallowing, the upper esophageal sphincter relaxes and the food bolus is pushed into the cervical section of the esophagus. A primary peristaltic wave is generated, transferring the bolus to the stomach. This primary peristaltic wave will be followed by secondary waves if the esophagus is not cleared of material. Relaxation of the lower esophageal sphincter accompanies the primary peristaltic wave, allowing entry of the food bolus into the stomach.

The most common esophageal disorders encountered in private practice include esophagitis, megaesophagus, esophageal strictures, and esophageal foreign bodies. Less commonly encountered disorders include great vessel anomalies, lower esophageal hiatal disorders, esophageal neoplasia, spirocercosis, cricopharyngeal dysphagia, esophageal diverticulae, and esophageal fistulae.

Recognition of Esophageal Disorders

Common clinical signs of esophageal disease include regurgitation, dysphagia (difficult swallowing), ptyalism (excessive salivation), extension of the head and neck, repeated swallowing attempts, and pain. Regurgitation is a hallmark sign of esophageal disease and needs to be differentiated from vomiting. Regurgitation is defined as the passive retrograde expulsion of material from the esophagus while vomiting is an active process mediated by a central reflex. Vomiting is usually associated with abdominal contractions and might show prodromal signs of nausea (lip smacking, increased salivation, discomfort or anxiety) or the presence of bile in the ejected material.

Oropharyngeal dysphagia, a less common clinical syndrome, should be differentiated from regurgitation. Clinical signs of oropharyngeal dysphagia include multiple swallowing attempts with a single bolus, dropping food or water from the mouth or nostrils, and difficulty drinking. When possible, having the owner video record the episodes may be helpful in distinguishing oropharyngeal swallowing disorders from esophageal motility disorders.

One of the most frequent complications of esophageal disorders is aspiration pneumonia; this is the most common cause of death in animals with esophageal motility disorders. Dogs with aspiration pneumonia secondary to esophageal disease can present with fever, inappetence, coughing, mucopurulent nasal discharge, and pulmonary crackles. Dogs with chronic and severe esophageal dysfunction may present with weight loss and poor body condition scores secondary to inadequate food intake. Dogs with foreign bodies or esophagitis are usually painful during swallowing. Foreign bodies are often associated with an acute onset of regurgitation. The presence of esophageal disease at the time of weaning is more commonly seen with congenital idiopathic megaesophagus, vascular ring anomalies or congenital stenosis. The history may indicate a recent anesthetic procedure that could cause reflux esophagitis and potential stricture, exposure to caustic medications (e.g., doxycycline) or foreign bodies. Signs of concurrent neuromuscular disease can be seen in dogs with megaesophagus secondary to myasthenia gravis.

Diagnostic Approach to Esophageal Disease

Plain thoracic and cervical radiographs are the initial step in all animals with clinical signs and histories consistent with esophageal disease. Radiographs are useful in the identification of megaesophagus, radiopaque foreign bodies, and hiatal defects. In addition, the lungs and mediastinum can be evaluated for any evidence of aspiration pneumonia or pneumomediastinum associated with esophageal perforation.

A contrast esophagram should be considered when plain radiographs do not identify a lesion. The contrast study can be performed under fluoroscopy or using plain radiography (see Chapter 53). The use of fluoroscopy helps in the evaluation of esophageal motility. Contrast studies can be useful in the identification of radiolucent foreign material, strictures or neoplasia. Contrast esophagram studies are usually contraindicated in animals with megaesophagus because of the high risk of aspiration pneumonia. A water-soluble iodinated contrast agent is preferred if esophageal perforation is suspected.

Esophagoscopy can be useful for the diagnosis of esophageal neoplasia, esophagitis, strictures, and perforation. This minimally invasive procedure allows the direct visualization of the esophageal mucosa and lumen and can be used to obtain biopsies, retrieve foreign bodies, balloon esophageal strictures or deploy esophageal stents.

Specific Esophageal Disorders

Megaesophagus

Congenital Megaesophagus

Megaesophagus is a condition characterized by diffuse esophageal dilation and decreased or absent esophageal motility. Megaesophagus may be a congenital or acquired (adult-onset) disease. A familial predisposition has been identified in several breeds including the Great Dane, German shepherd, Irish setter, Chinese shar-pei, Newfoundland, miniature Schnauzer, Labrador retriever and fox terrier breeds, as well as Siamese cats. In the wirehaired fox terrier, congenital megaesophagus is inherited as a simple autosomal-recessive trait, while in miniature Schnauzers it is transmitted as either a simple autosomal-recessive or dominant trait. Affected dogs usually start having clinical signs of regurgitation at or shortly after weaning.

The main differential diagnosis that should be considered in young dogs with regurgitation at the time of weaning is a congenital vascular ring anomaly. Plain radiographs are usually sufficient to differentiate between these disorders, although contrast studies are necessary in some cases.

The etiopathogenesis of congenital megaesophagus is unclear. Esophageal motility and nerve stimulation studies in dogs with megaesophagus indicate a defect in the afferent neural pathway, while the efferent neural pathway appears to be intact.

The prognosis for congenital megaesophagus is guarded to poor. Some dogs can be managed for months to years while others rapidly succumb due to uncontrolled regurgitation and aspiration pneumonia. Breeding of affected patients is not recommended. Treatment details for megaesophagus are discussed below.

Acquired Megaesophagus

Acquired megaesophagus can occur in any breed or age. Acquired megaesophagus may be primary (idiopathic) or secondary to multiple disorders, particularly diseases causing neuromuscular dysfunction.

The most common cause of secondary acquired megaesophagus in dogs is myasthenia gravis(MG). MG may be congenital (rare) or acquired. Acquired MG is an autoimmune disorder characterized by autoantibodies directed against the acetylcholine (Ach) receptors of skeletal neuromuscular junctions. These antibodies bind to the Ach receptors, reducing the number of receptors available for normal neuromuscular transmission. When acetylcholine is released from presynaptic vesicles at the nerve terminal, it is unable to bind to the receptors on the postsynaptic muscle fiber membrane. Depending on

the clinical presentation, MG can be classified as generalized, focal or acute fulminant. Generalized MG usually presents with generalized muscular weakness that worsens after exercise; megaesophagus has been well documented in these cases. Acute fulminant MG usually presents as a flaccid tetraparesis and acute respiratory distress.

The gold standard for the diagnosis of acquired MG is the detection of serum autoantibodies directed against Ach receptors. An Ach receptor antibody concentration of ≥0.6 nmol/L is considered positive. Approximately 2% of dogs with generalized MG, however, are negative for Ach receptor antibodies. A presumptive diagnosis can be made by a positive response to an ultra short-acting anticholinesterase agent (Tensilon test: edrophonium chloride IV at 0.1–0.2 mg/kg). This test can lead to a cholinergic crisis in nonmyasthenic patients or if accidentally overdosed, producing bronchoconstriction, bradycardia, salivation, lacrimation, retching, diarrhea, and vomiting. In this situation, atropine sulfate should be administered IV (0.02–0.04 mg/kg IV). Dogs with focal or generalized MG are treated with anticholinesterase agents such as pyridostigmine bromide (1–3 mg/kg PO q8–12 h or 0.01–0.03 mg/kg/h as a constant rate IV infusion) or neostigmine bromide (2 mg/kg/day PO in divided doses to effect or 0.04 mg/kg IM q6h).

Focal MG usually affects the motor fibers of cranial nerves innervating the larynx and pharynx. Megaesophagus associated with focal MG can be misdiagnosed as idiopathic acquired megaesophagus, and assessment of anticholinesterase antibody titers is strongly recommended in the work-up of the great majority of dogs with esophageal motility disorders.

Endocrine diseases such as hypoadrenocorticism and hypothyroidism have historically been associated with megaesophagus. Megaesophagus has been reported in dogs with primary, secondary and atypical hypoadrenocorticism. Proposed causes include altered muscle carbohydrate metabolism due to a lack of physiologic cortisol production, and the effects of abnormal sodium and potassium concentrations on membrane polarization. An adrenocorticotropic hormone (ACTH) stimulation test is necessary for the diagnosis. Although a definitive association between hypothyroidism and megaesophagus has not been proven, there are reports of dogs with hypothyroidism and megaesophagus. There is also an association between MG and hypothyroidism and thyroid function should be evaluated concurrently with diagnostic testing for MG.

Megaesophagus has also been described as a paraneoplastic syndrome. According to one study, megaesophagus was present in 40% of dogs with thymoma. Thymoma also has been associated with MG in dogs and cats. Complete thymus resection can result in resolution of megaesophagus. However, nonresectable thymoma in dogs with megaesophagus has a poor prognosis.

Idiopathic megaesophagus is the most common cause of megaesophagus in dogs. It usually affects large-breed dogs between 5 to 12 years old. The etiopathogenesis is unknown. There is no sex or breed predilection. Many dogs affected with idiopathic megaesophagus have a very dilated and aperistaltic esophagus.

Treatment of Megaesophagus

The treatment of dogs with idiopathic megaesophagus is entirely supportive and symptomatic, while animals with acquired megaesophagus should be treated specifically for the underlying disease. Thoracic radiographs are recommended to monitor and document esophageal dilation and evaluate for aspiration pneumonia.

Frequent feeding of small, high-calorie meals with the patient in a cranially elevated position will help meet nutritional requirements and reduce regurgitation. Upright feeding, holding the dog in vertical position, or using "Bailey" chairs are often effective strategies for controlling regurgitation in many dogs. Very weak patients or those in whom the regurgitation is uncontrollable might benefit from placement of a gastrostomy tube. The optimal food consistency depends on the patient and should be tailored to each individual dog.

The most common complications of megaesophagus are aspiration pneumonia and esophagitis. Aspiration pneumonia should be treated using broad-spectrum antibiotics. Culture and sensitivity testing of a transtracheal wash or bronchoalveolar lavage sample is useful to guide antibiotic choice. Esophagitis can also worsen megaesophagus and lead to strictures.

The use of prokinetic medications in dogs with megaesophagus has not been shown to have any benefit. Metoclopramide and cisapride exert their actions on smooth muscle and do not have any action on skeletal muscle, thus they are not useful in dogs with esophageal hypomotility. These medications may also increase the tone of the lower esophageal sphincter, decreasing esophageal emptying. In cases of esophageal reflux, however, these medications might be useful because they decrease the episodes of reflux and esophagitis. Bethanecol binds and stimulates cholinergic (muscarinic) receptors and may be helpful in stimulating esophageal propagating contractions.

Prognosis for Animals with Megaesophagus

The prognosis for patients with megaesophagus depends on the underlying disease and the presence of secondary complications such as aspiration pneumonia. In dogs with MG, resolution of megaesophagus can occur within

the first six months. Dogs with congenital megaesophagus have a more guarded prognosis. Some dogs can recover and acquire normal esophageal function if dietary management is begun early. The prognosis for idiopathic megaesophagus in adult dogs is poor and spontaneous recovery rarely occurs. Most dogs eventually die due to aspiration pneumonia.

Esophagitis

Esophagitis can be defined as chronic or acute inflammation of the esophageal mucosa. Esophagitis can be caused by a chemical or caustic injury (acid, drug-induced), esophageal foreign body, gastroesophageal reflux, radiation, or food retention secondary to megaesophagus. The degree of inflammation can be mild, with lesions localized in the mucosa, or severe, affecting the muscularis layer.

The administration of oxytetracycline and doxycycline has been associated with esophagitis in cats. Other orally administered medications including clindamycin, nonsteroidal antiinflammatory drugs, and bisphosphonates can also produce esophagitis.

Esophageal foreign bodies can cause severe esophageal inflammation in dogs and cats. They are usually located in the thoracic inlet, at the base of the heart or the lower esophageal sphincter.

Gastroesophageal reflux is a consequence of movement of gastric content into the esophagus. Exposure of the mucosa to the refluxed gastric acid, digestive enzymes, and bile acids can rapidly induce inflammation. Gastroesophageal reflux has been associated with anesthesia, hiatal hernias, neoplasia affecting the distal esophagus or lower esophageal sphincter, and delayed gastric emptying. Anesthesia is a known risk factor for gastroesophageal reflux. The duration of the anesthesia and preanesthetic agents used appear to influence the risk of gastroesophageal reflux. Medications that decrease the lower esophageal tone, such as thiopentone, propofol, morphine, xylazine, and atropine, can increase the risk of reflux. Prolonged fasting (24 hours) before anesthesia is associated with a higher risk of gastroesophageal reflux.

Clinical signs of esophagitis include decreased appetite, odynophagia (painful swallowing) or dysphagia, ptyalism, coughing, and regurgitation. Some animals only show subtle signs with decreased appetite and increased salivation. Clinical signs consistent with esophagitis 1–4 days after an anesthetic procedure are suggestive of esophageal reflux, and should be managed aggressively to decrease the risk of esophageal stricture formation. Dogs with chronic vomiting should be monitored closely. The final diagnosis of esophagitis is done by direct visualization of the esophageal mucosa via endoscopy. Focal or diffuse mucosal erythema with increased friability is often seen.

Treatment

Treatment of esophagitis is focused on the elimination of the underlying cause and allowing inflammation to resolve. Esophageal foreign objects need to be treated as an emergency and retrieved as soon as possible. Administration of drugs associated with esophagitis (doxycycline, oxytetracycline, clindamycin) should be discontinued. The main cornerstones of the treatment of esophagitis are acid suppression, mucosal protection via sucralfate administration, and supportive care. In some cases, supportive care may require interventions to provide nutritional support, such as percutaneous endoscopic gastrostomy (PEG) tube placement. The use of prokinetic medications is controversial, but is recommended when reflux esophagitis is suspected.

The most common acid suppressants used in dogs and cats are proton pump inhibitors (PPIs) and histamine-2 receptor antagonists (H_2-blockers). Proton pump inhibitors covalently bind to and irreversibly inhibit the H^+-K^+-ATPase proton pumps. PPI medications are available in both oral (omeprazole) and parenteral (pantoprazole, esomeprazole, lansoprazole) formulations. H_2-blockers act by blocking the action of histamine on parietal cells in the gastric mucosa, decreasing the production of acid by these cells. PPIs have proven to be more effective at raising intragastric pH than histamine-2 receptor antagonists. Administration of PPIs twice daily (0.7–1 mg/kg q12h) rather than once daily is recommended to effectively increase the intragastric pH in both dogs and cats. The combination of PPIs and H_2-blockers is not superior to the administration of a PPI alone.

Sucralfate is an aluminum salt of a sulfated disaccharide that, when activated in an acidic environment, forms a paste-like material that binds to and protects exposed submucosa and the mucosa from acid exposure. Sucralfate is generally administered as a slurry 3–4 times per day, separate from food and other medications.

Prokinetic medications such as metoclopramide and cisapride are useful to increase the tone of the lower esophageal sphincter and enhance gastric motility. In cases of gastroesophageal reflux, the use of metoclopramide (2 mg/kg q24h as a constant rate infusion [CRI]) or cisapride (0.5 mg/kg q8h PO) is recommended.

Anesthesia is the main cause of gastroesophageal reflux and esophagitis in dogs and cats. The position during anesthesia has not been identified as a risk factor. The frequency of reflux is greatest in abdominal procedures. When acid reflux is confirmed, esophageal lavage

with water, followed by 20 mL of 4.2% bicarbonate, is recommended.

In severe cases of esophagitis, placement of a gastrostomy tube may be indicated to ensure adequate caloric intake, while also reducing esophageal pain and further irritation of the esophageal mucosa.

Esophageal Strictures

Esophageal strictures arise as the result of severe esophageal inflammation affecting the muscularis layer. During the healing process of these lesions, intramural fibrous contraction may occur, leading to a band of scar tissue that produces a circumferential narrowing of the esophageal lumen.

The main clinical signs associated with esophageal strictures are regurgitation, weight loss, coughing, salivation, anorexia, odynophagia, and vomiting. Benign esophageal strictures are usually a consequence of severe esophagitis due to esophageal reflux secondary to anesthesia or foreign bodies. Malignant esophageal strictures are associated with neoplasia. Strictures secondary to gastroesophageal reflux are often located between the thoracic inlet and the diaphragm, whereas strictures cranial to the thoracic inlet are usually associated with foreign body injuries.

Clinical signs and the history of the patient will typically suggest the presence of an esophageal stricture. Barium contrast studies, using conventional radiography or fluoroscopy, are useful diagnostic tools. Endoscopic visualization of esophageal stricture is the most reliable method of diagnosis, and has the advantage that treatment can be immediately initiated. Circumferential narrowing of the esophagus, with intraluminal fibrous tissue bands, is usually visualized.

Treatment

There are two preferred techniques typically used for the treatment of benign esophageal strictures: bougienage and ballooning.

Bougienage involves the use of rounded, rigid or semi-rigid instruments that are pushed through the esophagus to progressively stretch the stricture. Different sizes are used serially to gradually open the stricture. The bougienage technique applies both radial and shearing forces to the fibrous tissue at the site of the stricture. Wire-guided bougienage appears to be safe and is commonly associated with a good outcome.

Esophageal ballooning is performed by passing an inflatable balloon into the stricture. The balloon dilates and becomes rigid when inflated, applying a radial force to the stricture. The balloons are positioned into the lumen using endoscopy or fluoroscopy guidance. Balloon dilation does not apply shearing forces to the stricture tissue.

Esophageal ballooning and bougienage are reportedly equally safe and effective. The number of repetitions of the dilation necessary varies between patient (with most requiring 1–4 sessions); both methods have success rates of 70–88%. The interval between dilation attempts is usually 7–10 days. Both methods have been associated with complications, including mucosal tearing, hemorrhage, and esophageal perforation. When dilating an esophageal stricture, the aim is to return the patient to normal or at least manageable swallowing function that will allow sufficient nutritional intake. Dilation of the esophagus to the prestricture diameter is usually unnecessary, as many animals will show marked improvement in swallowing function with less than complete dilation of the esophagus.

During the series of dilation treatments, it is critical to aggressively manage esophagitis and prevent further damage from gastroesophageal reflux. Sucralfate suspensions, antacids (PPIs), and prokinetics (cisapride, metoclopramide) are generally indicated to protect the mucosa, reduce acid secretion and increase the tone of the lower esophageal sphincter. The use of systemic corticosteroids is controversial in these patients and further studies are necessary to evaluate their efficacy. Intralesional corticosteroid injection using triamcinolone can be used instead of systemic corticosteroids. Mitomycin-C can also be used topically at the stricture site, after dilation, to reduce collagen formation and the risk of recurrence of the stricture.

Esophageal Foreign Bodies

Esophageal foreign bodies are more common in dogs than in cats. The most common foreign bodies in dogs are bone fragments and rawhide type chews. In cats, string or linear foreign bodies attached to the base of the tongue are the most frequently encountered. Esophageal foreign bodies are most commonly found between the base of the heart and the diaphragm.

Clinical signs associated with foreign bodies include regurgitation, gagging, anorexia, and retching. The severity of esophageal damage depends on both the type and duration of the obstruction. Animals with esophageal perforation or aspiration pneumonia commonly present obtunded, febrile, anorectic, and with coughing.

Radiopaque foreign bodies can be diagnosed using thoracic radiographs. Thoracic radiographs are also useful to rule out the presence of aspiration pneumonia or esophageal perforation. Contrast radiography is useful to reveal radiolucent foreign material. Direct visualization

of the foreign body using esophagoscopy confirms the diagnosis, and is typically a prequel to treatment.

Treatment

Esophageal foreign bodies are considered medical emergencies. Esophagoscopy can be used to confirm and retrieve the foreign material using a variety of grasping instruments. Foreign bodies located close to the lower esophageal sphincter may be able to be pushed into the stomach. The long-term prognosis is usually excellent although short-term complications are common. The most common complications include esophagitis, aspiration pneumonia, and esophageal perforation (pneumothorax). Dogs with moderate and severe esophagitis are more prone to develop strictures.

When extensive esophageal perforation or necrosis is present, surgical removal is recommended. Esophageal surgery has been associated with a higher risk of esophageal dehiscence due to the segmental blood supply, the absence of a serosal layer and the movement and tension of the surgical site. The most common complications include dehiscence, pyothorax, and pleuritis. Transthoracic esophagostomy retrieval of foreign bodies has been associated with a survival rate of 77–93%.

Medical treatment for esophagitis is necessary after retrieving the foreign material. Recheck thoracic radiographs are useful to identify pneumothorax and/or pneumomediastinum secondary to esophageal perforation. Small esophageal perforations may be able to be medically managed with antibiotics and supportive care. In cases of severe esophageal injury, after retrieval of the foreign body, the placement of a gastrostomy tube should be considered.

Vascular Ring Anomalies

Vascular ring anomalies (VRAs) are congenital malformations of the embryonic aortic arches that affect both dogs and cats, producing esophageal constriction. Persistent right aortic arch (PRAA) is the most common anomaly in dogs and cats; this anomaly is associated with entrapment of the thoracic esophagus. PRAA occurs when the aorta develops from the embryonic right fourth aortic arch rather than the left fourth aortic arch. As a consequence, the esophagus is constricted between the ligamentum arteriosum (LA) dorsally, pulmonary artery on the left, aorta on the right, and the heart ventrally. Although VRAs have been reported in many breeds of dogs and cats, German shepherds, Irish setters and the Labrador retriever may be predisposed.

Regurgitation and failure to thrive are the most common clinical signs and are often present at the time of weaning. Thoracic radiographs often reveal dilation of the esophagus cranial to the base of the heart; plain radiography is also useful to screen for concurrent aspiration pneumonia. When plain radiographs are nondiagnostic, a barium contrast study may aid in visualization of esophageal obstruction at the base of the heart. Direct visualization of the esophageal mucosa via esophagoscopy may be useful to differentiate between extraluminal and intraluminal compression.

Treatment

Definitive treatment of PRAA involves surgical ligation and transection of the ligamentum arteriosum via thoracoscopy or thoracotomy. Esophageal hypomotility and regurgitation may persist after surgical ligation and the risk of this outcome increases with the duration of clinical signs. In a recent study evaluating the short- and long-term outcome following surgical repair of PRAA, the long-term outcome for dogs was excellent in 30%, good in 57%, and poor in 13%. Patients with persistent regurgitation after surgery are treated supportively as described for idiopathic megaesophagus, with upright feeding, small, frequent meals, and restraint of the animal in a "Bailey" type chair.

Motility Disorders of the Alimentary Tract

Reto Neiger, Dr. Med Vet, PhD, DACVIM (SAIM), DECVIM-CA[1]
and Silke Salavati, Dr. Med Vet, PhD, DipECVIM-CA, MRCVS[2]

[1] *Small Animal Clinic Hofheim, Hofheim, Germany*
[2] *Royal School of Veterinary Studies, University of Edinburgh, Edinburgh, Scotland*

Gastrointestinal (GI) motility disorders are a diagnostic and therapeutic challenge. They can consist of delayed or accelerated transit times as well as impaired or inappropriate relaxation anywhere in the GI tract. Delayed transit is the most common form. This may be a primary localized neuromuscular disorder, part of a more generalized GI motility disturbance (e.g., dysautonomia) or secondary to systemic health problems (metabolic, toxic, inflammatory, neoplastic, obstructive, etc.).

Motility Disorders of the Esophagus

Physiology of Esophageal Motility

The esophagus acts as a simple tube for the transport of food from the oral cavity to the stomach. Between swallows, it is collapsed but can distend markedly to accommodate a food bolus. Structurally, it is of similar composition to the remainder of the GI tract, but it lacks a serosa. In dogs, the muscular layer (responsible for the motor function) is composed of two layers of striated muscles spiraling in oblique bundles and crossing each other at right angles. In cats, there is a transition zone from striated to smooth muscle at the level of the heart.

There are two sphincters: the upper esophageal sphincter (UES), consisting of the cricopharyngeus muscle, and the gastroesophageal sphincter (GES), which is a thickening of the esophageal muscle at the junction to the stomach.

Esophageal transport of a food bolus – as part of the complicated swallowing act – is under complete autonomic neuronal control. Efferent neurons from the nucleus ambiguous in the medulla oblongata innervate the striated muscle (dogs and cats) and the smooth muscle (cats) via the vagus nerve. Once the food bolus is voluntarily pushed caudally into the oropharynx, a complex reflex is instituted, that starts with cricopharyngeal relaxation. The food bolus is then passed through the UES into the cervical esophagus. Immediately thereafter, the UES closes, preventing material from entering the trachea or being pushed back into the pharynx. Continuous peristaltic contractions move the food aborally, where it passes through the relaxed GES (primary esophageal peristalsis). In a case where the first peristaltic wave is inadequate for complete transport, secondary esophageal peristalsis occurs, where local esophageal distension generates another peristaltic wave.

Clinical Signs of Esophageal Motility Disorders

The classic clinical sign of esophageal disease is regurgitation. Additional common complaints are dysphagia, hypersalivation, retching and gagging, odynophagia, and repeated swallowing attempts. Less common signs are anorexia and lethargy. Both dogs and cats can show signs of aspiration pneumonia (fever, tachypnea, coughing, dyspnea).

On physical examination, low body condition score/weight loss or poor growth might be apparent. Rarely, a dilated esophagus can be palpated in the cervical region. Bradycardia, loss of pupillary light reflexes, decreased tear production (demonstrated by a Schirmer tear test), dry mucous membranes, and constipation/diarrhea in combination with megaesophagus are indicative of a dysautonomia.

Causes of Esophageal Motility Disorders

In small animals, primary esophageal motor dysfunction is poorly defined and infrequently recognized, except for idiopathic megaesophagus and esophageal diverticula in dogs. A high prevalence of subclinical primary esophageal dysmotility has been reported in certain dog breeds

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

(Chinese shar-pei, bouvier des Flandres) and in young dogs (up to 2 years of age). The reported prevalence of abnormal esophageal motility in cats is 0.05%.

Secondary esophageal dysmotility is seen in most animals with obstructive or inflammatory esophageal disease; these will not be covered in detail in this chapter (see Chapter 52). Obstructive disorders can be grouped into intraluminal (foreign body), intramural (neoplasia, granuloma, stricture) or extraluminal (vascular ring anomaly, mediastinal mass), whereas inflammation (esophagitis) is frequently due to gastroesophageal reflux disease (GERD).

Megaesophagus

Megaesophagus is defined as generalized esophageal dilation with hypo- or amotility and can be primary (idiopathic) or secondary (acquired). It has to be differentiated from localized esophageal dilation, which can be frequently observed proximal to obstructive disorders. However, early cases of megaesophagus might have only segmental dilation, which may become generalized with time. In addition, not all dogs with abnormal esophageal motility progress to megaesophagus.

Idiopathic megaesophagus may be congenital or acquired. In some dog breeds (Great Dane, German shepherd, Irish setter, golden retriever, Labrador retriever, greyhound, Newfoundland, shar-pei), a familial predisposition is reported, while in others (miniature schnauzers and fox terriers) an autosomal dominant inheritance trait has been discovered. In cats, megaesophagus is uncommon. The acquired adult-onset form is most commonly idiopathic (>70%) or secondary to other systemic disorders, especially those causing neuromuscular dysfunction.

The pathogenesis of megaesophagus in dogs is still poorly understood, but defects in afferent neural pathways have been suggested, while efferent neuromuscular pathways seem to be intact. Decreased motor responses of the UES and GES to intraluminal stimuli have been reported.

Ancillary diagnostic tests are performed in dogs with megaesophagus with the intent to detect an underlying cause (e.g., myasthenia gravis), as treatment of the underlying disorder might lead to complete resolution of esophageal dilation, and to identify co-morbidities such as aspiration pneumonia. Initial tests can include a complete blood count (CBC) and determination of C-reactive protein (or other acute phase proteins) as a measure of the severity of secondary inflammation/infection. Measurement of acetylcholine receptor antibody (AchRA) titer by an accredited laboratory can aid the diagnosis of myasthenia gravis and should be done in all dogs with megaesophagus. Focal myasthenia gravis occurs in the absence of muscle weakness and is the second most common cause (≈25% of cases) of acquired megaesophagus. Endocrinopathies such as hypoadrenocorticism and hypothyroidism have frequently been implicated as a cause of megaesophagus in the dog. However, the association of megaesophagus with hypoadrenocorticism is rare. In almost all dogs that simultaneously suffered from hypoadrenocorticism and megaesophagus, Na:K ratios were abnormally low. Consequently, an adrenocorticotropic hormone (ACTH) stimulation test is only indicated in these dogs if electrolyte abnormalities (hyponatremia and hyperkalemia with a Na:K ratio <27) are observed.

Other potential tests that could be considered in dogs with megaesophagus, on an individual basis, include blood lead concentrations (lead poisoning), edrophonium chloride challenge test (generalized myasthenia gravis) or electromyography in a dog with generalized muscle weakness (polyradiculoneuritis, polymyositis, etc.).

Diagnostic Tests to Assess Esophageal Motility

Survey radiographs do not assess esophageal motility, but can be informative regarding luminal obstructions, dilation/ diverticula, strictures, and megaesophagus.

The esophagus is not visible in its physiologic state as it has the same opacity as the surrounding soft tissue. A mildly air-filled esophagus or small "pockets" of air can be present due to physiologic transient dilation, aerophagia (anxiety, dyspnea) and during sedation/anesthesia. Both left and right lateral radiographic views might be necessary in some cases to diagnose esophageal dilation.

Megaesophagus is characterized radiographically via visualization of a dilated, enlarged, air-filled esophagus (sometimes also filled with fluid or ingesta). The trachea can show some ventral deviation. The caudodorsal thorax might appear hyperlucent.

If plain radiographs are inconclusive, contrast studies (esophagrams) can be helpful. They should not be performed if the cause of regurgitation is already clear on the plain radiographs. The use of barium sulfate in cases where perforation cannot be excluded/is suspected (pneumomediastinum) or where the risk of immediate regurgitation is high should be avoided. Ideally, contrast studies of the esophagus should be limited to the use of iodine-containing media.

Immediately after oral administration of contrast (10–20 mL/animal at a time), a few longitudinal parallel esophageal folds outlined by barium can be visible in the normal canine esophagus, while cats show additional transverse mucosal folds in the caudal third of the esophagus (so-called "herringbone" pattern). To assess subtle motility disorders limited to the passage of solid food,

contrast can be mixed with food and the radiographs can be repeated.

To diagnose functional cricopharyngeal and esophageal dysmotilities that do not lead to dilation (achalasia, cricopharyngeal bars), a sliding hiatal hernia (type I) or GERD, contrast-enhanced videofluoroscopic esophagography (fluoroscopy) is the imaging modality of choice, as it provides continuous, dynamic and real-time assessment of the entire swallowing process. Conscious animals are placed in lateral or sternal position. Neat liquid barium, barium paste, barium mixed with canned food (all administered via syringe) or barium-soaked kibble (in animals willing to eat) can be used. Three to five swallows are observed in real time with at least one followed all the way into the stomach.

Esophagoscopy is rarely useful to investigate functional dysphagia as esophageal motility cannot be assessed under general anesthesia, but it can be performed to remove esophageal foreign bodies, detect esophagitis/GERD, esophageal tumors or hiatal hernias. Esophageal mucosal biopsies can be useful in the diagnosis of GERD, esophagitis, and neoplasia, but can be difficult to retrieve due to the firmness of the mucosa and the difficulty in achieving an oblique or 90° angle.

Esophageal manometry allows assessment of the intraesophageal pressure generated by peristalsis and provides clinically important information on esophageal motor function. Recently, high-resolution impedance manometry has become the standard for the evaluation of esophageal function in humans. This technique has recently been used in dogs (Figure 53.1) and while technically demanding and limited to a research setting at the moment, it gives an overall highly informative assessment of esophageal motility.

Treatment of Esophageal Motility Disorders

Medical treatment of esophageal dysmotility in dogs qnd cats is typically unrewarding. Management of megaesophagus is directed towards treating the inciting cause (e.g., use of pyrido- or neostigmine in myasthenia gravis) and based on the optimization of feeding regimens. Feeding from an elevated position, sometimes aided by using specialized feeding chairs, and the attempt to avoid complications like aspiration pneumonia are the most important measures. The ideal type of food (kibbles, gruel, homogenized food, etc.) for individual patients has to be found in a "trial-and-error" fashion. If an underlying disease process is suspected, empirical treatment is often initiated until test results (e.g., AchRA titer) are available. Aspiration pneumonia has to be treated aggressively, usually with intravenous fluids and antibiotics, coupage, and potentially secretolytics. If esophagitis is suspected or proven, oral sucralfate suspension and proton pump inhibitors (to avoid GERD) should be prescribed.

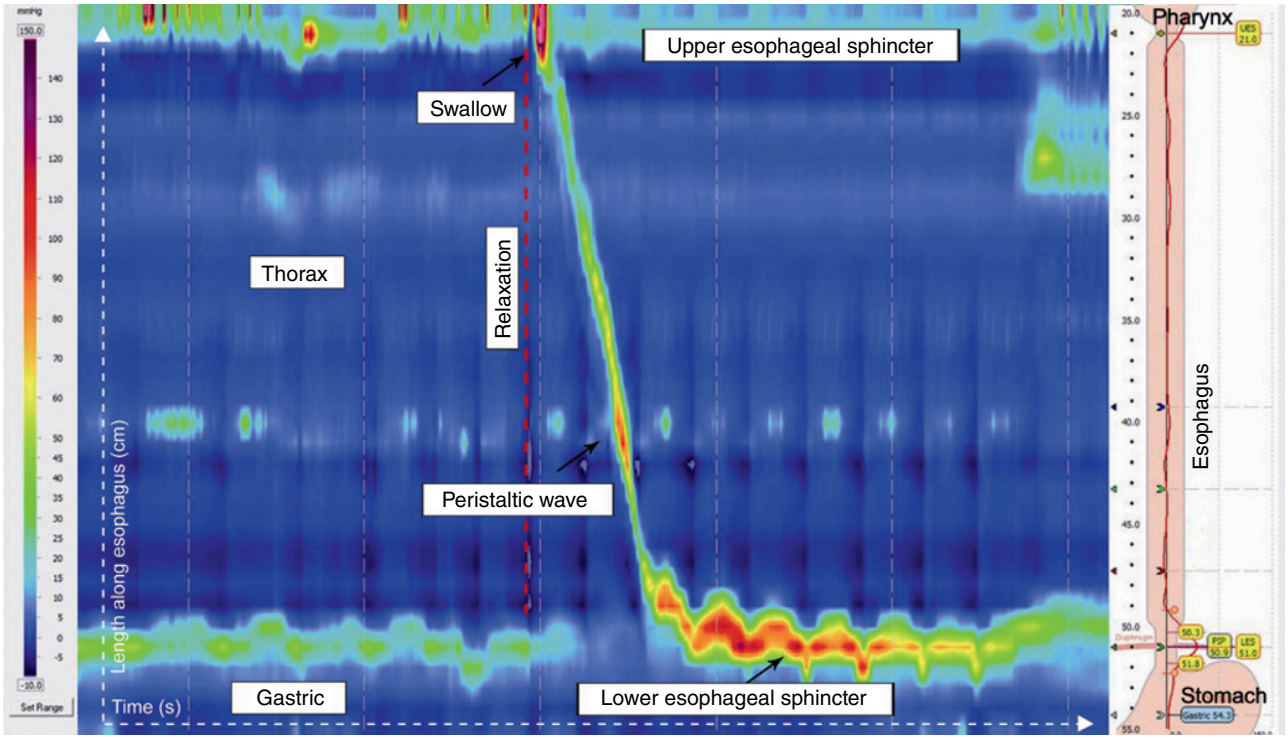
Motility Disorders of the Stomach

Gastric motility is a highly coordinated process involving neuromuscular and hormonal signals and is triggered as a response to either the presence of food in the stomach or a range of different local (mechanical or functional) or systemic diseases. There are three separate types of gastric motility disorders: accelerated gastric emptying, retrograde transit (reflux), and delayed gastric emptying.

Physiology of Gastric Motility and Emptying

Functionally, the stomach can be divided into the proximal (consisting of cardia, fundus, first third of the corpus) and distal (distal two thirds of the corpus and antrum) compartments. The proximal compartment is responsible for the accommodation of food and liquids and characterized by slow tonic contractions. The distal compartment is characterized by phasic propagating contractions generated by pacemaker cells (interstitial cells of Cajal [ICC]) that lead to mechanical milling of gastric contents (called trituration) and their final expulsion through the pylorus. Pressure and amplitude of these contractions increase in an aboral direction.

Digestive motility resulting in gastric emptying occurs in three consecutive phases:



1) propulsion (proximal part of the antrum contracts)
2) emptying and mixing (pylorus opens partially and duodenal peristalsis is momentarily halted while particles up to 2 mm pass the pylorus)
3) retropulsion (larger particles are propelled back into the corpus).

Interdigestive motility occurs to empty nondigestible food particles/foreign bodies, swallowed saliva, and small amounts of mucus and cellular debris. In the dog, this motility pattern is called the migrating motor complex (MMC) and starts with intense contractile activity in an aboral direction ("clean sweep") followed by a period of relative quiescence and a short phase of irregular undirectional contractions. Interdigestive motility in the cat is uniquely associated with long fused migrating spike burst contractions interspersed with short periods of irregular activity.

Clinical Signs of Gastric Dysmotility

In dogs with delayed gastric emptying, clinical signs can include gastric distension and vomiting of undigested or partially digested food >8 h after feeding (when the stomach should be empty). In cats, the importance of gastric emptying disorders remains unclear. Clinical signs include anorexia, vomiting, regurgitation, and weight loss.

(b)

Figure 53.1 (a) Physiologic swallow pressure topography of a healthy dog extending from the pharynx to the stomach. The colors reflect the intensity of the pressures; red stands for high and blue for low pressure (color scale on the left). The upper and lower esophageal sphincters are clearly detectable as high-pressure zones. There is a relaxation of both sphincters following a swallow. (b) Dog with esophageal manometer catheter in place. *Source:* Courtesy of Jennifer Kempf and Peter Kook, Vetsuisse Faculty, University of Zurich, Switzerland.

Gastroesophageal reflux disease is detected more frequently in dogs than cats. It can occur spontaneously or be related to general anesthesia. In both species, it can result in ptyalism, retching, regurgitation or vomiting, pain when swallowing and dysphagia (see Esophageal Dysmotility, earlier). Occasionally, excessive grass eating and cough are also reported in dogs.

The frequency of duodenogastric reflux in dogs is unclear. However, it has been proposed to lead to bilious vomiting syndrome (BVS), which is characterized by vomiting of bile and mucus after a prolonged fasting period.

Accelerated gastric emptying is rarely a problem leading to clinical signs in dogs, but is hypothesized to be the cause of vomiting in hyperthyroid cats. Acute infectious or obstructive diseases of the gastrointestinal tract can also lead to secondary hyperperistalsis of the stomach, but hypoperistalsis, vomiting/retching, and diarrhea are more frequent presenting complaints.

Other signs of gastric dysmotility or its underlying causes can include anorexia, belching, pica, weight loss or abdominal pain. In animals with dysautonomia, gastric hypomotility is one of many problems due to denervation of the autonomous nervous system. Hence, other clinical signs typically associated with this disease, such as dry eyes and nose, mydriasis, regurgitation, and constipation, are often predominant.

Physical examination findings can range from no detectable abnormalities to the presence of an enlarged abdomen (gastric distension), decreased or increased bowel sounds, and nonspecific/cranial abdominal pain. Rarely, neuromuscular abnormalities may also be observed if severe metabolic or systemic derangements (electrolyte abnormalities, dysautonomia) are present.

Causes of Gastric Dysmotility

Delayed Gastric Emptying

Delayed gastric emptying is probably underdiagnosed in both dogs and cats, especially in cases where no obvious obstruction of gastric outflow is present. Mechanical obstructions (gastric neoplasia, hyperplasia, polyps, foreign material) are usually easy to diagnose based on history, physical examination and diagnostic imaging procedures and are not further discussed in this chapter. However, diagnosis of functional problems (due to either local or systemic disorders) is not as straightforward.

A number of primary causes of functional gastric stasis have been described in the dog, including infectious and/or inflammatory diseases, peptic ulcers, and following surgical procedures. Systemic disorders suspected to affect gastric motility include electrolyte disturbances (especially hypercalcemia, hyper- or hypokalemia), disorders of acid–base balance, septicemia, pancreatitis, peritonitis, systemic inflammatory response syndrome (SIRS), dysautonomia, and metabolic diseases such as diabetes mellitus

Gastric dilation-volvulus (GDV) in large and giant dog breeds has been speculated to be caused by delayed gastric emptying, but evidence for the influence of size or weight on gastric emptying times and the presence of gastric dysmotility in dogs with GDV is controversial.

Diseases of the large intestine (e.g., colitis, constipation) can potentially also delay gastric emptying via reflex mechanisms.

The clinical importance of gastric emptying disorders in the cat is unknown. There are a few case reports of delayed gastric emptying in cats with rare conditions such as pylorospasm, hyperplastic gastropathy, and dysautonomia. Delayed or dysfunctional gastric emptying is suspected in conjunction with conditions like diabetes mellitus, pancreatitis, and inflammatory bowel disease (IBD) but specific investigations into these diseases as causes of gastric dysmotility in cats are lacking.

Retrograde Transit

Gastroesophageal reflux disease and duodenogastric reflux are retrograde transit disorders. Neither of these conditions has been extensively investigated in small animals. GERD is more often associated with diseases of the esophagus or the distal esophageal sphincter, and occurs most commonly during or after general anesthesia.

Duodenogastric reflux can lead to BVS (also called fasting vomiting) in dogs. Clinical signs of BVS improve in most cases by changing the feeding regimen (frequent feeding of small meals) and administration of prokinetics and gastroprotectants. This suggests an underlying abnormality in gastrointestinal motility, but no further investigations have been performed to date. No reports exist of duodenogastric reflux in cats apart from its occurrence with experimental devascularization and ulceration of the stomach.

Accelerated Gastric Emptying

Accelerated gastric emptying (for example, in acute infectious or obstructive disease) is usually associated with hypermotility of the entire GI tract; hence diarrhea can be the predominant problem, or occur alongside other clinical signs. Isolated hypermotility of the stomach has not been reported in dogs.

Diagnostic Tests to Assess Gastric Motility and Emptying

Several methods have been used to assess gastric motility – especially gastric emptying times – in small animals. Their diagnostic usefulness and availability for the practitioner are summarized in Table 53.1.

Table 53.1 Methods to assess gastric emptying in small animals and their diagnostic usefulness and availability to the practitioner

Technique	Information gained	Availability in pets
Plain radiographs	+	+++
Contrast radiographs (barium)	++	+++
Contrast radiographs (BIPS)	+	++
Ultrasonography	+	++/+++
Endoscopy	(+)	++/+++
^{13}C-based breath tests	++	+ /++ (referral /research)
Blood tracers (paracetamol)	Unknown	+ (if reference method to measure paracetamol is available)
Scintigraphy	+++	+ (referral/research)
CT or MRI	–	++
Manometry	++	+ (referral/ research)
Wireless motility capsule	+++	+ (referral/ research)
Surface electrical resistance	(+)	– (research)

BIPS, barium-impregnated polyethylene spheres; CT, computed tomography; MRI, magnetic resonance imaging.

Diagnostic Imaging for Gastric Motility Disorders in Routine Veterinary Practice

Plain abdominal radiographs showing liquid or solid gastric contents after a fasting period of >6–8 hours in the dog and >4 hours in the cat should raise the suspicion of delayed gastric emptying. If no obvious cause can be identified, serial radiographic imaging after oral administration of contrast media (i.e., liquid barium sulfate, iodinated contrast) can be performed (for the full protocol see section on small intestinal dysmotility later).

This method only evaluates emptying of liquid contents, which is less relevant, and can appear normal even though emptying of solids is impaired. Liquids (including neat barium) should be emptied from the stomach within three hours in dogs and within 60 minutes in cats (50–70% of cats have an empty stomach at 15 and 30 minutes, respectively). Completion of gastric emptying when barium is mixed with food can be variable in both dogs and cats (4–16h), and barium can separate from the food, making this method unreliable to assess solid-phase gastric emptying in small animals.

Barium-impregnated polyethylene spheres (BIPS) were originally designed to mimic solid-phase gastric emptying and to detect GI obstructions. They are commercially available in two sizes (1.5 and 5 mm diameter), with the smaller theoretically being emptied with digestive contractions and the larger with interdigestive motility. Attempts have been made to assess gastric emptying times using BIPS in both dogs and cats, but the data are not reliable. In one study using dogs, the time to emptying of half the administered BIPS from the stomach was nearly twice as long as that of simultaneously administered, radiolabeled food. In cats, gastric emptying of 1.5 mm BIPS also did not parallel "true" gastric emptying of a solid radiolabeled meal, but rather assessed interdigestive motility. Therefore, interpretation of solid-phase gastric emptying with BIPS cannot be recommended in small animals.

Technologic advances have facilitated the availability and feasibility of using abdominal ultrasonography to assess gastric emptying. Even though gastric motility can be visualized with ultrasound and the frequency of antral contractions has been reported in healthy dogs (4–6/min during emptying), no standardized protocol to assess gastric emptying is available. Also, as this method is based on the estimated change in antral volume, it might not accurately reflect gastric emptying if antral contents are moved into the fundus by the antral contractions. This procedure requires a skilled operator and the administration of a test meal or liquid of a defined volume, which can be challenging in veterinary patients. At this stage, ultrasound cannot be recommended to assess gastric emptying in a routine setting.

Diagnostic Tests Currently Restricted to Referral Centers or Research Facilities

Radioscintigraphy is considered the gold standard method to assess gastric emptying and has been used in a number of studies to determine physiologic gastric emptying times and validate new tests. Due to the need for special facilities and equipment, this technique is not often applied in small animal patients. Most commonly, ^{99m}technetium bound to tracer substances to avoid GI absorption (i.e., albumin colloid) is used. "Dual isotope" methods where solid- and liquid-phase gastric emptying are assessed simultaneously (using both ^{99m}technetium

and ^{111}indium) have also been described. Typical gastric half-emptying times when using canned food are around 70 minutes in dogs and 2–4 hours in cats.

Magnetic resonance imaging (MRI) and computed tomography (CT) imaging have so far not been used in veterinary patients to assess gastric emptying, although these modalities have been used in human patients. One complicating factor might be the need for sedation or general anesthesia, which can influence GI motility. Some protocols for sedation have been evaluated regarding their influence on gastric emptying, but the results are inconsistent, especially in cats. In dogs, a combination of acepromazine and butorphanol was shown to significantly prolong GI tract emptying times and decrease motility.

Noninvasive methods to detect smooth muscle contractions based on measurement of changes in electrical resistance across the epigastric region after ingestion of a test meal using standard ECG electrodes have been assessed in dogs. Because of the sensitivity of these methods to artifacts induced by even slight body movements, their future application in dogs and cats is probably confined to research purposes.

Methods that might have potential to be used in a routine clinical setting involve plasma or breath tracers. The paracetamol (acetaminophen) absorption test has been described for assessment of liquid- and solid-phase gastric emptying. Plasma drug concentrations are measured in serial blood samples after ingestion of paracetamol in solution, and the rate of gastric emptying is related to the appearance of paracetamol in the blood, as it is poorly absorbed from the stomach but rapidly from the duodenum. However, this test has so far only been used in a research setting and not been validated against scintigraphy.

Breath tests have been studied comparatively well to assess gastric emptying in dogs and to a lesser degree in cats. These tests involve the ingestion of a stable ^{13}C-labeled substrate which is rapidly absorbed (e.g., octanoic acid or sodium acetate) and metabolized to $^{13}CO_2$, which is then detectable in exhaled breath. The test protocol is simple, labelled tracers are comparably cheap and no special equipment or expertise is required. Breath samples can be collected from animals with a facemask, which does not involve excessive restraint. Samples can be stored for up to 60 days in sealed containers and can be sent to the laboratory for analysis, where the ^{13}C:^{12}C ratio is determined by infrared or mass spectrometry. From these data plotted against time, gastric emptying times and coefficients can be calculated. Normal gastric half-emptying times determined by breath test are around 2.7–3.4 hours in dogs and four hours in cats. ^{13}C-breath tests show acceptable to good correlation to scintigraphy and ultrasonography, respectively, in dogs and good correlation compared to scintigraphy in cats.

Treatment of Gastric Dysmotility

No guidelines for the appropriate indication, combination, and duration of motility-modifying therapies for gastric emptying disorders are available. Due to the diagnostic challenges discussed above, correct assessment of most gastric motility disorders or any therapeutic effect is difficult. It is important to investigate, diagnose, and treat any underlying disease leading to dysmotility before motility-modifying drugs are administered (Table 53.2).

Motility Disorders of the Small Intestine

Small intestinal (SI) motility ensures the efficient absorption of nutrients (mixing of chyme with digestive enzymes, optimal contact of ingesta with the intestinal mucosa) and orderly aboral movement of content, including indigestible residues. Motility is also critical in preventing bacterial translocation, which is achieved by constant net aboral flow of luminal contents and the unidirectional "valve" function of the ileocecal junction, preventing backflow of cecal contents.

Physiology of Small Intestinal Motility

Similar to gastric motility, physiologic motility of the SI in dogs consists of digestive contractions (uncoordinated circular segmentation and highly coordinated propulsive peristalsis) and interdigestive motility (interdigestive migrating motility complexes [IDMMCs]). In cats, IDMMCs do not exist; instead, they show migrating spike complexes that are less vigorous than the canine counterpart.

Dogs have been extensively used to understand the physiology of intestinal motility, the importance of neurotransmitters, hormones, and other polypeptides and the effect of different dietary components on GI transit times. Very little of the information gained from experimental studies in dogs can be directly translated into veterinary practice.

There is evidence for breed and/or size differences in GI transit times in dogs, with larger breeds showing longer transit times compared to miniature breeds. This might be partially due to the relative size of the GI tract compared to body weights: the GI tract of dogs >60 kg comprises 2.8% of their total body weight, compared to 7% in small-breed dogs (<5 kg). Hence, breed and age characteristics must be taken into account when assessing SI or total GI transit times.

Clinical Signs of Hypo- and Hypermotility of the Small Intestine

Clinical signs of small intestinal dysmotility can be variable, and heavily depend on the underlying cause. Assessing the animal's signalment and taking a thorough history including any drug administration, potential for accidental ingestion of medication(s), toxins or foreign material, vaccination status, contact with other animals, recent surgical procedures, etc. can help to initially classify the possible problem.

Local diseases (within the abdominal cavity or the GI tract) are more likely to cause clinical signs obviously associated with intraabdominal organs, ileus or GI obstruction (abdominal pain, vomiting, diarrhea, but also anorexia, constipation) whereas systemic diseases can present with a variety of signs not necessarily immediately associated with the GI tract (e.g., mydriasis, dry nose and eyes, and prolapse of the third eyelid in dysautonomia or generalized neuromuscular signs in muscular dystrophy).

Physical examination in patients with signs of GI dysmotility can be variable and depend on the underlying problem. Signs can be unspecific (lethargy, poor body condition), point towards a local intraabdominal process (nausea, abdominal pain, distension, mass, fluid-filled intestines) or be suggestive of a more generalized systemic problem (generalized weakness, neurologic abnormalities). Depending on the severity of fluid losses through vomiting and/or diarrhea, clinical signs can also be dominated by dehydration or hypovolemia (circulatory shock) or even SIRS.

Diseases Associated with Dysmotility of the Small Intestine

Most reports regarding SI motility focus on functional or mechanical GI ileus. Ileus is defined as the inhibition of propulsive bowel activity, irrespective of the pathogenic mechanism.

In small animals, SI ileus due to a primary (systemic or local) neuropathy or neuromuscular disease is much less common than secondary ileus, for which the causes are multiple.

Dysautonomia and Other Neuromuscular Diseases

Dysautonomia is a generalized neuropathy first described in cats in the United Kingdom. Subsequently, this disease has been documented worldwide in dogs and cats. It is characterized by generalized autonomic dysfunction with megaesophagus/esophageal hypomotility, gastric and small intestinal distension/hypomotility, and urinary bladder distension. Degenerative lesions are found in autonomic ganglia, the spinal cord and axons, but the cause for these changes is unknown. Diagnosis is based on typical clinical signs, ophthalmic pilocarpine test and (postmortem) histopathology. Supportive care (with or without chronic topical piloacarpine) is the only treatment option. Prognosis is grave in most cases.

Muscular dystrophy has been described in the golden retriever (X-linked genetic disorder), rarely other dog breeds and cats, and is primarily characterized by progressive muscular weakness. It is typically caused by mutations in the dystrophin gene responsible for muscle structure and metabolism. Affected dogs and cats show hypertrophy of skeletal musculature, tongue, diaphragm, esophagus and sartorius muscle and atrophy of others. Clinical signs apart from muscle weakness and tremor include dysphagia, gastroparesis, abdominal pain, and intestinal distension. In one postmortem canine study, petechial hemorrhages, ecchymosis, and ulceration of the gastric mucosa and generally dilated intestinal loops were described, which was suggested to be indicative of decreased intestinal transit. Most dogs die of cardiac or respiratory failure within 8–9 months.

One case of visceral myopathy in a 6-month-old domestic shorthair kitten with a six-day history of anorexia, vomiting, and diarrhea has been reported. Severely dilated loops of hypomotile intestine were found and 20 cm of jejunum was resected. On histopathology, the distal jejunum showed a markedly atrophic longitudinal muscle layer with focal degeneration, calcification, loss of myocytes, and replacement by fibroblasts. The cat was alive and doing well 20 months after surgery.

Postoperative Ileus and Short Bowel Syndrome

Postoperative ileus, defined as "ileus that develops following abdominal surgery, typically resolving spontaneously with 2–3 days," is more frequent in humans than dogs and has not been reported in cats. Laparotomy and manipulation of the viscera are the main postulated etiologies but other factors, such as anesthetic agents or postoperative opioid administration, can contribute. Diagnosis can be based on clinical signs such as nausea, vomiting, intestinal distension and abdominal pain and via the exclusion of other causes of functional ileus (e.g., metabolic disorders, renal injury, septic peritonitis, pancreatitis, obstruction) postoperatively. Treatment consists of intermittent orogastric or permanent nasogastric tube placement to empty the stomach of excess fluid and gas, early postoperative ("trickle") feeding, as this might stimulate coordinated propulsive activity of the GI tract, and the administration of prokinetics. Prognosis is generally good to excellent.

Short bowel syndrome is defined as malabsorption due to insufficient intestinal surface area to an extent that fluid and nutrients to sustain life cannot be absorbed without specific nutritional support. There is evidence of

dysmotility of the remaining parts of the GI tract, with reduction of slow waves and disappearance of interdigestive motility. Clinical signs usually consist of watery diarrhea, steatorrhea, polyphagia, and weight loss. Total parenteral nutrition and aggressive medical management are often necessary in the early postoperative period, until oral feeding can counterbalance the nutritional needs. Stabilization of intestinal function should start within 1–3 months after surgery. Complete recovery occurs within 3–12 months, but depends on the extent of surgical removal of intestinal segments, with early reports demonstrating a poor prognosis in some cases with massive resections (74–88%).

Intestinal Pseudoobstruction

Intestinal pseudoobstruction or functional paralytic ileus is characterized by the presence of chronic intestinal dilation and dys- or amotility in the absence of mechanical obstruction. Only 12 cases of chronic intestinal pseudoobstruction have been reported in small animals (10 dogs and two cats) that showed clinical signs of chronic intestinal disease (anorexia, intermittent vomiting, diarrhea). Diagnosis was based on abdominal imaging with radiographs showing generalized intestinal dilation but no evidence of mechanical obstruction. Histopathology showed some recurrent common features in dogs such as atrophy or complete loss of smooth muscle fibers (n = 10), moderate to severe lymphoplasmacytic or mixed inflammation of the muscular layers (n = 7) with predominantly T cells being present (n = 4), and varying degrees of fibrosis/sclerosis (n = 6). In one dog, severely hyperplastic smooth muscle of the lamina propria and thickening of the muscularis mucosae were reported. In cats, the histologic picture was somewhat different: even though muscle atrophy was present, this was true only for the longitudinal muscle layers in certain segments of the jejunum in one cat. Seven out of the 10 dogs were euthanized due to progressive disease within days to five weeks after diagnosis.

Secondary Small Intestinal Hypomotility

Dogs and cats frequently suffer from obstructive intestinal diseases (foreign bodies, bezoars, neoplasia, volvulus), hence these conditions – together with neoplasia and intussusceptions – should always be considered as potential cause of dysmotility.

Few large-scale reports examining clinical abnormalities, causes, prognostic factors, and outcome in small animals with mechanical ileus are available. Of 704 examined cases, the average age was 4 years for dogs and 3 years for cats, with 60% being male. Mean duration of illness before presentation was four days and most common symptoms included inappetence, vomiting, lack of defecation, and abdominal pain. Mechanical ileus due to a solitary foreign body obstruction (plastic balls, stones, textiles) was the most common cause (69 cats and 338 dogs) followed by a linear foreign body (35 cats, 43 dogs) and neoplasia (24 cats, 195 dogs). Less common causes were intussusception, ileal obstipation, intraabdominal inflammatory or neoplastic adhesions, volvulus, incarcerations of intestinal loops, idiopathic intestinal paralysis, intestinal diverticula, and parasitic infections.

Diagnosis (history of foreign body ingestion, physical examination revealing abnormal intestinal palpation, diagnostic imaging confirming the suspicion of obstruction/ileus) is usually straightforward and the optimum treatment depends on the localization, size, material or underlying cause (i.e., neoplastic) of the obstruction. In most cases (>90%), surgical intervention is necessary. Long-term-survival can be achieved in >80% of patients. A longer duration of clinical signs, presence of a linear foreign body (as opposed to a discrete one), multiple surgical procedures/incisions of the intestine and intestinal perforation have been associated with increased mortality, whereas neither the degree of obstruction (partial or complete) nor the location of the foreign body had an effect on survival.

Obstruction due to neoplasia carries a much graver prognosis, with median survival times of six months for dogs and seven days for cats.

Intussusception is frequently found in young animals and often associated with parvoviral enteritis or other forms of acute gastroenteritis. There is some evidence for a breed predisposition in the German shepherd dog and pure-breed/pedigree cats. Prognosis is good if surgical reposition or resection is successful.

Functional SI dysmotility can be secondary to any type of infection or inflammation of the GI tract or within the abdominal cavity. Both hypo- and hyperperistalsis can occur, but reports of hyperperistalsis are scarce.

Parvoviral enteritis is the classic example of functional ileus secondary to infection. Generalized atony of the intestinal tract with distended and fluid-filled intestinal loops is a frequent finding on ultrasonography (75%) and weak peristaltic contractions indicative of functional ileus were observed in most of the remaining cases.

Sepsis or other serious medical illnesses requiring hospitalization in the intensive care unit (ICU) are known to be associated with gastrointestinal dysfunction in people. Both gastric and small intestinal motility is delayed in human ICU patients, which may lead to intolerance of enteral nutrition and increased risk of aspiration. Additionally, acute stress-induced gastropathy and ischemic colitis (both associated with risk of hemorrhage) is a common finding in human ICU patients. In the authors' experience, similar syndromes and complications also exist in small animals admitted to the ICU. We routinely and regularly assess the grade of gastric

filling in our ICU patients (especially patients with sepsis, SIRS, on mechanical ventilation, and those with increased risk of aspiration pneumonia) semiquantitatively via ultrasonography. If there is sufficient suspicion of GI hypomotility (gastric distension), prokinetic drugs like prucalopride or erythromycin are administered early. If oral medication is not tolerated, rectal administration can be tried. Even though the authors subjectively think this type of management decreases the risk of aspiration pneumonia and other complications, there is at this time no objective evidence that these interventions influence outcome of small animal ICU patients.

Acute pancreatitis causes substantial damage to the GI tract in people and rodent models. Usually, this is associated with acute necrosis, ischemia, and bleeding, but varying degrees of dysmotility have also been documented, likely due to cytokines being produced as part of the local inflammatory process. In dogs, the typical clinical signs associated with acute pancreatitis (vomiting) and the severity of abdominal inflammation in some patients suggest that GI dysmotility or ileus is commonly present. However, no data regarding GI dysmotility in pancreatitis in small animals are available.

There is some evidence that both acute kidney injury (e.g., in leptospirosis) and chronic kidney disease have an inhibitory function on orderly intestinal motility. In other conditions, GI dysmotility is suspected but not proven. One example is diabetes mellitus, where altered levels of neuropeptides have been documented in experimental animals. However, even in humans, the exact mechanism for small intestinal dysmotility in this endocrinopathy is not well understood. So far, no consistent correlation between changes in enteric neurotransmitters, numbers of ICCs (decreased markedly in one neuroanatomic human case report) and manometric or transit observations has been detected.

It is likely that (gastro)intestinal dysmotility is also present in other chronic conditions such as IBD, canine idiopathic large bowel diarrhea (CILBD), hepatitis/hepatopathies, etc. Unfortunately, no study investigating GI motility in these conditions in dogs and cats is available.

Iatrogenic and Toxic Causes of Gastrointestinal Ileus

Intestinal dysfunction is a common side-effect when opioid mu- and delta-agonists are administered as analgesics. Most commonly, constipation and vomiting are observed. This can occur immediately after the first dose and persist for the duration of therapy. In most cases, discontinuation of opioid treatment is sufficient to improve intestinal function. Occasionally, laxatives and other therapies may be used additionally to treat constipation.

A variety of toxins (e.g., mercury, thallium, lead), pharmaceuticals (antibiotics like lasalocid, nitrofurantoin, salinomycin), pesticides (e.g., organophosphates), organic solvents and other chemicals (e.g., acrylamide, hexacarbons) have been reported to cause peripheral neuropathies, which might include ileus or other forms of dysmotility of the GI tract (i.e., megaesophagus, etc.) although these are infrequently seen and poorly documented.

Diagnostic Tests to Assess Small Intestinal Motility or Transit Times

The outcome of SI motor activity depends on the patterning of contractions in both space and time; that is, where and when do the contractions occur with respect to each other? Methods to assess these relationships must address substantial technical challenges to gather functionally relevant information.

Diagnostic Imaging Procedures for Small Intestinal Transit Studies

Contrast studies of the SI are the most commonly used method to assess transit time or to search for intestinal obstruction in small animals. Neat liquid barium sulfate, ionic or nonionic organic iodine contrast media or, less frequently, contrast mixed with semisolid food is administered orally. The recommended dosage for liquid barium is 6–16 mL/kg body weight, with the high end of the dose range for cats and small dogs and the lower end for large dogs. The protocol for performing a contrast study of the GI tract in dogs and cats is summarized in Box 53.1. Usually, the final radiograph is taken after 12 hours to check the complete gastric and SI evacuation of contrast.

Barium-impregnated polyethylene spheres (see above) have also been used for SI transit studies. The sensitivity and specificity of this method, however, is low.

Contrast fluoroscopy is used in human medicine to detect mucosal disease and stenoses that may induce secondary changes in motility, transit, and absorption. However, this technique is insensitive for the direct detection of abnormal transit times. Observation times are limited (radiation exposure) and once the majority of contrast has entered the small intestine, overlying loops of bowel hinder the interpretation. Fluoroscopy has not been reported for assessment of small bowel transit in small animals.

Ultrasonographic assessment of small intestinal motility is challenging due to observer variability, interference from intraluminal gas and the difficulty of finding objective measures to assess contractions. Even though two studies found that Doppler ultrasound techniques (pulsed-wave and duplex Doppler, respectively) allow graphic visualization and qualitative and quantitative

Box 53.1 Guidelines for performing a contrast passage of the gastrointestinal tract

Preparation	24 h fast or immediately if foreign body or perforation is suspected No sedation or general anesthesia
Type of contrast media	1) Liquid barium sulfate (used at a concentration of 30% weight/volume, which may require dilution. Higher concentrations are too opaque, especially with digital systems) • Preferred option 2) Water-soluble iodine-containing contrast (diluted 1 part to 2–3 parts water) • Indicated if rupture of parts of the alimentary tract cannot be excluded or if endoscopy is necessary afterwards • As these media are hypertonic, they osmotically attract water to the gastrointestinal lumen which can exacerbate dehydration and leads to dilution of contrast 3) Mixture of 1. or 2. with food • Does not always correlate with solid-phase transit time (contrast can separate from food) • Admixed food particles cannot always be distinguished from pathologic filling defects of the gastrointestinal tube
Dosage of contrast media	Either 10–12 mL/kg BM or Medium-sized to large dog: 5–7 mL/kg BM Small dog and cat: 10–15 mL/kg BM • Administer via syringe or gastric tube if necessary • The stomach has to considerably fill with contrast media • There should not be an interruption of visualization/filling of the entire gastrointestinal tract, as this might cause false interpretation of radiographs
Timing of radiographs (always both lateral and ventrodorsal views)	Dog • Immediately before and after contrast media administration • Additionally at 15, 30, and 60 min; then every 15–60 min until barium reaches rectum • Later radiograph times must be adjusted for every patient; a "standard" protocol is just a starting point and will probably need to be modified • If transit is quick, radiographs at 10–15-min intervals may be required • Depending on pictures so far, late additional radiographs after 12 and 24 h (until stomach has completely emptied and all contrast media has reached the colon) • If an abnormalitiy is suspected, it is best to obtain multiple radiographs close together to confirm persistence of the lesion (with iodine-containing media: half the above-mentioned time-points) Cat • Immediately before and after contrast media administration • Additionally at 5, 20, 30, 40, 60 and 120 min • Late additional radiographs after 6 and 12 h (with iodine-containing media: identical time-points) BEWARE: Do NOT omit any of the radiographs or "only" perform radiographs at the late time-points (6–24 h after administration) as important subtle changes or evidence of partial obstructions can be missed!
Tips for practical execution and overall interpretation	• Rule of thumb: at the end of the examination the stomach has emptied completely and all contrast is in the large intestine • The above-mentioned times are guidelines. For individual cases they might vary depending on passage timings • Fluoroscopy can be helpful for initial orientation, but is not routinely necessary, increases radiation exposure and is not always available • Have a stop-watch handy as well as a time indicator that can be placed on the radiograph film • Make sure enough staff are available at the necessary time-points

analysis of intestinal motion in dogs, these procedures are rarely used in routine practice.

Scintigraphy can potentially be used to assess small intestinal transit times. However, unless the test substance is delivered past the pylorus, this technique also includes gastric emptying. Therefore, scintigraphy is usually imprecise about actual small intestinal transit time and more accurately assesses orocecal transit time. In small animals, scintigraphy has rarely been used for assessing small bowel transit alone. Dual-scintigraphy (using ^{99m}technetium and ^{111}indium) can be used to assess whole-bowel transit times. More recently, scintigraphy has been used to assess GI motility in comparison to a wireless motility capsule, which gives accurate information about whole-intestinal transit times and their respective subsets.

Recording of Small Intestinal Muscle Contractions

These procedures are usually of an invasive nature (implanted strain gauges or luminal manometers) or can be used *ex vivo* only. As far as the authors are aware, no attempts at noninvasive detection of electrical potentials created by intestinal muscle contractions (as done with moderate success for gastric emptying) have been reported in small animals. It can be assumed, however, that they are extremely prone to artifacts created by patient movement.

Breath Tests and Other Tracer Tests

The lactulose or hydrogen breath test, which is the breath test most widely used to assess SI transit in humans, has also been applied to dogs. Nonabsorbable lactulose is fermented, yielding H_2 on reaching the colon. This hydrogen gas is rapidly absorbed and exhaled. Interpretation of hydrogen breath test results can be complicated if carbohydrate malabsorption is present. Additionally, the effect of diet is not entirely clear, hence this test is not currently recommended for routine use.

Salicylazosulfapyridine has been administered orally, intraduodenally or intracecally in experimental dogs as a SI tracer substance; the detection of its metabolite sulfapyridine in plasma correlates with SI transit time. Apart from drug metabolism studies, this tracer has not been used in a clinical setting or in dogs with GI diseases.

Treatment of Small Intestinal Dysmotility

Treatment of small bowel dysmotility is usually targeted to the specific etiology. Intestinal obstruction should be relieved surgically as soon as the patient is stable enough for general anesthesia. If infection, inflammation or sepsis is suspected, a search for the underlying cause, depending on the predominant clinical signs, followed by appropriate treatment should be initiated. If intestinal hypomotility is suspected to be drug induced, any medication with the potential to adversely affect GI motility should be discontinued.

Supportive treatment is mandatory to maintain fluid and electrolyte balance and perfusion of vital organs. Prokinetics (Table 53.2) should be used cautiously and only if elimination of the inciting cause and supportive treatment is not sufficient to restore SI motility. Especially in severe infectious enteritis, prokinetics are not recommended, as they might increase the risk for intussusception or volvulus. In postoperative ileus, however, or in patients requiring long-term intensive care, prokinetic agents have a place to decrease hospitalization time and co-morbidities such as aspiration pneumonia. Intestinal stasis in severely ill patients increases the risk of intestinal bacterial translocation, hence cautious feeding of small energy-dense meals (depending on what the primary condition is and what the patient tolerates) and prokinetic treatment can aid in maintaining small bowel function.

Motility Disorders of the Large Intestine

Physiology of Large Intestinal Motility

The large intestine is mainly responsible for the absorption of water and electrolytes, and storage of intestinal content, as feces enter the colon in a liquid state. There are three prominent patterns of colonic motility:

- segmentation contractions which separate and mix the ingesta, increasing the contact time with the mucosa for absorption
- antiperistaltic contractions propagating ingesta back toward the ileum, again slowing down intestinal transit and allowing additional time for absorption
- mass movements, which are unique to the large intestine. Also known as giant migrating contractions (GMCs), the mass movement consists of strong and prolonged peristaltic aboral contractions, which evacuate the entire large intestinal content.

In contrast to the interdigestive phases, when the colon shows no considerable motility, colonic contractions increase significantly following a meal. These so-called gastrocolic and duodenocolic reflexes are controlled by the enteric nervous system and ensure coordinated movement and orderly evacuation of the GI tract with the ingestion of a "new" meal.

Clinical Signs of Hypomotility and Hypermotility of the Large Intestine

Large intestinal (LI) diarrhea is a manifestation of colonic hypermotility and hypersecretion, typically characterized

Table 53.2 Mechanism and site of action, dosages and important clinical information for drugs with prokinetic actions in small animals

Class	Site of action	Dose	Other properties	Comments
Serotonergic 5-HT_4 agonists				
Cisapride	GES, stomach, intestine, colon, CRTZ	0.1–0.5 mg/kg PO TID-BID	5-HT_3 antagonist 5-HT_2 antagonist 5-HT_1 agonist	Removed from the human market due to severe cardiac arrhythmias; in some canine studies no effect on gastric emptying; in high doses (3 mg/kg) decreases gastric motility
Mosapride	Stomach, colon	0.25–2 mg/kg PO BID; 5 mg/cat BID	None	
Prucalopride	Stomach, small and large intestine	Dog: 0.01–0.16 mg/kg SID stimulates gastric emptying 0.6 mg/kg SID stimulates GI peristalsis 1–1.25 mg/kg SID induces migrating motor complexes (defecation) Dosages up to 2 mg/kg SID described Cat: 0.24–0.5 mg/kg SID	None	Can be administered rectally as well if oral administration is not considered safe (risk of aspiration) or gastric motility is severely impaired
Tegaserod	Small and large intestine	0.05–0.1 mg/kg PO or IV BID	5-HT_1 antagonist	Not currently on the market (allegedly increased risk of cardiovascular disease in people)
Motilin-like substances				
Erythromycin	GES, stomach, small and large intestine	0.5–1 mg/kg PO or IV BID	5-HT_1 antagonist	Induces interdigestive motility, which might lead to "dumping" of gastric contents into the duodenum before appropriate digestion can take place
Acetylcholinesterase inhibitors				
Ranitidine	Stomach, colon	1–2 mg/kg PO BID-TID or slow IV/CRI	H2-histaminergic antagonist	Probably only mild to no prokinetic effects
Nizatidine	Stomach, colon	1 mg/kg IV BID; 2.5 mg/kg PO SID–BID	H2-histaminergic antagonist	Probably even less effective than ranitidine
Others/Miscellaneous				
Bethanechol	Esophagus	5–15 mg/dog PO TID	Cholinomimetic substance	
Mirtazapine	Stomach, others unknown	0.6 mg/kg PO SID In experimental dogs: 2 mg/kg SID	Noradrenergic and specific serotonergic tricyclic antidepressant	Limited clinical data available, but at 2 mg/kg SID showed accelerated gastric emptying times in experimental fistulated dogs

Source: Modified from Washabau and Day (2013). Reproduced with permission of Elsevier.
BID, twice a day (*bis in die*); CRI, continuous rate infusion; CRTZ, chemoreceptor trigger zone; GES, gastroesophageal sphincter; GI, gastrointestinal; IV, intravenous; PO, by mouth (*per os*); SID, once a day (*semel in die*); TID, three times a day (*ter in die*).

by increased defecation frequency, decreased fecal volume per defecation, tenesmus, increased fecal mucus, and the occurrence of fresh blood (hematochezia).

Large intestinal hypomotility results in constipation, which is defined as absent, infrequent or difficult defecation (tenesmus). In its most severe form, constipation leads to obstipation where impacted, hard and dry feces make normal defecation impossible. Typically owners observe frequent attempts to defecate, tenesmus and dyschezia (difficult or painful defecation) with little or

no feces produced. Animals might vocalize during attempts at defecation. Other possible signs are anorexia, lethargy, vomiting, and an abnormal stance (hunched up). Infrequent passage of watery material and mucus, which has bypassed the impacted feces, might be wrongly interpreted as diarrhea.

Animals with LI diarrhea will frequently be normal on physical examination, even though in some cases rectal palpation might reveal irregular mucosal surface or rectal masses. Impacted feces and, depending on the severity of the problem, dehydration, abdominal pain, and debilitation are findings in animals with decreased colonic motility or obstruction resulting in constipation, obstipation or even megacolon.

Diseases Associated with Dysmotility of the Large Intestine

Increased Large Intestinal Motility

As increased LI motility is part of the manifestation of every type of "colitis" (acute or chronic), the number of underlying diseases is manifold. In dogs, this includes infectious (e.g., *Trichuris vulpis*, toxins from *Clostridium perfringens* infection, *Prototheca zopfii*) and noninfectious (e.g., food hypersensitivity) causes, diseases with inflammatory (IBD, granulomatous colitis [GC] of boxers and bulldogs) or neoplastic infiltration of the colonic wall, as well as a number of "idiopathic" disorders where hypermotility is implicated as a primary cause; these include fiber-responsive colitis and CILBD. The latter is also often called irritable bowel syndrome (IBS), spastic colon, nervous/stress-induced colitis or mucoid colitis. In these dogs, inciting stressors can sometimes be identified (travel, changes in daily routine, loss of other pets or family members). They can show submissive or anxious behavior (urination, separation anxiety, fear of noise), but tend not to be aggressive.

Canine idiopathic large bowel diarrhea is defined by colonic dysfunction in the absence of identifiable structural, biochemical, or microbiologic abnormalities and thus is a diagnosis of exclusion. While no studies have shown a pathophysiologic mechanism in dogs, abnormal myoelectrical activity leading to abnormal LI motility is likely part of this disease in humans, in combination with psychosocial factors, altered pain, and visceral reception. The prevalence of CILBD ranges from as low as 5% to 26% in dogs. It is more commonly found in large breeds and those under stress (police/customs, guide dog for the blind, herding) or dogs that are easily overexcited.

Decreased Large Intestinal Motility

Constipation can be due to intestinal or systemic problems. Intestinal causes are mostly obstructive (intraluminal [stricture, fecolith, tumor] or extraluminal [prostatomegaly, pelvic fracture, perianal tumor, pseudocoprostasis]) or dietary (foreign material [bone, stones, garbage, hair]) in origin. Systemic problems can be caused by external factors (long inactivity, confinement [hospitalization]), drugs (opioids, barium, sucralfate, calcium channel blocker, anticholinergic) or be part of metabolic problems (dehydration, hypokalemia, hypercalcemia). Finally, neuromuscular dysfunction may also result in decreased LI motility. Here, colonic hypomotility is frequently associated with lumbosacral spinal cord problems (Manx cat deformity, neoplasia, degenerative disease, injury) and feline idiopathic megacolon, and less frequently with ganglioneuritis (one dog reported), dysautonomy (Key–Gaskell syndrome), and canine hypothyroidism.

Megacolon is more commonly seen in cats than dogs. It is defined as persistently increased large bowel diameter, often as an end-result of chronic constipation. Idiopathic megacolon accounts for about two-thirds of all feline cases of constipation. Its etiopathogenesis is incompletely understood, but dilation of the colon appears to be due to functional disturbances of the colonic smooth muscle cells. Lesions seem to begin in the descending colon and then progress to involve the ascending colon. Affected cats are usually middle-aged (mean 5–6 years) with males (70%) more commonly affected. Repeated episodes of obstipation are often reported. Diagnosis is reached when all other causes (mechanical obstruction, inflammation, neoplasia) have been excluded and typically involves neurologic assessment, diagnostic imaging studies (with and without contrast), and histopathology.

Assessment of Large Intestinal Motility or Transit Times

Real-time assessment of LI motility is difficult to perform and thus complete GI or orocecal transit times are usually investigated.

Diagnostic Imaging Procedures Available in Routine Practice

On survey radiographs, size and opacity of the LI are extremely variable and formed feces are of a heterogeneous opacity. Nevertheless, a ratio of the maximal diameter of the colon to L5 length >1.48 is a good indicator of feline megacolon (sensitivity 77%, specificity 85%). Contrast radiographs after rectal administration of positive (barium) or negative (air) contrast media or their combination (double contrast studies) might be indicated in animals with LI diarrhea or constipation to exclude an obstruction but they do not show true LI motility. The LI should not be assessed on a SI contrast study as LI filling is incomplete and there is overlap with

parts of the SI. LI contrast studies should also not be done two hours after a cleansing enema, 6–12 hours after colonoscopy and 3–4 days after full-thickness colonic biopsies. Ultrasound has so far not been investigated to evaluate LI motility.

Measurement of Gastrointestinal Transit Times

Different ways to assess LI motility or whole-intestinal transit have been employed, but are so far limited to research purposes or require special equipment. The simplest way to assess oroanal transit time is to feed plastic markers of different colors and recover them from the feces. Different radiopaque markers have been used in healthy dogs as well. Similar to assessment of gastric emptying (see earlier), radioscintigraphy has also been used to determine LI motility (e.g., with ^{111}In). Recently, total GI transit times and LI transit times were measured with a wireless motility capsule system in dogs. Other tests used in human medicine, such as colonic manometry or MRI, have so far only been used in experimental dogs to assess LI motility and are not useful for routine diagnostics.

Treatment of Large Intestinal Dysmotility

Treatment of Idiopathic Colitis and CILBD

Treatment of LI dysmotility secondary to infectious or inflammatory colitis, neoplasia or mechanical impairment is directed towards the underlying cause. Treatments for IBD with LI involvement, food hypersensitivity, fiber-responsive colitis and CILBD overlap frequently, as all involve some form of dietary modification (see later). This also explains why definitive diagnosis and accurate separation of these disease entities can be difficult.

Dietary modifications often include the change to a novel protein (and possibly carbohydrate) source or a hydrolyzed protein diet. Alternatively, increasing the amount of dietary fiber or adding bulk-forming agents (e.g., a commercial high-fiber diet or the addition of psyllium 1–3 tbsp/day or unprocessed wheat bran 1–5 tbsp/day) to the food also frequently leads to clinical improvement.

Antibiotics usually have no place in treating "idiopathic" colitis. However, the authors have noticed that some dogs improve with the administration of metronidazole or tylosin, similar to antibiotic-responsive chronic enteropathy/IBD, even if constipation or LI diarrhea are the only presenting complaints.

Antiinflammatories can aid in controlling LI symptoms in some dogs. As in small intestinal forms of IBD, this might include the administration of steroids (if all other causes of clinical signs, especially infectious diseases, have been excluded), for example prednisolone (1–2 mg/kg SID to BID) or budesonide (0.05–1 mg/kg/day with the total dose not exceeding 3 mg q8h). Alternatively, sulfasalazine (15–30 mg/kg BID to TID, maximum 6 g/day) has been particularly useful in controlling idiopathic colitis in some dogs. However, this is usually done on an empirical basis, and the decision regarding which dogs can or need to be treated with either of those antiinflammatory compounds is often arbitrary.

When CILBD is suspected (and all other causes of colitis have been ruled out), treatment should start with dietary modifications (fiber supplementation; see earlier). The remainder of treatment depends on the nature of clinical signs (intermittent, alternation between constipation and diarrhea, abdominal pain/cramping) and their suspected inciting cause. Different types of bulking agents (psyllium, kaolin, pectin) can help in times of diarrhea. Alternatively, motility modifiers or antispasmodics may be tried (Table 53.3). Antispasmodic drugs might relieve some pain and sedatives reduce stress effects. Most dogs only require treatment for a day to two weeks, with some requiring long-term treatment. Stressors should be avoided and behavioral therapy can be considered. Drugs modifying behavior, including amitriptyline, can be tried in refractory cases of CILBD (see Table 53.3). The prognosis of CILBD is good, particularly for dogs that respond to fiber supplementation.

Treatment of Constipation

Management of constipation depends on the severity and the underlying cause, which should be addressed first (mechanical obstruction, pelvic fracture, neurologic disorder, etc.). If possible, drugs that may cause constipation (opioids, diuretics, antispasmodics, anticonvulsants, sucralfate, NSAIDs) should be minimized or discontinued. In overweight animals, weight loss should be encouraged and their activity increased. Cat litter boxes should always be kept clean, to encourage defecation, and water intake should be increased (availability of water bowls, addition of water to food).

In addition, or as sole treatment in mild cases, dietary modification is recommended. This can again consist of bulk-forming agents (high-fiber diet, added psyllium or bran) or the administration of lactulose or other laxatives (see Table 53.3). A single enema or rectal suppository on an outpatient basis can also be considered.

In more severe or refractory cases, manual removal of impacted feces and several warm water enemas (in many cases requiring general anesthesia) are necessary. Adequate amounts of intravenous fluids need to be administered to correct dehydration and possible electrolyte abnormalities and to prevent worsening of obstipation. Constipation is most commonly a recurring problem and long-term prophylactic measures (dietary

Table 53.3 Treatments for chronic idiopathic large bowel disease (CILBD)

Class	Name	Dose	Comment
Fiber	Psyllium	Daily dose: ½ tablespoon for toy breeds 1 tablespoon for small-breed dogs 2 tablespoons for medium-breed dogs 3 tablespoons for large-breed dogs	Median dose was 1.3 g/kg/day in one study
	Canned pumpkin	1–4 tablespoons mixed with food per day	
	Coarse wheat bran	1–4 tablespoons mixed with food per day	
	Commercially available diets with high fiber contents	Feeding recommendation by weight/the manufacturer	Available from reputable pet food manufacturers
Motility-modifying agents	Loperamide	0.04–0.2 mg/kg PO q8–12h	Not for prolonged use
	Diphenoxylate	0.05–0.1 mg/kg PO q6–8h	Often in combined preparations with atropine sulfate
Laxatives	Lactulose	1 mL per 4.5 kg PO BID–TID	Hyperosmotic
	Bisacodyl	5–20 mg per dog PO SID	Stimulant/prokinetic
Antispasmodics (neurotropic)	Chloriazepoxide (5 mg) and clidinium bromide (2.5 mg)	0.1–0.25 mg/kg clidiniium PO BID–TID for a few days	Librax®. Can be given prophylactically or metaphylactically as well as therapeutically
	Propantheline	0.25 mg/kg PO TID (round dose to nearest 3.75 mg)	Do not use for longer than 48–72 h
	Hyoscyamine	0.003–0.006 mg/kg PO BID–TID	Not for prolonged use
	Butylscopolamine/hyoscin	0.5–0.8 mg/kg PO SC IM or IV SID–TID	Inhibits M1 muscarinic acetylcholine receptors in the GI and urinary tract, does not cross blood–brain barrier. Often in combination with metamizole
	Dicyclomine	0.15 mg/kg BID–TID	
Antispasmodics (musculotropic)	Mebeverine	2.5–5 mg/kg PO BID	
	Pinaverium	1 mg/kg PO BID	
	Trimebutine	0.33 mg/kg PO TID	
Behavior-modifiying agents	Amitriptyline	1–2 mg/kg PO SID–BID	The atypical tricyclic antidepressant clomipramine exists as an authorized preparation for use in dogs and is claimed to have better anticompulsive properties. Amitriptyline is bitter/distasteful. Some caution and careful monitoring are warranted in patients with cardiac or renal disease
	Selegiline	0.5–1 mg/kg PO SID	Dopamine agonist. Dose can be increased to 2 mg/kg SID if no response after 2 months
	Clomipramine	1–2 mg/kg PO BID	Tricyclic antidepressant. Increase gradually up to 3 mg/kg PO BID if necessary after 14 days

Source: Modified from Lecoindre and Gaschen (2011). Reproduced with permission of Elsevier.
BID, twice a day (*bis in die*); IM, intramuscular; IV, intravenous; PO, by mouth (*per os*); SC, subcutaneous; SID, once a day (*semel in die*); TID, three times a day (*ter in die*).

adjustment and laxative therapy) are often needed permanently.

Chronic treatment of constipation and idiopathic megacolon might require prokinetic treatment. Drugs that show some effect on colonic motility include cisapride and prucalopride. The influence of H2 receptor antagonists on colonic motility is not entirely clear. Newer drugs that might have some positive effect on colonic motility in dogs (lubiprostone, mirtazapine) have not been thoroughly tested in clinical cases.

Subtotal colectomy should be considered in cases of feline idiopathic megacolon refractory to conventional (diet, laxatives) and prokinetic treatment.

Prokinetics

Prokinetic drugs are divided into serotonergic 5-HT_4 agonists, motilin-like drugs, dopaminergic D2 antagonists, H2-receptor antagonists, and novel compounds (see Table 53.2).

5-HT_4 Agonists

Drugs acting on gastrointestinal 5-hydroxytryptamine (5-HT_4 or serotonin) receptors have potent prokinetic effects. Of the various 5-HT_4 agonists, cisapride has been most extensively studied, but was withdrawn from most of the European and US markets due to lethal cardiac side-effects (torsade de pointes tachycardia) seen in humans. Other 5-HT_4 agonists include mosapride (available in Japan), prucalopride (available in the USA and Europe), and tegaserod (also removed from the market for similar reasons as cisapride).

The gastric prokinetic properties of cisapride have been documented in many experimental settings, but in some studies, no effect on gastric emptying in dogs was observed. In high doses (3 mg/kg), it can even slow emptying of solids.

Mosapride has been shown to restore gastric motility in dogs with vincristine- or prednisolone-induced gastric hypomotility in healthy experimental dogs, but seems to have no effect on the distal intestinal tract.

Prucalopride stimulated gastric emptying in a dose-dependent manner at relatively low doses (0.01–0.16 mg/kg), stimulates physiologic gastrointestinal peristalsis/defecation at higher doses (approximately 0.6 mg/kg) and induces MMCs at still greater doses (around 1 mg/kg) in dogs.

Naronapride (ATI-7505) is marketed as a selective 5-HT_4 agonist without the cardiac side-effects in humans, but only one study has assessed its gastric prokinetic properties in dogs so far. It was found to be orally bioavailable in dogs with an increase in coordinated antral and small bowel contractility but little effect on colonic motor activity.

Motilin-Like Drugs

The antibiotic drug erythromycin accelerates gastric emptying by inducing phase III contractions of the interdigestive MMCs, even when used in a subantibiotic dosage. These contractions are similar to those induced by the endogenous gastrointestinal hormone motilin. Several synthetic erythromycin derivates have been developed; for example, EM574, which is 250 times more potent than erythromycin itself in inducing MMCs and has no antibacterial properties. Similarly, mitemcinal (GM-611) has been shown to accelerate gastric emptying in healthy dogs as well as to improve delayed gastric emptying in a canine model of diabetic gastroparesis. Another synthetic erythromycin derivative, ABT-229, accelerates gastric emptying, motility index, and gastroduodenal coordination in a dose-dependent manner. This compound is around 40-fold more potent than erythromycin.

One potential complication that can arise from the stimulation of interdigestive motility is that it can lead to "dumping" of gastric contents into the duodenum before they have been acidified and denatured appropriately. This can then lead to inadequate absorption of nutrients and osmotic diarrhea.

Dopaminergic D2 Antagonists

There is no convincing evidence that dopaminergic D2 antagonists like metoclopramide and domperidone have prokinetic effects on the canine stomach, even though metoclopramide in particular has been advocated for this purpose for years. Consequently, these drugs should not be used solely for this indication in dogs.

Metoclopramide has no effect on complete gastric emptying times or corporeal contractions in experimental dogs. Regarding its effects on MMC disruption or inhibition as well as antral contractions, study results are inconsistent. When emptying of solid and liquid contents were assessed separately, metoclopramide slowed solid gastric emptying (cooked liver), while accelerating emptying of liquids (5% dextrose). There is some potential evidence from several studies that metoclopramide might improve antropyloroduodenal coordination and the frequency of pyloric and duodenal contractions in experimental settings, possibly by enhancing acetylcholine effects. However, there was no acceleration of gastric emptying in dogs after GDV surgery. Effects of metoclopramide might be dose dependent, as the standard dose

(0.2–0.4 mg/kg) did not reduce gastroesophageal reflux; however, a high dose (1 mg/kg followed by a CRI with 1 mg/kg/h) reduced reflux. Thus, metoclopramide might not be harmful in a dog with suspected gastric hypomotility, especially as nausea and vomiting might also be present and its antiemetic effects via 5-HT_3 antagonism are undisputed, but metoclopramide cannot induce a strong prokinetic effect, particularly in cases with complete gastric atony.

Domperidone decreases the frequency of corporeal, pyloric, and duodenal contractions and deteriorates antropyloroduodenal coordination by decreasing the frequency of contractions spreading from the antrum or pylorus to the duodenum. It is therefore not indicated as a prokinetic agent in the dog.

Itopride (Ganaton®, Abbott) is used to treat functional dyspepsia in people. It is a prokinetic benzamide derivate, unlike metoclopramide and domperidone. This drug has both antidopaminergic and antiacetylcholinesterase actions. Its gastroprokinetic dose, when administered intraduodenally in healthy experimental dogs, was 1–3 mg/kg while at doses of 10–100 mg/kg it inhibited apomorphine-induced vomiting. It seems to have similar prokinetic effects to cisapride and mospride when given orally.

Histamine H_2-Receptor Antagonists

Some H_2-receptor antagonists (ranitidine and nizatidine, but not cimetidine or famotidine) have prokinetic effects mediated by cholinergic mechanisms, especially on gastric smooth muscle or, in the case of ranitidine, also on isolated small intestine.

The gastric prokinetic properties of ranitidine have been assessed in both rodents and humans. However, neither in healthy subjects nor in various diseases (gastric stasis in intensive care patients, peptic ulcers, and others) have the effects on gastric emptying, gastric volume/retention or pH been consistent. Some studies suggest acceleration of liquid gastric emptying times as well as faster passage of a motility capsule, possibly based on an increase in phase III motor activity. Other studies show no effect on gastric motility, and two studies even demonstrate a dose-dependent delay in gastric emptying. In dogs, only a few studies are available assessing the effect of ranitidine of gastroesophageal reflux during anaesthesia (where it had no apparent effect) or on GI transit times using a wireless motility capsule (also no effect).

Nizatidine has also been studied extensively regarding its gastric prokinetic properties in experimental rodents and humans. Most studies seem to agree that it has more consistent gastroprokinetic effects than ranitidine or famotidine. In addition, it also enhances colonic peristalsis in humans. In experimental dog models, it was as potent as cisapride in accelerating solid-phase gastric emptying, but clinical studies or extensive *in vivo* studies in dogs are lacking.

Novel Prokinetic Compounds

Several new drugs and compounds have been tested for their prokinetic properties in dogs. Some have a defined mechanism of action, some are herbal extracts where the principal component is not identified. This includes DA-9701 (marketed as Motilone® in Korea), which is an extract from *Corydalis* tubers (a genus of plants in the Papaveraceae family with about 470 species, also sometimes known as Chinese poppy) and *Pharbitis* seeds (plants belonging to the Convulvulaceae family and often used synonymously to morning glory, which is another genus [*Ipomoea*]of this family). This substance lead to improvement of gastric accommodation and increased postprandial volume in healthy experimental dogs, but the effects on gastric emptying are unclear.

Lubiprostone (Amitiza®, Mallinckrodt) is used in the management of chronic idiopathic constipation or inflammatory bowel disease with constipation in humans. It is a selective type-2 chloride channel (ClC-2) activator and hence increases chloride ion transport and fluid secretion into the intestinal lumen. This compound has been shown to accelerate gastric emptying in healthy experimental dogs, as well as small bowel and colon transit and interdigestive motility.

Mirtazapine (several brand names) is a noradrenergic and serotonergic antidepressant used in small animals as appetite stimulant. One study in healthy experimental dogs has shown that it can accelerate gastric emptying times when given at a high dose, but it is unclear if this translates to a clinical setting yet.

To the authors' knowledge, none of the drugs mentioned above have been used outside a research setting or in spontaneously occurring disease in dogs.

Exocrine Pancreatic Insufficiency in Dogs and Cats

Panagiotis G. Xenoulis, Dr Med Vet, PhD

College of Veterinary Medicine and Biomedical Sciences, Texas A&M University, College Station, TX

Exocrine pancreatic insufficiency (EPI) results from an inadequate production of pancreatic enzymes from pancreatic acinar cells, leading to maldigestion and clinical signs of weight loss, polyphagia, and diarrhea. There are currently no studies estimating the prevalence of EPI in the general canine and feline population, but EPI is considered the second most common disease of the exocrine pancreas in small animals (after pancreatitis). Although EPI is considerably more common in dogs than in cats, in the past few years EPI has been diagnosed with increasing frequency in the feline population, likely due to increased awareness of this condition in cats and the availability of better tests for its diagnosis.

Pathogenesis

In humans, it has been estimated that EPI occurs when more than 90% of the exocrine pancreas (i.e., pancreatic acinar cells) is destroyed. When that happens, the functional capacity of the remaining exocrine pancreas is inadequate for the production and secretion of sufficient amounts of:

- enzymes for the digestion of protein, fat, and carbohydrate
- bicarbonate for neutralization of gastric acid entering the duodenum
- pancreatic intrinsic factor for the absorption of cobalamin in the ileum
- antimicrobial proteins for regulation of small intestinal microbiota.

Therefore, EPI has multiple consequences.

The main consequence of EPI is deficient intraluminal digestion of nutrients. This is mainly the result of insufficient production and secretion of pancreatic proenzymes and enzymes by an inadequate number of pancreatic acinar cells. However, this is not the only mechanism leading to nutrient maldigestion and malabsorption in EPI. Studies have shown that there is also altered activity of intestinal mucosal enzymes and impaired intestinal function. In some cases, these functional abnormalities are accompanied by mucosal pathology. Although the exact reason for these abnormalities is unknown, it is speculated that the lack of trophic influence of pancreatic secretions, as well as bacterial overgrowth in the small intestine, may play a role. In addition, acid injury of the intestinal mucosa may occur, as a result of lack of neutralization of gastric acid entering the duodenum.

Another major consequence of EPI is related to cobalamin absorption. The exocrine pancreas is a major source of intrinsic factor in the dog and the main one in the cat. Therefore, EPI leads to a significant reduction in or even total absence of intrinsic factor in the intestinal lumen, which in turn leads to cobalamin malabsorption and cobalamin deficiency at both the intracellular and extracellular level. Overgrowth of cobalamin-binding bacteria in the small intestine may also be a contributing factor. Severe cobalamin deficiency is typically recognized by low serum cobalamin concentrations. Cobalamin deficiency has been shown to have major biochemical implications (e.g., defective amino acid metabolism and DNA synthesis) and has also been shown to be a negative prognostic factor in animals with gastrointestinal diseases, including EPI.

Alterations in the intestinal bacteria and small intestinal bacterial overgrowth are likely common in animals with EPI due to the lack of antibacterial properties of pancreatic secretions. Intestinal dysbiosis is believed to contribute to clinical signs of EPI and might often be a reason for treatment failure, especially when proper antibiotic treatment is not used.

Etiology

Current studies on the etiology of EPI in dogs have investigated specific canine breeds predisposed to developing this disease. Therefore, information from those studies

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

involves certain breeds and may or may not hold true for other breeds.

Most studies available to date have investigated the etiology and pathogenesis of EPI in German shepherd dogs (GSD) and rough-coated collies, and in those breeds EPI is most commonly the result of pancreatic acinar atrophy (PAA). In those breeds, PAA likely is the result of an immune-mediated condition resulting in atrophic lymphocytic pancreatitis, as evidenced by histopathology of the pancreas in dogs during the development of PAA. Eventually, this chronic inflammation, which is limited to the exocrine portion of the pancreas, leads to total destruction of pancreatic acinar tissue and PAA. In those breeds, PAA is most likely acquired and almost certainly has a genetic basis. The earlier belief that EPI in these breeds has an autosomal recessive mode of inheritance has been largely abandoned, and a polygenic inheritance pattern is currently suggested. Genome-wide association studies in GSD have failed to identify any specific genes or major loci associated with EPI, suggesting that EPI in this breed might have several different genetic causes or might be the result of multiple loci with small effects. Further studies are required to identify the genes involved in the development of PAA in GSD and other dog breeds. In addition, the roles that various environmental factors might play in association with a predisposing genetic background have not been investigated.

Pancreatic acinar atrophy is typically considered to be by far the most common etiology of EPI in the overall canine population. Although PAA can be the cause of EPI in any canine breed, other etiologies might be more common in certain breeds. End-stage chronic pancreatitis leading to pancreatic fibrosis is likely the most important etiology after PAA, and it has been reported as a cause of EPI in several studies. Chronic pancreatitis can be especially difficult to diagnose in dogs and cats and, therefore, in most cases a diagnosis of chronic pancreatitis has not been reached by the time EPI is diagnosed. In chronic pancreatitis, both endocrine and exocrine pancreatic cells may be destroyed and therefore EPI may be accompanied by diabetes mellitus in some cases.

Recently, isolated pancreatic lipase deficiency has been reported as a cause of EPI in dogs. In these cases, all other pancreatic enzymes and proenzymes are synthesized and secreted normally. Isolated pancreatic lipase deficiency causes severe lipid maldigestion and malabsorption, leading to the typical signs of EPI despite the fact that there is no deficiency in other pancreatic enzymes. The cause of isolated pancreatic lipase deficiency in dogs is unknown.

Other possible causes of EPI in dogs include pancreatic duct obstruction, pancreatic hypoplasia or aplasia, and pancreatic neoplasia. All of these are extremely rare causes of EPI in dogs.

Chronic pancreatitis is believed to be the most common cause of EPI in cats. PAA has been reported in three cats with EPI and is therefore believed to be a considerably less common cause of EPI in this species compared to dogs. Other causes of EPI in cats may include pancreatic aplasia or hypoplasia, pancreatic tumors, isolated deficiencies of pancreatic enzymes, and pancreatic duct obstruction (for example, as a result of neoplasia, *Eurytrema procyonis* infestation, and complications from cholecystoduodenostomy surgery).

Signalment

Dogs and cats of any breed can develop EPI. However, certain groups are clearly predisposed. The most well-described breed predisposition for EPI involves the GSD. Studies in North America and Europe have shown that GSDs have increased prevalence of EPI, with this breed representing approximately 60% of all cases of EPI. Other breeds predisposed to EPI include rough-coated collies, Cavalier King Charles spaniels, cocker spaniels, West Highland white terriers, and chow chows. No breed predispositions have been described for cats.

Dogs of almost any age can develop EPI, with a reported age range extending from 3 months to 17 years. When considering all dogs with EPI, the disease more commonly appears in young adult dogs (median age 3 years). However, within the group of dogs with EPI, there are subgroups that have different ages of onset. Specifically, the onset of the disease might be at an earlier age in certain breeds (median 18 months for chow chows; median 3 years for GSDs and rough-coated collies) compared to other breeds (median 7 years for Cavalier King Charles spaniels). These differences may in part reflect differences in the etiology of EPI; for example, EPI as a result of PAA typically develops in young adult dogs (usually by the age of 5 years). EPI that develops in older dogs (such as Cavalier King Charles spaniels) might be more likely to be the result of chronic pancreatitis rather than PAA, because more time is believed to be required until pancreatic acinar cells are destroyed as a result of chronic low-grade inflammation.

Cats of any age can develop EPI, with some cats diagnosed at less than 1 year of age. However, EPI is more commonly diagnosed in middle-aged to older cats, with a mean age of 8 years.

Exocrine pancreatic insufficiency can occur in both male and female dogs. Most studies agree that females are slightly predisposed compared to males. No sex predilection has been reported for cats.

Clinical Features

The classic and most common presentation of dogs with EPI involves a chronic history of weight loss (Figure 54.1), a normal or increased appetite, and diarrhea, which is

Figure 54.1 This dog presented with significant weight loss due to EPI. The dog had lost 10 kg during the last few months. This is a common clinical presentation of dogs with EPI although weight loss is often not as severe.

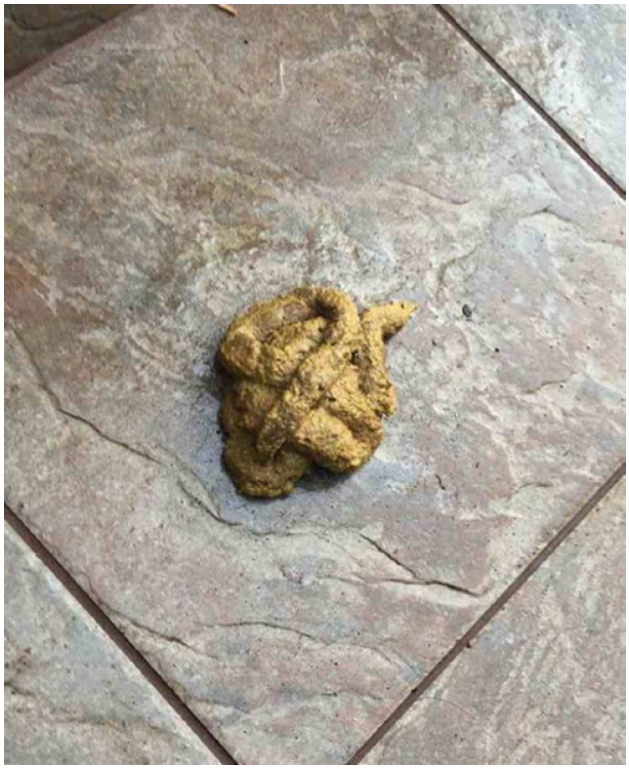

Figure 54.2 The feces from the dog in Picture 1. The feces are large in volume and semi-formed. This is a common finding in dogs with EPI.

usually characterized by passage of large volumes of semiformed feces (Figure 54.2). However, it is not uncommon for some dogs with EPI to present with a clinical picture that deviates from the classic presentation. In those cases, periods of anorexia, absence of diarrhea, and occasionally watery diarrhea or vomiting might be seen. Other possible clinical signs include coprophagia, borborygmus, flatulence, abdominal discomfort, and a poor hair coat. In some cases, EPI may be subclinical and those cases can only be diagnosed with appropriate laboratory testing (see section on Trypsin-Like Immunoreactivity). Dogs may remain in the subclinical phase for years or sometimes for life.

Cats with EPI have a similar presentation to dogs. In a retrospective study of 150 cases of feline EPI, the most common clinical sign was weight loss (which was often the only clinical sign), followed by loose stools, poor hair coat, anorexia, increased appetite, depression, watery diarrhea, and vomiting. It is likely that many of these clinical signs reflect concurrent diseases such as chronic pancreatitis and inflammatory bowel disease. In cases where chronic pancreatitis is the cause of EPI, polyuria and polydipsia may be seen as a result of concurrent diabetes mellitus.

Diagnosis

The diagnostic evaluation of animals suspected of having EPI should always take into consideration the clinical presentation, general clinicopathologic findings, and the results of diagnostic modalities used to specifically assess pancreatic structure, function, and pathology.

Routine Clinical Pathology

Findings of complete blood count (CBC), chemistry profile, and urinalysis are typically unremarkable in animals with EPI. When present, routine blood test abnormalities (e.g., increased hepatic enzyme activities, hypoalbuminemia, hyperglycemia) reflect concurrent diseases such as inflammatory bowel disease and diabetes mellitus.

Trypsin-like Immunoreactivity

Trypsin-like immunoreactivity (TLI) measures serum concentrations of trypsin and trypsinogen and is the test of choice for the diagnosis of EPI in dogs. This test is highly sensitive and specific for the diagnosis of EPI. Animals with EPI produce and secrete lower than normal amounts of trypsinogen in serum and therefore a subnormal TLI concentration (usually defined as <2.5 µg/L) in an animal with compatible clinical signs is sufficient to make a diagnosis of EPI. A TLI result well within the reference range is sufficient for excluding EPI in the vast majority of cases, and a normal TLI result should direct clinicians towards the investigation of other disorders as the cause of the observed clinical signs.

One exception to this rule is the case of isolated pancreatic lipase deficiency, where the patient has EPI but

secretion of trypsin and trypsinogen is normal and therefore serum TLI concentrations are also normal. In these cases, the diagnosis of EPI is quite challenging. The current assays for the measurement of pancreatic lipase concentration (i.e., Spec-cPL) are not suitable for the accurate measurement of pancreatic lipase concentrations at very low concentrations, and therefore isolated pancreatic lipase deficiency cannot be diagnosed using these assays. Although epidemiologic studies are lacking, isolated pancreatic lipase deficiency in dogs is considered to be an uncommon cause of EPI.

Single TLI results within the equivocal range (usually between 2.5 and 5.7 µg/L) in dogs with clinical signs of gastrointestinal disease need to be interpreted with caution. In these patients, subsequent retesting of serum TLI may show either a normal concentration or progression to EPI. Therefore, patients with canine TLI (cTLI) results in the equivocal range should be investigated for chronic intestinal disease, while cTLI concentrations should also be measured a few weeks later.

Some dogs with no clinical signs characteristic of EPI have repeatedly subnormal (<5.7 µg/L) cTLI concentrations. These dogs have been shown to have subclinical EPI and some, but not all, are expected to develop clinical EPI in the future. The time of progression from the subclinical to the clinical disease varies greatly and might be from a few months to years. Thus, these patients should be closely monitored for the development of clinical signs of EPI and cTLI testing should be repeated periodically. It should be noted that a single serum cTLI concentration is not sufficient for diagnosing subclinical EPI.

Because renal disease might increase serum cTLI concentrations and obscure a diagnosis of EPI, reevaluation of nondiagnostic serum cTLI concentrations in azotemic dogs suspected of having EPI is recommended. Similarly, concurrent pancreatitis might falsely increase the serum cTLI concentration.

Due to the fact that EPI appears to be less common in cats than in dogs, diagnosis of this disease has been less well investigated and is more challenging in this species. Similar to dogs, the feline TLI (fTLI) test appears to be the most reliable test for the diagnosis of EPI in cats with a specificity of at least 85%. The sensitivity of this assay for the diagnosis of feline EPI has not been evaluated to date. Although there are currently two assays that measure fTLI in serum (one radioimmunoassay that is available in the USA and one ELISA available in Europe), only one of those assays (the radioimmunoassay) has been reported to be analytically validated; this test is available through the Gastrointestinal Laboratory at Texas A&M University. Similar to dogs, it can be recommended that nondiagnostic serum fTLI concentrations in azotemic cats suspected of having EPI be reevaluated, because renal disease might falsely increase serum fTLI concentrations. The same is true for cats with concurrently increased serum feline pancreatic lipase (fPLI, Spec-fPL) concentrations indicating pancreatitis.

Trypsin-like immunoreactivity testing can be performed in animals that are already on enzyme supplementation without this affecting the results. TLI assays are species specific and do not measure trypsinogen and trypsin of other species.

Pancreatic Fecal Elastase

An ELISA for the measurement of pancreatic elastase in feces is commercially available and is marketed in Europe (Shebo Biotech, Germany) for the diagnosis of canine EPI. It is considered to be specific for EPI, although a recent study reported false-positive results in 23.1% of cases and the sensitivity of this test has not been sufficiently evaluated. The fact that this test is easy and quick to perform might make it a reasonable initial approach for dogs with suspected EPI, but a positive test result must be verified by measurement of a serum TLI concentration. This test might also be useful for EPI cases that are due to pancreatic duct obstruction. However, to date such cases have only been anecdotally reported in the veterinary literature.

Other Tests

Serum amylase and lipase activities have been shown to have no value in the diagnosis of EPI in either dogs or cats. Canine pancreatic lipase immunoreactivity concentrations are low or undetectable in most dogs with EPI, but commercial assays for the measurement of serum PLI concentration (Spec-cPL and Spec-fPL) are not useful for the diagnosis of EPI in dogs and cats, respectively, because they have been optimized to detect changes in the higher levels of their respective working ranges.

Measurement of the fecal proteolytic activity has been used in the past for the diagnosis of EPI in dogs and cats. A plethora of other tests, including microscopic examination of feces and the bentiromide absorption (BT-PABA) test, have also been used for the diagnosis of EPI. These tests often give false-positive and/or false-negative results, and many of them are impractical, expensive or of limited availability, and thus are not recommended for the diagnosis of canine or feline EPI. However, these tests may be useful in special cases where serum TLI concentration is in the normal range (e.g., EPI due to pancreatic duct obstruction) but EPI is heavily suspected based on the clinical picture.

Histopathology

Exocrine pancreative insufficiency is a functional and not a histopathologic diagnosis, and thus histopathology

is not indicated for the diagnosis of EPI in dogs and cats. While it is believed that more than 90% of the pancreatic parenchyma needs to be destroyed in order for clinical signs of EPI to develop, it is almost impossible to accurately determine the extent of pancreatic atrophy either grossly or histopathologically, and thus whether acinar cell loss is leading to EPI. The utility of histopathology is limited to determination of the underlying cause of EPI (PAA or pancreatitis). Even then, in dog breeds that have been shown to be predisposed to EPI due to acinar atrophy (i.e., German shepherds, rough-coated collies), histopathology is redundant. Therefore, histopathology should only be used in atypical cases where the cause of EPI needs to be determined.

Treatment

The vast majority of animals with EPI require lifelong treatment with pancreatic enzyme supplementation, with or without other treatments. Although pancreatic enzymes are essential for digestion, alternative pathways for digestion of some nutrients do exist and therefore rare animals may compensate for the loss of pancreatic enzymes and display only minimal clinical signs without treatment.

Table 54.1 summarizes the treatment options for dogs and cats with EPI.

Pancreatic Enzyme Supplementation

Pancreatic enzyme supplementation is the cornerstone of EPI treatment in the vast majority of cases. There are several different types of products that can be used for the management of EPI in animals and differences in efficacy may exist among them. Options generally include enteric-coated preparations, uncoated enzyme powder (as powder or in capsules), and raw pancreas. Most commercially available products contain pancreatic enzymes and proenzymes that are derived from porcine pancreas (in the form of dried extracts), while raw pancreas (which also contains pancreatic enzymes and proenzymes) is usually obtained from cattle or pigs.

Only a small proportion of the orally administered pancreatic enzymes remains functionally intact by the time they reach the small intestine. It has been reported that up to 85% of pancreatic enzyme activity can be lost in the stomach due to the acid pH and/or the action of gastric pepsins. Therefore, enteric-coated preparations have been developed to protect the enzymes from degradation in the stomach. There has been considerable discussion regarding the comparative efficacy of different products for the treatment of EPI. To add to the confusion, results of available studies have been conflicting. An early study suggested that enteric-coated preparations were less effective than uncoated preparations, while a more recent study suggested that there was no

Table 54.1 Treatment options for dogs and cats with exocrine pancreative insufficiency (EPI)

	Dosage regimen		
Medication	**Dog**	**Cat**	**Comments**
Pancreatic enzymes			
Powder	1–2 teaspoon per 10 kg in each meal	0.5–1 tsp per meal	Mix with food just prior to feeding (powder) or give with food (enteric-coated formulations)
Enteric-coated formulations			Titrate to the minimum effective dose when clinical signs are in remission
Raw pancreas	50–100 g per meal, mixed with food	30–90 g per meal, mixed with food	Rarely, may cause oral bleeding and irritation. In these cases dose reduction is indicated
Antibacterials			
Tylosin	10–25 mg/kg q12h	10–25 mg/kg q12h	Treat for a minimum of 4 weeks
Metronidazole	10–15 mg/kg q12h	10–25 mg/kg q12h	The benefits of antibacterial treatment are uncertain in cats with EPI
Vitamin supplements			
Cobalamin (in the form or cyanocobalamin or hydroxycobalamin)	250–1000 μg, SC, weekly for 6–8 weeks or orally, daily for 8 weeks	250 μg, SC, weekly for 6–8 weeks, or orally, daily for 8 weeks	Measure serum cobalamin concentrations every 3–6 months after initial supplementation and treat as necessary with additional supplementation
Acid suppression medications			Not generally indicated

difference between coated and uncoated products. However, these studies were retrospective and uncontrolled. A more recent blinded, randomized, controlled trial showed that dogs receiving an enteric-coated pancreatic enzyme product responded better to treatment compared to dogs receiving identical but uncoated product. Therefore, enteric coating seems to be beneficial, although the results of this study may not be applicable to all preparations of enteric-coated pancreatic enzymes. In a recent retrospective study of 150 cats with EPI, there was no difference in the efficacy of different pancreatic enzyme products suggesting that all products might be similarly effective.

Fresh raw pancreas contains pancreatic enzymes and can be used to effectively manage animals with EPI. Raw pancreas should be fresh-frozen in aliquots, and each aliquot should be used with one meal. Raw pancreas is likely the most economical option for pancreatic enzyme supplementation but it is also associated with certain limitations. First, it can be difficult to obtain and inconvenient for most owners to process raw pancreas. More importantly, raw animal tissues might be contaminated with important pathogens (e.g., *Salmonella* spp., *Campylobacter* spp.) and may pose a risk for infection to both humans and animals. For these reasons, raw pancreas is not commonly used for the treatment of EPI in animals.

All dogs and cats with clinical EPI should receive pancreatic enzymes. Regardless of the product used, pancreatic enzymes are added to each meal. Preincubation of the food with pancreatic enzymes is not necessary. The starting dose varies depending on the manufacturer but is usually titrated to individual patients after initial treatment and resolution of clinical signs. In many animals, doses can be significantly reduced long term to the lowest effective dose. Enzyme supplementation therapy is required for the rest of the animal's life. Side-effects from pancreatic enzyme use are rare but may include oral bleeding and irritation that typically resolve with dose reduction.

Antibacterials

Some animals with EPI do not respond to pancreatic enzyme replacement therapy alone. In a large percentage of animals with EPI, this is believed to be partially due to small intestinal dysbiosis and/or bacterial overgrowth (SIBO), which might be present as a result of loss of the bacteriostatic effects of pancreatic secretions and the presence of excess undigested substrates that can be used by intestinal bacteria. However, studies of antibacterial use in dogs with EPI have not shown improved treatment response or prognosis consistently. In addition, no studies have compared the efficacy of different antimicrobial agents in the treatment of dogs and cats with EPI.

Because small intestinal dysbiosis/SIBO is believed to be common in dogs with EPI and is notoriously difficult to confidently diagnose, antimicrobials are usually used in conjunction with pancreatic enzyme supplementation at the beginning of EPI treatment. Alternatively, antimicrobials can be added to the treatment regimen if there is poor response to treatment with pancreatic enzymes alone. Antimicrobials commonly used include metronidazole, tylosin, and oxytetracycline, and are typically used for a minimum of 2–4 weeks (see Table 54.1). Some animals might need multiple courses of antibiotics throughout their lives. The role of intestinal bacteria and dysbiosis is much less clearly defined in feline EPI. Choices for antibacterial treatment in this species are similar to those in dogs, and can be used in cases that do not respond to treatment with pancreatic enzyme and cobalamin supplementation (see Table 54.1).

Cobalamin Supplementation

As mentioned previously, hypocobalaminemia and cobalamin deficiency are especially common (>80% of cases) in dogs and cats with EPI. Therefore, serum cobalamin concentrations should be measured in all animals with EPI. Cobalamin deficiency can lead to various gastrointestinal and systemic complications, and severe hypocobalaminemia has been reported to be a negative prognostic factor in dogs with EPI and cats with chronic gastrointestinal disease, that often co-exists with EPI in this species. Cats with cobalamin deficiency have been shown to have abnormalities in amino acid metabolism. In a recent publication reviewing 150 cats with EPI, cobalamin supplementation favorably affected the response to treatment, even in cats with normal serum cobalamin concentrations. Therefore, correction of cobalamin deficiency is important in both dogs and cats with EPI.

Because cobalamin deficiency can lead to cobalamin malabsorption, oral supplementation of cobalamin was considered not to be effective in dogs and cats with EPI. However, recent evidence suggests that oral supplementation of cobalamin might be equally effective in these cases. Cobalamin should be administered subcutaneously using the following dosage regimen: 250–1250 µg (depending on the size of the animal) once a week for six weeks, followed by an injection one month after that. Oral cobalamin should be administered at 250 µg (cats) or 250–1250 µg (dogs, depending on the size), daily, for 8 weeks. Serum cobalamin concentrations should

be checked one month after the last dose and then monitored periodically (e.g., every six months) as some animals may require repeated cycles or life-long cobalamin supplementation.

Dietary Modification

There are two major dietary factors believed to be important in the management of dogs with EPI: the fat content of the diet and the amount and type of dietary fiber. Historically, it has been suggested that a fat-restricted diet should be offered to dogs with EPI because adequate fat digestion and subsequent resolution of clinical signs may not be achieved with enzyme replacement therapy alone. One of the problems encountered with the use of low-fat diets in dogs with EPI is that weight gain could be difficult and slow to achieve, especially in large-breed and cachectic dogs. In addition, low-fat diets may contribute to deficiencies of fat-soluble vitamins given the fact that fat digestibility does not normalize after enzyme supplementation.

Studies in dogs with EPI failed to show a clear benefit of any diet (including low-fat diets) over another. In fact, different diets appeared to be more suitable for different dogs, suggesting that several diets should be tried in patients with EPI until the most appropriate one for a specific animal is identified. Therefore, the routine and exclusive use of fat-restricted diets in all dogs with EPI is not currently recommended. High-fat diets should probably be avoided, however, at least during the initial stabilization phase. In some cases, there might be no need to change the animal's original diet, if it is complete and balanced. The type of fat (e.g., long-chain vs medium-chain triglycerides) also does not seem to play a crucial role in the response to treatment.

It has been suggested by some authors that high-fiber diets should be used in dogs with EPI. However, there is no convincing evidence in the literature for such recommendation. High-fiber diets might prohibit weight gain in hyporexic animals as a result of low caloric density. In addition, certain types of fiber can impair the activity of pancreatic and brush border enzymes, potentially leading to reduced digestibility of nutrients. Therefore, high-fiber diets are currently not recommended in dogs with EPI.

No studies have evaluated the use of specific diets in cats with EPI. Therefore, dietary recommendations are based mainly on clinical experience and extrapolation from clinical experience with dogs. Fat-restricted diets should be avoided if possible, for the same reasons mentioned above for dogs. In addition, cats are strict carnivores and protein and fat are their main energy sources, while carbohydrates (which are often increased in fat-restricted diets) should be generally kept at low levels. As in dogs, high-fiber diets should probably be avoided in cats with EPI.

Histamine-2 Receptor Antagonists and Proton Pump Inhibitors

Histamine-2 receptor (H2 receptor) antagonists and proton pump inhibitors (PPIs) have been recommended by some as adjunctive treatment in animals with EPI. A large proportion of pancreatic enzymes, especially lipase, is inactivated in the stomach due to low pH. It has been hypothesized that acid-suppressing medications may reduce the hydrolysis of pancreatic enzyme supplements in the stomach through the increase of gastric pH, thus increasing efficacy. Obviously, this applies only to uncoated enzyme supplements and raw pancreas. However, no studies have evaluated the efficacy of acid suppression in the treatment of EPI in dogs and cats, and therefore their usefulness is questionable. In addition, the potential problem of reduced efficacy of enzyme supplements due to hydrolysis in the stomach could be overcome by increasing the dose of enzymes or by using products with enteric coating. Therefore, the routine use of acid suppression medications is currently not recommended.

Prognosis

Although clinical improvement is noted in the vast majority of dogs and cats treated appropriately for EPI, a percentage do not respond well to treatment for reasons that have not been clearly defined. Good initial response to treatment is seen in approximately 60% of dogs and cats with EPI, with the remaining animals showing either partial (~20%) or poor (~20%) response. Partial or poor response is usually indicated by the animals remaining underweight or having soft stools.

Median survival time for dogs with EPI has been reported to be approximately five years. The most important parameter that affects survival seems to be initial response to treatment, with animals that have a good initial response surviving on average almost eight times longer than those with poor response. Therefore, animals that respond well to initial treatment seem to survive for long periods. As mentioned above, hypocobalaminemia has been shown to be a negative prognostic factor, and animals with severe hypocobalaminemia survive half as long as animals without severe hypocobalaminemia. The nature and severity of clinical signs, signalment, and different therapeutic interventions do not seem to have important prognostic significance. No data are available for survival and prognosis in cats with EPI.

Etiology/Pathophysiology

Pancreatitis in the dog includes an array of presentations, from low-grade inflammation incidentally discovered to animals with severe, life-threatening systemic disease. Clinically, veterinarians often use the term chronic pancreatitis (CP) to describe instances where the clinical signs are mild, whereas acute pancreatitis (AP) is the term used when there is greater severity and a rapid onset of clinical signs. This clinical classification, however, does not always correlate with the histologic classification.

Histologically, AP is defined as neutrophilic inflammation, without fibrosis or exocrine atrophy, which is usually present within the body of the pancreas and/or peripancreatic fat. There have been extensive experimental studies, predominantly in rodent models, of initiating events of AP. In essence, AP develops when inert zymogens (precursors of digestive enzymes) are activated within pancreatic acinar cells rather than within the duodenal lumen. If this occurs at a low level, safeguards such as pancreatic secretory trypsin inhibitor (PSTI) come into play and mop up the activated pancreatic enzymes within the body of the pancreas. Once PSTI is overwhelmed, there is an influx of proinflammatory cytokines (especially interleukin-8) and neutrophils. Other inflammatory pathways are then also stimulated including the complement, kallin-kallikrein, and nitric oxide pathways. Circulating anti-inflammatory mediators (such as alpha-macroglobulins) can initially counteract this inflammatory state, but in many situations are themselves overwhelmed. When pro-inflammatory pathways overcome defences, there is reduced pancreatic microcirculation, as well as ongoing inflammation and necrosis within the pancreas due to neutrophil migration and adherence. This inflammation and necrosis theoretically therefore starts in the pancreatic acinar cells, but when severe spills out into the peripancreatic fat.

Although some dogs with AP may have self-limiting disease or mild clinical severity (mild abdominal pain, vomiting), others develop systemic complications due to activation of the multiple inflammatory cascades. The cause of abdominal pain is considered to be distension of the pancreatic capsule, or via stimulation of mesenteric pain receptors by inflammatory exudate. The pathophysiology of pain is quite complex: the nociceptive (ascending) pathway travels via the dorsal horn, and is mediated by amino acid (glutamate and aspartate) and neuropeptide (substance P, neurokinin A, and calcitonin gene-related peptide) release. If there is ongoing nociceptive input, activation of N-methyl-D-aspartate (NMDA) receptors may occur, which is considered a key step in the development for central sensitization. Vomiting occurs due to both central and peripheral stimulation of vomiting pathways, but the exact mechanism has not been confirmed for AP. Systemic effects of AP relate both to the clinical signs (hypovolemia, etc.) and the presence of circulating proinflammatory mediators.

There are many potential factors that may initiate or trigger the initial activation of pancreatic zymogens within the acinar cells. Experimentally, it has been shown that co-localization of lysosomal granules and zymogen granules leads to zymogen activation. This effect appears to be amplified by a reduction in acinar cell pH, and is considered to be the mechanism by which activation occurs in people with sudden increases in intracellular calcium (as can occur during cardiopulmonary bypass). In dogs, the most commonly implicated causes of AP include dietary indiscretion, drugs, trauma, and unknown (or idiopathic). High-fat, low-protein diets in particular are clearly implicated in causing AP in dogs and rodent models; clinically this is typically in association with long-term feeding of urolithiasis diets. There is a large list of drugs that may cause idiosyncratic pancreatitis, but the most frequently implicated drugs include azathioprine, potassium

bromide, and organophosphates. Onset of pancreatitis can occur immediately after starting these medications. In some cases, there is delayed onset of drug-induced pancreatitis, particularly in humans; this would make the link more difficult to prove in dogs. Trauma is also well recognized as a cause of AP but the pancreatic trauma is usually one of a constellation of abnormalities. Often, no inciting cause is identified; however, unobserved dietary indiscretion may still occur in these cases.

Chronic pancreatitis (CP) is defined histologically as lymphocytic-plasmacytic inflammation of the pancreas and peripancreatic area with presence of concurrent fibrosis. Although pancreatic function is generally preserved, dogs with CP can develop diabetes mellitus or exocrine pancreatic insufficiency associated with the fibrosis. The etiology of CP is poorly understood in dogs. The currently accepted rationale for CP in humans is called the sentinel acute pancreatitis event (SAPE) hypothesis. With the SAPE hypothesis, pancreatic acinar cells initially come under some type of oxidative stress (e.g., fats, alcohol, oxidative products in the bile), but do not develop any inflammation or fibrosis. When the acinar cells are sufficiently stimulated by the oxidative stress, a pro-inflammatory response occurs (the acute pancreatitis event). If the oxidative stresses are removed at this point, the pancreas generally heals with no ongoing consequences. However, if there is perpetuation of low-grade inflammation in response to continued oxidative stresses, stellate cells that migrate to the pancreas in response to secretion of proinflammatory cytokines are stimulated, leading to periacinar fibrosis. It is not certain if SAPE occurs in dogs, as many or most of the oxidative stressors do not generally occur chronically in the canine population, but the rationale appears logical to apply.

There are also multiple genetic abnormalities that predispose humans to CP, including mutations of cationic trypsinogen, which cause spontaneous production of trypsin in the acinar cells. To date, no similar genetic mutation has been identified in dogs, although investigations are still ongoing. Additionally, autoimmune disease is strongly suspected to occur in cocker spaniels, and may be similar to the autoimmune form of pancreatitis identified in people. Obstructive causes of CP are not common in dogs, and dietary indiscretion is not thought to be as important a trigger for CP as it is for AP.

Epidemiology

The true incidence of pancreatitis is difficult to determine, as definitive antemortem diagnosis is often problematic. In one study assessing dogs submitted for postmortem at a first opinion practice, the prevalence of CP was 34%, with over half of those classified as having moderate or marked pancreatic inflammation. Similarly, inflammation or fibrosis was identified in approximately 50% of dogs in a postmortem study at a referral institution. There appears to be a breed predisposition for spaniel breeds, particularly cocker spaniels. This may reflect the dog population in the study region, but anecdotal evidence would support this statement to hold in a wider dog population. These prevalence studies raise two major points. Firstly, CP is probably grossly underrecognized due to the difficulties in diagnosing the condition antemortem. Secondly, histologic changes may not be clinically important, and postmortem studies may actually overemphasize the importance of CP or the sensitivity of various tests.

The incidence of AP is similarly difficult to determine, although it is a condition that occurs worldwide. Anecdotal reports would suggest that AP is the most commonly diagnosed emergency presentation of the gastrointestinal system in dogs. In most reports, middle-aged, overweight dogs appear to be predisposed.

History and Clinical Signs

Acute Pancreatitis

The clinical presentation of AP is initially related to the development of gastrointestinal clinical signs: vomiting, anorexia, and abdominal pain. Abdominal pain may be subtle or difficult to determine initially but can be manifested as severe (e.g. crouching in prayer position and excessive restlessness). The severity of these clinical signs along with the duration of onset also determines the findings. Animals may be weak or obtunded and in hypovolemic shock if there is a rapid reduction in circulating blood volume and vasoconstriction due to systemic inflammation. This spectrum of clinical signs is incorporated in Table 55.1. Rectal temperature can be increased (due to inflammation) or decreased (due to shock), and some dogs may also present with neurologic signs. Roughly one-third of dogs will also reportedly have diarrhea or melena.

Co-morbidities such as diabetic ketoacidosis (DKA) may be present. It is considered probable that DKA develops secondary to overwhelming destruction of the pancreatic tissue; however, it is also possible that the acidotic state in DKA leads to pancreatitis. However, with preexisting or undiagnosed diabetes, dogs can be expected to also have a history of polyuria/polydipsia and weight loss.

The systemic nature of severe inflammation also means that animals may have respiratory signs (due to development of acute lung injury and/or pleural effusion), neurologic abnormalities (due to thromboembolic

Table 55.1 Classification of clinical signs into severity categories

Severity of presentation	Mild	Moderate	Severe
Gastrointestinal signs	Vomiting 1–2 times/past 12 hours	Vomiting 4–6 times/past 12 hours; occasional regurgitation; melena; hematochezia; no gut sounds auscultated in 24-hour period	Vomiting or regurgitation 6 times/past 12 hours, or for longer than 36 hours; no food for >3 days; plus any of the following: melena, absent gut sounds 24 hours, hematochezia
Dehydration	Skin tent	Skin tent, weak pulses	Marked skin turgor, prolonged capillary fill time, injected mucous membranes, tachycardia, weak/thready pulses
Abdominal pain	May be unsettled and respond when abdomen palpated	Decreased response to surroundings, stretches and looks around at abdomen, flinches or snaps on abdominal palpation	Non-responsive to stimuli, screams, cries or snaps when moving or abdomen palpated
Heart rate (HR)	Tachycardia with no pulse deficits	Occasional ventricular premature complexes or sustained HR >180/min	Paroxysmal or sustained ventricular tachycardia
Respiratory rate	Normal	Dyspnea or tachypnea (>40 breaths/min)	Signs consistent with pneumonia, pleural effusion
Vascular forces	Normal systolic blood pressure (BP) and albumin >18 g/L	Systolic BP <60 or >180 mm Hg or albumin <18 g/L	Systolic BP <60 and >180 mmHg and serum albumin <18 g/L

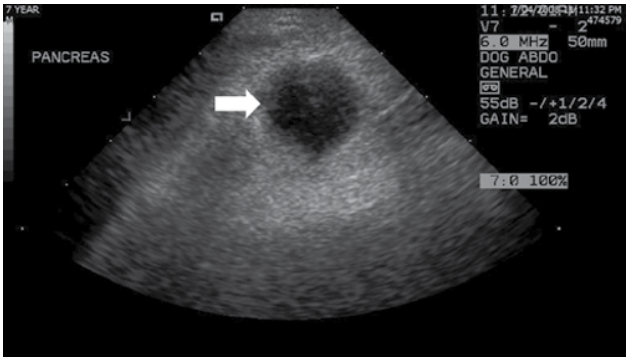
disease), cardiac arrhythmias, and signs associated with renal failure (oliguria, obtundation).

Local complications can also occur, such as extrahepatic bile duct obstruction (EHBDO); EHBDO may develop due to physical obstruction of the bile duct by an enlarged and inflamed pancreas, or due to decreased motility of the bile duct mediated by local peritonitis. Regardless, dogs with EHBDO are jaundiced, although as a complication it generally occurs late in the progress of disease and often the dog appears to be recovering. Another local complication is the development of fluid-filled regions within the pancreas, often associated with necrosis (Figure 55.1). These acute fluid collections may be incidental findings, but often are associated with a sudden increase in abdominal pain. True pancreatic abscessation is extremely unlikely in dogs, and pseudocysts develop weeks following an acute episode of pancreatitis.

Chronic Pancreatitis

Chronic pancreatitis is generally a milder presentation than AP. In some circumstances, there may be no associated detectable clinical signs. In other dogs, there may be a single episode or waxing and waning loss of appetite, mild vomiting, and abdominal pain. Diabetes mellitus may occur in conjunction with CP, and so flares of pancreatic inflammation may coincide with periods of insulin resistance. Similarly, CP may be concurrent with exocrine pancreatic insufficiency and the clinical signs of the latter may predominate.



Diagnosis

Routine Laboratory Tests

Routine hematology is fairly nonspecific in pancreatitis, although a stress leukogram is usually present. As AP is a systemic inflammatory condition, there may also be changes in other white blood cell concentrations.

Biochemical changes reflect the degree of dehydration and hypovolemia present (increased total protein, azotemia, electrolyte derangements, etc.) but are not pathognomonic for pancreatitis. Total lipase and amylase activities can be markedly increased in AP, but can also be normal in severe AP and increased with nonpancreatic disease. Both renal disease and administration of dexamethasone can increase serum lipase and/or amylase activities, without primary pancreatitis being present. Due to the inherent issues with sensitivity of routine lipase assays, a catalytic assay utilizing a more selective lipase substrate (1,2-o-dilauryl-rac-glycero-3-glutaric acid-{6′-methylresorufin} ester [DGGR]) has been recently assessed. The DGGR assay appears to have higher sensitivity than routine lipase assays, and has similar findings to ELISA-based measurements of specific pancreatic lipase concentrations (details of this test are given later). Often dogs with AP have grossly lipemic serum, and although this may be a consequence of fat saponification during the disease, fasting serum cholesterol and triglycerides should be measured 1–2 weeks after recovery to ensure that hyperlipidemia is not an inciting factor.

(b)

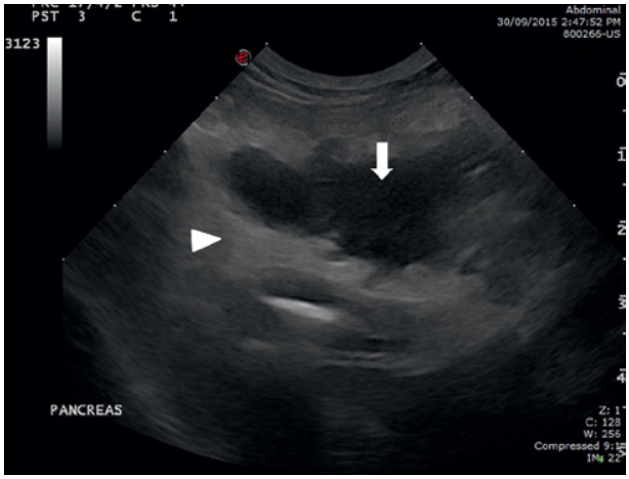

Figure 55.1 (a) Ultrasound image of pancreas with large fluid-filled lesion (*white arrow*). (b) Irregular and ill-defined fluid collection (*white arrow*) surrounded by hyperechoic fat (*arrowhead*). If either of these were present in a dog with increasing levels of pain, then percutaneous drainage should be recommended.

Pancreas-Specific Biochemistry

Until the past decade, pancreas-specific enzymes such as trypsin-like immunoreactivity or trypsinogen activation peptide have not been considered useful in diagnosing either AP or CP. Canine pancreatic lipase (cPL) has been developed into a commercially available ELISA test (Spec-cPL), and is now used widely in veterinary practice. It is thought that cPL is only produced in the pancreas, and is affected less by non-pancreatic disease than total lipase. There have been some studies that show clearance of cPL is not affected by acute or chronic reductions in glomerular filtration. The reference interval for the laboratory ELISA is <200 µg/L in healthy dogs, with results >400 µg/L considered consistent with a diagnosis of pancreatitis in dogs with compatible clinical signs. There is also an in-clinic rapid semiquantitative assay (SNAP-cPL™, Idexx Laboratories) that shows good alignment and reproducibility with the laboratory-based ELISA.

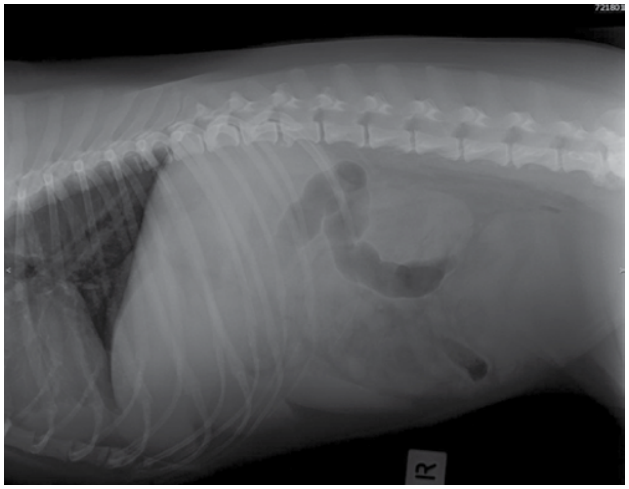
There have been a number of studies evaluating cPL for the diagnosis of pancreatitis (Table 55.2). Overall, cPL should be considered highly specific for pancreatitis. Sensitivity of the cPL assay appears to be high in animals with AP, but less so for CP. When interpreting cPL, it should be remembered that pancreatic inflammation may be present, but not be the cause of the clinical presentation. The most relevant application of this is when there are duodenal foreign bodies or septic peritonitis that can cause "bystander" pancreatic inflammation. Misdiagnosis in this situation could fail to identify that surgical correction is required.

Pancreatic elastase (PE-1) is another enzyme considered to be pancreas specific. There is a commercially available canine PE-1 (cPE-1) ELISA (ScheBo·Elastase 1-Canine, ScheBo Biotech AG, Giessen, Germany). It appears that PE-1 has wide variation in healthy dogs, and similar sensitivity and specificity to cPL when assessing dogs with severe AP (see Table 55.2). However, this premise should be tested in a larger cohort of dogs.

Diagnostic Imaging

Diagnostic imaging is an important component of the investigation of dogs presenting with signs of abdominal disease. The major indication for abdominal radiographs is to rule out the presence of surgical disease such as intestinal obstruction or gallbladder rupture. The changes associated with AP are nonspecific on radiographs and include loss of detail in the cranial abdomen, and on the VD view, pushing of the proximal duodenum laterally (Figures 55.2 and 55.3).

Ultrasound is generally accepted as the most useful diagnostic imaging modality to evaluate the pancreas in clinical practice. Full abdominal ultrasound is recommended to assess for the presence of free fluid or other diseases. Changes described in CP are fairly vague, and it is considered that this diagnosis is difficult to make definitively via ultrasound. Pathognomonic signs of AP include an enlarged, hypoechoic pancreas surrounded by bright, hyperechoic fat and mesentery (Figure 55.4).



To date, more advanced imaging modalities such as magnetic resonance imaging (MRI) or computed tomography (CT) are infrequently performed in dogs with AP, due to the prolonged anesthesia required and the accepted sensitivity of ultrasound. The use of CT imaging in people is more frequently done, and can identify infected necrosis and other changes with a high degree of sensitivity.

Table 55.2 Summary of sensitivity and specificity for various laboratory testing in dogs from various studies

Study	Number of dogs	Method of diagnosis	Analyte assessed	Sensitivity (%)	Specificity (%)

(a)

(b)

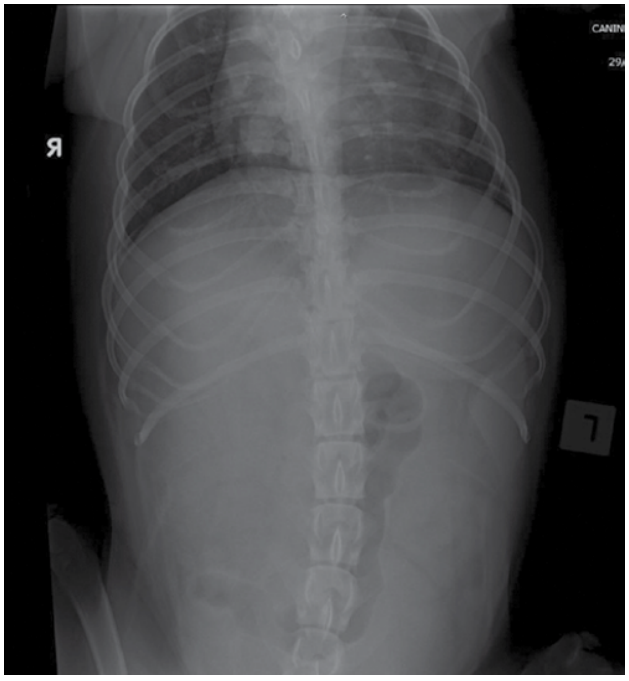

Figure 55.2 Abdominal radiographs of a dog with free fluid (lateral (a) and VD (b)). The cause of the effusion cannot be determined by radiographs alone. Fluid analysis and further imaging is required.

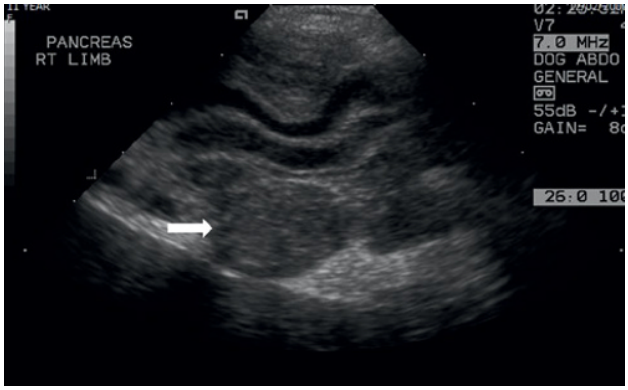

Cytology and Histology

Cytology is not used frequently in evaluating dogs with AP. However, abdominal fluid analysis should form part of the work-up to ensure that a septic or neoplastic process is not missed. Dogs with AP will generally have a suppurative, non-septic exudate present. A recent study in a small number of dogs with AP determined that measurement of cPL in peritoneal fluid had a sensitivity of 100% when using a cut-off value >500 µg/L. Caution

should be applied before relying extensively on this, as the study had only a few dogs with inflammatory/septic exudates as comparison.

Aspiration of fluid-filled collections within the pancreas may have a therapeutic benefit (described later). Fine needle aspirates (using a 25 G needle) can safely be obtained from the pancreas and may be beneficial in some cases of CP. Cytology is generally considered of marginal utility in AP, as there is often such a large degree of necrosis and inflammation that the samples are nondiagnostic and/or cellular criteria overlap with malignancy.

Histologic evaluation of pancreatic biopsy is considered the gold standard for diagnosis of pancreatic pathology. This is seldom obtained in dogs with AP, due to the morbidity associated with this procedure. The most common finding in dogs with AP is widespread necrosis of pancreatic and peripancreatic tissue. In dogs with milder, more intermittent clinical signs, exploratory laparotomy is more commonly indicated. The stomach, intestines (distal and proximal small intestine), mesenteric lymph nodes, and liver should all be sampled in addition to the pancreas.

A summary of the diagnostic approach recommended when dogs present with severe signs compatible with AP is shown in Figure 55.5.

Therapy

Acute Pancreatitis

Treatment of AP is generally supportive and nonspecific. The major "triad" of treatment is IV fluids, analgesia, and nutritional support. Fluid therapy should be tailored to the individual dog, with correction of electrolyte losses and restoration of circulating blood volume and acid–base balance being of the utmost importance. A recent study in humans suggested that using alkalinizing fluids (Hartmann's solution) produced a better response than acidifying solutions (saline) and so extrapolation would suggest that this (or alternatively, lactated Ringer's solution) would be a good first-line fluid choice in dogs. The volume of IV fluids required to correct blood volume may be higher than can be tolerated, and potentially lead to pulmonary edema or other signs of volume overload. In those circumstances, the use of colloid therapy may be of benefit. There is little to no evidence that using plasma will be beneficial in dogs with AP unless they have overt coagulation disorders.

Analgesia is essential in dogs that have AP, even if little pain is observed. Abdominal pain can be categorized as mild, moderate or severe (see Table 55.1). The principle behind analgesia in these situations is to start with the maximal combination/dose considered necessary for the level of pain and then titrate down (rather than starting low and titrating up if ineffective). Ideally, analgesic protocols in AP should avoid the use of drugs such as fentanyl that dramatically reduce gastrointestinal motility. However, if pain is not controlled by the recommended protocols, then using fentanyl as a constant rate infusion (CRI) should be considered. The addition of methylnaltrexone may mitigate the decreased GI motility in those circumstances.

A partial mu-agonist such as buprenorphine or full mu-agonist such as methadone should be considered as the baseline therapy (starting at maximum doses and intervals: 10–40 µg/kg q6–8h and 0.1–0.5 mg/kg q4–6h respectively, then tapering down). If pain is moderate then ketamine (5–20 µg/kg/min) and lidocaine (25–50 µg/kg/min) CRIs should be started at the higher dosage end. Once pain is well controlled, the ketamine should be reduced first, followed by lidocaine and then tapering of the opioid. With severe pain, epidural morphine (0.1 mg/kg q12–24h) or a fentanyl CRI (0.2–0.8 µg/kg/min) should be given, along with the lidocaine and ketamine as above. Once pain is controlled, the epidural/CRI is swapped for intermittent opioid, then all are tapered as previously described.

If possible, oral gabapentin (10 mg/kg q12–24h) could also be administered. If there is a sudden relapse of pain, the pancreas should be reexamined via ultrasound for the presence of a fluid collection. In people, aspiration of fluid collections is recommended when they are sterile, in preference to surgical debridement. Even in infected necrosis, control with antibiotics is undertaken before any surgical procedures. As virtually all the fluid collections in dogs will be sterile, and pancreatic surgery is associated with high morbidity and mortality rates, percutaneous drainage of fluid-filled areas is advocated for dogs as well. This can be performed using mild sedation and fine needle aspiration.

Nutritional support is the third major component of management. In people and dogs with critical illness, lack of enteral nutrition has been shown to perpetuate systemic inflammation as well as leading to mucosal atrophy and other changes. In mild-to-moderate cases of AP, the current rationale is to start enteral feeding if there has been no/little enteral nutrition for more than five days. In severe cases of AP, the earliest possible enteral nutrition is advocated. Dogs with severe AP can tolerate esophageal tube feeding, and so surgery or prolonged anesthesia to insert jejunostomy tubes is not essential. If the animal is moribund or unable to withstand a general anesthesia, then nasoesophageal tube feeding should be started as soon as possible. Once they are able to have GA safely, then an esophageal (E) tube should be inserted. Dogs can still be offered food by

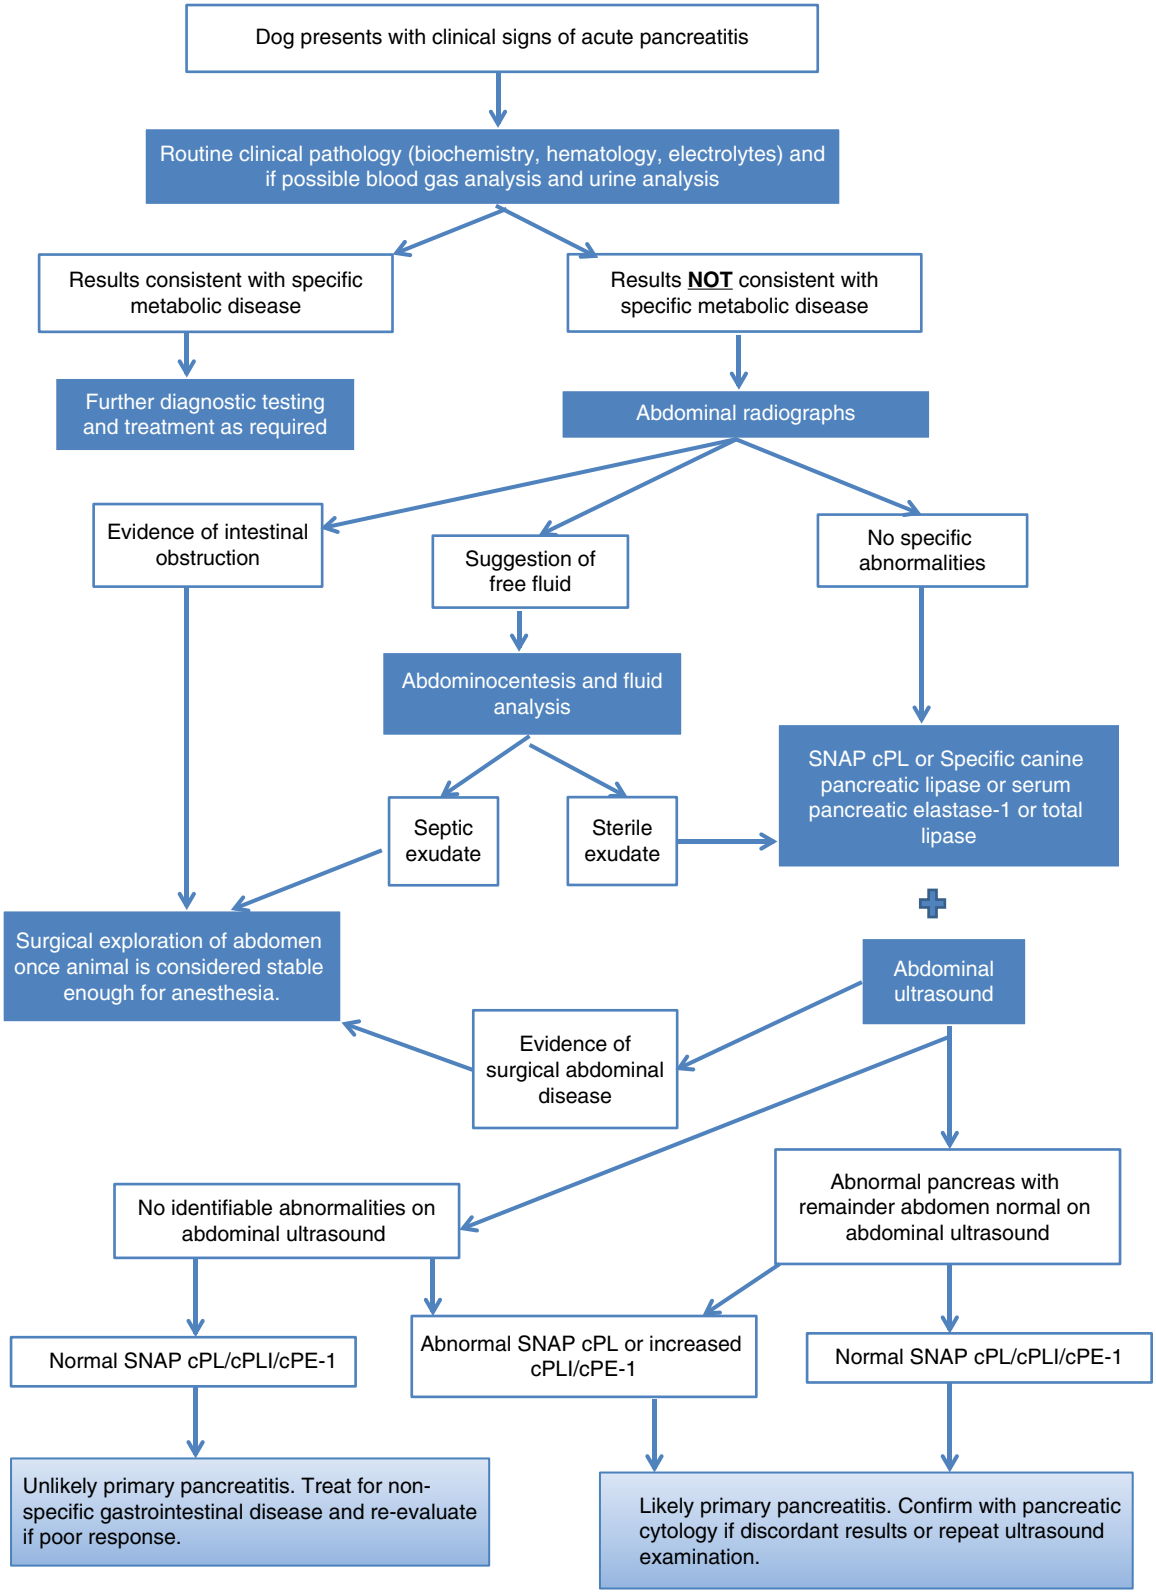

Figure 55.5 A diagnostic algorithm for the diagnosis of acute pancreatitis in the dog. *Source:* Mansfield (2013). Reproduced with permission of Elsevier.

mouth, and can be sent home with an E tube in place if necessary.

The biggest complications associated with interventional enteral nutrition are aspiration pneumonia and tube site infection. Close attention should be paid to the tube site to avoid the latter. To avoid regurgitation and development of aspiration pneumonia, it is not recommended to feed full resting energy requirements (RER) unless the feeding is extremely well tolerated. Rather, the first 24 hours should be 25% RER and titrate up slowly each day. Similarly, there is no evidence that a specific diet will result in improved outcome or speed of recovery, and as such any balanced convalescent diet for dogs is generally well tolerated.

Another important aspect of management of AP is to reduce vomiting and control nausea. Due to the role of substance P in mediating abdominal pain and vomiting, maropitant should be considered a first-line antiemetic drug. If vomiting is poorly controlled, or the dog appears to have severe nausea, then additional medications such as ondansetron (0.5 mg/kg IV then q12–24h) can be added. There is a theoretical disadvantage in using metoclopramide as it inhibits dopamine in rodent models. Due to the potential prokinetic benefits of metoclopramide a CRI should still be considered if decreased GI motility is thought to be contributing to nausea/inappetence.

There is little to no evidence that administering gastric acid suppressants does anything to reduce morbidity of AP in dogs. However, if there is melena or hematemesis then use of a proton pump inhibitor should be considered. The presence of any systemic complications such as pleural effusion or ventricular tachycardia should be assessed and treated as required. Antibiotics are not necessary unless bacterial translocation is considered likely.

The area most likely to undergo investigation in the future is targeted antiinflammatory therapies and analgesic agents. Similarly, the use of corticosteroids may be further evaluated, particularly when hypotension appears to be nonresponsive to fluid therapy.

Follow-Up

If an inciting cause (such as drug or food) is known, then this should be removed. Dogs can be discharged with feeding tubes in place if required, and a low-fat diet is currently recommended. This should generally be fed for 1–2 weeks and then the dog should be reevaluated and fasting serum triglyceride and cholesterol concentration measured. If these are high, investigations should be undertaken for underlying causes of hyperlipidemia and treatment, including diet, continued as appropriate. If there is no hyperlipidemia, dogs can be transitioned back to their regular diet. Analgesia may be necessary in the early stages following hospitalization, and medication such as tramadol or gabapentin dispensed.

Anecdotally, tramadol may cause inappetence and so gabapentin may be a better alternative. In people, after a bout of severe AP subclinical EPI exists for approximately four weeks following resolution. It is not certain if this occurs in dogs, but it may be therapeutically useful to supplement pancreatic enzymes for a short period after discharge. Animals should not be discharged if they still need antiemetic therapy.

Chronic Pancreatitis

Unfortunately, treatment options for CP are poorly explored, and the benefit of proposed treatments is unsupported. It does make sense to look for underlying causes of CP that can be corrected, such as hyperlipidemia. If there is hyperlipidemia, then an underlying endocrinopathy should be considered, particularly hypothyroidism. If both triglycerides and cholesterol are increased, then an inherent defect in lipid metabolism is more likely. In the absence of an endocrinopathy, treatment should initially consist of feeding a low-fat diet, with <15% dry matter as fat. Other treatments such as omega-3 fatty acid supplementation (20–30 mg/kg day) can also be used, but should be gradually introduced as they can cause gastrointestinal signs in their own right. If triglycerides (TG) alone are high and do not decrease with dietary management then gemfibrosil (7.5–10 mg/kg PO q12h) may be used. Other less well-established treatments such as chitin (binds lipids in the diet) and niacin (to reduce liver TG synthesis) may also be beneficial. For treatment of high cholesterol (with normal TG) when dietary treatment is ineffective, a statin (HMG CoA-reductase inhibitors) may be used. Safety margins are high for this group of drugs in dogs, and a dosage of 10–20 mg PO once daily is currently recommended for lovastatin. If the animal is not hyperlipidemic, there is no evidence for benefit from feeding a low-fat diet. However, this is frequently done in practice and if the diet is well balanced, long-term feeding of it is unlikely to cause harm.

If no underlying cause is diagnosed and CP is confirmed or strongly suspected, then the dilemma is whether to treat with analgesia alone or with additional antiinflammatory/immune suppression. Ideally, immune suppression should be used only when there is histologic confirmation of lymphocytic inflammation within the pancreas. If the dog is not diabetic, prednisolone is the drug of choice for both immune suppression and to treat inflammation/fibrosis, albeit at different dosages for the different effects. Prednisolone has been removed from the register of drugs that can potentially cause

pancreatitis in people, and studies have shown that glucocorticoids do not cause any histologic changes in dogs. If the dog is diabetic, it is not appropriate to use prednisolone due to increased insulin resistance. Ciclosporin is a viable treatment option for CP in diabetic dogs, but it is expensive in medium to larger breeds. Azathioprine has been implicated as causing pancreatitis in dogs, but this is a weak association. More importantly, it has not been shown that dogs with preexisting idiopathic or dietary-induced pancreatitis are more likely to develop reactions to azathioprine.

The pathogenesis of pain in CP is complex and multifactorial. Studies in humans have shown that the degree of fibrosis is not related to the degree of pain, and that interaction between the nervous system and inflammatory process is crucial. Major mediators of pain in CP appear to be calcitonin gene-related peptide (CGRP) and substance P, acting through the neurokinin-1 receptor. Therefore, during acute bouts of inflammation, treatment with a NK1 receptor antagonist such as maropitant may be of benefit in multiple ways (antiemetic, reducing pain and potentially directly attenuating the systemic inflammatory response). Additionally, the concept of neuronal plasticity suggests that the longer inflammation has been present, the more severe the pain associated with it will be. The most effective method of long-term analgesia that can be administered at home in dogs is probably tramadol, and/or gabapentin.

Prognosis

The reported mortality rate for AP in dogs ranges from 27% to 58%. This reported rate may not reflect the mortality in general veterinary practice, as the reports originate from referral centers, and euthanasia for non-medical reasons (i.e., financial) may also exert an influence. Even taking these factors into account, there apparently is a higher mortality rate in dogs with AP than the 5–15% reported in human studies. Chronic pancreatitis is unlikely to carry a high mortality rate if it occurs in isolation, but as a co-morbidity it may exert a negative prognosis on other co-existing diseases.

Conclusion

The pancreas should be considered in a similar light to the liver, in that many intraabdominal diseases can cause secondary inflammation and changes within the pancreas. To attribute clinical signs in a dog to pancreatitis, all other abdominal diseases such as septic peritonitis or intestinal foreign body obstruction, for instance, should be excluded. Treatment of acute and chronic pancreatitis is nonspecific and supportive. This too suggests that exclusion and management of concurrent or primary disease are often more important than a definitive diagnosis of pancreatitis in itself.

Pancreatitis in the Cat

Craig Ruaux, BVSc (Hons), PhD, MACVSc, DACVIM (SAIM)

School of Veterinary Science, Massey University, Palmerston North, New Zealand

In the veterinary profession, attitudes to pancreatitis in cats have undergone a massive shift in relatively recent times. From an earlier perspective that pancreatitis was an uncommon disease in the cat, recent findings and the introduction of new diagnostic testing modalities have led to the understanding that pancreatitis is actually common in the feline patient. Pancreatitis may actually be one of the most common diseases of the domestic cat, and is often an important co-morbidity with other diseases. This is particularly true of diseases of the gastrointestinal tract and liver. The actual importance of pancreatitis in the overall health of the domestic cat remains somewhat unclear, in part due to the very different pathology of most cases of pancreatitis in this species and the markedly different way in which cats tend to manifest this disease when compared to dogs.

In large part, this relatively recent change in attitudes to feline pancreatitis has arisen with the development and ready availability of much more sensitive and specific diagnostic tests for this disease. Advances in the resolution and availability of ultrasound imaging, new noninvasive diagnostic tests for specific markers of pancreatic tissue integrity and increased willingness to obtain pancreatic biopsies and histopathologic assessment have all been extremely valuable in advancing our knowledge of this disease.

The purpose of this chapter is to provide an overview of the presenting signs and histories, diagnostic approach to, and current recommendations for the management of pancreatitis in the domestic cat.

Clinical Signs and Symptoms of Pancreatitis in Cats

History and Physical Examination Findings

A quite remarkable difference between companion animal species is seen in the way that pancreatitis manifests. While specific reporting of clinical signs seen in cats with either suspected or actually confirmed pancreatic disease is uncommon in the veterinary literature, aggregation of results from several studies has provided data on clinical signs and owner complaints in 136 cats; these findings are summarized in Table 56.1.

One remarkable observation from the aggregated data in Table 56.1 is that the most common clinical sign in cats with pancreatitis, across a variety of studies spanning several decades, is decreased appetite, followed closely by lethargy. Vomiting and abdominal pain, both frequent clinical signs of pancreatitis in dogs, were reported in less than 50% of feline patients. The actual case outcomes and severities of clinical presentations in the cats aggregated for Table 56.1 range from mild disease with "incidental" findings of pancreatic disease through to objectively severe, life-threatening or terminal disease. Based on clinical signs alone, there is no way to distinguish the severity of pancreatic disease or predict the histopathologic findings if biopsies are to be taken. While some authors have suggested that chronic pancreatitis in the cat is a less severe disease, this is probably an unfounded belief; cats with chronic pancreatitis can present with objectively severe presenting signs (most likely associated with an acute worsening of their disease, or an "acute on chronic" disease presentation).

Given that both decreased appetite and lethargy are nonspecific signs, and are also common reasons for presentations of feline patients for veterinary care, it is not surprising that pancreatitis is becoming a much more common diagnosis in feline medicine. In light of these data, pancreatitis should be considered a reasonable and important differential diagnosis for any cat presenting with vague, nonspecific clinical signs.

Physical examination findings in cats with pancreatitis are also often unrewarding. Clinical signs such as cranial abdominal pain and guarding, commonly encountered in canine patients, are uncommon in cats with diagnoses

Table 56.1 Historical and clinical findings in cats with confirmed pancreatic inflammatory disease

Clinical sign	Frequency (#cats/ total cases reported)	Frequency (% of cats)
Reduced appetite	113/136	83
Lethargy	105/136	77
Dehydration	88/136	65
Vomiting	58/136	43
Abdominal pain	27/73	36
Icterus	40/136	29
Weight loss	22/96	16

of pancreatitis. This may be due to the tendency of feline patients to "hide" clinical signs, the relatively subtle nature of pain manifestation in many cats, and a tendency to interpret struggling or resisting examination as a normal response on the part of feline patients. Often, the most important findings on physical examination in feline patients with pancreatitis are signs and symptoms of co-morbid disease (palpably thickened gastrointestinal tract, icterus, poor body condition), or findings that are important in the assessment of the overall state of health of the patient (state of hydration, presence of free abdominal fluid, alterations in body temperature). As with the histories of cats with pancreatitis, these vague, diffuse, and nonspecific findings in most cats with pancreatic inflammatory disease mean that pancreatic disease is a reasonable differential diagnosis in essentially any cat that presents unwell.

Characterization of Pancreatitis in the Cat

Typically, pancreatitis has been divided into acute and chronic diseases, based on histologic differences in human and canine patients. Generally speaking, "acute pancreatitis" is either neutrophilic or hemorrhagic and is associated with rapid onset of severe symptoms, marked abdominal pain and potentially life-threatening acid–base and electrolyte disturbances. By comparison, "chronic pancreatitis" is typically associated with fibrous replacement of pancreatic tissue and the presence of a lymphocytic inflammatory infiltrate. Although chronic pancreatitis is being recognized more frequently in canine patients, most clinicians consider acute pancreatitis to be the most common form of the disease in dogs.

In cats, chronic pancreatitis is the most commonly diagnosed disease following histologic assessment of pancreatic biopsies. As in humans and dogs, this diagnosis is based on the presence of lymphocytic or plasmacytic cellular infiltrates and, typically, some degree of fibrosis. In some studies, >80% of cats with pancreatic disease show this form of pancreatic infiltrate. Remarkably, at least one necropsy-based study of cat pancreata has suggested that signs of pancreatic inflammation, including lymphocytic-plasmacytic infiltration and fibrotic change, are common in cats with no history suggestive of pancreatic disease.

One problem with the terminology of pancreatitis, particularly the distinction of acute vs chronic pancreatitis, is the implication of differing chronologies of the disease. This is particularly problematic in the feline patient. While it is generally safe to assume that cats with longer histories of recurrent clinical signs such as lethargy, decreased appetite, and recurrent vomiting do indeed have chronic pancreatitis, the converse is not necessarily true. Given the subtle nature of clinical signs and historical complaints in many cats with pancreatic disease, and the waxing/waning nature of clinical signs in most chronic lympho-plasmacytic diseases, it is not valid to assume that a cat with a new presentation of relatively acute clinical signs actually has "acute pancreatitis" as defined histologically. As discussed earlier, there is no reliable way to distinguish necrotizing or hemorrhagic pancreatitis from lympho-plasmacytic disease in feline patients. Therapeutic decision making should be based on assessment of the overall state of health of the patient on presentation, rather than assumptions that a patient may or may not have a particular form of the disease.

Noninvasive Diagnostics for Feline Pancreatitis

Routine Clinical Chemistries

Routine clinical chemistry and complete blood count (CBC) evaluations are a critical part of the approach to any unwell feline patient. In the context of cats with a suspicion of pancreatitis, the most important aspect of the routine chemistry panel and CBC is the assessment of the overall physiology of the patient. There are very few to no findings on routine clinical pathology panels that can be considered highly sensitive or specific for pancreatitis in the cat. One exception to this would be the "pancreas-specific lipase" assays that are beginning to be promoted more heavily in some routine chemistry panels, and are discussed in more detail later.

In the dog and human patients, traditionally we have relied on the measurement of serum amylase and lipase activities to establish a diagnosis of pancreatitis, with the expectation that these activities will be markedly elevated. While these tests are admittedly low sensitivity and specificity in both dogs and people, marked elevations in patients with compatible clinical signs are at least strongly supportive of the clinical suspicion of pancreatitis.

In the cat, a long-standing belief in veterinary medicine is that amylase and lipase activities have essentially no diagnostic utility, with unacceptably low sensitivity and specificity in this species. While there is a large element of truth to these assertions, these opinions are based on a limited number of publications that assessed a small number of cats, and all dated from a period before the veterinary profession came to truly appreciate the very different manifestations of this disease in the cat. The low specificity reported for these tests may owe as much to false-negative diagnoses based on an incorrect understanding of the way in which this disease presents in the cat.

Common clinical pathology abnormalities encountered in cats are related to organ systems that are commonly compromised or involved in co-morbid diseases. Abnormalities in liver enzyme activities (both alanine aminotransferase [ALT] and alkaline phosphatase [ALKP], suggesting both hepatocellular compromise and cholestasis), azotemia, alterations in acid–base status, hypocalcemia, and inflammatory leukograms (typically left-shift neutrophilia) are all encountered relatively commonly. Some studies have suggested that marked hypocalcemia is a negative prognostic factor, likely due to sequestration of calcium in saponified abdominal fat, a phenomenon that tends to accompany hemorrhagic and necrotizing pancreatic pathology.

Specialty Diagnostic Tests

Noninvasive diagnostic testing relies on the use of marker compounds, detectable in the serum or some other sample such as urine, that are specific to the organ of interest and are altered in disease states of that organ. Ideally, the marker compound will be altered with disease of the primary organ, but unaltered by changes in other organ systems or by concurrent medical therapy. In the case of pancreatic disease, these marker compounds are usually digestive enzymes of some type. The use of typical amylase and lipase activity assays has already been discussed. More recent diagnostic tests that have been investigated include serum concentrations of trypsin-like immunoreactivity (fTLI), feline pancreatic lipase (now offered as the Spec-fPL™ assay), and activity tests using more "pancreas-specific" lipase substrates, particularly DGGR-lipase activity.

While trypsinogen/fTLI is pancreas specific, and is released in conditions of pancreatic disease, the peak changes in this enzyme are relatively short and soon after the onset of disease, and some other diseases (specifically small intestinal disease and severe azotemia) can be associated with elevations in fTLI without histologic evidence of pancreatic disease. This combination of transient changes in serum concentrations and minor alterations with other, nonpancreatic diseases results in fTLI testing having only moderate sensitivity and specificity for the diagnosis of pancreatitis in the cat. The greatest utility of fTLI testing lies in the ruling in or out of exocrine pancreatic insufficiency in feline patients (see Complications of Pancreatitis in Cats, later).

Serum concentrations of feline pancreatic lipase (Spec-fPL) and lipase activity assays using more highly selective assay substrates both show greater utility than routine amylase/lipase activities and the fTLI test; these tests are discussed in greater detail later.

Specific Pancreatic Lipase Test

Feline-specific pancreatic lipase (fPLI) refers to a particular protein, a lipase enzyme, synthesized and released solely by the pancreas in cats. This particular enzyme's concentration in serum is measured using the serum Spec-fPL assay, available either as a "cage-side" SNAP test or via specialty clinical pathology testing. This assay relies on monoclonal antibodies directed against the feline protein which are highly species specific. The use of canine PLI tests with feline samples can result in a false-negative rule-out of pancreatic disease in the cat.

As the fPLI protein is specifically and exclusively synthesized in the exocrine pancreatic tissue, the concentrations in the serum are dependent on the rate of synthesis and the "leakage" of the protein into the interstitial space and then the circulation. Conditions associated with increased cellular leakage (generally, some form of pancreatitis) are associated with increased serum concentrations of this protein, so the detection of increased circulating fPLI protein (i.e., a high Spec-fPL test result) is suggestive of pancreatic disease, particularly in cats with compatible clinical signs.

The sensitivity and specificity of fPLI testing have been investigated in several studies. Reported sensitivities and specificities for this test are 67–100% and 67–82%, respectively. In one moderately large study (n = 182 cats) using the Spec-fPL assay, the overall sensitivity for this test was 79%, with a specificity of 82%, for detection of pancreatitis in this group. Overall, the Spec-fPL has the highest reported sensitivity and specificity (at the time of writing) of any diagnostic modality for the detection of pancreatitis in the cat.

The use of Spec-fPL measurement as a prognostic marker and monitoring parameter for recovery has also received some attention. Marked elevation of Spec-fPL (values >20 µg/L) has been associated with a poorer prognosis in cats hospitalized with pancreatitis. There are no data in the literature suggesting that greater elevations in Spec-fPL are associated with poorer response to therapy in cats with chronic pancreatitis, assuming adequate management of co-morbidities. A much greater factor influencing response to chronic pancreatitis in cats is adequate management of chronic enteropathy and

the identification and treatment, if present, of cobalamin deficiency in these cats.

Pancreas-Specific Lipase Assays

The lipase activity assays used in most commercial laboratories and bench-top analytic systems rely on lipase within the serum sample cleaving a substrate of some sort; this cleavage then results in a change in the test solution (such as changing pH or color) that can be measured, giving a value for lipase activity. There is a large number of lipase activity substrates that can be used, and the substrates typically used by high-throughput commercial laboratories are different from those used in the bench-top systems. Even within bench-top systems, there are differences in substrates between differing manufacturers. For this reason, the comparison of lipase activity assays between two different systems is generally fruitless and does not yield any useful data.

Many tissues in the body contain quite high amounts of lipase. Obviously, the exocrine pancreas is very rich in these enzymes but other organs, including the liver, gastric mucosa, and duodenal mucosa, contain lipase activity. These lipases can be released from these other organs in disease states, and contribute to the total circulating lipase activity. The specificity of a lipase assay for detection of pancreatic disease thus depends on the specificity of the substrate used for pancreatic lipase. This substrate specificity varies markedly between substrate types.

One substrate with greater specificity for pancreatic lipase that has undergone some investigation in cats is 1-2-o-Dilauryl-rac-glycero-3-glutaric acid-(6'-methylresorufin) ester (DGGR). A DGGR-based clinical chemistry assay has been validated for use in feline serum samples, and the sensitivity and specificity of the test compared with the use of both Spec-fPL testing and abdominal ultrasonography. The DGGR-based assay had similar, if slightly lower, sensitivity and specificity to the Spec-fPL assay in the assessment of cats with clinical signs compatible with pancreatitis. In a similar follow-up study, the DGGR-based assay was found to show the best agreement with both Spec-fPL and abdominal ultrasonography in cats with hypo- or mixed-echoic pancreatic parenchyma, findings that are generally considered consistent with acute pancreatic disease.

Overall, DGGR-based lipase activity assays likely have clinical utility in feline patients, and an elevated activity value in an unwell feline patient should prompt further assessment for the presence of pancreatic disease. However, this approach is reliant on the use of this specific substrate in whichever analytic system is being employed. Information regarding the actual substrates used by the various reference laboratories and in-house chemistry systems commonly found in veterinary practice is not readily available at this time.

Pancreatic Biopsy and Histology

Pancreatic biopsy and histologic examination is generally considered the "gold standard" for the detection of pancreatic disease, including pancreatitis. Unfortunately, pancreatic biopsy is still a relatively uncommon part of the approach to feline patients, for a variety of reasons. Chief among these is likely cost to the client and the invasive nature of celiotomy to obtain biopsies. Recently, however, the use of laparotomy and laparoscopy-assisted biopsy techniques has provided a lower cost, less invasive method for obtaining pancreatic biopsies, usually in concert with liver and intestinal biopsy procedures.

Surgical biopsy of the feline pancreas has been shown to have a low risk for complications such as postsurgical pancreatitis, assuming that the patient is adequately hydrated and hemodynamically stable at the time of surgery. Side-effects and postsurgical morbidity are uncommon in cats undergoing surgical biopsy of the pancreas using punch biopsy instruments or crush-fracture techniques using hemostats. Pancreatic biopsy, particularly in cats undergoing assessment for gastrointestinal disease, is justified in many cases and should be considered part of the routine samples collected during exploratory celiotomy or laparoscopic exploratory procedures.

While biopsy samples are rightly considered the most effective way of assessing pancreatic disease, a number of shortfalls of this technique must be recognized. Even with laparoscopic procedures, the collection and assessment of histologic samples are still more expensive and have higher risk to the patient than the use of noninvasive testing such as clinical chemistries. In addition, pathology within the pancreas is often heterogeneous in distribution, and differing areas may show differing cellular infiltrates or levels of activity. This may lead to incorrect diagnosis of the overall state of the pancreas when only a single sample is taken, as is often the case with laparoscopic biopsies of the pancreas in the cat. Finally, there is a well-recognized variability between individual pathologists with respect to assessment and description of pancreatic samples. Histologic scoring systems for pancreatic disease have been proposed and published, including for the cat, but the use of these systems is generally limited to research publications and retrospective case series descriptions. It is uncommon for histopathologists to report pancreatic biopsy samples using these scoring systems in veterinary medicine.

Interpretation of Specialized Tests

Interpretation of the specialized tests used for the diagnosis of pancreatic disease in cats is sometimes complicated, particularly if the test is part of a broad-ranging panel used in the initial assessment of a patient if there is no clear initial diagnosis being assessed. Part of the

difficulty of assessing these tests comes from the observation that we do not truly know the prevalence of pancreatic disease in the feline population. While at least one study suggests that pancreatic pathology is quite common in the feline population (approximately 60% of cases necropsied, where the patient was *not* suspected to have pancreatic disease), one caveat about this study is that these were still, largely speaking, unwell cats that were necropsied. If the true prevalence of pancreatic disease in the feline population is as high as 60%, then an unexpected finding of a high Spec-fPL concentration or DGGR-lipase activity on sentinel chemistry panels may be a true indication of pancreatic disease. While the pancreatic disease present may not be an important *clinical* finding, this does not mean that this is an incorrect *diagnostic* finding. This is particularly true when the clinical chemistry panel is being run on an apparently healthy patient as part of a health monitoring or wellness program.

An additional important factor in the interpretation of these tests is the very variable, and often subtle, clinical signs and histories of this disease, as previously discussed. When clinical chemistry panels and Spec-fPL tests are being run as part of a broad-ranging assessment in a cat that is known to be unwell, but with no clear initial indication of why, abnormalities in these tests are a strong indication of likely *clinically significant* disease. It is inappropriate to discount these findings in these patients, and important to consider that pancreatic disease is, to all indications, common in the sick cat population and also a common co-morbid condition with other diseases.

Diagnostic Imaging

Along with the specialized noninvasive testing methods discussed above, diagnostic imaging is commonly used in the assessment of pancreatic disease in the cat. Of the various methodologies available, high-resolution abdominal ultrasonography typically has the greatest diagnostic yield. It also allows further assessment of other abdominal organs that may be involved in co-morbid diseases, such as the hepatic parenchyma, biliary tree, and intestinal walls.

Plain abdominal radiography, while commonly used in cats with suspected abdominal disease, has a very low diagnostic yield in cats with pancreatitis. The pancreas is not visible on plain abdominal radiographs, and changes commonly seen in dogs with pancreatitis ("ground glass" appearance, loss of local contrast, widening pyloric angle) are infrequent in cats due to the differing underlying pathology in most cases. While abdominal radiography has some possible advantages in terms of lower cost and greater availability, the very low diagnostic yield is a contraindication for its use in most cases.

The increasing availability of high-resolution abdominal ultrasonography in companion animal practice has dramatically improved the use of diagnostic imaging to characterize pancreatic disease in the cat. Observation of pancreatic enlargement, hyperechoic mesentery and abdominal fat, altered parenchymal echogenicity (most commonly hypoechogenicity or a mixed pattern), abdominal effusions, pancreatic cysts or pseudocysts, corrugation of the duodenum, and dilation of the pancreatic duct are all considered consistent with pancreatitis in cats with consistent clinical signs. These findings are specific indicators of the presence of pancreatic pathology, but their sensitivity for accurate diagnosis in cats with histologically confirmed pancreatitis is quite variable, with reported sensitivities ranging from ~11% to 80%. Sensitivity of abdominal ultrasound for the detection of feline pancreatic disease is highly dependent on operator skill and equipment resolution. Given the variable and often low sensitivity of abdominal ultrasound examination in the diagnosis of pancreatitis in cats, this modality cannot be reliably used as a "rule-out" test for this disease. However, significant additional information useful for management of these cases is often obtained, particularly when screening for co-morbid conditions such as cholangitis/cholangiohepatitis or the presence of extrapancreatic disease that could explain the clinical signs. Therefore, abdominal ultrasonography, carried out by a well-trained and experienced operator, is recommended in all cats where there is a clinical suspicion of pancreatitis.

In humans, the use of abdominal computed tomography (CT) examination is considered highly useful in the assessment of pancreatic disease. This modality allows the assessment of pancreatic architecture, presence and severity of fibrotic change and detection of both common inciting causes for pancreatitis in humans (such as gallstones) and other co-morbid diseases. The utility of abdominal CT for the assessment of feline pancreatic disease is much lower than in humans. This is due to the much smaller mass of pancreatic tissue in the cat, and less common presence of severe architectural distortions due to fibrosis. Additionally, abdominal CT examination of cats typically requires general anesthesia, which may be contraindicated in severely unwell cats and also leads to significant additional cost. CT examination has been reported in cats in a small number of publications; the overall sensitivity and specificity were not higher than those seen with less invasive testing such as Spec-fPL or abdominal ultrasonography, and thus abdominal CT cannot be recommended as a part of the diagnostic approach to pancreatic disease in the cat at this time.

Approaches to Management of Pancreatitis in Cats

Care of Cats Hospitalized for Pancreatitis

As previously discussed, it is not possible to distinguish so-called "acute necrotizing" pancreatitis from chronic lymphocytic-plasmacytic pancreatitis in the cat, regardless of presenting clinical signs, history or chemical findings. The approach to the management of cats with this disease is determined by the overall degree of health of the patient as assessed by initial examination and screening chemistries. Cats presenting with a suspicion of pancreatitis that are showing other signs of systemic illness, marked abdominal pain, systemic inflammatory response syndrome (pyrexia, tachycardia, tachypnea), hypothermia or hypotension should be considered to have severe disease, and immediate hospitalization and aggressive stabilization therapy are recommended. If multiple abnormalities are detected on routine chemistry panels, particularly if hypoalbuminemia and/or hypocalcemia are present, this is a strong indication of severe disease associated with significant risk of in-hospital mortality.

Cats with severe disease require careful monitoring, appropriate fluid therapy, and effective analgesia. In humans and dogs, severe pancreatic disease is inarguably painful, and while cats may not show as many overt signs of pain, such as vocalization or abdominal guarding, there is no reason to suspect that this disease is not painful in cats as well. Many of the clinical signs at presentation of severe cases, such as tachypnea and tachycardia, resolve rapidly with effective pain control interventions.

Initial screening chemistry panels are important to assess for other co-morbid or complicating diseases, particularly extrahepatic biliary duct obstruction, hepatic lipidosis, and diabetes mellitus (which may proceed to diabetic ketoacidosis). Samples should also be drawn for special diagnostic testing (i.e. Spec-fPL assay or DGGR-lipase). If available, patient-side SNAP tests for Spec-fPL can give initial support to a clinical suspicion of pancreatitis, but these tests should not be relied on to rule out the disease, and measurement of a quantitated value through a reference laboratory is recommended as soon as possible. Pending results of specialized diagnostics, the management of these cases follows typical management protocols for acute abdomen/septic shock patients.

The initial aims of therapy are to replace circulating fluid volumes, restore end-organ perfusion, and maintain organ function. Obtaining effective perfusion of the pancreas is particularly important, as pancreatic ischemia is a significant inciting cause for the development of necrotizing pancreatitis. With the combination of aggressive fluid therapy and increased endothelial "leakiness," it is critical to monitor total protein and, if necessary, restore and maintain plasma colloid oncotic pressure. Colloid fluids, such as synthetic hydroxyethyl starches, are often highly beneficial in the initial resuscitation of these cases. Fresh-frozen feline plasma can also be considered, and likely provides oncotic support while replenishing coagulation cascade proteins; however, there is little information in the veterinary literature regarding use of plasma in severe feline pancreatitis cases. Substantial electrolyte abnormalities, particularly hypokalemia and hypocalcemia, should be anticipated in these cats. Supplemental potassium is administered in combination with crystalloid fluids following routine guidelines for concentrations based on serial determination of serum potassium concentrations, typically every eight hours during the initial resuscitation phase.

Drug Therapy in Feline Pancreatitis

Effective analgesia and control of vomiting are important aspects of management of severe pancreatitis in all species. A selection of medications that are often useful in the management of pancreatitis in the cat is summarized in Table 56.2.

Narcotic pain control is typically indicated in cats with sufficiently severe pancreatitis to warrant hospitalization. Transdermal fentanyl patches (25 µg/h) can be very effective for longer term (up to 72 h) analgesia without the need for frequent handling and injection in these patients, but initial therapy with an injectable or sublingual agent (commonly buprenorphine) is necessary as it can take up to 12 hours for therapeutic fentanyl concentrations to be reached. Maropitant, a neurokinin-1 receptor antagonist, is both an effective antiemetic and may have antinociceptive effects in the viscera. The combination of maropitant with a 5-HT_3 receptor antagonist, such as ondansetron or dolasetron, often provides effective control of vomiting and nausea in these patients with minimal need for repeated handling during the day. Together, obtaining adequate analgesia and control of nausea/vomiting are important for the overall well-being of the patient, and increase the likelihood of an early return to voluntary eating.

Early Nutritional Management

Long-standing dogma for the management of severe pancreatitis in humans and canine patients has been that these patients should be maintained *nil per os* for some period, with introduction of food occurring only after cessation of vomiting for a minimum of 12 hours, and often 24 hours or more. This attitude is being supplanted by early enteral nutrition strategies in both humans and, more recently, dogs. Preliminary evidence suggests that early enteral nutrition in these species is

Table 56.2 Medications commonly used in the management of severe pancreatitis in the feline patient

Class	Drug	Mechanism	Main indication	Dose and route
Analgesic	Buprenorphine	Opioid	Acute, severe	0.01–0.02 mg/kg SC, IM, IV, TM
	Fentanyl	Opioid	Acute, severe	25 µg/h patch, 5 µg/kg IV bolus, CRI 2–4 µg/kg/h
	Butorphanol	Opioid	Acute, severe	0.1–0.5 mg/kg SC, IM, IV
Antiemetic Antinausea	Maropitant	Neurokinin-1 receptor antagonist	Acute, severe chronic	1 mg/kg SC q24h, 2 mg/kg PO q24h
	Dolasetron or ondansetron	5-HT_3 receptor antagonist	Acute, severe	0.8–1.0 mg/kg IV q24h
	Metoclopramide	Dopamine D2 receptor antagonist	Acute, severe	0.2–0.5 mg/kg PO, SC, IM q6–8h, 1–2 mg/kg/24h CRI
Antacid	Omeprazole	Proton pump inhibitor	Acute, severe	1.0–1.3 mg/kg PO q12h
	Pantoprazole	Proton pump inhibitor	Acute, severe	0.7–1.0 mg/kg IV q12h
	Ranitidine	Histamine H2 receptor antagonist	Acute, severe	0.5 mg/kg PO q12h

CRI, constant rate infusion; IM, intramuscular; IV, intravenous; PO, by mouth (*per os*); SC, subcutaneous.

associated with shorter ICU and hospital stays, lower total costs of care, and fewer complications during initial management. With cats, the potential for development of hepatic lipidosis as a complication of severe pancreatitis and inadequate caloric intake must also be considered. While currently there is limited information in the veterinary literature regarding the use of early enteral nutrition in cats with severe pancreatitis, the author uses this modality regularly, and quite aggressively. In many cats, assisted feeding devices such as esophagostomy tubes are placed during the first 24–36 hours of hospitalization to achieve early return to feeding. For both hepatic lipidosis and diabetic ketoacidosis, a return to caloric intake is critical to their successful management, and the presence of pancreatitis (either as an inciting disease or a complication) does not alter the importance of a return to positive caloric balance in these diseases.

Outpatient Management of Cats with Chronic Pancreatitis

Cats presenting with less severe clinical signs, perhaps with histories of vomiting, weight loss or other gastrointestinal signs but without significant abnormalities on screening biochemical panels, can typically be treated on an outpatient basis. In these patients, collection of samples for specialized testing (Spec-fPL) is recommended, but there is less utility to the patient-side testing, as these patients will be treated on an outpatient basis in the same manner regardless of the initial patient-side test result. Cats that had originally presented with a suspicion of severe pancreatitis should also transition to this more chronic management approach once they are eating voluntarily and are able to be discharged.

Cats with a clinical suspicion of chronic pancreatitis are treated in essentially the same manner as cats with chronic enteropathies or diagnoses of idiopathic inflammatory bowel disease. There is no meaningful way to distinguish between chronic pancreatitis as a solitary disease entity and the presence of multiorgan inflammatory disease (so-called feline inflammatory disease or "triaditis"). Initially, dietary modification, typically by use of a novel protein source or hypoallergenic diet, is suggested. In contrast to dogs, where fat restriction is a cornerstone of management for most cases of chronic pancreatitis, fat restriction is not recommended in the cat due to their high constitutive requirement for both fat and arachidonic acid intake. Many cats will respond to dietary manipulation; in those who fail to respond to dietary manipulation, it is rational to consider antiinflammatory or immune modulatory therapies, assuming that no other co-morbidities are present that would contraindicate the use of these medications.

A common additional finding in cats with chronic pancreatitis, particularly in those with significant gastrointestinal disease accompanying their pancreatic disease, is the presence of hypocobalaminemia. Cats with hypocobalaminemia (low vitamin B_{12}) are known to be less responsive to treatment for other diseases, such as chronic inflammatory bowel disease, if this hypocobalaminemia is not addressed via supplementation. Supplementation of cats with cobalamin is straightforward, and can be carried out using injectable or oral supplementation regimes. In some cats, particularly those with diffuse small intestinal disease, serum folate

concentrations are also low. Supplementation of cats with low folate has not been investigated as thoroughly as cobalamin supplementation, but is also readily achieved with oral supplement products. Often, initial supplementation by injection followed by oral supplementation in the home environment provides a good balance between costs, convenience, and ease of owner compliance.

Complications of Pancreatitis in Cats

Given the apparent frequency of chronic pancreatic disease in the feline population, the occurrence of severe complications is actually remarkably low. While objectively severe disease in cats presenting with hemodynamic shock, systemic inflammatory response syndrome and abdominal pain is life-threatening and associated with a substantial risk for mortality if not addressed appropriately, most cats with chronic pancreatitis require life-long management for their disease, but other than waxing and waning clinical signs, most do not develop additional complicating diagnoses.

The two most common and important complications of pancreatic disease in the cat are exocrine pancreatic insufficiency (EPI) and diabetes mellitus.

Chronic pancreatitis is most likely the most common cause of EPI in cats. Loss of exocrine tissue due to ongoing inflammation and fibrosis can eventually lead to the development of clinical signs related to insufficient digestive enzyme synthesis. In comparison to dogs, and a recurring theme in feline medicine, the way in which EPI manifests in cats is different in terms of both history and clinical signs reported. While in the dog the most common cause of EPI is an early-onset pancreatic acinar atrophy (PAA), in the cat the disease is an end-result of a chronic, typically years-long inflammatory disease. Dogs with EPI secondary to PAA are usually young and usually are otherwise healthy, with good to ravenous appetites. In the cat, there is typically a long history of poor appetite and possible weight loss resulting from the underlying pancreatitis. By the time cats reach an end-stage of chronic pancreatitis, they are usually chronically unwell, and they do not develop compensatory polyphagia. Cats also are less likely to produce voluminous stools and frank steatorrhea; this is probably due to the very prolonged course of the disease in this species, which allows other compensatory mechanisms (such as intestinal brush border enzyme upregulation) to be more effective.

Exocrine pancreatic insufficiency should be suspected in any cat with a history of diagnosed chronic pancreatitis that then goes on to show worsening clinical signs, particularly weight loss. In some cases weight loss will be the only additional clinical sign that suggests the onset of EPI.

Diagnosis of EPI in the cat is based on the measurement of serum concentrations of TLI, not Spec-fPL. While Spec-fPL values are almost invariably very low in cats with EPI, this is also seen in some normal cats, resulting in an unacceptably low specificity of the Spec-fPL assay for the diagnosis of EPI in cats. DGGR-lipase activity assays have no diagnostic utility for EPI in cats, as most cats with EPI show DGGR-lipase activities that are indistinguishable from normal cat values.

Diabetes mellitus can develop in cats with chronic pancreatitis due to progressive loss of islet tissue with inflammation and fibrotic change. These cats may spend extended periods as "prediabetic" patients, with reduced glucose tolerance. The actual frequency of chronic pancreatitis as a cause of diabetes mellitus in the cat is unknown, and likely underestimated, due to the low frequency of pancreatic biopsy in these cats. The occurrence of diabetes mellitus in feline patients can significantly complicate their management for chronic pancreatitis, particularly if the cat is being managed with glucocorticoid medications to mitigate inflammation. Equally, the presence of chronic pancreatitis in a diabetic cat is a common cause of difficulty in achieving adequate glycemic regulation, and chronic pancreatitis is one of the most important diseases to screen for in cats with diabetes that is hard to regulate. The difficulty of managing diabetic cats with chronic pancreatitis, and the confounding influence of glucocorticoid therapy on glycemic regulation, makes one of the strongest arguments for early intervention using predominantly dietary changes in the management of chronic pancreatitis in the cat.

Rectoanal Diseases – Medical and Surgical Management

Craig Ruaux, BVSc (Hons), PhD, MACVSc, DACVIM (SAIM)[1] *and Milan Milovancev, DVM, DACVS-SA*[2]

[1] *School of Veterinary Science, Massey University, Palmerston North, New Zealand*
[2] *School of Veterinary Medicine, Oregon State University, Corvallis, Oregon, USA*

Rectoanal diseases are frequent reasons for presentation of companion animals for veterinary attention. Clinical signs and symptoms, such as straining, "scooting," fecal incontinence, and paradoxical diarrhea, are very distressing to owners. An effective approach to recognition and management of these diseases relies on a thorough history and clinical examination, including rectal examination wherever possible. In smaller patients, and those that resent digital rectal palpation, effective sedation is needed to allow this examination to proceed. Diseases involving the distal rectum and perineum are often well characterized by local examination and palpation, but the intrapelvic rectum can be difficult to fully assess, as many important structures (pelvic urethra, cranial prostate in larger dogs, intrapelvic lymph nodes) are difficult to reach. Diagnostic imaging of this area is also challenging in many cases. Contrast-enhanced CT examination is the imaging method of choice for many of these cases.

In this section, a variety of rectoanal diseases is briefly discussed. For some diseases, medical management is appropriate, while in others surgical management is the primary management modality.

Anal Sac Adenocarcinoma

Clinical Presentation

Incidental finding or visible perianal mass/swelling, tenesmus, polyuria/polydipsia, anorexia or inappetence, lethargy, weight loss, constipation, or posterior weakness.

Pathophysiology

Anal sac adenocarcinoma arises from malignant transformation of the secretory epithelium of the anal sacs.

Diagnosis and Medical Management

In up to a third of dogs, anal sac adenocarcinoma is discovered as an incidental finding on routine examination. When clinical signs are present, they may be a result of the local mass effect (straining to defecate, constipation due to enlargement of retroperitoneal and intrapelvic lymph nodes with metastatic disease). In some cases the primary presenting complaint is polyuria and polydipsia resulting from loss of concentrating capacity due to hypercalcemia. Routine clinical chemistry panels will often reveal both total and ionized hypercalcemia, with or without concurrent hypophosphatemia. A finding of hypercalcemia in a dog undergoing assessment for polyuria and polydipsia should prompt thorough anal sac and rectal digital examination, using sedation if necessary. With advanced disease and metastasis to the abdominal lymph nodes dorsal displacement of the colon may be visible on plain abdominal radiographs. Abdominal ultrasonography and, if available, computed tomography will usually have a much greater diagnostic yield than plain abdominal radiography. On diagnosis, complete pretreatment staging calls for either three-view thoracic radiographs and/or computed tomography. Conclusive diagnosis can usually be obtained by examination of fine needle aspiration cytology of the mass. In some cases, the cytology may be interpreted as "hepatoid" but a benign cytologic appearance does not rule out anal sac adenocarcinoma.

Surgical Management

Preoperative patient staging for sublumbar lymph node and/or pulmonary metastasis is mandatory as this information influences surgical approach (e.g., determines whether concurrent sublumbar lymph node extirpation is indicated). Surgical removal of the affected anal sac is performed via closed anal sacculectomy. The size and

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

adherence of the mass to the surrounding tissues influence the technical difficulty of the surgery. By the time of diagnosis, most tumors have caused enough distortion and adhesion to the perineal tissues (i.e., external anal sphincter, rectal wall, caudal rectal nerve) to be significantly more challenging than anal sacculectomy for nonneoplastic causes. Removal of involved external anal sphincter muscle is tolerated with loss of up to two-thirds of the circumference of the anus, as well as the ipsilateral caudal rectal nerve, with most dogs regaining fecal continence after a variable period of transient incontinence. Some dogs may have bilateral anal sac adenocarcinoma, which requires meticulous surgical technique to preserve fecal continence.

The most common complication after surgical excision of anal sac adenocarcinoma is tumor recurrence, with rates up to 42–45% reported. Other less common complications include surgical site infection, hypocalcemia, tenesmus, perianal fistula, and death.

Prognosis

Postoperative adjuvant therapy in the form of chemotherapy and/or external beam radiation therapy is quickly becoming the standard of care as several reports have documented prolonged survival in patients receiving multimodal treatment. With surgery alone, reported median survival times range from 7.9 to 16.4 months. In dogs receiving postoperative adjuvant melphalan, median survival time was 20 and 29.3 months in dogs with and without sublumbar lymph node metastasis, respectively. Another study combing postoperative radiotherapy with mitoxantrone reported medial overall survival of 956 days with one- and two-year survival rates of 87% and 66%, respectively. A large (over 800 dogs) multicenter retrospective study in preparation at time of writing found prolonged median survival time (approximately five years) for dogs with sublumbar lymph node metastasis that were treated with surgery and chemotherapy, which was similar to the overall survival time for dogs without metastasis treated with surgery alone (J Liptak, personal communication).

Anal Sac Impaction

Clinical Presentation

Anal sac impaction is one of the most common rectoanal diseases in companion animal practice, and a very common cause for presentation of dogs in particular. The clinical signs are of tenesmus, "scooting," excessive licking of the perineum region, and pain on palpation of the anal sacs (which are distended). Overall, smaller breed dogs appear to be predisposed to anal sac impaction.

Pathophysiology

Impaction of the anal sacs can occur secondary to a variety of primary causes or inciting disorders. Inadequate emptying of the anal sacs may occur in obese dogs, dogs consuming "low-residue" diets with reduced fecal bulk, and in dogs with seborrhea (which results in increased secretion of the sebaceous glands within the anal sacs). Complications of anal sac impaction can occur, such as anal gland abscessation.

Diagnosis and Medical Management

In most cases, diagnosis and management of anal sac impaction is fairly straightforward. Diagnosis is based on palpation of the enlarged anal sac on routine physical examination. In many cases, diagnosis and management are concurrent, as the impacted sacs may be able to be gently manually expressed. Heavily impacted and painful glands may require sedation of the patient and irrigation of the sacs with saline. Uncomplicated cases are then managed by addressing diet, providing regular opportunities for the dog to defecate, and client counseling. Sacs that have become abscessed should be cultured and appropriate antibiotic treatment administered. Uninfected impacted anal sacs do not warrant antibiotic therapy.

Surgical Management

The decision to proceed with surgical intervention for anal sac impaction or abscessation is based on failure to respond to appropriate medical management, including lancing, flushing, culture and sensitivity testing, use of appropriate antimicrobials, and prevention of self-trauma (i.e., use of an Elizabethan collar). Surgical intervention generally consists of anal sacculectomy and may be performed unilaterally or bilaterally, depending on the patient's condition. When planning bilateral anal sacculectomy, it may be prudent to separate the two procedures by 2–4 weeks to allow any transient neuropraxia-related fecal incontinence to resolve before performing surgery on the contralateral side.

Anal sacculectomy for nonneoplastic disease can be performed using either an open or closed technique. With either method, the following principles apply: remove the entire gland such that no secretory epithelium remains in the patient; minimize trauma to the external anal sphincter muscle and avoid damage to the caudal rectal nerve (branch of the pudendal n.) to

prevent fecal incontinence; and ligate the anal sac duct near its opening, removing it *en bloc* with the gland itself. These goals are most readily achieved with the patient positioned in sternal recumbency in a perineal stand with the tail in an elevated position and an anal purse-string suture placed cranial to the opening of the anal sac ducts. If a closed technique is chosen, the anal sac itself can be distended with various materials (e.g., yarn, silicone sealant, Foley balloon catheter, plaster of Paris, agar base gel, dental molds, etc.) to facilitate palpation of the gland itself during dissection. Closure is typically performed in two layers; 3-0 or 4-0 monofilament absorbable suture for the subcutaneous tissues and either similarly sized nylon skin sutures or an intradermal skin closure can be used.

Prognosis

The prognosis for patients with anal sac impaction is generally excellent, regardless of whether they require surgical intervention or respond to medical management.

Atresia Ani and Rectoanal Strictures

Clinical Presentation

Atresia ani is the most common congential rectal/anal anomaly in dogs (Figure 57.1). Four types are recognized: type I (stenosis), type II (persistent anal membrane with the rectum ending immediately cranial to the imperforate anus), type III (as with type II but the rectum ends further cranially), and type IV (terminal rectum and anus may be normal but there is a discontinuity in the rectum with a blind pouch within the pelvic canal). These animals appear normal until 2–4 weeks of age at which time they become unthrify, anorexic, and restless with abdominal distension, possibly with perineal bulging.

Figure 57.1 Type II atresia ani in an 8-week-old mixed-breed puppy. Note the imperforate anus and absence of rectal lumen. This particular puppy presented later than is typical for this disorder due to the concurrent presence of a rectovaginal fistula that prevented colonic and rectal obstruction. Note also the abnormalities in vulval anatomy.

Rectoanal strictures appear to be more common in cats than dogs, but can occur in either species, most typically after trauma (iatrogenic or spontaneous). Clinical signs may vary depending on the underlying cause, but include tenesmus, dyschezia, hematochezia, and passing of ribbon-like feces. Megacolon is a possible sequel, especially in cats with chronic partial rectal narrowing (e.g., due to malunion after pelvic fractures).

Pathophysiology

The functional diameter of the distal colon, rectum or anus is reduced, due to either congenital (atresia ani) or acquired anatomic abnormalities.

Diagnosis and Medical Management

Atresia ani may be diagnosed at the time of birth, or in the neonatal period, with failure of the infant to defecate and possibly the development of abdominal distension. Later, adult-onset disorders are usually presented for constipation/obstipation, and can have a history of prior trauma or injury to the pelvis or perianal region.

Surgical Management

Atresia ani type I is treated with gentle bougienage. Type II and III atresia ani are treated surgically via a vertical incision at the anal dimple with caudal advancement of the rectum. The rectum is sutured to the skin at the level of the anus in two layers using 4-0 or 5-0 monofilament absorbable simple interrupted sutures. Dissection must be particularly gentle as the tissues are friable and every effort must be made to preserve the anal sphincter as well as opening to the anal sacs, both of which are typically normal and present. Animals with type IV atresia ani may require an abdominal approach with or without a pelvic osteotomy to access and anastomose the rectum.

Treatment chosen for anorectal strictures is dictated by the severity and location of the stricture. Mild cases may respond to bougienage, but more severe conditions may require surgical resection and anastomosis. However, recurrence of stricture after surgical resection and anastomosis, especially in cats, is relatively common.

Prognosis

Surgical repair of type I or II atresia ani often results in long-term survival and fecal continence. Patients with type III or IV atresia ani have poorer outcomes and the prognosis depends on the possibility of reconstructing the terminal rectum.

Prognosis following treatment for anorectal stricture largely depends on the underlying cause. Benign causes may carry a good prognosis but strictures associated with rectal adenocarcinoma are associated with a more guarded to poor prognosis. Surgical complications following rectal stricture resection and anastomosis may include dehiscence with sepsis and/or recurrence of stricture.

Constipation, Obstipation, and Megacolon

Clinical Presentation

Constipation and obstipation are both manifestations of difficult defecation, and fall within a spectrum of severities. Constipation is defined as difficult or effortful defecation, but feces is passed after some effort. Obstipation is a state of more severe constipation, and may result in intestinal obstruction. Both constipation and obstipation are the result of disorders in large bowel motility that slow fecal transit, but an implication of both diagnoses is that there is some degree of large bowel and rectal motility remaining. Obstipation should be treated aggressively, and the early use of promotility agents is recommended in many cases, as failure to restore functional motility in these patients can result in progression to megacolon, a state in which all large bowel and normal rectal motility is lost. Once established, megacolon is not effectively treated with laxative or prokinetic medications, as both of these families of medications require some degree of intrinsic motility in order to be effective.

Pathophysiology

Constipation and subsequent obstipation can result from any disorder or abnormality that slows fecal transit through the large intestine, decreases large intestinal and rectal motility, or mechanically obstructs passage of the fecal material to the rectum and anus. Slower passage of fecal material results in greater dehydration of the large intestinal content, as water absorption by the large intestinal mucosa continues unabated. Progressive overloading of the large intestine will eventually lead to large intestinal atony and flaccid paralysis, as seen with chronically obstructed urinary bladders. Similarly to the urinary bladder, loss of large bowel intrinsic motility is almost universally irreversible, resulting in megacolon.

Diagnosis and Medical Management

A history of unproductive straining or tenusmus, in concert with a readily palpable, heavily feces-laden large intestinal loop in the mid to distal abdomen, establishes a diagnosis of constipation readily. Differentiation of constipation/obstipation from megacolon can be more challenging, however. On plain abdominal radiographs, measurement of the maximal colon diameter:L5 vertebral body length ratio has been suggested as a method to help differentiate constipation from megacolon. A colon diameter:L5 length ratio of >1.48 has a sensitivity of approximately 77% with a specificity of 85% for establishing a diagnosis of megacolon. Similarly, a ratio of <1.28 is a strong indicator of a normal colon (sensitivity 96%, specificity 87%).

In patients where imaging findings do not suggest the presence of megacolon, medical treatment for constipation and obstipation is indicated. Particularly for patients with obstipation, it is critical to clearly indicate to the animal's owners that failure to treat effectively may lead to life-long, severe consequences.

Most uncomplicated cases of constipation can be treated with warm water, saline or water-lubricant enemas. Laxative medications, such as lactulose or emollient, paraffin-based products, can be trialed. The diet history should be considered, and addition of indigestible fiber as a bulking agent may be necessary. In patients with more severe disease, and definitely if constipation has progressed to obstipation, more aggressive treatment may be required.

Some patients with long-standing constipation/obstipation can present with quite severe dehydration, electrolyte, and acid–base abnormalities; this is particularly common in feline patients. Patients presenting with evidence of significant dehydration and fluid deficits should be stabilized with parenteral fluid therapy, possibly over 24 hours or more, before anesthesia for deobstipation and enema therapy. In these patients, the dehydration is more immediately life threatening than the fecal load, which has typically been present for days to weeks.

Patients with obstipation should be treated with prokinetic medications after obstipation is relieved. Unfortunately, only a small number of medications is available that may assist with large intestinal motility. Two medications with at least some evidence to suggest they are worth trialing are low-dose erythromycin and cisapride.

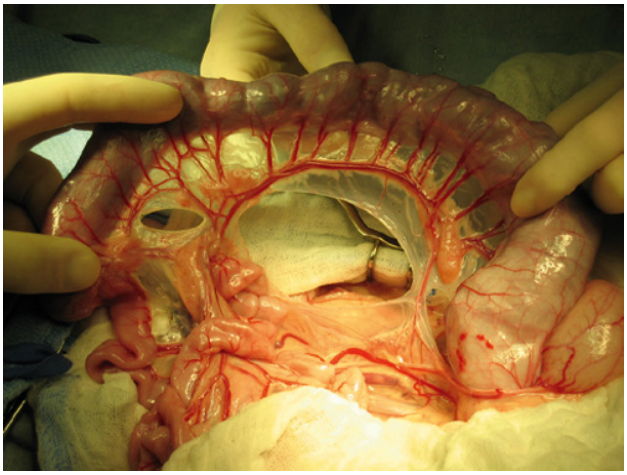

Figure 57.2 Intraoperative view of a severely distended and atonic colon in a feline patient with idiopathic megacolon. Patients in whom constipation and obstipation have progressed to this degree are best managed via subtotal colectomy.

Failure of medical management for obstipation is not uncommon, and likely reflects failure to recognize that the disease has already proceeded to megacolon. In patients that have proceeded to megacolon, surgical intervention is warranted (Figure 57.2).

Surgical Management of Megacolon

Megacolon should be treated via surgical subtotal colectomy once clinical signs progress beyond the ability of medical management to maintain the patient's quality of life. This is typically soon after diagnosis, as the condition is generally progressive and quickly becomes refractory to dietary modification, laxatives, prokinetics, and/or enemas. Although surgical treatment is essentially an intestinal resection and anastomosis, several anatomic factors combine to make this procedure significantly more challenging than a typical midintestinal resection and anastomosis. These include tension at the level of the ileocecocolic junction, lack of physical space to suture the aborad intestinal segment due to the bony pubis, a higher bacterial load within the colon compared to other segments of intestine, potential luminal disparity between the two segments of bowel to be sutured together, proximity to the ureters, and necessity for specific transection locations if preserving the ileocolic valve.

Surgical subtotal colectomy should aim to remove as much of the colon as possible to prevent recurrence. Some surgeons prefer to preserve the ileocolic valve with the idea that it may reduce duration of diarrhea postoperatively, as there is some support for this concept in the published literature. Regardless of whether the valve is removed or not, a transient period of watery to mucoid diarrhea postoperatively can be expected, lasting from several weeks up to three months. Various methods of anastomosis (end-to-end, end-to-side, side-to-side) have been described, including hand-suturing, GIA and TA stapling devices, transanal or transcecal circular end-to-end anastomotic stapling, and biofragmentable anastomotic rings. Excellent outcomes have been reported with all the above methods and the exact technique chosen should depend on the planned resection, surgeon experience, and equipment availability.

In cases of secondary megacolon due to pelvic canal narrowing, typically due to malunion following pelvic fracture, a pelvic osteotomy may be required. Duration of clinical signs has been associated with outcome, with cats that have had clinical signs for less than six months experiencing better resolution of constipation postoperatively. Cases with longer durations of clinical signs may require a combination of subtotal colectomy along with pelvic osteotomy to resolve their condition.

Prognosis

The long-term prognosis after surgical treatment of megacolon via subtotal colectomy in both dogs and cats is generally considered excellent, with four-year survival rates reported of 90–100%. Patients should be monitored for potential postoperative complications such as dehiscence with development of septic peritonitis, stricture, and/or recurrent constipation.

Perianal Fistulae

Clinical Presentation

Perianal fistulation, as the name implies, is the development of ulcerative, fistulated tissue tracts in the perianal skin. Owner history generally includes excessive anal and perianal licking, the presence of foul-smelling discharge, dyschezia, and tenesmus. Affected dogs are often extremely painful, and show a "dropped" tail posture. These patients often resent tail handling during physical examination, and may need to be deeply sedated or anesthetized to allow full examination. The perianal skin shows areas of ulceration and draining tract/fistula formation; these fistulas may extend up to 7 cm deep, and the entire circumference of the anus may be affected (Figure 57.3). Anal gland impaction and abscess formation are common co-morbidities, but they are not a prerequisite for development of this disorder.

Perianal fistulation can be a devastating disease, with some dogs showing altered temperament and increasing difficulty in handling due to ongoing pain.

Figure 57.3 Composite images of the perineum of an 8-year-old spayed female German shepherd dog with perianal fistula formation. The left panel shows the dog at diagnosis, while the right panel shows progress in resolution of the lesions at five weeks following commencing cyclosporin-A treatment. This dog also has an ulcerated perianal adenoma at the 12 o'clock position.

Pathophysiology

Perianal fistulae are most commonly encountered in the German shepherd dog, with over 80% of reported cases being in this breed. Sporadic cases are recognized in other medium- to large-breed dogs. This disease, in common with many of the apparently immune-mediated gastrointestinal diseases, is most commonly recognized in middle-aged to older dogs. In the German shepherd dog a linkage to specific major histocompatibility complex types has been documented. Recent work has suggested that the underlying genetic and immunologic defect in these dogs is similar to that underlying perianal fistula formation in some forms of Crohn disease in humans. The underlying pathology of this disorder is not well characterized in either the dog or humans. The disease is generally thought to revolve around inappropriate inflammatory response to commensal microbes on the skin or in feces, dietary components, or possibly to a combination of both immunogens. Approximately 50% of dogs with perianal fistula formation have concurrent colitis or both small and large intestinal inflammatory disease, suggesting the presence of a systemic dysregulation of gastrointestinal immune function.

Treatment Approaches

Both surgical and medical management approaches may be considered for dogs with perianal fistula formation, with some cases requiring a combined approach. The mainstay of therapy, though, remains immune modulation with ciclosporin or tacrolimus. If necessary and indicated, surgical removal of impacted or abscessed anal glands (see Anal Sac Impaction) and aggressive resection of fistulated tissue are associated with resolution of clinical signs in some dogs, and should be considered in dogs with deep fistulae and extensive disease.

Medical management of perianal fistula revolves around immune modulation therapy. Ciclosporin and tacrolimus, both of which block early T cell activation, are the mainstay drugs for medical management of this disease (Table 57.1). In one study, five of 10 dogs with anal fistulae treated with topical tacrolimus showed complete resolution of clinical signs at 16 weeks, while 9/10 showed at least "noticeable improvement." Interestingly, most of the dogs that failed to show resolution were sexually intact, and neutering/spaying is recommended as part of the treatment regime if not previously performed.

At least some dogs will respond to dietary modification following aggressive surgical resection, with one recent study of 33 dogs reporting 29/33 having complete resolution at one year following surgery when dogs were exclusively fed a fish- and potato-based hypoallergenic diet.

Pseudocoprostasis

Clinical Presentation

Pseudocoprostasis refers to the accumulation of fecal matter in the hair surrounding the anus. This condition is recognized in both dogs and cats, typically in long-haired breeds. Presenting complaints from owners are typical of rectal/anal disease, and include unproductive straining to defecate, tenesmus, dyschezia, excessive anal/perianal grooming, and a foul odor.

Table 57.1 Drugs commonly used in the management of rectoanal disease in the dog and cat

Agent	Indication	Typical dose	Administration notes
Anti-inflammatory, immune modulating			
Predniso(lo)ne	Chronic idiopathic inflammatory diseases	1–2 mg/kg/day, tapering to minimum effective dose	Counsel owner that withdrawal from high doses is risky.
Cyclosporin	Anal fistula	3–5 mg/kg SID	Tacrolimus is more expensive than cyclosporin, but topical use provides greater cost-effectiveness
Tacrolimus	Anal fistula	0.1% Topical ointment, cover affected area SID to BID	
Laxative			
Lactulose	Constipation	0.5 ml/kg TID	
Prokinetic			
Cisapride	Constipation, early megacolon	2.5–5.0 mg/cat TID	Pharmaceutical-grade cisapride is no longer marketed, but reagent-grade material remains accessible via compounding pharmacies
Prucalopride	Megacolon	Limited data available	$5–HT_4$ receptor agonist, potential replacement for cisapride

BID, twice a day (*bis in die*); SID, once a day (*semel in die*); TID, three times a day (*ter in die*).

This condition most commonly accompanies or follows the presence of diarrhea. Poorly formed stool accumulates and dries in the perianal hair, resulting in hair clumping and poor drainage of the underlying skin. Obstruction of the anal opening and pain due to pulling action on the hair result in distress on defecation and often lead to constipation.

Secondary perianal dermatitis is common, and increases the risk of maggot infestation.

Diagnosis is straightforward, and made entirely by physical examination. Clipping of the hair surrounding the anus to remove the dried fecal material is necessary to allow proper examination of the skin and anal glands, and is also fundamental to initial treatment.

Treatment Approaches

Clipping of the impacted hair mats and gentle cleaning of the perianal skin are typically all that is required for the treatment of uncomplicated cases. Attention to the cause of underlying diarrhea, and owner counseling to maintain grooming of the perianal skin and, for more chronic cases of diarrhea, regularly bathing the patient are important for longer term management and prevention of recurrence.

More complicated cases, featuring maggot infestation, deep pyoderma of the perianal skin or anal glad abscesses, may require additional topical medical or surgical management, as appropriate. The prognosis is good for full recovery, assuming that owners remain diligent in maintaining effective grooming.

Rectal Foreign Bodies

Clinical Presentation

Foreign bodies lodged in the rectum typically present with signs of constipation, including straining to defecate, tenesmus, and occasionally paradoxical diarrhea. The owner history may reveal evidence of foreign body consumption and bouts of vomiting or poor appetite in the prior several days. Very rarely, linear or penetrating foreign bodies are found in the rectal area, but most foreign bodies of this type cause signs in the more cranial segments of the gastrointestinal tract.

Pathophysiology

In most cases, the large intestine is obstructed by the foreign body, resulting in excessive fecal loading and constipation signs. Most rectal foreign bodies are objects (either food or toys/other foreign objects) that have been voluntarily consumed and pass through the gastrointestinal tract, before accumulating sufficient adherent firm material to obstruct in the rectum, often just cranial to the anal sphincter.

Diagnosis and Medical Management

Diagnosis is typically made on physical examination and palpation of the object. Once detected, most rectal foreign bodies can be removed readily using manual distraction and adequate lubrication. The patient should be

deeply sedated or anesthetized for these procedures. In some cases, foreign bodies can be broken up using rectally passed heavy forceps, aiding their eventual passage.

Surgical Management

Surgical management of rectal foreign bodies is not typically required as nonsurgical removal is almost always possible. In the event of rectal tears or trauma developing as a consequence of a rectal foreign body, surgical repair of the defects may be indicated (see Rectal Tears and Trauma section).

Prognosis

Most rectal foreign bodies are removed with minimal to no complications and prognosis is excellent.

Rectal Polyps

Clinical Presentation

Adenomatous rectal polyps are the most common benign tumor of the rectum. The most common site for these growths is at the terminal rectum or anorectal junction. Affected animals present with hematochezia, tenesmus, dyschezia, and/or diarrhea.

Pathophysiology

In dogs, most rectal polyps are thought to arise as a consequence of long-standing colonic and rectal wall inflammation. Fibrous proliferation of the submucosa results in the development of polypoid "proud" intrusions into the rectal lumen. The mucosa covering the polyps is usually also dystrophic, raising some concerns that these may be preneoplastic lesions. There is little support for this concern, however, with the great majority of these lesions being benign.

Diagnosis and Medical Management

Often, the primary presenting sign for dogs with rectal polyps is hematochezia, usually accompanied by tenesmus, but usually without other overt evidence of constipation. Many rectal polyps are located in the very distal rectum, 1–3 cm orad to the anal sphincter, and are readily palpable on digital rectal palpation.

Routine diagnostic imaging, including abdominal ultrasonography, usually has a low diagnostic yield for these lesions.

Proctoscopy/colonoscopy is very valuable in assessing these lesions, allowing visualization of the lesion base and extent for adequate surgical planning, and also to assess the remainder of the rectal mucosa and distal colon, as more than one lesion may be present. The rectum and distal colon are adequately assessed using rigid proctoscopes, and these instruments may also allow sufficient room for removal of pedunculated lesions using polyp snares. More complete examination of the entire colon requires the use of flexible colonoscopes and adequate preprocedural preparation, such as administration of oral laxative solutions and preanesthetic enemas (Figure 57.4).

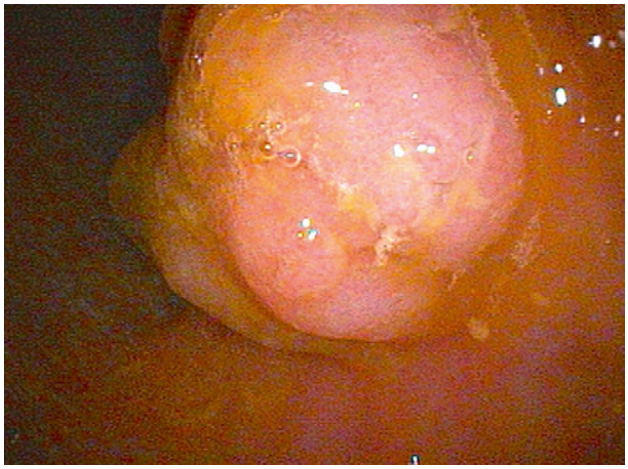

Figure 57.4 Endoscopic view of a benign rectal polyp in a dog. A large, semipedunculated mass is visible, and the mucosal epithelium is mildly disorganized and folded.

Medical management of rectal polyps can be attempted via diet modification (increasing indigestible fiber) and trial treatment with either oral or topical (via foaming enema) glucocorticoid administration. These strategies have variable, and usually poor, efficacy. Large polyps associated with frequent hematochezia and tenesmus are generally best managed via surgical removal.

Surgical Management

Most benign adenomatous polyps can be surgically removed via a transanal rectal eversion procedure (also called a "rectal pull-out"). Stay sutures are placed cranial to the lesion and used to prolapse the rectum around the mass. Metzenbaum scissors or a scalpel blade are used to resect the mucosa around the base of the tumor down to the muscularis, avoiding a full-thickness incision. The mucosal defect is sutured using monofilament absorbable suture in a single, simple continuous or simple interrupted layer. The mass should always be submitted for histopathology to confirm a benign tumor. Postoperative antibiotics are usually not indicated.

Some benign rectal polyps can be more extensive and warrant a more aggressive surgical approach. See the Rectal Tumors section for more details.

Prognosis

The prognosis for dogs with benign rectal polyps is good, but a regular monitoring schedule should be instituted to assess for recurrence and potentially progression of disease towards a malignant state. If caught early in the course of disease, lesions undergoing malignant transformation treated appropriately (e.g., carcinoma *in situ* resected with histologically complete surgical margins) can be successfully treated with good long-term survival.

Rectal Prolapse

Clinical Presentation

Depending on whether only anal mucosa is protruding or all layers of the terminal rectum are protruding as a cylindrical mass, rectal prolapse can be classified as either partial or complete, respectively. Most commonly occurring in younger animals, prolapse is typically a secondary condition, caused by tenesmus from presence of parasites, foreign bodies, or urogenital diseases.

Pathophysiology

Rectal prolapse is generally due to excessive straining, and may be seen in any patient that has an underlying disease that will result in tenesmus. Rectal prolapses are most commonly diagnosed in younger animals, likely reflecting the higher frequency of parasite infestation and other diarrheal diseases in these patients. Prolapse can also occur secondary to straining due to constipation, but this is less common than with the diarrheal diseases.

Following initial prolapse of the rectal mucosa, venous congestion of the prolapsed tissue will result in swelling. This swelling may actually increase straining, leading to a progressive worsening of the prolapse that can proceed to complete prolapse (Figure 57.5).

Figure 57.5 Rectal prolapse in a puppy with a history of diarrhea. Note the prolapsed, swollen mucosa with areas of drying and early devitalization. This dog was successfully treated with lubrication, gentle manual pressure to reduce the prolapsed tissue, and a purse-string suture.

Diagnosis and Medical Management

Although the diagnosis of a rectal prolapse may be straightforward, identification of the underlying cause may be more challenging. A thorough history and physical exam (including a well-lubricated digital rectal examination) are essential, with additional diagnostics to consider including fecal examination, complete blood count, serum biochemical profile, urinalysis ± culture, and abdominal imaging.

Initial treatment attempts are directed at lubrication of the prolapsed segment of rectum with manual replacement via digital pressure. Tissue edema can be reduced to aid with reduction by application of a topical 50% dextrose solution or live yeast cell derivatives (available for treatment of human hemorrhoids). An anal purse-string suture (nonabsorbable monofilament) is placed after reduction, tightened around a syringe case inserted into the anus to prevent overtightening. The suture is maintained for 3–5 days while the underlying condition is treated.

Surgical Management

For patients that have failed more conservative treatment as described earlier, or for those with prolapsed tissues that have undergone necrosis, surgical partial rectal amputation with or without colopexy may be indicated.

Surgical rectal amputation is performed in stages, using Metzenbaum scissors to resect the prolapsed necrotic portion of the rectum and anastomosing the cut section using monofilament absorbable suture in an interrupted or continuous pattern. The author prefers to perform this procedure in thirds, to prevent the cranial

end of the cut rectum from retracting prior to suturing. Three to five stay sutures placed cranial to the proposed site of resection help maintain exposure. Suturing should be performed in a single layer, ensuring each bite engages the submucosa to minimize risk of postoperative dehiscence, leakage, or stricture.

Colopexy may help prevent recurrence of rectal prolapse. In cats failing more conservative management (purse-string placement), because of a high rate of rectal stricture following circumferential rectal amputation, colopexy is preferred as long as the prolapsed tissue is considered viable. Two methods of colopexy have been described: nonincisional and incisional. Nonincisional colopexy uses two rows of five or six simple interrupted sutures between the antimesenteric colonic wall and the left abdominal wall. Incisional colopexy requires the creation of a linear incision in the serosamuscularis of the colon with a matching incision in the peritoneal lining of the left abdominal wall with two simple continuous suture lines joining the two incisions, similar to incisional gastropexy. In either technique, secure purchase of the colonic submucosa is important to ensure a successful colopexy. No differences have been reported in outcomes after either colopexy technique.

Prognosis

The prognosis depends on the underlying cause of the prolapse. Uncomplicated prolapse in young animals, often associated with gastrointestinal parasitism, is frequently responsive to minor therapeutic interventions (e.g., purse-string) and the prognosis can be excellent. More severe cases have necrosis of prolapsed tissue with significant underlying co-morbidities.

Rectal Tears and Trauma

Clinical Presentation

Rectal trauma causing perforation is a relatively rare condition that may result from pelvic fractures, foreign objects, iatrogenic causes (e.g., examination, thermometers, enemas, surgery), or penetrating wounds. Depending on the degree of rectal trauma and duration of injury, animals may present in varying degrees of septic shock and/or rectocutaneous fistulation.

Pathophysiology

Clinical signs develop from contamination of the perineal tissues with feces, leading to abscessation and/or sepsis. If a perforation occurs cranial to the retroperitoneal reflection, septic peritonitis may develop.

Diagnosis and Medical Management

Careful physical examination is the primary method for diagnosis of rectal trauma. Rectal tears are most commonly located in the distal (extraperitoneal) portion of the rectum. A complete blood count and serum biochemistry profile are recommended for patients suspected of sustaining rectal trauma. Diagnostic imaging (ultrasound and/or negative contrast pneumoradiography) can be performed to further characterize the defect.

Small, partial-thickness rectal tears will resolve with medical management. However, larger or full-thickness tears require prompt surgical intervention. Medical treatment with correction of electrolyte abnormalities, hypotension, and administration of appropriately targeted antimicrobials is important prior to surgery.

Surgical Management

The surgical approach used will depend on the location and extent of the tear. Transanal rectal eversion with stay sutures will allow access to distal tears, but larger defects will require a perineal approach (dorsal or lateral), possibly combined with an abdominal approach with or without pelvic osteotomy. Placement of drains is typically indicated to address perineal tissue contamination. Secure closure of the rectal wall, typically with monofilament absorbable suture in one or two layers, is of the utmost importance to resolution of the condition and ensuring a good long-term prognosis. Because a perineal surgical wound is typically heavily contaminated with feces, it may be partially closed or left open to heal by second intention.

Prognosis

Appropriately managed rectal perforations should heal with a good prognosis, but the patient may be threatened by concurrent trauma to other organ systems associated with the inciting cause of rectal perforation. Therefore, the prognosis depends on co-morbidities and aggressive management of polytrauma patients is recommended. If dehiscence of the rectal tear occurs, a rectocutaneous fistula may form which requires reoperation.

Rectal Tumors

Clinical Presentation

For the purposes of this chapter, rectal tumor is taken to refer to any neoplastic or hyperplastic process affecting the rectum or internal anus other than benign inflammatory polyps, which have been described separately.

The clinical signs accompanying rectal tumors are similar to most other rectal diseases, featuring histories of straining to defecate and occasionally the presence of narrow "ribbon-like" stool due to partial restriction of the rectal lumen. Hematochezia is variably present, depending on the involvement of the mucosa. Tumors such as adenocarcinoma and mucosal lymphoma often present with histories of hematochezia, while tumors affecting the muscularis and deeper mural layers, such as leiomyoma or GI stromal tumors, usually do not feature hematochezia.

Pathophysiology

Rectal tumors result from neoplastic or hyperplastic changes in normal tissue of the rectum or anal sphincter. Any of the various tissue types within the rectum can be involved (mucosa, secretory epithelia, smooth muscle, lymphoid tissue, etc.), but tumors affecting other than the epithelia (such as leiomyoma or GIST tumors) are uncommon. Of all the potential rectal tumor types, adenocarcinoma (possibly resulting from malignant transformation of rectal polyps) is the most common.

Diagnosis and Medical Management

Direct digital rectal examination will often reveal the presence of intrarectal masses, and may allow some determination of mucosal vs deeper mural location. Accessibility of mass lesions will depend upon the depth of the lesion within the rectum, the size of the animal and examiner's reach. Effective digital rectal examination often requires sedation of the patient, particularly with smaller animals.

Routine diagnostic imaging, such as abdominal radiography, has a low yield in the assessment of rectal tumors. Abdominal ultrasound examination can also fail to fully appreciate the size and location of rectal tumors within the pelvic canal. In patients where rectal malignancies are suspected, a combination of colonoscopy (allowing biopsy and assessment of the adjacent mucosa) and abdominal/pelvic CT examination (for staging, assessment of bone involvement and invasion into other pelvic organs such as the urethra or prostate) is generally recommended.

Medical management of nonpolypoid masses in the rectum is generally fruitless. Dietary change to "low-residue" diets and use of laxatives such as lactulose will improve clinical signs in some patients and can allow a degree of conservative management, but most patients will require surgical management for the best long-term treatment effect and prognosis.

Surgical Management

In preparation for surgery of the rectum, many surgeons recommend feeding a low-residue diet for 4–5 days preoperatively and avoiding enemas in the three days preceding surgery. Perioperative antibiotic cover typically consists of cephalosporins but some surgeons prefer metronidazole or other agents that may target colorectal anaerobic bacteria. The need for postoperative antibiotics depends on degree of contamination during surgery, but is typically not necessary beyond 24 hours postoperatively.

Rectal surgery can be divided into two general categories: procedures that can be performed from a perineal or transanal approach and procedures that require an intraabdominal approach. The first is the simpler and more commonly performed option. The exact distance accessible depends on the patient's size and should be assessed via digital rectal exam prior to deciding upon the approach. Transanal rectal eversion (i.e., prolapse; also called "rectal pull-out" procedure; Figure 57.6) using stay sutures allows access to tumors of the distal rectum. If not circumferential in nature, such tumors may be removed by scalpel blade and hand-sewing, or by use of a thoracoabdominal stapling device. For circumferential lesions, a transanal rectal pull-through resection and anastomosis may be performed.

The author prefers to transect and suture the circumference of the rectum in thirds, preventing the orad segment from retracting too far cranially. A grossly normal tissue margin of 0.5–1.0 cm is typically feasible with either transanal rectal eversion or transanal rectal pull-through. If larger margins are required based on preoperative diagnostics, a more aggressive surgical approach is required, as described below.

Figure 57.6 Early intraoperative view of a rectal pull-through procedure to remove a large, benign rectal polyp (2 cm diameter) in a Labrador retriever.

Surgical removal of tumors not confined to the distal rectum is performed via a perineal or anal approach, which can be combined with intraabdominal dissection to mobilize the descending colon along with the cranial end of the rectum. Preservation of the external anal sphincter muscle may be possible, depending on the tumor location and extent. Pelvic osteotomy techniques may need to be employed. This is an advanced procedure used for malignant tumors of the rectum (e.g., carcinoma) and can allow for removal of up to 6 cm of grossly normal tissue margins *en bloc* with the primary tumor, as well as extirpation of regional lymph nodes. Morbidity (especially fecal incontinence) and mortality with combined approaches can be significant but dogs surviving the postoperative period can experience long-term disease-free intervals.

Prognosis

Prognosis depends upon the histologic tumor type, margin status, and staging results. Benign tumors (e.g., adenomatous polyps, *in situ* carcinomas, leiomyomas) can be cured with surgical resection. Rectal lymphoma, although rare, carries a good prognosis following surgery and chemotherapy, with a reported overall median survival time of 1697 days. Canine rectal adenocarcinoma carries a worse prognosis, with reports ranging from six to 24 months, depending on staging and completeness of excision.

Dysbiosis and the Use of Pre-, Pro- and Synbiotics

Jan S. Suchodolski, MedVet, Dr Med Vet, PhD, AGAF, DACVM

College of Veterinary Medicine & Biomedical Sciences, Texas A&M University, College Station, TX, USA

The Importance of the Gastrointestinal Microbiota

The intestinal microbiota is the collection of all live microorganisms (bacteria, fungi, protozoa, and viruses) that inhabit the gastrointestinal (GI) tract. The word *microflora* is often used in older textbooks, but microbiota (from *bios*, Greek: life) is the technically correct term.

The total microbial load in the intestine is estimated to represent between 10^{12} and 10^{14} organisms, which is about 10 times the number of cells composing the host body. Because the majority of intestinal bacteria cannot be cultured using commonly used plating techniques, molecular tools (mostly targeting the 16S rRNA gene) are now the standard for identification of microbiota, and have improved our understanding of the complex microbial diversity in the intestine. It is estimated that the intestine harbors several hundred bacterial phylotypes. The microbiota differs substantially on the species and strain level in each individual animal yet despite these differences, the metabolic end-products in the intestine are similar between individuals. This new insight into the complexity and individuality of the gastrointestinal microbiota has increased research efforts to better understand the importance of a balanced microbial ecosystem for regulation of host immunity in health and disease.

The interactions between intestinal bacteria and the host immune system are mediated through various mechanisms, either via direct contact between bacteria and the innate immune system (e.g., via Toll-like receptors, NOD2 receptors), or through microbial-derived metabolites. These metabolites can be either directly produced by bacteria (e.g., vitamins, short-chain fatty acids [SCFA]), or may be primary host metabolites that are converted through bacterial enzymes into secondary metabolites (e.g., conversion of primary to secondary bile acids, tryptophan into indole). Consequently, many studies in humans and animals have associated intestinal dysbiosis, defined as alterations in intestinal microbiota composition and/or richness, with various disorders such as inflammatory bowel diseases (IBD), granulomatous colitis, obesity, diabetes mellitus, and allergies. For these reasons, the normalization of dysbiosis appears to be a prudent therapeutic goal.

The Gastrointestinal Microbiota in Healthy Dogs and Cats

We are just beginning to understand the complexity of the microbiota and are only at a very early stage in our abilities to properly assess the entire microbiota and its functions. The microbiota varies along the GI tract, and there are also clear differences between the mucosa-associated and luminal microbiota. Additionally, we are not yet able to fully assess the interactions between the microbiota and the host immune system. Several recent studies have described which bacterial groups reside in the GI tract of dogs and cats, and some initial work has been done to understand the metabolic interactions between microbiota and host.

Studies using traditional bacterial culture estimated that the bacterial load in the small intestine of healthy dogs is typically 10^2–10^5 cfu/g of small intestinal content, but can reach as high as 10^9 cfu/g. In the colon, the number of cultivable bacteria is much higher, with up to 10^{11} cfu/g. Molecular studies using high-throughput sequencing are now the standard for microbiota characterization and have identified many novel and important bacterial genera that were previously not appreciated in the canine and feline GI tract.

The predominant phyla in the feces of healthy dogs are Bacteroidetes, Firmicutes, Fusobacteria, and Proteobacteria. Lower abundance phyla (less than 1% of

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

the micriobiota) include Spirochaetes, Tenericutes, and Verrucomicrobia. The Firmicutes can be divided into several subgroups on a family and genus level. It comprises many phylogenetically distinct bacterial groups. These groups (e.g., *Ruminococcus* spp., *Faecalibacterium* spp., *Dorea*), together with Bacteroidetes and Actinobacteria (i.e., *Bifidobacterium*) are producers of metabolites that have direct impacts on host health. For example, bacteria can utilize complex carbohydrates (e.g., starch, cellulose, pectin, and inulin) as nutrient sources, and their fermentation produces SCFA (e.g., acetate, propionate, and butyrate). These act as energy sources for the host, regulate intestinal motility, and are important growth factors for epithelial cells. SCFA are also important antiinflammatory molecules, as they induce immunoregulatory T cells (T_{reg}). Other bacteria-derived metabolites, such as indoles (a byproduct of tryptophan degradation) or secondary bile acids, are also antiinflammatory, thereby maintaining immune homeostasis and strengthening intestinal barrier function.

The microbiota primes the immune system, aids in the defense against potential intestinal pathogens, and provides nutritional benefits to the host. Bacteria communicate with the host's innate immune system through cell-associated receptors such as Toll-like receptors (TLR) and dendritic cells. The resident intestinal microbiota is also a crucial part of the intestinal barrier, due to the phenomenon of "colonization resistance" which protects the host from invading pathogens through competition for oxygen, nutrients, and adhesion sites on the mucosa.

The Gastrointestinal Microbiota in Disease

There is clear evidence that altered microbial communities play a role in the pathophysiology of various disorders. Chronic dysbiosis is likely an important environmental risk factor for development of several chronic diseases in genetically susceptible individuals. For example, recent epidemiologic studies in humans have linked antibiotic administration in early childhood with an increased risk for development of allergies and obesity. Also, antibiotic-induced reductions in gut microbiota diversity were a risk factor for higher mortality outcomes in allogeneic hematopoietic stem cell transplantation. These initial data in humans suggest that dysbiosis is clinically relevant and the correction of dysbiosis would appear to be a prudent therapeutic goal. However, at this time, there are still only limited clinical data available to guide specific treatments for correction of dysbiosis in dogs and cats.

Dysbiosis occurs in various forms; it may be due to overgrowth of specific pathogens, or due to more general changes in bacterial groups, and/or changes in the functional and immunomodulatory properties of the gastrointestinal microbiota. All these forms overlap to some extent.

There are several physiologic mechanisms that regulate microbial colonization in the GI tract. Gastric acid, bile, and pancreatic enzymes all have antibacterial roles and eliminate a proportion of ingested organisms. Intestinal motility is an important regulator of bacterial adhesion to the mucosa in the small intestine. Microbes that are unable to adhere to the epithelium will be pushed to the large intestine, which has a more stagnant motility and therefore higher bacterial numbers. The ileocolic valve is a natural barrier that prevents retrograde migration of bacteria from the large to the small intestine.

Any changes in these mechanisms may lead to dysbiosis, but whether this leads to disease will depend on the susceptibility of the individual, as not every animal exposed to these risk factors will develop disease. For example, acid suppression therapy increases gastric and duodenal bacterial counts in humans, but not all patients show clinical signs. Similarly, dogs with experimentally induced exocrine pancreatic insufficiency (EPI) have increased bacterial numbers in the proximal small intestine. Rapid diet changes, dietary indiscretion, changes in the architecture of the intestine, or changes in intestinal motility (i.e., surgical creation of intestinal loops, short bowel syndrome, and resection of the ileocolic valve) are also associated with dysbiosis. The development of dysbiosis may then lead to changes in gastrointestinal physiology that will negatively impact function of the GI tract. Examples are an altered intestinal barrier with increased intestinal permeability and direct damage to the intestinal brush border and enterocytes leading to nutrient and vitamin malabsorption. An overgrowth in specific bacterial groups may lead to increased competition for nutrients and vitamins and to increased deconjugation of bile acids, resulting in the creation of potentially deleterious metabolites.

The intestinal microbiota also plays a role in the pathogenesis of IBD. Intestinal inflammation leads to a shift towards gram-negative bacteria (i.e., Proteobacteria) that may perpetuate the disease. Existing dysbiosis may trigger alterations in the immune system, which in turn diminish the colonization resistance of the resident microbiota. Several studies in dogs and cats have reported increases in Enterobacteriaceae in the GI tract of dogs and cats, and these are associated with inflammation and altered mucosal architecture. In contrast, a reduction in some major bacterial groups (i.e., Lachnospiraceae, Ruminococcaceae, *Faecalibacterium prausnitzii* and *Clostridium coccoides* subgroups) occurs in GI disease, suggesting a loss of normal and protective microbiota in GI disease (Figure 58.1).

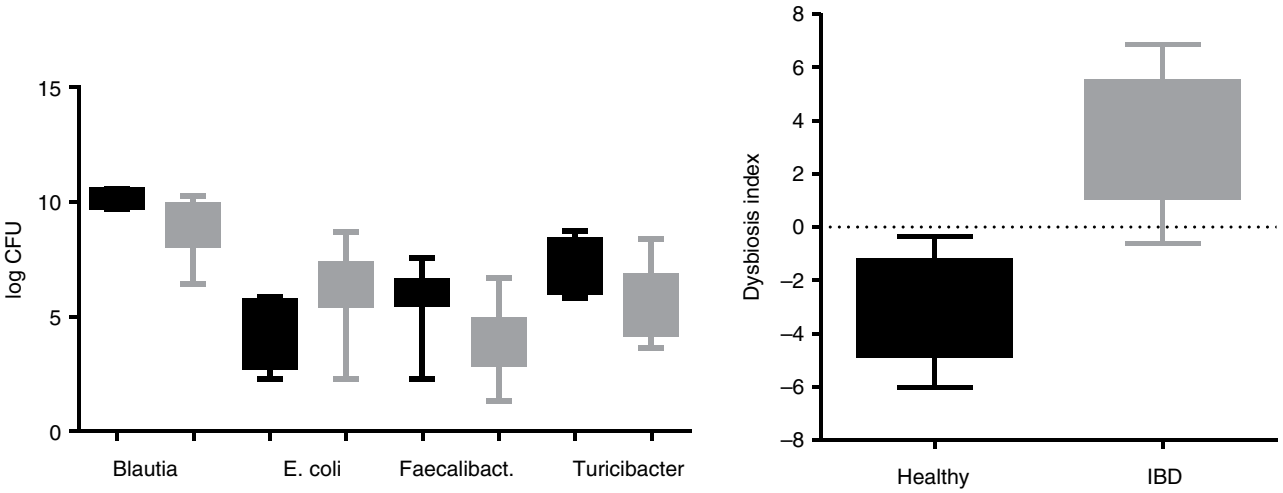

Figure 58.1 Dysbiosis in dogs with IBD. (*Left*) Several major bacterial groups are decreased in healthy dogs (*black*) vs dogs with IBD. In contrast, *E. coli* is typically increased in IBD. These data illustrate that IBD is associated with loss of normal and protective microbiota. (*Right*) The same data are displayed as an dysbiosis index (DI) that summarizes the abundances of these major bacterial taxa as one single numerical value (a positive number indicates dysbiosis).

These groups are mainly producers of SCFAs and other immunomodulatory metabolites. Consequently, decreased fecal propionate, reductions in secondary bile acids, and a reduction in indole concentrations are reported in dogs with acute and chronic diarrhea. This depletion of commensal groups and their respective immunoregulatory metabolites may impair the ability of the host to downregulate the intestinal immune response, and dysbiosis becomes a part of the pathophysiology of the chronic disease process.

Therapeutic Approach to Dysbiosis

As outlined earlier, the intestinal microbiota will affect the health status of the host, and shifts in bacterial groups have been associated with GI diseases such as antibiotic-responsive diarrhea and IBD. Dysbiosis is defined as an altered composition of the microbiota, yet some disorders may be associated with changes in microbiota function (e.g., reduced SCFA, altered bacterial enzymes) rather than shifts in microbial communities. These functional changes are difficult to detect, as there is no comprehensive method to assess the entire microbiota, including its metabolism and its interactions with the host immune system. The microbiota varies along the GI tract, and between mucosal and luminal sites. Because all these factors potentially play roles in the development of clinical signs, assessment of bacterial changes in intestinal (fecal) samples most often does not reveal the entire disease process. Nevertheless, it is now better understood which bacterial groups and which metabolites are commonly altered in GI disease.

The best therapy for dysbiosis is currently unknown. At this time, therapy is based on empirical approaches with improvement of clinical signs being the most useful outcome measure. Due to vast interindividual differences in the intestinal microbiota, it is difficult to define what constitutes a normal and balanced intestinal ecosystem. Dietary manipulation, the administration of antibiotics or pre- and/or probiotics are common strategies. It is important to note that while such interventions may cause shifts in the composition of the intestinal microbiota, these changes are largely individual to each animal. Clinical experience shows that dietary changes or antibiotic administration often lead to an improvement in GI signs, although the exact mechanism remains unclear. Antibiotics can eliminate specific pathogens or can lead to more general modulations of the intestinal microbiota. This may result in a lesser burden of stimulating antigens. While in some animals, the use of antimicrobials is useful (e.g., animals with ARD), their use may exacerbate dysbiosis in other GI diseases that do not respond to antibiotics. Recent epidemiologic studies in humans have suggested that the chronic use of antimicrobials is a strong risk factor for the development of asthma, obesity, and diabetes mellitus. Therefore, alternative approaches to antibiotic therapy to treat dysbiosis are desirable.

Probiotics, Prebiotics, and Synbiotics

Probiotics are currently defined as live microorganisms, which when administered in adequate amounts confer a health benefit on the host. Synbiotics are a combination of probiotics and prebiotics. They are often administered

together to add a growth substrate for the administered probiotic. Prebiotics are nondigestible food ingredients (e.g., fructooligosaccharides [FOS] and galactooligosaccharides [GOS]) that are added to diets to stimulate the growth of native probiotic bacteria. Prebiotics are typically added to diets to enhance the growth of endogenous microorganisms or stimulate their metabolism. The target groups for prebiotic administration, for example *Bifidobacterium* spp., were believed to be major bacterial groups in the canine and feline GI tract before the advent of molecular studies. However, only minor changes in microbiota are typically induced through prebiotics, as the administered compounds fulfill only some of the nutrient requirements for their target bacteria, and other essential nutrients remain at growth-limiting amounts. In addition, because of the individuality of the microbiota, not every animal will have the same bacterial strains and enzymes that are needed to utilize the administered prebiotics. Therefore, only a portion of animals will respond with increases in the targeted bacterial groups. It is also unclear whether the bacterial groups necessary for prebiotic utilization are present in animals with dysbiosis. Consequently, there are no published clinical studies that have evaluated prebiotics in animals with GI disease.

Prebiotics may be useful in stimulating the microbiota and immune system in healthy animals, but their benefit in animals with GI disease has not been widely explored. In contrast, more clinical data are available about probiotics (or synbiotics), and this will be discussed in more detail below.

Selection of Probiotics

The intestinal microbiota is an important modulator of the immune system. Administration of specific bacterial strains as probiotics can potentially mimic the effects of the normal microbiome. It is important that the clinician and client understand that every bacterial strain may differ substantially in its functional and immunologic properties. Therefore, not every strain will elicit the same response, and ideally strains are selected for the right disease and the right patient based on clinical studies. Information regarding strain designations is critically important in clinical studies, to be able to select the proper product containing the clinically tested strain. However, in veterinary practice there are few clinical data available. There are many commercial products available containing various strains that have not been tested in clinical studies.

In the US, probiotics are considered to be nutritional supplements and, therefore undergo little regulatory scrutiny. Unfortunately, many commercial products lack acceptable quality. For example, in one study almost 50% of products did not list any information about the organisms (i.e., did not provide the strain designation) and their numbers. Also most products did not contain the stated numbers of bacteria. Therefore, at this point it is recommended to only select probiotic products that have clinical and published data behind them.

There are only a few probiotic strains with extensive *in vitro* as well as clinical data (mostly in humans) published in primary literature (e.g. VSL#3 strains, *Lactobacillus* GG, *E. coli* Nissle, *Saccharomyces boulardii*). There are data available based on clinical studies in veterinary patients for the following products: *Enterococcus faecium* SF68 (Fortiflora®), Visbiome®, SIVOY®, and Proviable®.

Currently, selection of bacterial strains for most commercial probiotic products is mostly based on their ability to survive the passage through the stomach and small intestine, their ability to adhere to mucus, and *in vitro* immunomodulation. Furthermore, strains are selected that are on the safety list of the FDA, as these are approved for human and animal use, and no additional safety data are necessary. These strains are typically lactic acid bacteria (*Lactobacillus*, *Bifidobacterium*, *Enterococcus*, *Streptococcus*), as these bacterial genera were traditionally believed to confer health benefits. However, due to the complexity of the microbiota, there is no clear correlation between changes in these bacterial groups and health and disease. While lactic acid bacteria are still the most commonly used probiotic strains, in the future novel products may become available containing bacterial groups that are more abundant and depleted in GI disease (e.g., *Faecalibacterium*, *Blautia*, etc.).

The actual mechanisms through which probiotic strains can elucidate beneficial effects are numerous. Some probiotic strains have been shown to modulate the immune system, such as enhancing IgA production and pathogen phagocytosis and stimulating release of antiinflammatory cytokines. Other probiotic strains help to restore mucosal barrier function. Probiotics can also help protect the host from pathogenic bacteria through the production of antimicrobial substances, and through competitive exclusion of pathogens by preventing adhesion, occupying binding sites, or consuming vital nutrients.

While often probiotics are believed to modulate the intestinal microbiota, recent studies suggest that they have no appreciable effect on the overall composition of the intestinal microbiota, as only minor changes were observed in fecal samples in healthy as well as diseased dogs. Rather than changing the entire microbiota, some strains may adhere to the mucosa and directly communicate with the immune system; this has been shown for Visbiome strains in dogs with IBD. In order to impart a health benefit to the host, a probiotic must be able to

survive passage into the gut, adhere to epithelial cells, and proliferate within the GI tract. Even those probiotic strains that fulfill these criteria appear to colonize the GI tract for only relatively brief periods of time, and are usually eliminated within a few days after the end of administration. Therefore, if the goal of therapy is to have a long-term impact on the patient, long-term daily administration of probiotics in high doses is required.

Clinical Data on Probiotics in Veterinary Medicine

In veterinary medicine, we are currently lacking well-designed, properly powered studies that have been reproduced by independent research groups. There are, however, some promising data on a variety of probiotic preparations. These include the prevention and treatment of antibiotic-associated or stress-related diarrhea (boarding, traveling, working dogs), and the prevention and treatment of gastrointestinal signs during periods of dietary change (weaning in puppies and kittens, new diets). Recent studies have also shown antiinflammatory properties of some probiotics in dogs with IBD.

The greatest amount of data is available for amelioration and/or shortening of acute diarrhea. In a large double-blind, placebo-controlled study of shelter cats, significantly fewer animals (7% vs 20% in the placebo group) that received *Enterococcus faecium* SF68 (Fortiflora, Purina; 2 billion cfu/day) developed diarrhea for greater than a two-day duration. Similarly, administration of *Bifidobacterium animalis* strain AHC7 (Prostora®, IAMS; 100 billion cfu/day) to dogs with acute idiopathic diarrhea reduced the time to resolution by 2.5 days and decreased the percentage of dogs that required adjunctive use of metronidazole (38% vs 50% in the placebo group). Probiotic strains (450 billion cfu/day; Visbiome, Exegi Pharma) led to lower mortality when given to puppies with confirmed parvoviral enteritis (90% vs 70% in the placebo group).

Fewer published studies are available regarding dogs with chronic enteropathies (CE). A probiotic cocktail (200–400 billion cfu per dog per day; Visbiome, Exegi Pharma) has been trialed in dogs with idiopathic IBD. Clinical activity and histology scores were reduced similarly to dogs treated with standard therapy (prednisone and antibiotics). Furthermore, the probiotic induced regulatory T-helper lymphocytes (FoxP3) and protein expression that were associated with enhanced mucosal barrier function. In cats, one published open-label trial assessed the use of a multistrain synbiotic product containing lactic acid bacteria and a blend of fructo- and galactooligosaccharides (5 billion per day; Proviable-DC, Nutramax Laboratories) and reported that 72% of owners perceived an improvement in their cat's diarrhea following a 21-day course of supplementation.

Generally, it is believed that prophylactic administration of probiotics may be a more successful strategy for prevention of GI disease. Experimental studies in animal models have consistently shown that probiotic administration before induction of inflammation has a higher success rate compared to therapeutic administration. However, this approach is often not practical in clinical medicine. Also, it is not clear whether long-term administration of probiotics to healthy animals is useful. But if trigger episodes for diarrhea are anticipated, prophylactic administration of probiotics may be prudent. Also, antibiotics induce dysbiosis and may lead to diarrhea, and this is an area where probiotics may be especially useful. For example, administration of *Saccharomyces boulardii* to dogs with experimental lincomycin-induced diarrhea prevented the development of diarrhea, but was not successful in treating diarrhea once it developed.

Safety of Probiotics

Theoretically, probiotics have the potential to cause systemic infections; they can produce deleterious metabolites and can transfer antibiotic resistance genes. However, side-effects are very rarely reported. A limited number of case reports in humans have shown that probiotics (i.e., *Lactobacillus* spp.) can potentially translocate and cause septicemia in hospitalized patients. A study in humans with severe pancreatitis found increased mortality with probiotic therapy. It is currently recommended that probiotics should be used with caution in immunocompromised patients.

Concurrent Antibiotic Use

Probiotics, like any other bacteria, can be either susceptible or resistant to concurrently administered antibiotics. For the prevention of antibiotic-associated diarrhea, antibiotics and probiotics are prescribed concurrently. Many of the prescribed bacterial groups such as *Lactobacillus*, *Enterococcus*, and *Bifidobacterium* spp. are generally resistant to commonly used antibiotics such as metronidazole and tylosin. Therefore, concurrent administration should be acceptable. For other antibiotics, it may be useful to separate antibiotic and probiotic administration by a few hours if feasible.

Species Specificity of Probiotics

There is some thought that a probiotic should be species specific (i.e., the probiotic strain has been isolated from

the same animal species that it will be used in). This theory is based on the fact that the intestinal microbiota differs between different animal species. Furthermore, a host-specific probiotic may be better adapted to its target organism (e.g., stomach pH, bile acid composition, adherence to epithelial cells). However, while it is known that the resident microbiota differs between different animal species, it has never been demonstrated that probiotic effects are species specific. The microbiota differs dramatically even within animals of the same species, so the concept of a species-specific probiotic may not be entirely accurate. Several *in vivo* (based on animal models) and *in vitro* (based on the adherence to epithelial cells) studies have shown that human and canine probiotics are capable of conferring a health benefit to other animal species.

Diagnosis and Management of Chronic Enteropathies

Karin Allenspach, Dr Med Vet, PhD, Diplomate ECVIM-CA

College of Veterinary Medicine, Iowa State University, Ames, IA, USA

Definition

Chronic enteropathies (CE) are a group of idiopathic intestinal disorders characterized by chronic persistent or recurrent gastrointestinal (GI) signs, with histologic evidence of inflammation in the lamina propria of the small intestine, large intestine, or both. The diagnosis of CE is one of exclusion and a full diagnostic work-up needs to be done to rule out all known causes of GI inflammation. Currently, endoscopic evaluation and histopathology of intestinal biopsies is the only way to definitively diagnose CE. Although the exact etiology of CE is unknown, it is widely accepted that the pathogenesis involves a complex interplay among host genetics, the intestinal mucosal immune system, the environment, and the intestinal microbiota.

Classification of Chronic Enteropathies

Chronic enteropathies are classified according to the inflammatory cell present and the area of intestine affected, the most commonly encountered CE being lympho-plasmacytic enteritis in both dogs and cats. Eosinophilic enteritis is thought to be the second most common CE, while granulomatous enteritis is rare. Neutrophilic infiltration is also rare in both canine and feline inflammatory gastrointestinal disease.

Clinically, CE patients can be classified retrospectively depending on their response to treatment. The most common recommendation for these patients is to apply a sequential approach to treatment, with the goal of identifying groups of dogs that respond to a certain treatment. Those responding entirely to an elimination diet or a hydrolyzed diet are diagnosed as food-responsive diarrhea (FRD). Those responding to antibiotics are classified as antibiotic-responsive diarrhea (ARD), and CE patients that do not fall into either of these two categories and require immunosuppressive medication to control their clinical signs are commonly classified as having steroid-responsive diarrhea (SRD). As patients with SRD have, ideally, undergone a thorough work-up to exclude other known causes for intestinal inflammation, these patients can also reasonably be diagnosed as having idiopathic inflammatory bowel disease, or IBD.

Certain breeds are highly susceptible to the development of specific unique forms of inflammatory enteropathies; examples include the immunoproliferative enteropathy of basenjis, the protein-losing enteropathy (PLE) and protein-losing nephropathy (PLN) complex in soft-coated wheaten terriers, IBD with PLE in Norwegian lundehunds and granulomatous colitis in boxer dogs.

Etiopathogenesis

In the last few decades, the study of human IBD and animal models of this disease has led to significant advances in our understanding of the pathogenesis of CE in companion animals. These studies have shown that the pathogenesis is complex, involving an overly aggressive cell-mediated response due to the loss of tolerance to antigens of the commensal microbiome and food antigens in genetically susceptible hosts (Figure 59.1).

Genetics

The heritability of human IBD is not fully understood. Genome-wide association studies have revealed over 200 loci that are variably associated with the development of the disease. It is therefore believed to be an autoimmune disease with polygenetic inheritance. Most loci that have been found to play a role in the pathogenesis of human IBD can be traced to proteins in the innate immunity pathways, as well as some involved in autophagy and

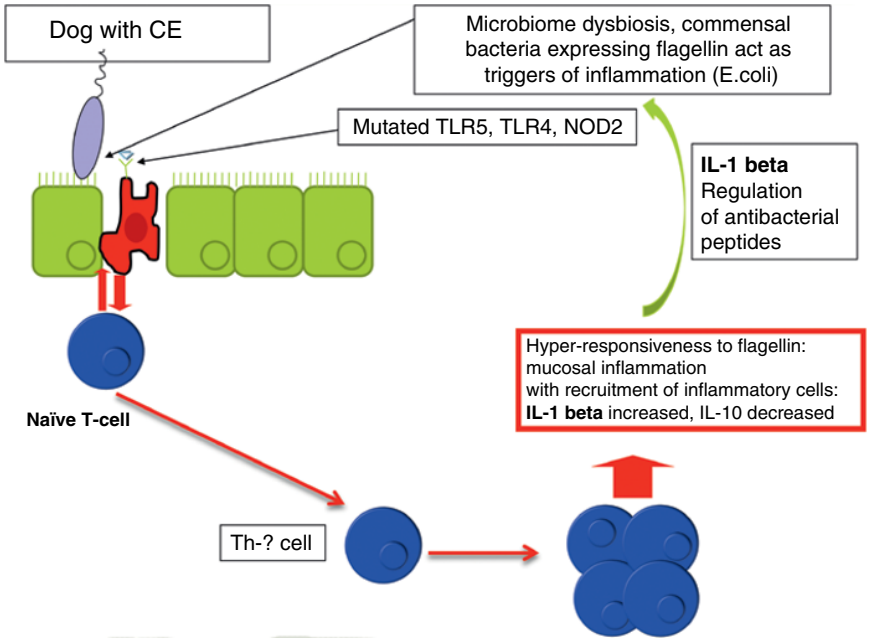

Figure 59.1 Current hypothesis of pathogenesis of CE in dogs. Genetic mutations in pattern recognition receptors of the innate immune system, such as Toll-like receptors, render the intestinal immune system hyperresponsive to commensal bacteria. This leads to danger signals being transferred to T cells in the lamina propria, resulting in increased production of proinflammatory cytokines such as IL-1-beta and decreased production of anti-inflammatory cytokines, such as Il-10. This in turn leads to microbial dysbiosis, which intensifies the trigger for further inflammation.

Th17 cell pathways. These pathways are at the center of gut mucosal immunology, and have led to the discovery of novel biologic treatment options in people with IBD.

The mode of inheritance of CE in companion animals is also incompletely understood, and may differ between dogs and cats and across breeds. A number of breed predispositions have been described in canine CE, thus strongly supporting a role for host genetics. However, few causal genetic defects have been identified to date.

Using candidate gene analysis, polymorphisms in certain pattern recognition receptors of the innate immune system (such as Toll-like receptor [TLR] 4 and TLR5) were shown to be significantly associated with CE in German shepherd dogs (GSDs). In addition, the same polymorphisms in TLR5 were associated with IBD in a heterogeneous population of dogs consisting of 38 different breeds. However, as in human IBD, it is likely that defects in multiple genes involving several regulatory pathways are needed to bring about disease. Therefore, further genetic studies such as genome-wide association are needed in both canine and feline IBD to highlight the complex pathogenesis of this disease.

The Intestinal Mucosal Immune System

The concept that immunoregulation is impaired in patients with CE is supported by observations of increased numbers of immunoglobulin-producing plasma cells and T cell subsets in canine and feline IBD. Inflammation seen in CE is thought to result from the inappropriate cytokine production by these different T cell subsets. In people, Crohn disease (CD) is associated with a Th1 and Th17 cytokine profile and ulcerative colitis (UC) with a Th2 profile, whereas in dogs there is a mixed Th1 and Th2 profile, with no specific bias towards one or the other. Th17 cells seem to play an important role in human IBD, with interleukin (IL)-17 and IL-22 being highly expressed in the intestinal mucosa. However, in dogs, Th17 cell cytokines were not found to be elevated and therefore are believed to be of minor importance. One newer study identified that an innate cytokine, IL-1-beta, was expressed at higher levels in canine FRD cases, and decreased after successful treatment with dietary measures. More studies are needed to investigate this important pathway in canine CE. In cats, the inflammatory infiltrate has been shown to be associated with increased IL-1, Il-8, and IL-12 expression, and correlated with clinical severity of disease and mucosal adherence of bacteria, especially Enterobacteriaceae, *E. coli*, and *Clostridium* spp.

Other immunologic components may also play a role in the inappropriate inflammation seen in a subset of dogs with CE. Indeed, one study demonstrated that CD11c-positive dendritic cells (DCs) were significantly decreased in the intestinal mucosa of dogs with IBD. DCs are important in regulating the immunologic balance and are responsible for eliciting either an inflammatory or a tolerant immune response to an antigen. Thus, a decrease in the number of DCs in the inflamed mucosa of dogs with CE may explain the exaggerated inflammation seen in this disease.

The Intestinal Microbiota

The importance of commensal bacteria in the pathogenesis of human IBD has been well documented in animal

models. Chronic intestinal inflammation does not develop in mice reared in germ-free environments. In addition, the role of luminal bacteria in the pathogenesis of human IBD is strongly supported by the fact that clinical symptoms improve following intestinal washes and antibacterial treatment. Similarly, a subset of canine IBD patients (ARD patients) respond solely to antibiotics with subsequent relapse of clinical signs on withdrawal. This notion, in addition to recent discoveries of genetic mutations rendering pattern recognition receptors hyperresponsive to bacteria in the intestinal lumen, makes it likely that the microbiome plays an important role in canine and feline CE as well.

In recent years, investigation into the microbiome of the intestine has moved away from bacterial culture, but has used molecular methods such as polymerase chain reaction (PCR) to determine the variety and species present in the sample. Using such molecular methods, the microbiome of people with IBD was found to be of decreased complexity compared to samples from healthy controls. Similarly, the species richness in the duodenal lumen of dogs with IBD is reduced. Some species are also found to be significantly over- or underrepresented compared to healthy controls, such as a reduction in members of the phyla Bacteroidetes and Firmicutes, whilst there is an abundance of *E. coli*. Dogs with CE also exhibit a dysbiosis, with an abundance of members belonging to the Enterobacteriaceae family. In addition, dogs with CE have significantly higher number of clones belonging to Proteobacteria and a significantly lower abundance of Clostridia. Therefore, the compositional changes of the microbiota seen in CE emphasize the role of bacteria in this complex disease and may well contribute to ongoing inflammation.

Epidemiology

Few larger studies of CE in dogs are available which can be used to predict treatment responses in clinical cases. One larger study, with over 70 cases, has shown that about 60% of cases seen in a referral population are FRD, and that these dogs go into remission very quickly, within about 10–14 days of starting dietary intervention. FRD dogs also seemed to be more commonly younger, large-breed dogs with colitis signs. The other groups in this study consisted of about 30% of dogs that responded to steroids, and about 10% that were steroid resistant and needed rescue treatment with cyclosporin. A newer study comprising over 200 dogs at another referral center confirmed these findings, with about 65% of dogs in the FRD group, 16% in the ARD group, and 19% in the SRD group. Outcome was significantly better in FRD groups at various time points over a year after diagnosis, and the worst outcome was seen in the ARD group. The latter was probably due to relapses being very common in ARD dogs, as their clinical signs invariably flare up when antibiotics are discontinued. Furthermore, clinical severity indices were lowest in the FRD groups and serum albumin concentrations were lowest in the SRD groups, which are known predictors for outcome.

History, Clinical Signs, and Diagnostic Work-Up

Faced with a small animal patient exhibiting signs of possible intestinal disease, the first differentiation should be to establish whether it is an acute or chronic disease. Diarrhea, vomiting, dehydration, weight loss, lethargy, and melena can all be signs of small intestinal disease. The disease is acute if the signs have been present only for a few days, but if disease persists for more than three weeks and/or is intermittently present for more than three weeks, it is defined as chronic.

The next step in taking a thorough history is to determine whether the animal shows signs of small intestinal, large intestinal or mixed diarrhea (Table 59.1).

Diagnostic Work-Up of Chronic Small Intestinal, Large Intestinal or Mixed Diarrhea

Once the clinical signs have persisted for more than three weeks, more work-up is required in order to investigate the correct diagnosis. In chronic cases, it is more common for systemic, nongastrointestinal problems to cause the signs, and therefore the first diagnostic steps must be directed at excluding these extragastrointestinal causes (Box 59.1).

The use of clinical severity indices such as the Canine Chronic Enteropathy Clinical Activity Index (CCECAI)

Table 59.1 Differentiation of small intestinal and large intestinal diarrhea according to clinical signs

	Small intestinal	Large intestinal
Volume	xxx	x
Mucus	–	xxx
Frequency	x	xxx
Tenesmus	–	xxx
Dyschezia	–	xxx
Weight loss	–	xxx
Vomiting	x	x
General condition	xxx	–

Box 59.1 Causes of intestinal disease

Causes of chronic small intestinal disease

Extragastrointestinal (metabolic) causes
- Hepatic disease (portosystemic shunt!)
- Hyperthyroidism (cats)
- Addison disease (dogs)
- Renal insufficiency
- Pancreatic
- Exocrine pancreatic insufficiency (EPI)
- Chronic pancreatitis

Gastrointestinal causes
- *Giardia* infection, *Tritrichomonas* infection (cats)
- Chronic partial obstruction
- Lymphangiectasia
- Neoplasia: lymphosarcoma
- Food intolerance/food allergy
- Chronic enteropathies/inflammatory bowel disease
  - Eosinophilic
  - Lympho-plasmacellular

Causes of chronic large intestinal disease

Gastrointestinal causes
- *Giardia* infection, *Tritrichomonas* infection (cats)
- Chronic partial obstruction
- Neoplasia: adenocarcinoma, lymphoma
- Polyps
- Food-responsive diarrhea
- Chronic enteropathies/inflammatory bowel disease:
  - Eosinophilic
  - Lympho-plasmacellular
  - Granulomatous

is recommended for all patients at the time of work-up (Box 59.2).

These indices are easily calculated by adding up severity of clinical signs and can give valuable prognostic information. A CCECAI of >12 has been shown to be associated with a much worse clinical prognosis. In these cases, an abbreviated clinical work-up with endoscopy being scheduled earlier, as well as early aggressive treatment, may be indicated.

The diagnostic assessment of chronic gastrointestinal inflammation involves exclusion of other potential causes of the gastrointestinal signs, and thus a full diagnostic work-up needs to be done to rule out all known causes of extragastrointestinal inflammation first. Commonly, this involves complete blood cell count, serum biochemical analysis, urinalysis, and fecal analysis for helminth and protozoal parasites (such as *Giardia*; in addition *Tritrichomonas* in cats should be considered). Further blood tests are indicated if none of the following tests shows any abnormalities: trypsin-like immunoreactivity to exclude exocrine pancreatic insufficiency, pancreatic lipase immunoreactivity (Spec-cPL, Spec-fPL for dogs and cats respectively) to assess the possibility of pancreatic disease, ACTH test or basal cortisol concentration to exclude hypoadrenocorticism and cobalamin concentrations to assess the absorptive function of the distal small intestine. Total T4 and FeLV/FIV should also be assessed in cats. Abdominal ultrasound will be most helpful to determine whether the small and/or large intestine is affected and if there are any mass lesions that need surgical intervention rather than endoscopic evaluation. In the case of PLE, specific findings on ultrasound, such as speckles in the mucosa, can also be useful additional information.

If the results of these tests do not point to an obvious cause for the clinical signs and the patient is stable (i.e., has a normal appetite, good attitude, not lethargic, no to minimal weight loss, normal serum protein concentration with no intestinal thickening on diagnostic imaging) then a well-conducted therapeutic trial with an elimination diet or hydrolyzed diet for at least two weeks can be performed. If there is no response to a trial within two weeks after starting the diet, it is unlikely that the patient is suffering from food-responsive disease (food allergy or food intolerance). Intestinal biopsies for histopathology are collected from those patients that fail to respond to empirical therapy or that are showing worsening of their clinical signs. Most patients with chronic enteropathies can be diagnosed by obtaining endoscopic biopsies, as long as at least 12–15 biopsies from the duodenum, ileum, and/or colon are taken. It is important to realize that good-quality biopsies are critical in order for histopathology to be useful, so more than 10 biopsies per site are usually recommended to make a diagnosis. In some rare cases, a diagnosis of lymphoma can be missed if no full-thickness biopsies are obtained, especially in cats and if the ileum has not been sampled.

Serum and Fecal Markers of Disease

Serum Albumin Concentrations in Dogs

Decreased serum albumin concentrations have been identified as a negative prognostic indicator in both retrospective and prospective studies of canine IBD. PLE accounts for the loss of albumin through the gut mucosa in severely affected dogs with IBD. PLE in dogs can be associated with severe lympho-plasmacytic IBD, intestinal lymphoma, or, rarely, primary lymphangiectasia. One study described 12/80 (16%) dogs with hypoalbuminemia and 4/80 (5%) dogs with panhypoproteinemia.

Box 59.2 Canine Chronic Enteropathy Clinical Activity Index (CCECAI)

Attitude/activity
0 = normal
1 = slightly decreased
2 = moderately decreased
3 = severely decreased

Appetite
0 = normal
1 = slightly decreased
2 = moderately decreased
3 = severely decreased

Vomiting
0 = normal
1 = mild (1× per week)
2 = moderate (2–3× per week)
3 = severe (>3× per week)

Stool consistency
0 = normal
1 = slightly soft feces or fecal blood, mucus or both
2 = very soft feces
3 = watery diarrhea

Stool frequency
0 = normal
1 = slightly increased (2–3× per day)
2 = moderately increased (4–5× per day)
3 = severely increased (>5× per day)

Weight loss
0 = none
1 = mild (<5%)
2 = moderate (5–10%)
3 = severe (>10%)

Albumin levels
0 = albumin >20 g/L
1 = albumin 15–19.9 g/L
2 = albumin 12–14.9 g/L
3 = albumin <12 g/L

Ascites and peripheral edema
0 = none
1 = mild ascites or peripheral edema
2 = moderate amount of ascites/ peripheral edema
3 = severe ascites, with pleural effusion and peripheral edema

Pruritus
0 = no pruritus
1 = occasional episodes of itching
2 = regular episodes of itching, but stops when dog is asleep
3 = dog regularly wakes up because of itching

Score:

Total score 0–3 Clinically insignificant	Total score 4–5 Mild disease	Total score 6–8 Moderate disease	Total score 9–11 Severe disease	Total score ≥12 Very severe disease

Seven of these 12 dogs were eventually euthanized due to intractable IBD, identifying decreased serum albumin concentrations as one of the major risk factors associated with a poor outcome. In another recent prospective study, 12/58 (21%) cases initially presented with hypoalbuminemia. Of these 12 dogs, seven were panhypoproteinemic with severe hypoalbuminemia (mean albumin level 1.1 g/dL) and three of those were eventually euthanized. However, it is important to note that relatively mild reductions in serum albumin (>2.0 g/dL) were already associated with an increased risk of refractoriness to treatment. At this level, most patients will not yet show any clinical signs of hypoalbuminemia, such as ascites, peripheral edema, or pleural effusion, but are already at risk of euthanasia because of intractable disease.

Another study found that severely hypoalbuminemic dogs that had failed to improve on immunosuppressive doses of steroids were successfully treated with cyclosporin. This suggests that early aggressive treatment in hypoalbuminemic dogs may potentially decrease mortality rates in severely ill animals. Serum albumin concentrations can also be a good measure of monitoring such patients, as improvement of serum albumin concentrations above 2.0 g/dL usually indicates treatment success, even if clinical improvement has been seen earlier in some of these cases. It is therefore recommended to serially evaluate serum albumin concentrations every 2–3 weeks in order to assess when treatment can be tapered off or discontinued.

Serum Albumin Concentrations in Cats

There is not much published information available regarding serum albumin concentrations in cats with chronic intestinal disease. PLE as a clinical syndrome likely does not exist in cats, as clinical signs such as ascites and peripheral edema do not usually occur in cats with hypoalbuminemia due to intestinal disease. In addition, the hypoalbuminemia seen in such cases is usually mild. However, there is accumulating evidence that cats with chronic intestinal disease and decreased albumin serum concentrations may have concurrent pancreatic disease.

In one recent retrospective study, cats diagnosed with IBD and serum feline pancreatic lipase (Spec-fPL) concentrations ≥12.0 µg/L had a lower median serum albumin concentration than cats with IBD and a normal Spec-fPL concentration. Further analysis in this study did not identify hypoalbuminemia as a predictor of negative outcome on survival.

Therefore, hypoalbuminemia in cats with chronic intestinal disease should prompt the clinician to measure Spec-fPL concentrations and/or to perform abdominal ultrasound examination in order to evaluate any concurrent pancreatic disorders. Depending on the severity of the hypoalbuminaemia, the clinician's approach to treatment might be altered.

Serum Cobalamin Concentrations in Dogs and Cats

Serum cobalamin concentrations should be measured in any small animal patient with chronic intestinal disease. As cobalamin is absorbed in the ileum, decreased serum cobalamin concentrations are most commonly seen when this part of the small intestine is affected. However, absorption of cobalamin also involves intrinsic factor, which in dogs and cats is mainly produced in the pancreas. This is the reason why most small animals with exocrine pancreatic insufficiency will have low serum cobalamin concentrations. Furthermore, serum cobalamin concentrations have been shown to be a negative prognostic factors in dogs with CE. If cobalamin serum concentration is below the reference range, the risk for later euthanasia increases to a factor of 10. It is therefore important to supplement dogs with hypocobalaminemia while they undergo treatment for IBD, as this risk of euthanasia can be reversed by supplementation.

Serum cobalamin concentration has long been known to be an important negative prognostic factor in cats with chronic enteropathies. The prevalence of decreased serum cobalamin concentrations in cats with chronic gastrointestinal signs has been reported to be 16–60%. In cats, it has also been reported that cobalamin supplementation can improve clinical signs regardless of the underlying diagnosis and even if given as the sole treatment for their disease. It is therefore recommended that cats with chronic intestinal disease be supplemented with cobalamin regardless of whether a specific cause for the disease can be identified. Recent studies have also shown preliminary data indicating that cobalamin can be given orally to supplement deficiencies. However, large amounts have to be given by this route of administration and concentrations decreased much more rapidly after discontinuation of oral treatment, compared to injectable forms.

Supplementation Recommendations for Cobalamin

Supplementation of cobalamin should be given parenterally (SC) as a weekly injection for at least six weeks. Exact dosages are not reported, as it is a water-soluble vitamin and cannot be overdosed. For tested recommendations, please visit the website of the Texas GI lab (http://vetmed.tamu.edu/gilab).

Canine Pancreatic Lipase

Canine pancreatic lipase (now measured with the Spec-cPL assay) has recently become available as a commercial test and is useful in the assessment of possible pancreatitis in dogs. However, it can also be elevated in dogs with a primary diagnosis of CE. In a retrospective study of 50 dogs with IBD, clinical signs, age, serum lipase and amylase activities, albumin and cobalamin concentrations, abdominal ultrasound examination, histopathologic review of intestinal biopsies, management of IBD, and follow-up in dogs with CE were evaluated. Sixteen dogs with increased cPL and 32 dogs with normal cPL values were compared. No significant differences were found in clinical activity score, serum amylase activity, serum lipase activity, serum cobalamin concentration, serum albumin concentration, abdominal ultrasound scores, and histopathology scores for IBD. There was also no difference in the frequency of steroid treatment between the groups. Interestingly, dogs with elevated Spec-cPL had a higher risk of a poor follow-up score and were significantly more likely to be euthanized at follow-up.

These data suggest that elevated Spec-cPL in canine IBD identifies a subset of these patients that could also have chronic subclinical pancreatitis. In patients which have been diagnosed with CE and also have elevated Spec-cPL without overt imaging evidence of acute pancreatitis, it is recommended to discuss treatment options for IBD that will also treat possible autoimmune pancreatitis. The author has had anecdotal success with cyclosporin at 5 mg/kg SID for eight weeks in such cases.

C-Reactive Protein

C-reactive protein (CRP) is a serum acute phase protein that can be elevated in many different diseases. In people with IBD, several indices of clinical disease activity incorporate measurements of CRP. In dogs, a similar correlation between the Canine IBD Activity Index (CIBDAI) and CRP serum concentrations has been found in one large study incorporating 58 dogs. CRP was elevated when compared to normal in 28 of the 58 dogs in this study, which had CIBDAI scores above 5 (which represents mild to moderate disease activity). In these dogs CRP decreased significantly after successful treatment.

In another study, CRP did not seem to be very helpful, as it was only elevated in 6/21 dogs with CE. Based on available published data, it is possible that CRP is useful as an additional assessment tool in severely ill patients, even though a large percentage of dogs with IBD do not show any elevations in CRP. Interpretation of elevated levels may also be hampered by increases of CRP related to diseases other than IBD.

Fecal Alpha-1-Proteinase Inhibitor

Fecal alpha-1-proteinase inhibitor (alpha-1-PI) can be used as a test for dogs in which the clinician suspects PLE but clinical signs are not overt. Alpha-1-proteinase inhibitor is a plasma protein of similar size to albumin. If the intestinal mucosal barrier is compromised and loss of protein into the intestinal lumen occurs, alpha-1-PI is lost at approximately the same rate as albumin. Unlike albumin, however, its proteinase inhibitor properties protect alpha-1-PI from being degraded by intestinal proteases. Therefore, it is able to persist throughout the intestinal transit and is passed undamaged in the feces, in which it can then be measured.

Prompt diagnosis of PLE in a patient with IBD is important, as hypoalbuminemia is a risk factor for a negative outcome and the cause should be treated aggressively in order to improve survival. The alpha-1-PI assay is especially valuable in a patient with intestinal disease that also suffers from concurrent renal or hepatic disease. In these patients, measurement of fecal alpha-1-PI can help assess which portion, if any, of the protein loss can be attributed to the intestine. This test is so far only available at the Texas GI lab and ideally, three consecutive freshly collected, frozen fecal samples should be submitted in order to improve the accuracy of the test. This means that fecal alpha-1-PI is to date not a useful test for practitioners outside North America.

Polymerase Chain Reaction for Antigen Receptor Rearrangement from Intestinal Biopsies

Polymerase chain reaction for antigen receptor rearrangement (PARR) amplifies the highly variable T or B cell antigen receptor genes, and is used to detect the presence of a clonally expanded population of lymphocytes. This test has been advocated to be useful when applied on endoscopic biopsies if a diagnosis of intestinal lymphoma is suspected but not confirmed by conventional histopathology. It is, however, important to note that dogs with CE can in up to 20% of cases have biopsies which test positive for clonality. The test therefore needs to be evaluated as an additional measure to help with the differentiation of intestinal lymphoma versus CE, but should not be used as the sole differentiating factor or even the gold standard. Other tests that can help with this question are immunohistochemistry for B and T cells, abdominal ultrasound and possibly fine needle aspirates of enlarged mesenteric lymph nodes, if they are present.

Perinuclear Antineutrophilic Cytoplasmic Antibodies

Perinuclear antineutrophilic cytoplasmic antibodies (pANCA) have been useful in the diagnosis of human IBD for decades. These antibodies are serum autoantibodies similar to antinuclear antibodies (ANA), which seem to be more specific for intestinal disease than ANA in dogs. They are detected by indirect immunofluorescence assays where a typical pattern of perinuclear staining of canine granulocytes can be seen.

In the first study which assessed the possible clinical usefulness of pANCA in dogs with IBD, sensitivity for pANCA was 0.51 and specificity ranged between 0.56 and 0.95. pANCA proved to be a highly specific marker for CE in dogs when the group of dogs with chronic diarrhea of other causes were tested against the group of dogs with CE (specificity 0.95). This is in agreement with reports from human medicine that show a specificity of up to 94% for pANCA when distinguishing between IBD and healthy controls as well as patients with non-IBD diarrhea. Furthermore, when pANCA were tested in a group of dogs with FRD versus SRD, a positive pANCA titer was significantly associated with FRD.

The pANCA assay could therefore provide valuable help to the veterinarian presented with the clinical picture of a dog with chronic diarrhea and possible IBD. If the result is positive, a food-responsive chronic enteropathy is highly likely, but if the result is negative, CE cannot be excluded.

pANCA also seem to be associated with the syndrome of familial protein-losing enteropathy in soft-coated wheaten terriers (SCWTs). pANCA were detectable in the serum of dogs on average 1–2 years before the onset of clinical disease and were highly correlated with hypoalbuminemia. This test could serve as a useful adjunct for this specific disease in SCWTs as an early screening test.

Care must be taken in interpreting a positive pANCA test result if other inflammatory or immune-mediated diseases are present in the dog. A recent study showed that many dogs with various vector-borne diseases or immune-mediated hemolytic anemia (IMHA) were positive for pANCA. Unfortunately, this test is not commercially available yet, but could become one of the standard tests for work-up of CE in the future.

Calprotectin and S100A12

Calprotectin and S100A12 are calcium-binding proteins that are abundant in the granules of neutrophils and macrophages. In people with IBD, serum and fecal concentrations of these proteins have been found to be increased compared to healthy people. In addition, fecal concentrations of calprotectin correlate very well with clinical disease activity in children with IBD.

An immunoassay for measurement of canine calprotectin in serum and fecal samples is now available, and it was shown that a serum calprotectin concentration of ≥296.0 µg/L as a cut-off had a sensitivity of 82.4% and specificity of 68.4% for distinguishing dogs with idiopathic IBD from healthy dogs. However, calprotectin concentrations were not significantly correlated with the clinical severity, serum C-reactive protein concentration, or severity of histopathologic changes. The clinical usefulness of this test when used in serum or fecal samples still needs to be confirmed in prospective studies.

Immunohistochemistry for P-Glycoprotein on Intestinal Biopsies

P-glycoprotein (p-gp) is a transmembrane protein functioning as a drug-efflux pump in the intestinal epithelium. Human patients with IBD who fail to respond to treatment with glucocorticosteroids express high levels of p-gp in lamina propria lymphocytes.

So far, two research groups have evaluated p-gp expression in biopsies of dogs with CE. In one study, duodenal biopsies from 48 dogs were evaluated by immunohistochemistry. The dogs treated with prednisolone showed a significantly higher p-gp expression in lamina propria lymphocytes after treatment compared with expression before treatment. In contrast, the group treated solely with an elimination diet showed no difference in p-gp scores before and after treatment. Moreover, a statistically significant association between refractoriness to steroid treatment and high p-gp expression was found in the steroid treatment group. In another recent study, p-gp expression was compared between dogs with CE and healthy controls, and was found to be higher in duodenal epithelial cells of dogs with CE compared to control dogs. These results indicate that epithelial and lamina propria lymphocyte expression of p-gp is upregulated in dogs with CE, and they are even higher after prednisolone treatment. In addition, high p-gp expression could indicate possible multidrug resistance and should be taken into account when dealing with dogs who have failed steroid treatment before.

Genetic Testing

Over the last decade, numerous genes have been found to be associated with an increased risk of development of IBD in human beings, many of them implicated in the innate immune response in the intestine. In dogs, it has always been obvious to clinicians that IBD could have a genetic component. This is particularly evident in breeds like the boxer, which is predisposed to granulomatous

colitis, and the German shepherd dog (GSD), which is predisposed to CE. Several mutations in TLR4 and TLR5 were found to be significantly associated with an increased risk of development of CE. In a follow-up study, we were also able to show that peripheral blood cells of dogs carrying the mutation are hyperresponsive to flagellin, which is the natural ligand for TLR5. This proves for the first time that a genetic mutation implicated in the pathogenesis of dogs with IBD has functional consequences on the protein level. Taken together, these findings make it very likely that TLR5 mutations are causally associated with canine IBD. Genetic testing for these polymorphisms could become important for breeders and practitioners in the future. However, it is likely that in multifactorial disease like IBD in dogs, other factors such as other genetic mutations and environmental factors will also play a major role in the pathogenesis of the disease.

Work-up and Diagnostic Tests: Abdominal Ultrasound, Endoscopy, and Histopathology

Diagnostic Imaging

Ultrasonographic study is the preferred imaging tool for the investigation of animals with GI disease. The whole of the intestinal tract can be examined and the wall thickness measured. Although CE may cause focal or segmental changes, it does not always induce changes that can be detected ultrasonographically, so intestinal biopsy is required to confirm the diagnosis. Neoplastic infiltration is more often focal, shows more severe thickening, and causes loss of wall layering when compared to inflammatory disease. In addition, lymph nodes tend to be larger and more involved in neoplastic disease. However, the overlap in the sonographic appearances of inflammatory and neoplastic infiltration makes definitive diagnosis difficult, requiring histopathology for differentiation.

Histology and World Small Animal Veterinary Association (WSAVA) Scoring of Intestinal Biopsies

Sampling of intestinal biopsies is considered to be an essential step to exclude neoplastic causes and confirm the presence of intestinal inflammation. However, the interpretation of intestinal biopsies is difficult and subject to controversy. In several recent studies looking at conventional histologic interpretation of intestinal biopsy samples, no correlation of clinical activity with histologic grading either before or after therapy was found. In addition, total lymphocyte counts as well as the number of infiltrating CD3 cells in the lamina propria cannot be used as markers for clinical activity of disease, as there is no difference in cell counts before and after treatment.

These findings suggest that the type and degree of histologic infiltrates in canine IBD may not be as helpful as in human medicine, where the clinical scores correlate very well with the histologic grading. Therefore, a new grading scheme for the histologic interpretation of endoscopically obtained biopsies from dogs and cats with IBD has recently been published by the WSAVA working group. The findings in this study suggest that microarchitectural changes seem to be much more important than cellular infiltrates when assessing histologic severity of disease. However, so far, there is limited information on how well this new grading system correlates with clinical disease. This notion was recently confirmed in a prospective study including 20 dogs with FRD. A second endoscopy was performed in these dogs after six weeks of dietary treatment, and WSAVA scoring was the same as before treatment. However, when looking at electron microscopic changes, mitochondrial and brush border changes indicated mucosa healing which was not obvious on light microscopy. In one retrospective study, the interpathologist variability was still very high even when using the picture guide from the original publication. In addition, it is of concern that the only parameter that correlated with clinical disease was the presence of lymphangiectasia and hypoalbuminemia.

Currently, there is lack of consensus between pathologists when using the WSAVA histopathologic guidelines for intestinal biopsies, and studies have demonstrated that these scores correlate poorly with clinical severity. Therefore, it is likely that additional criteria need to be assessed when scoring intestinal biopsies and further studies are needed to determine other immunologic components that are dysregulated in animals with CE.

Treatment and Prognosis

Inflammatory bowel disease patients that have mild to moderate clinical disease activity and normal serum albumin concentration are first treated sequentially with a dietary and antibiotic trial. If they fail to respond to either of these trials, immunosuppressive therapy is initiated (see following paragraphs).

FRD: Diet

A positive response to a dietary trial allows the patient's CE to be classified as FRD, a term which includes both dietary allergy and intolerance. The main options for a dietary trial include switching to a diet which leads to

antigenic modification (e.g., novel protein source or protein hydrolysate). Whichever type of diet is chosen, it must be palatable and introduced in gradually increasing amounts over 4–7 days. In dogs with FRD, a clinical response is usually observed within 1–2 weeks of changing the diet. One study demonstrated that dogs that respond to diet tended to be younger and had higher serum albumin concentrations and predominantly signs of large bowel diarrhea than dogs that did not respond to diet. FRD is highly prevalent among dogs with IBD (at least 60–70%) and a favorable response to elimination or hydrolyzed diets within two weeks has been shown to be associated with a very good prognosis over one year after diagnosis. It is important to note that in the studies that show these good outcome measures, the dogs were kept on the diet for at least 12 weeks after diagnosis before they were switched back to their original diet.

ARD: Antibiotics

An antibiotic trial typically involves oral administration of tylosin, 10–15 mg/kg q8h, oxytetracycline 20 mg/kg q8h, or metronidazole 10 mg/kg q12h. A positive response suggests ARD. The dog is typically maintained on antibiotics for 28 days; if signs recur after stopping then long-term antibiotic therapy with tylosin 5 mg/kg is used orally every 24 hours. In a recent large retrospective study where all dogs were sequentially treated, only 16% of dogs were ARD. All ARD dogs relapsed shortly after discontinuation of the antibiotics was attempted, making long-term management of these patients difficult. An additional decision-making factor may be the increasing problems with antibiotic resistance in our dog populations, making justifications of long-term treatment with antibiotics difficult. There is also accumulating evidence that antibiotic treatment has long-lasting effects on the intestinal microbiome, which may lead to lasting dysbiosis and in itself could amplify inflammation in the intestine. Many of these patients will therefore need steroids or other immunosuppressives to control their clinical signs long term.

Anti-inflammatory and Immunosuppressive Therapy

Patients that do not respond to a diet or antibiotic trial are usually administered oral prednisolone 2 mg/kg every 24 hours that is tapered over an eight-week period. However, as the side-effects of glucocorticoids are usually more marked in large- than small-breed dogs, azathioprine may be combined with glucocorticoid treatment at a faster taper in dogs weighing more than 30 kg. If there is poor response to immunosuppression or a relapse is seen after tapering, then consider oral cyclosporin at 5 mg/kg every 24 hours for 10 weeks. A response to prednisolone has been shown in up to only 50% of dogs with CE, so if more severe disease is present or severe side-effects of steroids are anticipated, other immunosuppressives can be an option. Many steroid-refractory canine CE cases can be rescued by cyclosporin single therapy. In cats, use chlorambucil 2–6 mg/m^2 q24h with prednisolone if there is inadequate response to glucocorticoid treatment alone. Hematologic parameters should be monitored regularly if chlorambucil is used. If the patient responds then the medication can be tapered gradually, starting with the steroid, to an q48h dosing regimen.

Budesonide is a glucocorticoid medication that has been preliminarily shown to be successful in the treatment of canine IBD. However, hypothalamic-pituitary-adrenal suppression and development of a steroid hepatopathy have been demonstrated in dogs, so the hepatic fist-pass effect of this drug in dogs may not be as great as in human beings. An optimal dose has not yet been determined, although anecdotally a dose of 1 mg/m^2 every 24 hours orally has been recommended. The response rate to budesonide was shown to be similar to the use of prednisolone (about up to 60%), and it should therefore be reserved for dogs that are known to respond to steroids but suffer severe side-effects. Some dogs will, however, still develop side-effects of steroid administration while on budesonide, so owners should be warned about this. Sulfasalazine (20–50 mg/kg q8h for 3–6 weeks) and related drugs are often used in dogs when IBD is limited to the large intestine. However, as side-effects include keratoconjunctivits sicca, tear production should be monitored regularly.

Treatment of Patients with Severe Protein-Losing Enteropathy

Protein-losing enteropathy is a recognized complication in a subset of CE cases and a low serum albumin concentration has been shown to be a poor prognostic indicator for CE. Patients with albumin concentrations below 1.5 g/dL are at risk of developing ascites, pleural effusion, and subcutaneous edema. Many of these patients will succumb to the disease within the first 1–2 months of starting prednisolone treatment. As some studies have shown better outcome with single-therapy cyclosporin at 5–10 mg/kg PO SID, this latter regime may be a better option for many of these patients. One recent study has also shown that the combination of prednisolone and chlorambucil was superior to prednisolone and azathioprine for survival. Evaluation of hemostatic function in these patients is recommended to ascertain if hypercoagulability has developed as a consequence of enteric protein loss. Concurrent therapy with ultra-low-dose

aspirin (0.5 mg/kg) or other platelet inhibitors is recommended in these patients in order to prevent thromboembolism. In addition, the use of elemental diets and partial parenteral nutrition may be indicated in some dogs with severe PLE.

It is worth mentioning that some PLE patients can fare relatively well with dietary treatment alone, and there are some studies that show that Yorkshire terriers may be a subgroup of dogs developing PLE which can be solely diet responsive. In such cases, it is indicated to try a low-fat diet first, and wait before adding in immunosuppressive treatment for 1–2 weeks.

Finally, these patients may also be at risk of complications associated with intestinal biopsy by laparotomy, so plasma transfusion, human albumin infusion or synthetic colloid may be indicated during anesthesia for endoscopy.

Adjunctive Therapy

The use of probiotics in people with IBD has led to some promising results, although there is still an insufficient number of large, multicenter, randomized, double-blind, placebo-controlled trials that investigate the efficacy of probiotics in human IBD. Similarly, only one randomized, placebo-controlled trial investigating the use of *E. faecium* probiotics in canine FRD as an adjunctive treatment has been performed so far. No additional effect could be demonstrated in the group of dogs receiving probiotics. More studies are needed to be able to make recommendations for the use of probiotics in cats and dogs with CE (see also Chapter 58).

Prognosis

One retrospective study demonstrated that only 26% of canine CE cases progress to complete remission, with intermittent clinical signs remaining in approximately half of cases, and 4% were completely uncontrolled, with 13% being euthanized because of poor response to treatment. This suggests that the prognosis of CE patients can be poor. The main negative prognostic indicator for CE was identified to be hypoalbuminemia in dogs. Clearly, more prospective treatment trials are necessary, especially in the severely affected and hypoproteinemic animals, in order to improve long-term survival in these cases.

Diseases of the Liver, Gallbladder, and Bile Ducts

60

Approach to the Patient with Liver Disease

Emma O'Neill, BSc, BVSc, PhD, DSAM, DECVIM-CA, MRCVS

School of Veterinary Medicine, University College Dublin, Dublin, Eire

The liver plays a central homeostatic role within the body, involved in the orchestration of a vast array of metabolic pathways. The metabolic functions performed include carbohydrate, protein and lipid metabolism, drug metabolism, vitamin storage and activation, endocrine hormone metabolism, removal of endogenous and exogenous toxins (e.g., ammonia) along with excretory, digestive, and storage functions (e.g., iron, copper, glycogen, triglyceride). The liver is also the site of synthesis of albumin and the majority of clotting factors and plays a key role in immune surveillance.

The liver's position, between the gastrointestinal tract and the systemic circulation, aids its roles in digestion, detoxification, and immune surveillance. However, it also leaves the liver vulnerable to injury from drug or toxin exposure and prone to the secondary effects of dysfunction at other sites in the body. The normal liver is typically functioning with significant reserve capacity (approximately 70–80%), providing an important buffer should an animal sustain liver injury. In addition, the liver has a huge regenerative capacity, affording the animal significant ability to recover from injury.

All of these features of liver function have an important impact on the clinical presentation of animals with liver disease. Symptoms of liver disease typically only become apparent once the reserve capacity of the liver has been exceeded, hence diseases may remain subclinical for long periods of time, with animals presenting later in the disease process. The vast array of liver functions is reflected in the wide variety of possible clinical symptoms. The early clinical signs typically observed include intermittent anorexia, polyuria/polydipsia, vomiting, and lethargy, all nonspecific signs that could be referable to other body systems. More specific clinical signs, such as jaundice or ascites, tend to occur later in the disease process. For example, jaundice occurs in only approximately 20% of dogs and 30–40% of cats with hepatobiliary disease and hence, although more specific, it is an insensitive indicator of hepatobiliary disease. The aim when approaching patients is to maintain a clinical suspicion of liver disease, particularly in patients with vague, waxing and waning signs, from a breed with known predispositions to hepatobiliary disease. The important challenge when approaching these patients is to diagnose the disease early in its course in order to provide a chance to intervene before the disease becomes too advanced and irreversible.

Hepatobiliary diseases rarely present with clinical features pathognomonic for a particular disease. However, there are distinct groups of clinical signs that can be appreciated to occur, reflecting important pathophysiologic mechanisms involved in liver disease. In view of this, a basic understanding of these mechanisms is helpful in order to understand both the clinical presentation of patients and the choice of tests to used diagnose them.

Pathophysiology of Important Clinical Presentations of Liver Disease

Cholestasis

Cholestasis is the term used for impaired bile flow, which can result from a wide variety of intra- and extrahepatic causes. Normal bile production starts with canalicular bile formation. The active secretion of bile salts by hepatocytes into the bile canaliculi results in a large osmotic gradient and secondary movement of water, which in turn drives bile flow. The bile flows sequentially along the biliary tree through bile ductules, various ducts and then finally into the common bile duct. Throughout this passage, it is modified by secretion and reabsorption of

Companion website: www.wiley.com/go/bruyette/clinical

fluid and inorganic solutes. The bile ducts contribute substantially to this bile formation and flow, with secretion of bicarbonate, chloride, and water. Approximately 50% of bile is released immediately into the gastrointestinal tract, while the remainder is stored and concentrated in the gallbladder. Intrahepatic cholestasis disrupts this bile flow mainly at the level of the hepatocytes, their canaliculi or the bile ductules, in the periportal zone (zone 1) of the liver lobule, whereas extrahepatic cholestasis results from obstruction of the common bile duct. In both of these situations, significant hepatic reserve and compensatory changes have the net result that, typically, overt clinical signs of cholestasis, such as icterus (jaundice), only result from diffuse liver pathology or severe impairment of the common bile duct flow.

Intrahepatic cholestasis occurs commonly to varying degrees in most clinical cases, with various proposed mechanisms involved. Damage to tight junctions separating the bile canaliculi from blood sinusoids can result from endotoxemia, sepsis, some *Leptospira* infections or following an adverse drug reaction. At the cellular level, swollen hepatocytes may directly obstruct bile flow through canaliculi or bile ductules. In addition, necrosis of hepatocytes may disrupt hepatic architecture, allowing communication between canaliculi and sinusoidal lymph or blood, aided by the inherent biliary pressure. Physical obstruction to bile flow from lobules can occur with any processes causing accumulation of tissue (inflammatory, neoplastic or collagen) in portal or periportal regions. This obstruction can occur at any level in the biliary tree with any process disrupting the normal architecture, for example in cirrhosis or with metastatic tumors. Extrahepatic cholestasis is far less common, with important causes including biliary or pancreatic adenocarcinoma, duodenal disease or pancreatitis causing blockage of the duodenal papilla.

Cholestasis can be recognized clinically in several ways which can be helpful to consider when approaching a clinical case. Severe cholestasis results in icterus. Less severe cholestasis can be recognized in varying degrees on the biochemistry panel. This is discussed further in the section on biochemical evaluation, but it is important to be aware of the frequency with which some degree of cholestasis occurs in a wide variety of liver disease.

Icterus

Icterus (or jaundice) is the yellow discoloration of tissues resulting from hyperbilirubinemia and the build-up of bile pigments (Figure 60.1).

Bilirubin is the major bile pigment and is the normal end-product of the catabolism of hemoproteins, a broad group of molecules including hemoglobin, myoglobin, and many enzymes located within the liver, (e.g., cytochromes). Senescent or damaged erythrocytes are removed from the circulation by cells of the mononuclear phagocyte system located within the spleen, liver, and bone marrow. These cells break down hemoglobin and release unconjugated, hydrophobic bilirubin into the circulation where it is carried, reversibly bound to albumin, to the liver for clearance. The hepatocytes take up the bilirubin and conjugate it, predominantly with glucuronide, to aid solubility for biliary excretion. This conjugated bilirubin is released into the intestine where it is not reabsorbed but is either excreted unchanged or degraded by intestinal bacteria to urobilinogen and then the stercobilins (brown fecal pigments).

Hyperbilirubinemia results from disruption of this normal production and/or processing of bilirubin and can be considered to result from three broad mechanisms.

- Prehepatic causes where there is increased production of bilirubin in excess of the hepatic capacity for excretion, for example severe hemolytic anemia.
- Hepatic causes where there is impaired uptake, conjugation, and excretion of bilirubin as a result of marked cholestasis. As described in the section on cholestasis, extrahepatic causes such as sepsis can also result in intrahepatic cholestasis due to cytokines directly inhibiting bilirubin transport.
- Posthepatic causes reflect reduced excretion of bilirubin due to disruption of bile flow within the extrahepatic bile ducts.

Portal Hypertension

Portal hypertension is abnormally high pressure within the portal circulation, the result of increased blood flow or resistance within the portal circulation or a combination of the two. It is an important consequence of a variety of clinical conditions, including liver disease, and is associated with significant morbidity and mortality. The development of multiple acquired portosystemic shunts (MAPSS) and ascites with or without hepatic encephalopathy (HE) are important sequelae of the condition and are essential to recognize clinically from a diagnostic, prognostic, and treatment perspective.

In health, the portal blood flow to the liver supplies 75–80% of liver blood supply through a low-pressure system. The portal pressure is kept low and relatively constant, despite variations in portal blood flow, by a large sinusoidal reserve capacity and the ability to adapt the blood flow as necessary to maintain compliance. In disease, changes in this compliance alter the inherent resistance to blood flow and hence the portal pressure. These changes may be static, in the form of structural changes such as fibrosis, or dynamic, such as increased production of inflammatory mediators and vasoconstrictor agents along with reduced production of vasodilator agents. In most cases, there will be a combination of these processes occurring progressively with activation of hepatic stellate cells and progressive injury. In addition, splanchnic vasculature tends to undergo progressive vasodilation, as a result of many of the vasoactive agents released, further aggravating portal hypertension due to increased portal blood flow.

Ascites

An important consequence of significant portal hypertension is ascites. Starling's law describes that the net movement of fluid between compartments is proportional to the balance between the relative hydrostatic and oncotic pressures in each region. Hence, the forces keeping fluid within the vascular space become imbalanced, with portal hypertension tending to favor fluid movement into the interstitium. Ascites develops once this fluid movement exceeds the capacity of the local lymphatic system. This situation is exacerbated by splanchnic vasodilation, which lowers the effective circulating blood volume due to pooling of blood. Over time, compensatory cascades, including the renin-angiotensin-aldosterone system, sympathetic nervous system and antidiuretic hormone release, produce blood volume expansion, further favoring the formation of ascites. Hypoalbuminemia and reduced oncotic pressure also tend to favor net fluid movement and the development of ascites, although typically this does not occur until albumin concentrations are below about 1.5 g/dL. These levels would be unusual for patients with liver dysfunction, occurring only with severe disease. A situation that happens more frequently in patients with liver disease is that a moderately reduced serum albumin (1.8–2.2 g/dL) occurs in combination with portal hypertension, resulting in exacerbation of the ascites.

Acquired Portosystemic Shunts

As portal hypertension reaches a threshold level, small embryonic vessels open up within the omentum and mesentery, allowing blood flow between the portal circulation and the vena cava. These acquired portosystemic shunts (APSS) may initially lower the portal venous pressure, but this effect is quickly mitigated by increased portal blood flow. The clinical importance of these APSS is that they result in a collateral circuit that effectively short-circuits the liver. The net result is the delivery of toxins from the gastrointestinal tract directly into the systemic circulation. These toxins can trigger the vomiting center, causing nausea, vomiting, and inappetence. Clinical signs of HE may also develop.

Hepatic Encephalopathy

Hepatic encephalopathy is a clinical syndrome of brain dysfunction occurring secondary to liver dysfunction. It is a fairly common cause of morbidity and potentially mortality in dogs with liver disease, occurring less frequently in cats. The clinical signs of HE can be quite variable, with early signs being quite nonspecific, for example, apathy or reduced alertness. In more advanced cases, circling, head pressing, altered mentation, salivation, seizures, stupor, and coma may occur (Figure 60.2).

The reserve capacity of liver function is such that, typically, HE only develops when there is concurrent significant impairment of parenchymal liver function and portosystemic shunting, a situation that can occur in patients with congenital or acquired portosystemic shunts (PSS). More rarely, HE can result from fulminant hepatic failure or inborn errors of ammonia metabolism. In cats, an obligatory requirement for arginine to allow normal function of the urea cycle means that arginine deficiency in this species (e.g., the result of anorexia) can also result in HE.

The pathogenesis of HE is complex and likely multifactorial. Normally, the liver removes neurotoxic substances from the portal circulation, preventing their delivery to the brain in the systemic circulation. HE develops with failure of this mechanism, the resultant delivery of toxins triggering neurotransmitter dysfunction and a

Figure 60.2 Dalmatian showing head pressing as a manifestation of hepatic encephalopathy.

constellation of potential clinical signs ranging in severity from apathy and reduced awareness to coma and unresponsiveness. The most commonly implicated toxin in HE is ammonia, although there are some cases where the plasma ammonia concentration is normal or only slightly raised despite signs of HE. Other potential triggers that have been studied include mercaptans, manganese, systemic inflammation, altered gamma-aminobutyric acid (GABA, an inhibitory neurotransmitter), benzodiazepine receptor signaling and altered catecholaminergic signaling due to changes in branched chain aromatic amino acid profiles. Whatever the underlying cause, the overall result is a disruption of brain function, typically leading to waxing and waning clinical signs.

Gastroduodenal Ulceration

Patients with hepatobiliary disease are predisposed to gastric and duodenal ulceration for a number of reasons. Portal venous hypertension is an important risk factor resulting in vascular stasis and venous congestion, which together increase the risk of mucosal ulceration due to reduced mucosal blood flow and secondarily reduced bicarbonate and mucus secretion. This risk is further increased in anorexic animals or those exposed to non-steroidal antiinflammatory drugs or potentially corticosteroids. Gastrointestinal ulceration and bleeding is an important consideration in any patient with HE that suddenly deteriorates or in any patient with liver disease that becomes more subdued or develops a reduced appetite.

Coagulopathy

The liver is involved in the manufacture of the majority of the coagulation factors, including fibrinogen (factor I), prothrombin (factor II) and factors V, VII, IX, X, XI, and XIII. The site of factor VIII production is controversial, but it is likely that the liver plays an important role in its production. It is also the site of the vitamin K-dependent activation of factors II, VII, IX, and X and protein C. In addition to this, the liver is involved in the clearance of activated clotting factors and the production of clotting factor inhibitors (e.g., antithrombin and alpha-1-antitrypsin) and fibrinolytic proteins such as plasminogen. Hence, in liver disease there is the potential for disrupted production of coagulation factors and their inhibitors along with impaired clearance of both activated coagulation factors and the products of the fibrinolytic system. The extent of the resulting abnormalities reflect the severity of the underlying liver disease, ranging from individual factor deficiencies to disseminated intravascular coagulation (DIC).

A study of 42 dogs with histologically confirmed liver disease demonstrated that one or more coagulation abnormalities was present in 57% of the dogs. These abnormalities ranged from single factor deficiencies in four of the dogs to DIC in three dogs. An older study suggested a figure of 93% of dogs with liver disease having abnormal coagulation parameters, although this study involved more severely affected cases. A study of 45 cats with liver disease showed that 98% of the cats had one or more abnormality detected. What is important to recognize clinically is that, whilst spontaneous hemorrhage may be rare in animals with hepatic disease, hemostatic abnormalities occur commonly. Hence, the clinician needs to exercise caution when considering interventional diagnostic procedures and a coagulation profile should be performed in all such cases.

Signalment

Patient signalment is very important when approaching the patient with hepatobiliary disease. There are a variety of known or suspected breed predispositions to hepatic disease which can be helpful to consider, particularly in view of the occult nature of many cases of early liver disease. Congenital portosystemic shunts (CPSS) have worldwide breed predispositions including Irish wolfhounds, cairn terriers, Labrador retrievers, dachshunds, Yorkshire terriers, Australian cattle dogs, Maltese terriers, and miniature schnauzers. In cats, the condition is seen most frequently in mixed-breed cats, although Persian and Himalayan breeds are also overrepresented. Additionally, copper-associated hepatitis has been

described in several breeds, including the Bedlington terrier, Dalmatian, Doberman pinscher, Labrador retriever, West Highland white, and Skye terriers. A recent study documented breeds at risk of developing chronic hepatitis in the UK (see Chapter 64). These included three breeds in agreement with a previous, older study from Sweden: the American and English cocker spaniel, Doberman pinscher and Labrador retriever, and additionally highlighted an increased risk in the cairn terrier, English springer spaniel, Great Dane, and Samoyed. However, it should be recognized that the gene pools in different countries can vary, such that certain breed characteristics and predispositions may be more regional.

In addition to the breed, the age at onset of clinical signs can be very helpful in aiding diagnosis of some hepatobiliary conditions. For example, animals with CPSS typically present at a younger age. This has classically been described to be less than 1 year of age, although increasingly older dogs seem to be recognized, presumably as clinicians are looking more widely for the condition. There have been reports of increasing numbers of miniature schnauzers not being diagnosed until they are over 7 years, presenting with only mild signs. Reports looking at the age and gender distribution of dogs presenting with chronic hepatitis have shown the mean age at diagnosis to be approximately 8 years when all breeds were considered together, although some breeds tended to present at a younger age (e.g., English springer spaniel). In general, females are overrepresented, although again there are occasional breeds where this does not appear to be the case.

History and Clinical Signs

A thorough history with good attention to detail is key to approaching any clinical case. This is particularly pertinent with potential hepatobiliary cases for a variety of reasons. As outlined in the introduction, the large hepatic functional reserve means that in order to diagnose diseases before there is significant, irreversible loss of healthy liver tissue, the clinician needs to identify cases with subtle and often vague clinical signs. Symptoms such as anorexia, vomiting, lethargy or mild polyuria/polydipsia, which are often waxing and waning, should alert the clinician that liver disease is a potential differential diagnosis. The onset of clinical signs may initially appear acute in nature but careful discussion with the owner might elucidate a more chronic background than initially described. Box 60.1 summarizes clinical signs that may be observed in animals with liver disease.

The potential for toxin exposure should always be considered so a detailed description of the animal's potential access to toxins and a history of any recent drug administration are extremely relevant. The clinician should maintain a high index of suspicion whenever a patient develops new clinical signs within four weeks of starting a new drug. There are many known potentially hepatotoxic drugs, common examples being phenobarbital and itraconazole, but most drugs have the potential for an idiosyncratic reaction in an individual patient. Consumption of a hepatotoxin is also possible, such as certain mushrooms, xylitol (contained in sugar-free sweets) or even herbal/dietary supplements that the owner might be administering.

Hepatobiliary disease can result in a very broad range of clinical signs reflecting both the sheer variety of functions the liver performs and the central role it plays in many metabolic and detoxifaction pathways. This central role means that hepatic disease can result in the secondary dysfunction of other organs, as in HE. It also places the liver in a position where it can itself become secondarily affected, for example with hyperadrenocorticism or hepatic lipidosis. The net result is that the clinician needs to be alert to this when approaching a case, aiming to first decide if hepatobiliary disease could be present in an animal but then, importantly, whether this represents a primary or secondary phenomenon. These key questions sound very straightforward, but they can be challenging to address in many patients and will be reconsidered as different aspects of the investigation of liver disease are explored.

Diagnosis

Biochemical Evaluation

The employment of clinical pathologic testing is central to the approach to animals with hepatobiliary disease. In many cases, recognition of abnormal test results often provides the first indication that liver disease may be present. It is not uncommon to detect high liver enzyme activities as the only abnormality on preanesthetic or health screens, prompting further investigation. In addition, as outlined above, in view of the typical presentation of hepatobiliary cases, it is important to use clinical pathology to aid in the diagnosis is liver disease early on in the disease process. Often at this stage the clinical signs may be vague and nonspecific with clinical pathology aiding greatly in the decision making and further defining of such cases.

The laboratory evaluation of hepatobiliary patients has several broad aims: to determine/confirm the presence of hepatobiliary disease and assess hepatic function, to aid in distinguishing primary or secondary hepatic disease and to contribute to diagnostic planning or

Box 60.1 Clinical signs and clinical examination findings that may occur in animals with liver disease

- Vague signs
  - Vaguely "off form"
  - Lethargy
- Signs related to gastrointestinal tract
  - Vomiting
  - Diarrhea
  - Anorexia
  - Weight loss
  - GI bleeding - melena
- Signs related to cholestasis
  - Jaundice
  - Acholic feces - with complete extrahepatic biliary obstruction
- Signs related to hepatic encephalopathy
  - Vague signs of dullness
  - Alterations in behavior
  - Ptyalism – particularly in cats
  - Head pressing
  - Disorientation
  - Stupor
  - Seizures
  - Vague neurologic signs, seizures or syncope may occur with hypoglycemia
- Signs relating to CPSS
  - Hepatic encephalopathy signs (see above)
  - Stunting
  - Microhepatica
  - Dysuria – relating to ammonium biurate urolithiasis
  - Hematuria – relating to ammonium biurate urolithiasis
  - Copper-colored iris (some cats)
- Signs relating to disorders of hemostasis
  - Gastrointestinal bleeding - melena
  - Increased bleeding from invasive procedures
- Signs relating to the urinary tract
  - Polyuria/polydipsia
  - Discolored urine – jaundice/hematuria
  - Dysuria (see above)
  - May have prolonged recovery from sedation/general anesthesia
- Clinical findings
  - Poor body condition score
  - Mucous membrane pallor
  - Abdominal discomfort – organomegaly, abdominal distension, inflammation (hepatic/peritonitis/cholecystitis)
  - Pyrexia – with some inflammatory, infectious or neoplastic causes
  - Ascites - relating to portal hypertension, hypoalbuminemia, biliary peritonitis or neoplastic effusion
  - Hepatomegaly +/- irregularity of liver margins – with infiltration, some inflammatory conditions
  - Skin lesions may be seen with hepatocutaneous syndrome (superficial, necrolytic dermatitis)

monitoring response to treatment. Occasionally, diagnostic testing may allow definitive diagnosis of hepatobiliary disease although more typically, it acts as a piece within the overall jigsaw. The biochemical tests directly utilized in the evaluation of liver disease comprise the liver enzymes and liver function tests, which appraise impaired metabolic function or synthetic capacity. However, evaluation of the full hematology and biochemistry panel is important to gain insight into the animal's general health. This aids clarification of the likelihood of another disease process that may either be the cause of a secondary hepatopathy or represent an additional consideration in patient management.

Enzyme Markers of Liver Disease

The liver enzymes evaluated can be divided into two main groups dependent on their cellular location and clinical utility. Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are the two most commonly measured markers of hepatocellular injury and are found primarily within the hepatic cytosol. Alkaline phosphatase (ALP) and gamma-glutamyl transferase (GGT) are the most commonly measured biliary enzymes. They are located mainly on hepatobiliary membranes and are markers of cholestasis or drug induction (see later). In general, the liver enzymes are sensitive indicators of liver disease or injury but are not specific. There are far more animals in which elevated liver enzyme activities are detected than actually have clinically significant liver disease. This lack of specificity arises from a combination of the susceptibility of the liver to secondary or "reactive" disorders, the ability of certain hormones or drugs, such as corticosteroids, to induce production of particular liver enzymes and the presence of isoenzymes within tissues other than liver. The clinical interpretation of the significance of liver enzyme elevations is challenging and must always be considered in the context of the patent, its history, and the full clinical pathology results.

It is important to realize that the liver enzymes do not offer any indication of liver function. In an animal with a primary hepatopathy, the magnitude of hepatocellular enzyme release may broadly relate to the number of hepatocytes affected, particularly in the acute setting. However, in view of the regenerative capacity of the liver, the magnitude offers no prognostic information. It is also

important to appreciate that in severe chronic disease, such as cirrhosis, the liver enzyme release may be minimal due to reduced hepatic synthetic capacity. In addition, the serial evaluation of serum enzyme activities can be more useful than a single time point in determining the importance of liver enzyme elevation and the likely prognosis in a patient. It is generally considered a favorable sign if values continue to fall gradually after a single liver insult whereas ongoing persistent elevation may indicate a chronic hepatopathy and the requirement for further investigation.

The serum enzyme activity at any point in time is dependent on the overall hepatic activity of the enzyme or the capacity for *de novo* synthesis (in response to cholestasis or drug induction), the serum half-life of the enzyme, and the cellular location of the enzyme (determining the ease of release of the enzyme, e.g., "leakage" of cytosolic enzymes). These factors vary not only between different enzymes but also between species, as will be discussed below. Hence, it is important to ensure species-specific criteria are being used when interpreting the values in a given patient. When evaluating the liver enzymes, it is important to consider the pattern of enzyme increase (hepatocellular or cholestatic), the magnitude of this change and the temporal pattern of the enzyme changes over time. For example, are they decreasing gradually, fluctuating or progressively increasing? The reference intervals for liver enzymes vary considerably between laboratories due to different assay methods. In view of this, it is more appropriate to consider the magnitude of increase in relation to the upper limit of the reference interval when comparing values between labs.

Hepatocellular/Leakage Enzymes

Alanine aminotransferase is a cytosolic enzyme that is released into the serum from hepatocytes with increased hepatocyte membrane permeability or following hepatocellular necrosis. This enzyme is considered to be a sensitive indicator of hepatocellular injury in dogs and cats and is also considered to be the most liver-specific enzyme in these species. Although ALT is also found in cardiac and skeletal muscle and the kidneys, this is not generally of clinical significance as the isoenzymes found in these other locations either have short half-lives or are present at low concentrations. However, occasionally severe muscle injury can result in ALT elevation.

The half-life of ALT in the dog is controversial, with reports ranging from about six hours to 2.5 days. What is clear is that the half-life is considerably shorter in the cat, with the result that smaller elevations are far more clinically significant in this species. The highest increases in ALT activity, in either species, are seen during acute hepatic inflammation or necrosis, the magnitude of elevation, in this setting, being roughly proportional to the number of hepatocytes affected but providing no insight into the severity of injury or its reversibility.

Rapid elevations in enzyme activity occur following changes in hepatocyte membrane permeability. Following experimental toxin administration, values rise sharply within 24–48 hours, peaking at values up to 100 times normal within approximately five days and then falling back to normal within 2–3 weeks. In general, with hepatic injury, a reduction in the enzyme activity of approximately 50% every 2–3 days would be viewed as a good prognostic sign. Elevated ALT activity can also occur with cholestasis due to the damaging effect of accumulated bile acids on hepatocyte membranes. The elevations that occur in this setting are typically more gradual in onset and are not as dramatic overall. Certain drugs can also result in ALT enzyme increases, for example anticonvulsant drugs or corticosteroids. These elevations tend to be dose dependent but also show considerable inter individual variation. The elevations seen with phenobarbital administration would typically be within the 4–5-fold range compared to a 10-fold or higher elevation occurring in animals with hepatotoxicity. However, the results need to be interpreted in light of the overall clinical picture and in combination with liver function evaluation where there is any concern.

The interpretation of ALT elevation in the clinical setting frequently poses a diagnostic challenge. Persistent elevations of ALT are characteristic of canine chronic hepatitis and can be the only abnormality noted on a blood panel in animals in the early stages of the disease. Hence, elevations in excess of twice the upper limit of the reference range occurring over 1–2 months are potentially significant and should not be disregarded. However, frequently up to five-fold elevations in ALT are observed in dogs with primary gastrointestinal diseases such as inflammatory bowel disease or pancreatitis. In addition, hemolytic anemia or cardiovascular disease can cause significant elevations in ALT secondary to hypoxia. Endotoxemia or sepsis can cause secondary hepatic changes, as can many endocrinopathies. These examples demonstrate the limitations of ALT; while it is very sensitive for the detection of hepatocellular insult and hence cases with potential primary hepatopathies, it is equally sensitive for the detection of secondary hepatopathies and "reactive" liver changes occurring in response to other systemic illness or drug exposure. In view of this, the clinician should interpret ALT activity in combination with the remainder of the clinical biochemistry, knowledge of the animal's breed and history along with maintaining an awareness of the potential interference of extrahepatic disease.

Aspartate aminotransferase is also a marker of hepatocellular damage within the group of "leakage" enzymes,

having a predominantly cytosolic location within hepatocytes. However, there is in addition a mitochondrial fraction, comprising about 30% of the total hepatic enzyme activity, which is only released during hepatocellular necrosis. The half-life of AST is about 4–20 hours in the dog and one hour in the cat. In general, in acute liver injury, elevations of AST mirror those of ALT although the overall values tend not to be as high (10–30-fold increases in the dog and up to 50-fold in the cat). Following the insult, the AST values should return to normal more quickly than ALT reflecting its shorter half-life. Hence, it has been suggested that persistent AST elevation in this setting is a poor prognostic sign. In cats, AST has been shown to be more sensitive than ALT for the detection of hepatobiliary diseases, with sensitivities reported to be approximately 83% and 76% sensitivity respectively in one report. Elevations in AST also occur with skeletal muscle disease so any elevation occurring in the absence of ALT elevation should be cross-referenced with creatinine kinase measurement to exclude this possibility. In general, most biochemical profiles offer only one hepatocellular enzyme measurement, typically ALT, and the measurement of AST in addition to this is unlikely to offer a marked clinical advantage.

Biliary Enzymes

Alkaline phosphatase is a membrane-bound enzyme that has been shown to have a high sensitivity (85%) but low specificity (51%) for the detection of hepatobiliary disease in dogs. The converse is true for cats, with reported values of 48% sensitivity and 93% specificity. These performances reflect differences in the half-lives and overall enzyme activity in the two species along with differences in the isoenzymes and their potential for induction (discussed further later).

In dogs and cats, there are a variety of tissues known to exhibit ALP activity, including intestinal mucosa, renal cortex, placenta, liver, and bone. There are two genes encoding ALP in the dog with post-translation modifications resulting in different isoforms of the enzyme. The tissue nonspecific ALP gene is responsible for the transcription of liver ALP (L-ALP), bone ALP (B-ALP), and kidney ALP (K-ALP), whereas the second gene encodes intestinal ALP (I-ALP). An additional isoenzyme, glucocorticoid-induced ALP (G-ALP), is important in the dog and is thought to represent a post-translational modification of I-ALP. In the dog, the total serum ALP (T-ALP) measured on clinical biochemistry profiles reflects the combination of L-ALP, B-ALP, and G-ALP; other isoenzymes fail to contribute to this measurement due to a combination of their short half-life and/or low overall tissue activities. In the cat, T-ALP comprises L-ALP and B-ALP due to a lack of G-ALP in this species, although placental isoenzyme has also been detected late-term in this species.

An appreciation of the contributions of these isoenzymes is important when interpreting biochemistry results. For example, B-ALP increases with osteoblastic activity and hence its contribution to T-ALP varies with age. In view of this, in young growing animals T-ALP is approximately twice the normal adult reference range purely as a result of increased B-ALP. In addition, elevations may occur in adult dogs with active bone lesions, such as osteomyelitis or osteosarcoma, but these are rarely more than five-fold increases. Where there is concern in interpretation, it may occasionally be helpful to look at an additional enzyme, such as GGT, with no bone isoenzyme, to clarify the situation. The isoenzyme that causes far more problems for interpretation is G-ALP, as discussed later.

Liver ALP is found predominantly within the periportal zone of the liver, bound to hepatocyte canalicular and sinusoidal membranes. The serum activity of this enzyme is increased in response to cholestasis (intra- and extrahepatic) and induction of *de novo* synthesis. ALP is released into the circulation by enzyme-induced solubilization from the hepatocyte membranes, a process that is enhanced by bile salts and hence increases with cholestasis. In the latter situation, accumulated bile salts also induce production of L-ALP, significantly enhancing the resultant increase in serum ALP activity. The half-life of L-ALP is approximately 70 hours in the dog and six hours in the cat. This short half-life in the cat, combined with a lower ALP activity in feline liver, is important practically. Clinically significant elevations of ALP activity in the cat are considerably smaller than those seen in the dog. Cats with hepatic disease may have ALP elevations two- or three-fold higher than normal as opposed to dogs where values are often more than four- or five-fold normal. This situation, in combination with the lack of G-ALP enzyme in the cat, results in the far lower sensitivity of ALP for liver disease in the cat (48%) but enhanced specificity (93%). In view of this, the interpretation of ALP elevation in dogs and cats differs considerably.

In dogs, ALP induction occurs in response to endogenous and exogenous corticosteroids and phenobarbital. The response to corticosteroids is rapid (increased ALP mRNA within 24–48 hours) and may occur following oral, topical (including ear/eye preparations) and parenteral exposure, with elevations in serum enzyme activity persisting for up to six weeks after exposure has ceased. In addition, a vacuolar hepatopathy, with glycogen accumulation within hepatocytes, occurs with exposure to excessive corticosteroid levels. This too may contribute to ALP elevation by generating intrahepatic cholestasis. The overall ALP elevations can be dramatic and complicate the interpretation of ALP activity in the dog. G-ALP,

as outlined earlier, is the product of the I-ALP gene. As with L-ALP, the hepatocyte is the site of *de novo* synthesis of G-ALP, with membrane accumulation and elution occurring in the same way. Exposure to endogenous or exogenous corticosteroids results in G-ALP induction and hence increased serum activity. It was hoped that measurement of the distinct isotypes of ALP within a serum sample would aid the interpretation of serum T-ALP, but this has not been found to be the case clinically. While normal dogs have low G-ALP (<15% T-ALP) and dogs exposed to corticosteroids have much higher G-ALP, the specificity of G-ALP for corticosteroid exposure is low. Elevations in G-ALP are observed in dogs with primary liver disease, diabetes mellitus, and other chronic illnesses. G-ALP synthesis is also induced in addition to L-ALP by phenobarbital.

In a published series of 270 dogs with histopathologically confirmed hepatobiliary disease, the most marked elevations of T-ALP were documented in dogs with cholestasis (median 10-fold increase) followed, in order of magnitude, by steroid-induced hepatopathy, chronic hepatitis, and hepatic necrosis (all medians approximately six-fold increase or slightly less). Periportal injury tends to result in more marked increases in T-ALP activity than centrilobular pathology. Hepatocellular and biliary carcinomas have also been documented to show increases in serum ALP activity, as have some nonhepatic tumors. Metabolic diseases with fatty infiltration of the liver, such as diabetes mellitus and hepatic lipidosis, are also associated with significant elevations in ALP. In general, extrahepatic causes of ALP elevation are less important in the cat and corticosteroid-induced ALP elevations do not occur in this species. As with ALT, the level of ALP elevation observed does not correlate with the underlying disease process and persistent elevation is a source of more concern than a single abnormal value. Elevations of ALP, like any clinical pathology test, must be interpreted in the context of other laboratory findings and in light of the patient's signalment and history. For example, Scottish terriers are known to have higher ALP activities than other breeds with an, as yet, poorly characterised underlying cause.

Gamma-glutamyltransferase is also a membrane-bound biliary enzyme. The serum GGT activity is largely derived from liver sources of the enzyme, with increased activity resulting from, as with ALP, *de novo* synthesis or increased elution from biliary membranes in response to cholestasis. In general, GGT elevations parallel rises in ALP. GGT also shows corticosteroid induction but, unlike ALP, has no bone isoenzyme and shows less induction with phenobarbital administration.

The relative diagnostic performances of GGT and ALP were compared in a study of 270 dogs with confirmed hepatobiliary disease. GGT was found to be more specific for liver disease than ALP (87% compared to 51%), but it showed considerably less sensitivity (46% compared to 85%). In this study, it was suggested that the diagnostic value of the enzymes could be increased by considering the two enzymes in series, first looking at ALP and then GGT. In this setting, the positive predictive value and specificity were improved without a major decrease in the negative predictive value. The specificity of increased ALP and GGT activity used in this series was 91%. When comparing the relative performance of the two enzymes in cats, the converse is true: GGT is more sensitive but less specific than ALP. In a study of 54 cats with hepatic disease, the sensitivity and specificity of GGT were found to be 83% and 67% respectively, compared to 48% and 93% for ALP. There was, however, one notable exception to this situation. In cats with hepatic lipidosis, ALP is more sensitive than GGT, with the latter within the reference interval or only mildly elevated in a number of cases.

In summary, the measurement of ALP is probably preferable to GGT in the dog but the converse is true for the cat. However, there are likely to be some additional benefits from the measurement of both enzymes.

Markers of Liver Function

Plasma Proteins

The liver is the exclusive site of albumin production and hence liver disease is an important differential diagnosis to consider in an animal with hypoalbuminemia. The liver's reserve capacity for albumin production is large and the half-life of albumin in the circulation is in excess of a week. In view of this, hypoalbuminemia tends to occur in animals with chronic hepatic disorders, such as cirrhosis, or with , where liver synthetic capacity is severely compromised. Hence, serum albumin measurement is a relatively insensitive measure of hepatic insufficiency. In addition to this, hypoalbuminemia is not specific for hepatic disease. It can occur with protein-losing enteropathies and nephropathies, exudative skin conditions, vasculitis, third space loss, acute blood loss, and secondary to inflammation, reflecting albumin being a negative acute-phase protein.

The liver produces alpha- and beta-globulins, whereas lymphoid cells produce gamma-globulins, meaning that the liver is not the exclusive source of the globulins measured on a biochemistry profile. Whilst hepatic synthetic failure may result in hypoglobulinemia, reflecting the liver's role in production, more commonly hyperglobulinemia occurs with acquired liver disease. This can result from a variety of causes including an underlying inflammatory disorder with enhanced gamma-globulin production, the generation of increased quantities of acute phase reactants (within the alpha- and beta-globulin fractions) or as a result of systemic immune

stimulation following decreased antigen clearance by Kupffer cells. It is important to note that in some cases, the globulin elevation may be sufficient to mask hypoalbuminemia if only the total protein concentration is measured on a blood panel.

Coagulation Factors

The role of the liver in the production of coagulation factors and the frequency with which coagulation parameter abnormalities occur were discussed earlier. As with albumin, whilst reduced coagulation factor production can result from hepatic synthetic failure, it is an insensitive indicator of dysfunction. In addition, the overlap between the liver's role in factor production, activation and clearance, along with fibrinolysis, make interpretation of the results of hemostatic testing challenging. From a clinical perspective, the evaluation of a coagulation profile is important in any patient suspected to have liver disease that is scheduled to have further invasive diagnostic procedures, such as a liver biopsy.

Protein Catabolism

The liver produces urea from ammonia, releasing it into the systemic circulation for renal excretion. The serum urea concentration may be close to or below the reference interval in patients with hepatic insufficiency, PSS, and urea cycle abnormalities. Reports have suggested that approximately 65% of dogs and cats with PSS have low blood urea levels, reflecting reduced synthetic capacity. However, as with other tests, this finding is not specific to liver disease. Serum urea concentrations may also be decreased by diuresis and medullary wash-out, malnutrition or a protein-restricted diet. Conversely, gastrointestinal bleeding can result in a disproportionately high serum urea concentration relative to serum creatinine and should alert the clinician to this possibility if observed on biochemistry results.

The catabolism of dietary amino acids and urea by bacteria within the gastrointestinal tract produces ammonia, which is normally cleared from the portal circulation by the liver. The bulk of this ammonia is then converted within the liver to urea during the urea cycle. In view of this, hyperammonemia can result from hepatic insufficiency, portosystemic shunting or dysfunction of the urea cycle. The latter group includes rare genetic cycle abnormalities, cobalamin deficiency or arginine deficiency (cats). The large reserve capacity of the urea cycle makes hyperammonemia a relatively insensitive test of liver function. The measurement of blood ammonia concentration is far more sensitive for the detection of acquired and CPSS, which effectively short-circuit the liver, with reported sensitivities ranging between 80–100% in dogs and just over 80% in cats. These values are increased further by the measurement of postprandial blood ammonia levels, with one paper showing sensitivities of 81% and 91% in pre- and postprandial samples. The reported sensitivity of ammonia for the detection of hepatocellular dysfunction in this paper was 36%, highlighting its limitation.

Another paper compared the diagnostic utility of plasma ammonia and fasting serum bile acids in the diagnosis of PSS in dogs. They found bile acids to be a little less sensitive, but considerably less specific than ammonia measurement, although the use of postprandial samples would have been likely to improve the sensitivity (see later). With adjustment of the cut-off value for the ammonia level to 75 µmol/L, the sensitivity and specificity for the detection of congenital or acquired PSS were optimized at 92% and 98% respectively. Hence, it can be very useful for the diagnosis of these conditions.

One of the limiting factors for ammonia measurement is the sample handling requirements. Samples should be collected immediately onto ice, the plasma separated from erythrocytes rapidly and the assay performed within 30 minutes, rendering measurement in a practice setting challenging. This problem is further compounded by the fact that the results of dry chemistry tests have frequently been shown to be unreliable. More recently, however, point-of-care analyzers have become increasingly available, offering a viable, more reliable option.

Carbohydrate Metabolism

The liver plays a central role in variety of pathways involved in carbohydrate metabolism, but from a diagnostic standpoint, the main assay relating to these functions is blood glucose. Hypoglycemia can occur with liver disease, although again this is a very insensitive test reflecting the significant reserve capacity for glucose production. Some cases of CPSS can present with hypoglycemia, as can animals with severe hepatic compromise such as massive hepatic necrosis or severe cirrhosis. Hepatic neoplasms can occasionally result in hypoglycemia due to either the release of insulin-like factors (e.g., IGF-2) or excessive glucose consumption. Glycogen storage diseases and rare congenital hepatic enzyme deficiencies can also result in hypoglycemia, as can a variety of extrahepatic diseases. Hence hypoglycemia is neither sensitive nor specific for the identification of hepatic disease.

Lipid Metabolism

The liver is involved in a variety of metabolic pathways, with the synthesis of cholesterol and lipoproteins most relevant from the point of view of laboratory results. The serum cholesterol and triglyceride concentrations observed in animals with liver disease vary considerably from normal to increased or decreased. Since these

analytes are also affected by a variety of other extrahepatic causes, neither test offers utility as a specific marker for liver disease. They are, however, useful in contributing to the overall clinical picture and may aid in the identification of relevant extrahepatic illnesses.

Hypercholesterolemia occurs with severe hepatic insufficiency or in animals with congenital or acquired PSS, but can occur with a variety of conditions, including gastrointestinal disease and hypoadrenocorticism. Hypercholesterolemia may occur with cholestasis, but again is not specific for liver disease as it can occur with endocrinopathies, protein-losing nephropathies, pancreatitis, and primary hyperlipidemias. A mild hypertriglyceridemia may occur with cholestasis. In addition, hypertriglyceridemia has been associated with a proportion of dogs with biliary mucoceles.

Others

Bilirubin metabolism was discussed in an earlier section. From a diagnostic standpoint, it is helpful to consider the potential causes of hyperbilirubinemia by dividing the causes into prehepatic, hepatic, and posthepatic. The former can be quickly identified by significant anemia and enhanced erythrocyte breakdown and once excluded, the presence of hyperbilirubinemia becomes far more specific for liver disease than many of the other clinical pathology analytes. Despite this, bilirubin measurement still has important limitations. As with other parameters, it is still a relatively insensitive measure of hepatic insufficiency, becoming elevated only once significant hepatic reserve is exhausted, for example with end-stage cirrhosis patients. In addition, hyperbilirubinemia does not distinguish between primary and secondary hepatopathies. Sepsis can cause significant cholestasis and hyperbilirubinemia, and many of the causes of posthepatic jaundice are extrahepatic, such as pancreatitis and pancreatic or duodenal neoplasia. In cats, hyperbilirubinemia is a more sensitive indicator of hepatobiliary disease than it is in dogs, reflecting the increased proportion of liver diseases in the cat that involve biliary disease.

When approaching a patient with hyperbilirubinemia, having excluded prehepatic jaundice, the next stage is to try to establish whether hepatic or posthepatic pathology is most likely. Evaluation of the remainder of the biochemistry panel is important to establish if there are other features suggestive of hepatic insufficiency, for example hypoalbuminemia, and to examine the hepatic enzyme activities. Typically, with posthepatic jaundice there is dramatic elevation of the cholestatic liver enzymes, more so than the hepatocellular leakage enzymes, hypercholesterolemia and no evidence of hepatic insufficiency. However, the picture is often not clear-cut, with hepatocellular enzyme activities increasing in patients with posthepatic cholestasis over time due to the toxic effects of accumulated bile salts, and markers of hepatic insufficiency unchanged due to their lack of sensitivity. Abdominal ultrasound is the next step in examining such a patient, and is typically the most useful method to distinguish between hepatic and posthepatic jaundice (see later). In some patients, the distinction between hepatic and posthepatic disease is blurred with their presentation involving components of each, for example cholangitis.

Bile Acids

Bile acids are steroid acids that are a normal constituent of bile and function in fat digestion within the intestine. The two primary bile acids, cholic and chenodeoxycholic, are synthesized in the liver from cholesterol and are then conjugated, mainly with taurine, before being excreted in bile for release into the gut or storage in the gallbladder. These conjugated bile acids are ionized at intestinal pH and function in fat digestion by aiding the formation of micelles. Intestinal bacteria metabolize some of the primary bile acids to the secondary bile acids, deoxycholic and lithocholic acid, within the gut lumen. Once in the ileum, primary and secondary bile acids bind to specific receptors, allowing their reabsorption and enterohepatic circulation. This system sees a maximum of approximately 5% fecal loss per day of bile acids, with the remainder returned to the liver in the portal circulation for removal and reexcretion. The daily losses are replaced by liver manufacture of new bile acids, maintaining a constant bile acid pool in the normal animal. This low-level replacement is not affected by reduced liver function.

This enterohepatic circulation of bile acids forms the basis of the serum bile acid assay, a dynamic liver function test. The rationale for this test is that reduced liver function or impairment of the enterohepatic circulation, due to either reduced biliary excretion or disruption of the portal circulation, results in elevation of the serum bile acid concentration measured in peripheral blood. The indications for its use are in the diagnosis of PSS and the assessment of liver function in cases where liver disease is suspected but hyperbilirubinemia is not present. The latter is a less sensitive indicator of hepatic dysfunction; once hyperbilirubinemia is present in a patient, the measurement of serum bile acids offers no further information.

A fasted serum bile acid is obtained after a 12-hour fast and assesses enterohepatic circulation in the fasted state. A postprandial sample taken two hours after feeding provides an endogenous challenge. The rationale for the latter is that feeding stimulates gallbladder contraction with release of stored bile and hence increased quantities of bile acids for enterohepatic circulation, thus providing an additional challenge for the assessment of liver function.

It has been shown that a proportion of PSS cases have results within the reference interval for fasting bile acids

but abnormal results on a postprandial sample. However, rather than the postprandial sample specifically providing additional information over the fasting sample, use of the paired pre- and postprandial samples together increases the overall sensitivity of the test. The postprandial bile acid value may be the lower of the two values in some cases, potentially reflecting factors such as gallbladder contraction during the fasting period, incomplete gallbladder contraction, delayed gastric emptying, altered intestinal motility, and decreased bile acid absorption. When interpreting these paired samples, the higher value should be interpreted. Most veterinary laboratories utilize enzymatic fluorimetric or spectrophotometric methodologies for the assay, which means that lipemia and hemolysis can affect the results. The reference intervals provided by individual labs vary based on their individual methodology but are generally very approximately <5 µmol/L and <10 µmol/L for pre- and postprandial values, respectively. However, some normal animals have values within these intervals, necessitating adjustment of the cut-off values used for interpretation.

Serum bile acid assays (SBA) represent one of the more sensitive measures of liver function available at this time. Their utility relies on the fact that they give an indication of liver function whereas liver enzymes offer markers of liver insult or drug induction. In general, the lower sensitivity of bile acids for the detection of hepatobiliary disease makes them poor screening tests. They are more appropriately employed as a function test to evaluate patients prescreened by routine biochemistry, with the aim of identifying those patients in whom a liver biopsy should be considered. One exception to this situation is their performance in patients with PSS. Sensitivity of 100% for the detection of PSS in cats and dogs has been quoted using cut-off values of 20 µmol/L and 25 µmol/L respectively, for postprandial samples. The sensitivities noted in these papers for the identification of other causes of hepatic dysfunction were considerably lower than these values, as has been noted elsewhere.

The values gained for SBA provide no indication of the underlying cause of hepatic dysfunction, do not differentiate between primary and secondary hepatopathies, and provide no information about disease severity or overall prognosis. An early paper identified 100% specificity for the presence of histopathologic abnormalities on hepatic biopsies using cut-off values of 20 µM/L for preprandial and 25 µM/L postprandial samples. These results were gained in a highly prescreened population, suspected by experts to have liver disease based on clinical findings and routine clinical pathologic testing. Hence, the prevalence of hepatobiliary disease in this population was high. This fact affects the test performance considerably and should be remembered when tests are being utilized in very different clinical situations. When SBA have been present on biochemistry panels and used more as screening tests, some spurious high values have been observed in animals with no other evidence of liver disease. Research suggests that these values may relate to bacterial overgrowth and the measurement of increased concentrations of deconjugated bile acids in some patients. In other animals, extrahepatic disease is likely to be resulting in high values and secondary hepatopathies.

The point is that care must be taken to consider the context in which test results are gained; the specificity of the test will be lower in a population with a lower prevalence of hepatobiliary disease. Using increased cut-off values for the assay will increase the specificity of the test, but this is usually at the expense of sensitivity.

Values above 40 µmol/L are more likely to indicate primary hepatic dysfunction unless underlying causes such as hyperadrenocorticism are identified. In view of this, the author typically takes this value as more indicative of the need for further evaluation, such as a liver biopsy. However, values between 20 and 40 µmol/L represent an important "gray-zone" and warrant critical evaluation in relation to the patient, its clinical signs, and the potential for extrahepatic causes. The evaluation of pre- and postprandial samples may aid clarification, if not already performed, and the test should be repeated after a period of time where there is any uncertainty. It should always be remembered that the test, while helpful and better than most measures of liver function, still has limitations. Where there is persistent liver enzyme elevation over time, even without elevation of SBA, a liver biopsy may well be indicated on a case-by-case basis (see later). Patients with values in the "gray-zone" with clinical signs suggestive of liver disease or those without clinical signs in which elevations persist with no other explanation are also likely to warrant a liver biopsy. The measurement of urine bile acids has been investigated but does not appear to offer particular advantage over the SBA.

Hematology

Mild to moderate anemia is common in patients with liver disease. The more common causes include anemia of chronic disease and gastrointestinal bleeding. Acute bleeding following liver biopsy, rupture of neoplasm or hepatic rupture, resulting from trauma or pathologic processes such as peliosis or hepatic amyloidosis, can also occur, as can hemostatic disorders. Morphologic changes in erythroctes (poikilocytes) are seen in some dogs with chronic liver disease. These include irregularly speculated cells, or acanthocytes and target cells, both of which are thought to result from altered phospholipid metabolism. In addition, microangiopathy with neoplasia

or DIC may result in the generation of schistocytes. A frequent finding in dogs with CPSS is microcytosis, thought to reflect altered iron metabolism.

There are no specific leukocyte changes seen with liver disease. An inflammatory leukogram may occur with any inflammatory, infectious (e.g., leptospirosis) or neoplastic process. In one report, 16 out of 36 dogs (44%) with chronic hepatitis were found to have an inflammatory leukogram. Thrombocyte changes may also be seen in dogs with liver disease, although again the changes are nonspecific. Thrombocyte counts may be reduced in animals with DIC and significantly lower thrombocyte counts were reported in dogs with chronic hepatitis and cirrhosis.

Urinalysis

Ammonium biurate crystals have been reported to occur in 40–70% of dogs with CPSS and may provide an early clue to diagnosis in such patients, although they are not a specific finding. Bilirubinuria can also be an important finding. Since cats have a high renal threshold for bilirubin and their renal tubules do not make bilirubin, its presence is always significant in this species. In dogs, lower levels of bilirubin are a normal finding, particularly in male dogs. High levels suggest hemolytic or hepatobiliary disease and discolored urine may be one of the first reasons an owner seeks veterinary attention for a jaundiced pet. Urine specific gravity may be reduced in animals with CPSS and hepatic insufficiency in line with the observed polyuria/polydipsia in these cases.

Serology

Dependent on the geographic location, serologic testing for a variety of infectious agents may be appropriate, for example *Leptospira*, *Neospora*, **Toxoplasma**, Rocky Mountain spotted fever, *Dirofilaria*, *Ehrlichia*, and systemic mycoses.

Genetic Tests

The deletion mutation that causes copper hepatotoxicosis in the majority of Bedlington terriers has been identified and is now available as a genetic test for the disease in this breed (www.vetgen.com). This test is run alongside a previously identified linkage marker to identify any dogs in the breed that are affected by copper toxicosis but do not have this specific deletion mutation. The occurrence of many chronic hepatopathies in specific breeds and the recognition of inheritance patterns in some of the breeds make it likely that more genetic tests will become available as the genetic bases of these diseases are identified.

Newer Tests

There are a variety of newer assays being investigated, for example, ^{13}C-labeled galactose breath test for assessment of liver function and serum protein C for the differentiation of portal vein hypoplasia without portal hypertension (formerly known as microvascular dysplasia) from PSS.

Summary of the Interpretation of Clinical Pathology

As discussed, there is no one clinical pathology finding that defines a specific diagnosis of hepatobiliary disease in dogs and cats. The clinician needs to interpret all the tests together in the context of the patient and its clinical presentation. Consideration of patterns of abnormalities in the clinical pathology tests rather than individual tests in isolation can be helpful in increasing or decreasing the index of suspicion of different conditions, as outlined in Table 60.1. Once this type of interpretation has been considered, the use of diagnostic imaging allows further refinement and direction towards either the pursuit of potential extrahepatic causes of the animal's signs and laboratory findings or more specific hepatic testing such as cytology or biopsy.

Diagnostic Imaging

Diagnostic imaging is a very important component of the investigation of a patient with suspected hepatobiliary disease, typically performed in combination with clinical pathology evaluation. Imaging can aid directly in the identification of hepatobiliary disease and the presence of any extrahepatic conditions that may be of relevance or directly contributing to the generation of secondary hepatopathies. In some situations, imaging may allow direct identification of the specific cause of the hepatobiliary disease, for example congenital PSS, although more typically it adds pieces to the overall clinical picture being built up for a given case. In some situations, prognostic information may be contributed, for example the finding of a very nodular and irregular liver in a dog suspected to have cirrhosis.

Abdominal ultrasound is particularly useful in guiding the approach to jaundiced patients, as outlined earlier, and the identification of biliary tract abnormalities such as biliary mucoceles or cholecystitis. It can also be helpful to establish if hepatic lesions are localized or generalized within the parenchyma and to provide guidance in gaining targeted biopsies or bile samples as indicated. Further detail on imaging in the investigation of hepatobiliary disease is covered in Chapter 61.

Table 60.1 Typical examples of use of pattern recognition in clinical pathology for canine liver disease

	ALT	ALP	Bilirubin	Serum bile acids	Ammonia	Albumin	Glucose	Other
Acute hepatitis/ hepatic necrosis	Rapid ++ to +++	Slower, + to ++	N to +++ with the latter in severe cases	N to +++ depending on overall severity	N to ++ depending on overall severity	N	May be low with fulminant disease	
Chronic hepatitis	Persistent + to ++ possible. May fluctuate over time	Persistent + to ++ May fluctuate over time	N to ++ possible but the latter only occurs with late-stage disease	N to ++	N to ++ but insensitive	N early in disease. More likely to decrease with later disease and often poor prognostic indicator	Usually N	May see poikilocytes. One report 44% inflammatory leukogram
Cirrhosis	N to ++	N to ++	N to +++ increased with disease progression	+ to +++ More sensitive than bilirubin	N to ++ Latter occurs late in disease process	Reduced	Hypoglycemia with end-stage disease. Poor prognostic indicator	May have low serum urea. May see poikilocytes
Congenital portosystemic shunts	N or +	N or +	N	Fasting samples may be N to ++ Postprandial samples typically ++ to +++	+ to +++ Postprandial sampling increases sensitivity	Frequently reduced	May be low	Microcytosis frequent finding in dogs. Ammonium biurate crystaluria common
Biliary tract obstruction	N to ++ The latter occurring with chronicity	+++	++ to +++	Increased but measurement not indicated with jaundice	N	N	N	Hypercholesterolemia
Nonobstructed biliary tract disease	N to ++ The latter occurring with chronicity	+ to ++	N	N May see mild increase if significant cholestasis	N	N	N	
Hepatic neoplasia	N to ++	N to ++	May see jaundice if biliary carcinoma. Other tumor types infrequently cause jaundice	N most commonly but may be +	Most commonly N	Most commonly N	Occasionally hypoglycemia with large hepatomas	May see hypercalcemia with lymphoma
Glucocorticoids	+ to ++ typically. Marked interindividual variation	+ to ++ Marked interindividual variation. Typically disproportionate increase in ALP compared to ALT	N	Usually N but + to ++ possible with vacuolar hepatopathy	Usually N	N	May also have mild hyperglycemia	May also be hypercholesterolemia
Benign nodular hyperplasia	Usually N or minimal increase	+ to +++	N	N	N	N	N	

N Within the reference interval.
+ Mildly increased.
++ Moderately increased.
+++ Markedly increased.
Scottish terriers and Siberian huskies are noted to have elevated ALP activities compared to the general reference interval for all breeds.
ALP, alkaline phosphatase; ALT, alanine aminotransferase.

Cytologic and Histopathologic Evaluation in Liver Disease

The results gained from diagnostic imaging and clinical pathology testing do not typically provide a definitive diagnosis in patients with liver disease, except in cases such as CPSS. The gold standard for diagnosis in these patients is usually histopathologic evaluation of a liver biopsy. The liver biopsy can provide a definitive diagnosis in some situations, for example neoplasia. In other cases, while a specific diagnosis may not be made, the biopsy provides important information about the pathologic reaction pattern observed, including the location of lesions, cell types involved, and the chronicity of the changes. This information is invaluable in guiding therapeutic intervention and providing prognostic information. In addition, follow-up biopsies offer an important guide to the clinician when assessing the response to therapy. Cytologic evaluation of samples may be considered in some situations and is discussed below. In general, liver histopathology offers significant diagnostic advantages over cytologic samples.

Cytologic Evaluation

It is possible to gain cytologic samples from liver patients by performing percutaneous ultrasound-guided fine needle aspiration of liver parenchyma or bile by cholecystocentesis. Percutaneous aspiration of ascitic fluid can also provide useful information. These techniques are minimally invasive and are associated with a low risk of complications. The clinician should exercise caution when approaching patients with hemostatic disorders, although the risk is far less with a fine needle aspiration compared to liver biopsy.

In general, the indications for fine needle aspirates of hepatic parenchyma are the same as those outlined later for liver biopsy. However, the main disadvantage of fine needle aspirates and cytologic evaluation is the limited diagnostic accuracy of this approach. The sample size gained provides a limited number of cells to evaluate, hemodilution may cloud interpretation and in addition, no morphologic information about the lesion is provided, as it is with histopathology.

Studies that have compared results gained with fine needle aspiration and histopathology have generally shown poor concordance rates. One study evaluated 56 dogs and 41 cats and showed agreement between fine needle aspirates and histopathology in approximately 30% of dogs and 50% of cats. The greatest agreement was seen with vacuolar hepatopathies, largely accounting for the higher accuracy in cats. However, this category also had a high rate of misdiagnosis as the primary underlying lesion was missed on cytologic examination in many cases. Since hepatic lipidosis in cats is frequently a sequel to an underlying disease rather than a primary diagnosis, this would place important limitations on cytology as a sole means of diagnosis. With diffuse or focal neoplastic disease, aspirates can prove useful; for example, a diagnosis of lymphoma may alleviate the need for a biopsy. However, this is not the case in all situations; the differentiation of nodular hyperplasia and hepatoma is not possible cytologically. In addition, the performance for canine inflammatory liver diseases is generally poor. This relates to both the importance of liver architecture in the categorization of the diagnosis (e.g., chronic hepatitis versus cirrhosis) and the chances of missing inflammatory cells where there are areas of fibrosis. Occasionally, infectious agents such as histoplasmosis can be diagnosed by fine needle aspiration.

Overall, the clinician must be aware of the limitations of fine needle aspirates of liver parenchyma and regard them more as a contributor of information rather than providing a definitive diagnosis in most situations. The main advantages are the safety aspects in high-risk patients and the general requirement for only limited sedation. They can also be performed quickly, contributing to patient planning and even a final diagnosis in some cases.

Cytologic evaluation of ascitic fluid in combination with analysis of the total protein content and cell count allows determination of the nature of the ascites, for example whether it is a transudate, modified transudate or exudate. In general, accurate categorization of the ascites aids in diagnostic planning by narrowing down the potential differentials considered in a case. For example, demonstration of an exudate with a bilirubin concentration greater than twice that of the serum would suggest bile peritonitis and should prompt surgical intervention. More frequently with liver disease, a modified transudate is obtained, resulting from portal hypertension and increased hepatic lymph leakage.

Bile cytology can also provide important information where clinical signs are suggestive of cholestasis or gallbladder abnormalities are detected ultrasonographically. These samples can be gained by cholecystocentesis either percutaneously by ultrasound guidance or directly during laparoscopy or laparotomy. The finding of bacterbilia and/or neutrophils within the bile supports a diagnosis of bacterial cholecystitis, or cholangitis if there is histopathologic evidence to support hepatic changes. In addition to cytologic evaluation, anaerobic and aerobic bacteriologic culture of bile should be performed. In the author's experience, bacteria are evident within bile far more frequently than inflammatory cells and occasionally provide evidence of a bacterial etiology in patients where bile culture proves negative due to antibiotic administration. In other patients, bacterial culture may be positive in the absence of any cytologic abnormalities.

In general, bacteriologic culture of bile yields far more positive results than culture of liver parenchyma.

Histopathologic Evaluation

Indications

As discussed earlier, the laboratory tests for liver disease rarely identify a specific etiology. Having employed clinical pathology and ultrasonography as diagnostic tests to identify potential liver disease, evaluation of a liver biopsy aids the provision of a diagnosis and prognosis and in guidance of therapeutic intervention. In general, a liver biopsy is indicated in the following circumstances.

- Asymptomatic patients with persistent, serial elevations in liver enzyme activities.
- Asymptomatic patients with abnormal hepatic function tests (e.g., fasting serum bile acid or postprandial serum bile acid).
- Where hepatic parenchymal abnormalities are identified ultrasonographically.
- Where there is unexplained hepatomegaly.
- To assess response to therapeutic intervention.
- Evaluation of animals with potential breed-specific hepatopathies.
- Any animal with progressive signs of liver disease.

It is important to recognise the potential for the occurrence of liver enzyme elevation and secondary "reactive" hepatopathies as a result of extrahepatic causes. Consideration of and, if appropriate, evaluation for the presence of potential extrahepatic causes, such as hyperadrenocorticism in dogs, hyperthyroidism in cats and gastrointestinal or pancreatic disease, is important before pursuing a liver biopsy, particularly where only liver enzyme elevation is noted on a biochemistry panel. The consideration of more than one liver enzyme activity, evaluation of results on more than one occasion and performing a liver function test, such as pre- and postprandial bile acids, can be helpful to clarify the situation where there is any doubt.

Prebiopsy Considerations

When planning liver biopsy, there are several important factors to consider, including risk to the patient and the type of biopsy procedure to be used. The main types of biopsy approaches available are ultrasound-guided needle biopsy, laparoscopic biopsy, and surgical biopsy. The most important potential complications of liver biopsy are hemorrhage, trauma to adjacent organs, and infection, the relative risks of which vary with the technique used and are discussed further later.

It is important to evaluate the overall clinical stability of a patient and hemostatic function prior to obtaining a liver biopsy. The circulatory status and potential for hemorrhage should be considered in addition to how well the animal will tolerate sedation or general anesthesia. The latter is particularly a consideration in patients with signs of HE where medical management to stabilize the patient prior to more invasive procedures is often necessary. A minimum database to screen hemostatic function should include a platelet count, prothrombin time (PT), and partial thromboplastin time (PTT). The measurement of buccal mucosal bleeding time (after establishing a normal platelet count on a blood smear) is also recommended due to some reports of increased complications due to primary hemostatic abnormalities (platelet dysfunction) rather than secondary hemostatic (coagulation factor) abnormalities. Measurement of fibrinogen along with fibrin degradation products (FDPs) and D-dimers to assess for increased fibrinolysis might also be considered. However, it should be noted that there is often poor correlation between coagulation parameters and major complications at liver biopsy. Although there is little veterinary literature published in the area, one study suggested that a platelet count below 80×10^9/L, a PTT more than 1.5 times the reference interval in cats and a PT above the reference interval in dogs were all associated with an increased risk of minor complications in animals undergoing ultrasound-guided needle biopsies.

Some clinicians suggest administration of vitamin K 24 hours prior to biopsy in all cases. It is certainly appropriate to treat any patients with prolonged coagulation screens, as administration has been shown to improve clotting times in many patients. The administration of vitamin K to all hyperbilirubinemic patients, particularly cats, is probably prudent in view of the role of bile in the adsorption of fat-soluble vitamins and the insensitivity of PT and PTT in detecting bleeding diatheses. The use of fresh-frozen plasma to deliver coagulation factors to patients with mildly increased PT and PTT is also an option. Following a liver biopsy, it is essential that patients are closely monitored over at least 12 hours for clinical signs of postbiopsy hemorrhage. Evaluation of heart rate, mucous membrane color, abdominal size, and mentation is important. Measurement of total protein and packed cell volume does not provide useful information when monitoring for acute hemorrhage.

Ultrasound-Guided Biopsy

Ultrasound-guided biopsies involve the use of a cutting-type needle which is ideally automated or semiautomated. These are spring-loaded needles similar to the manual Tru-cut style and help when coordinating operation of the ultrasound probe with one hand and the biopsy gun with the other. The fully automated devices initially fire the inner part of the needle containing the biopsy channel and then the outer cutting device rapidly afterwards. The semiautomated ones allow the operator

to position the inner part of the needle and then fire the outer section. There are advantages to each type but the semi-automated ones probably offer greater accuracy in positioning the needle for more precise sampling. There are reports of increased risk of fatal complications when using the fully automated Tru-cut biopsy needle in cats so its use in this species is not recommended.

The advantages of ultrasound-guided biopsy are the less invasive nature of the procedure compared to laparotomy and the need for sedation rather than general anesthesia in most patients. Multiple sites may be sampled along with the additional advantage of targeting potentially abnormal areas identified ultrasonographically. The relatively low cost to the owner and reduced recovery times are also beneficial. However, there are significant limitations to the technique. The risk of hemorrhage is important and is greater with this technique than with laparotomy or laparoscopy where there is more scope for both the detection of hemorrhage and intervention where necessary. Large-volume ascites is a contraindication for this type of biopsy technique as it may increase the risk of significant hemorrhage. Microhepatica is also a contraindication due to the risk of inadvertent damage to other tissues.

Another important limitation of Tru-cut style biopsies is the small sample size and hence the diagnostic accuracy of samples gained. A study looking at biopsy samples from 98 dogs and 26 cats compared the results gained by three different pathologists evaluating two needle biopsies (18 gauge automated string-triggered needle) and a wedge biopsy from the same animal. All three pathologists agreed on the morphologic diagnosis for a given patient 44% of the time using needle biopsies and 65% of the time when relying on evaluation of the wedge biopsies. Overall, the results gained from the needle biopsies concurred with those gained from the wedge biopsies in only 47% of dogs and 50% of cats. The discordance rate increased still further when patients with inflammatory or vascular disease or those with significant fibrosis were considered separately. The use of a 14 or 16 gauge needle rather than an 18 gauge needle is likely to increase the accuracy of diagnosis by increasing the average number of portal triads sampled. However, the risk of hemorrhage is increased with increased needle size. The use of a 16 gauge needle for dogs and 18 gauge for cats is often most practical, taking a larger number of needle biopsies (3–5) from multiple sites so that the risk of missing a lesion due to patchy distribution or small sample size is further reduced. Despite this approach, with the ultrasound-guided approach there is often a tendency to biopsy a more limited number of liver lobes than with surgical approaches due to the limitations of access and ease of imaging.

Surgical Biopsy

A wedge biopsy gained at laparotomy is another method for obtaining a liver biopsy. This may be performed by performing a random biopsy from the edge of a liver lobe using a guillotining suture or in a more directed way in an abnormal area using transfixing ligatures or a biopsy punch (see surgical texts for more detailed information about biopsy method). This approach offers the advantage of the clinician being able to grossly examine the liver and extrahepatic biliary tract along with other intraabdominal organs that may impact the liver, for example the pancreas and duodenum. There is also the option to biopsy other organs and gain bile samples for cytology and culture. Multiple, large biopsies may then be taken from areas the clinician identifies to be abnormal, potentially finding smaller lesions that may not have been apparent at ultrasound. This significantly reduces the problems of sampling error and allows samples to be gained from multiple liver lobes. This approach is not affected by liver size and allows attention to hemostasis with use of direct manual pressure and/or topical hemostatic agents (e.g., Gelfoam®). The main disadvantages of surgical biopsies are the more invasive nature of the procedure, the increased recovery time, and requirement for general anesthesia. The cost to the owner is also significant.

Laparoscopic Biopsy

Laparoscopic biopsy of the liver affords many of the advantages of surgical liver biopsies but is far less invasive and allows faster patient recovery. The clinician is able to grossly inspect the entire liver and extrahepatic biliary system, again taking bile samples as indicated. Surrounding structures can also be examined and in some cases biopsied, although the latter is more straightforward with laparotomy. The biopsy samples are taken using specially designed forceps and can be taken easily from multiple regions with clear visualization allowing attention to hemostasis. As with laparotomy, local pressure, hemostatic agents or electrocautery may be employed to limit any hemorrhage. The sample size gained is good, again reducing problems with sampling error. The main disadvantages of laparoscopy are the cost of equipment and the need for significant training. As with surgery, there is a need for general anesthesia and the cost is higher than ultrasound-guided sampling. A recent retrospective paper showed low complication rates, although potential complications, other than hemorrhage, include air embolism, damage to viscera with trocar placement and the potential for seeding of neoplastic cells through port sites. The latter would also be a potential complication with needle biopsies. Approximately 4% of cases in this study required conversion to a laparotomy.

Overall, there are significant advantages provided by surgical or laparoscopic biopsies and these are the

preferred choice of the author if the pet owner is willing to take this approach. When approaching cases with jaundice, it is important to utilize clinical pathology findings in combination with ultrasound to try to establish if jaundice is hepatic or posthepatic in origin (having excluded prehepatic – see earlier). If extrahepatic bile duct obstruction is suspected, laparotomy and laparoscopy allow direct visualization of the extrahepatic biliary system and local organs, evaluation of patency of the bile duct, bile sampling and, if necessary, cholecystectomy. Surgical intervention, such as biliary diversion or resection of a mass, is also possible with a laparotomy. Ultrasound-guided liver biopsy should be avoided in this situation due to risks of rupture to the biliary tree. The author still prefers the surgical or laparoscopic approach even in cases of suspected intrahepatic jaundice due to the advantages offered in examining and sampling the gallbladder and local organs. Ultrasound has been shown to be insensitive in diagnosing gallbladder rupture in dogs with both gallbladder mucoceles and cholecystitis. In addition, the sensitivity of ultrasound for detection of cholecystitis is not 100%. In view of this, direct evaluation can be useful.

In acute cases where ultrasound is suggestive of pancreatitis, surgical intervention should be avoided while initial symptomatic management is evaluated. Many such cases will improve without further intervention and the attendant risks of anesthesia and reduced pancreatic perfusion. Only if the jaundice persists despite this management is surgery indicated.

Liver Histopathology

There are a variety of additional stains that can be used along with the standard hematoxylin and eosin for further evaluation of liver histopathology. When a clinician performs a liver biopsy, they should be ready to work with the pathologist reading the biopsy. Providing a clear clinical history is imperative. Understanding that the biopsy represents only a small fraction of the overall liver is key. The clinician should always relate the information gained to the patient's clinical picture and bloodwork, remembering that there is the possibility of significant sampling error, as discussed in the sections above. The biopsy results should be used to guide the treatment by defining the disease processes noted within the sample (e.g., inflammation, vacuolation) rather than necessarily providing a definitive diagnosis.

In breeds in which copper-associated hepatopathies are known to occur, the measurement of hepatic copper is important. Ideally semiquantitative copper staining of biopsy samples and quantitative copper analysis of tissue should both be performed. The latter requires adequate sample size, which typically entails a wedge biopsy. Information for individual cases is probably best discussed with the pathologist involved.

Conclusion

Patients with hepatobiliary disease pose many diagnostic challenges to the clinician. The vast array of liver functions and its tremendous functional reserve mean that patients with significant disease can present in very diverse guises and often very late in the overall disease process. The challenge for the clinician is to become adept at identifying patients with liver disease early on, when they may have vague or minimal clinical signs, as these patients are the ones more likely to benefit from treatment. Diagnostic tests, such as clinical pathology, rarely offer a definitive diagnosis in patients with liver disease. Instead, they should be used to build up an overall picture guiding a rational approach to the patient. A liver biopsy is often necessary, providing the most accurate indication of the underlying disease process, severity, and prognosis.

Imaging in Hepatobiliary Disease

Esther Barrett, MA, VetMB, DVDI, DECVDI, MRCVSt

Wales and West Imaging, Chepstow, UK

The aim of diagnostic imaging in hepatobiliary disease is to provide information about the structure and, to a certain extent, the function of the hepatobiliary system. In common with the diagnostic imaging of all other organ systems, the imaging findings are rarely specific for a single disease process and it is not possible to exclude disease on the basis of apparently normal imaging findings. Hepatobiliary imaging should therefore be considered not as an isolated process but as an important part of the overall diagnostic work-up, with the imaging findings always interpreted in the light of all the other available information (patient history, findings on physical examination, results of laboratory investigations, etc.).

Radiography and ultrasonography are the techniques most commonly used in the diagnostic imaging of the hepatobiliary system. Although much less widely available, scintigraphy (nuclear medicine) is also a well-established hepatobiliary imaging technique, useful in providing functional as well as anatomic information. More recently, the advanced cross-sectional imaging techniques of computed tomography (CT) and magnetic resonance imaging (MRI) have become increasingly useful, especially in the anatomic mapping of complicated vascular anomalies and in the evaluation of, and potential surgical planning for, patients with liver masses.

Classification of Hepatobiliary Disease

In 2006, the WSAVA published the outcome of its hepatic standardization project, an initiative started in July 2000 with the aim of describing universally accepted standards and criteria for the diagnosis of all known liver diseases of dogs and cats. In establishing the recommended classification of different hepatobiliary diseases, ultrasonographic findings were considered an important feature, alongside clinical pathologic and histologic findings. As a result of this work, four main groups of liver disease have been established: parenchymal disorders, neoplastic disease, biliary tract disorders, and vascular disorders. In this chapter, the WSAVA classification system is used as a basis for describing the imaging features of commonly encountered hepatobiliary diseases.

Normal Hepatobiliary Anatomy

The canine and feline liver is the largest soft tissue organ in the abdomen and is divided by deep fissures into left and right, quadrate and caudate lobes. The left and right hepatic lobes are further divided into lateral and medial sublobes. The liver is located almost completely within the costal arch, with a convex cranial surface lying immediately adjacent to the diaphragm and an irregularly concave caudal surface lying in contact with the stomach, pancreas, duodenum, and right kidney. On the ventral aspect of the liver, the proximal aspect of the fetal falciform ligament usually remains as an irregular fat-filled fold (falciform fat).

The Biliary System

The canine gallbladder is typically pear shaped and lies between the quadrate and right medial lobes. The feline gallbladder, which is sometimes folded or bilobed, usually lies between two parts of the right medial lobe. The common bile duct is formed by the confluence of the cystic duct (from the gallbladder) with the hepatic duct/s (directly from the liver). The common bile duct leaves the liver at the porta hepatis, where it lies ventral to the hepatic arteries and the hepatic portal vein, and enters the proximal duodenum at the major duodenal papilla. In cats, the pancreatic duct usually joins the common bile duct before emptying via the major duodenal papilla into the proximal duodenum. In dogs, although both the

Companion website: www.wiley.com/go/bruyette/clinical

pancreatic duct and common bile ducts empty at the major duodenal papilla, they usually remain separate; an additional accessory pancreatic duct empties further distally, via the minor duodenal papilla.

Hepatic Vasculature

The liver is unique in having a dual blood supply. The proper hepatic arteries, which arise from the abdominal aorta via the celiac artery and enter the liver at the porta hepatis, supply approximately one-fifth of the blood supply. The remaining four-fifths of the blood supply is provided by the hepatic portal vein. The portal vein arises in the midabdomen, where it is formed by the confluence of the larger cranial mesenteric and smaller caudal mesenteric veins. It is joined by the splenic vein and gastroduodenal vein, before entering the porta hepatis, where it lies ventral to the hepatic arteries and dorsal to the common bile duct. On entering the liver, the portal vein divides into a smaller right portal branch, which arborizes into the right medial and lateral lobes, and a larger left portal branch, which arborizes throughout the remaining liver. Venous drainage from the liver is through several (usually three) short hepatic veins and multiple tiny tributaries, which empty into the caudal vena cava as it crosses the liver on the right dorsal aspect of the midline.

Lymphatic Drainage

Lymphatic vessels from the hepatic parenchyma and the gallbladder anastomose and drain together into the hepatic and splenic lymph nodes. Variable numbers (typically between one and five) of hepatic lymph nodes lie to the right and left of the hepatic portal vein, just caudal to the porta hepatis, and receive lymphatic drainage from the liver, stomach, duodenum, and pancreas. The splenic nodes are located along the course of the splenic artery and vein and receive lymphatic drainage from the esophagus, stomach, pancreas, spleen, omentum, and diaphragm, as well as the liver. Together with the gastric lymph nodes, which drain the liver mesentery, and the pancreaticoduodenal lymph nodes, the hepatic and splenic lymph nodes form the celiac lymph center.

Hepatobiliary Radiography

Radiographic Technique

A minimum of two orthogonal views, a ventrodorsal and either a right or left lateral recumbent view, is recommended for evaluation of the liver. Good radiographic technique is essential in order to obtain images of high diagnostic quality.

Radiologic Evaluation

The radiologic assessment of the hepatobiliary system relies on the logical evaluation of liver position, size, shape, opacity, and margination.

Normal Findings

The normal liver is of homogenous soft tissue opacity, merging with the soft tissue opacities of the diaphragm and gallbladder to form the "hepatic silhouette." On a lateral view (Figure 61.1a), the hepatic silhouette is approximately triangular in shape, with a sharply pointed caudoventral angle.

The liver lies within the cranial abdomen, immediately caudal to the diaphragm, with the right kidney and stomach lying against its caudal border. The "stomach axis" is an imaginary line running from the fundus to the pyloric antrum of the stomach. This axis, which is most easily recognized when a small amount of gas is present in the stomach lumen, provides a useful reference point for evaluating liver size. In most dogs and cats, the liver is almost entirely contained within the costal arch, and the gastric axis lies approximately parallel to the ribs; however, normal variations, both in the position of the caudoventral hepatic angle with respect to the costal arch and in the orientation of the gastric axis, may be seen between different dog breeds and ages. Deep-chested dogs typically have a relatively cranially located liver, with a more upright gastric axis, while the liver of barrel-chested dogs and puppies tends to extend further caudally and may protrude beyond the costal arch, resulting in caudal displacement and anticlockwise rotation of the gastric axis.

The caudoventral angle and ventral border of the liver are often highlighted against the relative radiolucency of the adjacent falciform fat on a lateral abdominal radiograph; this provides a clearly defined ventral margin, especially in cats, where the gallbladder is occasionally identified as a soft tissue bulge along the ventral hepatic border. The position of the cranial and caudal hepatic margins is inferred from the location of the diaphragm and stomach respectively. Dorsally, the caudate lobe of the liver lies adjacent to the right kidney; in most dogs, these two soft tissue structures merge into a single soft tissue opacity, and the caudodorsal margin of the liver cannot be seen. Cats typically have a larger amount of retroperitoneal fat, usually separating the caudodorsal liver from the right kidney and allowing the two structures to be identified separately.

The hepatic silhouette is less easily appreciated on a ventrodorsal radiograph (Figure 61.1a); while the position of the cranial margin is demarcated by the location of the diaphragm, the caudal margins are poorly defined and can only be inferred from the location of the stomach.

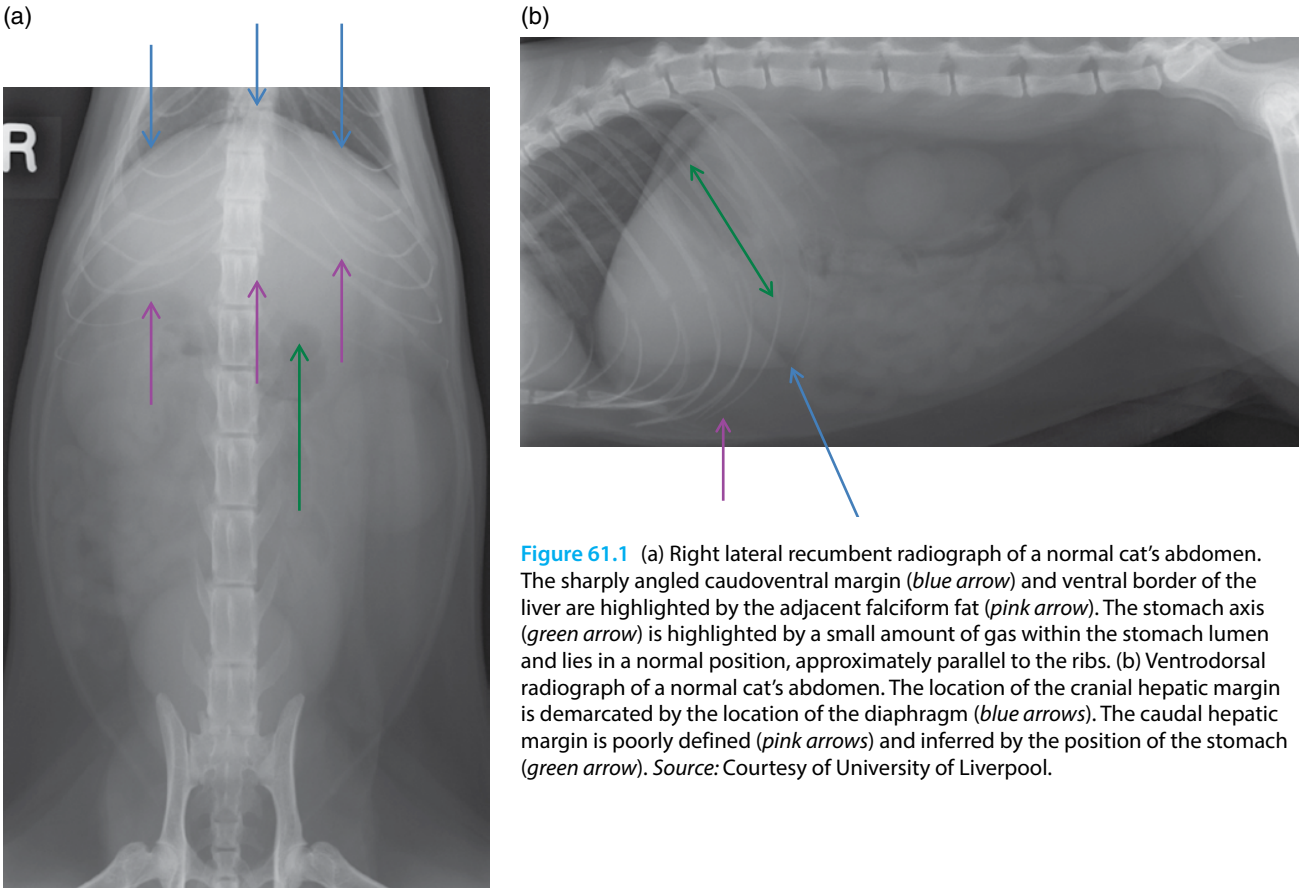

Figure 61.1 (a) Right lateral recumbent radiograph of a normal cat's abdomen. The sharply angled caudoventral margin (*blue arrow*) and ventral border of the liver are highlighted by the adjacent falciform fat (*pink arrow*). The stomach axis (*green arrow*) is highlighted by a small amount of gas within the stomach lumen and lies in a normal position, approximately parallel to the ribs. (b) Ventrodorsal radiograph of a normal cat's abdomen. The location of the cranial hepatic margin is demarcated by the location of the diaphragm (*blue arrows*). The caudal hepatic margin is poorly defined (*pink arrows*) and inferred by the position of the stomach (*green arrow*). *Source:* Courtesy of University of Liverpool.

In the dog, the caudal extent of the liver on the ventrodorsal view is similar on right and left sides; caudal to the liver, the stomach lies approximately perpendicular to the spine, with the fundus located on the left, the lesser curvature centrally and the pylorus and cranial duodenal flexure on the right. In the cat, the liver extends further caudally on the right, with the empty feline stomach located entirely on the left and the pylorus located approximately on the midline.

Changes in Position

Displacement of the liver from its normal subcostal position in the cranial abdomen is almost always due to abnormalities of the adjacent organs and structures rather than primary hepatobiliary pathology. Examples include the cranial displacement of the liver through a ruptured diaphragm and the caudal displacement of the liver due to increased thoracic volume.

Changes in Liver Size and Shape

Generalized hepatomegaly (Figure 61.2) is an increase in overall liver size, recognized on a lateral radiograph as caudal extension, and usually rounding, of the caudoventral hepatic margin beyond the costal arch, together with caudal displacement and anticlockwise rotation of the gastric axis.

Localized hepatomegaly (Figure 61.3) is usually more challenging to identify and in some cases may be difficult to differentiate from diffuse hepatic enlargement.

Lesions bulging from the surface of the liver will cause distortion of the normally smooth hepatic margins and are most easily recognized where they bulge from the ventral or caudal hepatic surfaces. Asymmetric displacement of organs caudal to the liver may be seen in patients with large unilateral lesions: a left-sided liver mass may cause caudal displacement of the stomach and spleen, while a right-sided mass may cause caudal displacement of the right kidney, pylorus and proximal duodenum, together with displacement of the stomach across to the left.

A small liver (*microhepatica*) (Figure 61.4) is usually completely contained within the costal arch and is recognized by cranial displacement of the stomach and clockwise rotation of the gastric axis.

An apparently small liver is often a normal finding in deep-chested dogs and may be difficult to differentiate from genuine microhepatica.

Changes in Opacity

Hepatobiliary mineralization is uncommon. Focal or multifocal mineralized areas are occasionally seen due to dystrophic mineralization of chronic parenchymal disease (see Figure 61.3). Dystrophic mineralization of

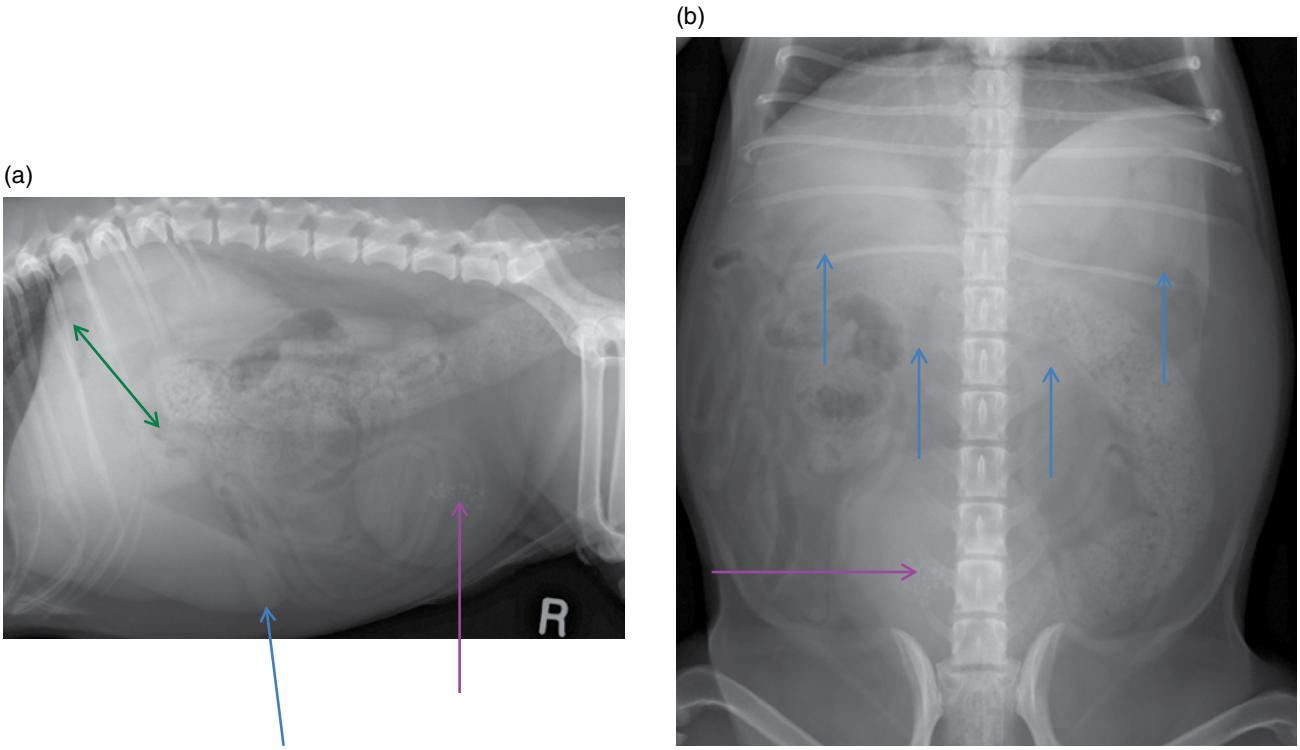

Figure 61.2 (a) Right lateral radiograph showing the abdomen of a dog with hyperadrenocorticism. An enlarged liver is identified extending well beyond the costal arch, with marked rounding of the caudoventral margin (*blue arrow*) and caudal displacement of the gastric axis (*green arrow*). Multiple radiopaque calculi are identified within this dog's urinary bladder (*pink arrow*). (b) Ventrodorsal radiograph showing the abdomen of the same dog with hyperadrenocorticism. The liver can be identified as a large soft tissue opacity occupying the cranial abdomen but the caudal hepatic margin (*blue arrows*) is poorly defined. The radiopaque calculi remain evident within the urinary bladder (*pink arrow*). *Source:* Courtesy of University of Liverpool.

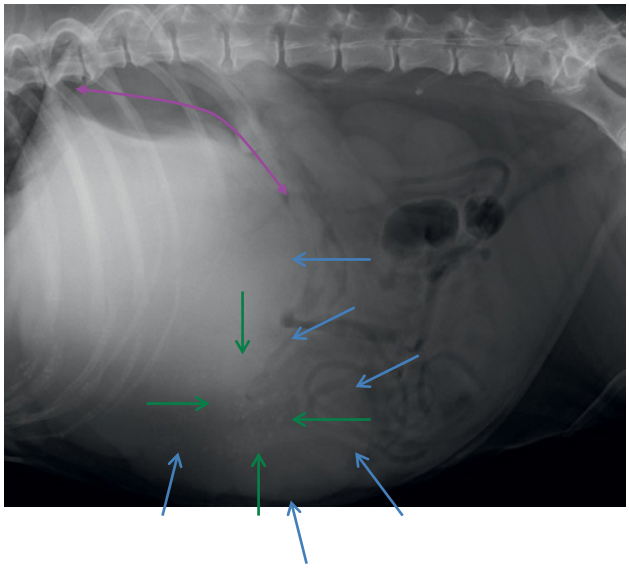

Figure 61.3 Right lateral recumbent radiography of a dog with large mass causing localized hepatomegaly. The mass bulges from the caudal aspect of the liver (*blue arrows*), displacing and compressing the stomach caudodorsally (*pink arrows*). Small mineralized foci scattered throughout the caudoventral aspect of the liver are consistent with dystrophic mineralization (*green arrows*). *Source:* Courtesy of University of Liverpool.

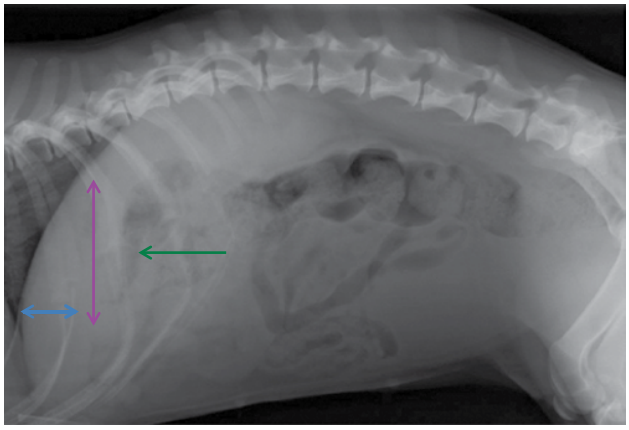

Figure 61.4 Right lateral recumbent radiograph of a female chondrodystrophic dog with microhepatica. A small liver (*blue arrow*) is identified with a very upright stomach axis (*pink arrow*) and a very cranially located transverse colon (*green arrow*). This patient is in poor body condition, with reduced serosal detail due to a lack of mesenteric fat. *Source:* Courtesy of University of Bristol.

the gallbladder wall may be recognized as fine curvilinear mineralization and choleliths are typically seen as multiple small mineralized opacities superimposed on the right cranioventral liver. Branching mineralization is occasionally recognized as an apparently incidental finding in older terrier dogs. The identification of gas opacity within the liver is even less common but may be seen as streaks or patches of gas opacity (e.g., in patients with emphysematous cholecystitis or abscessation) or as branching lucencies due to gas migrating throughout the biliary tree (e.g., due to emphysematous cholecystitis) or, very rarely, throughout the portal venous system.

Changes in Margination

Clearly defined ventral and caudoventral hepatic margins rely on the presence of abdominal fat highlighting the soft tissue opacity of the liver; loss of this clear margination may be seen in patients with ascites and in very young or emaciated patients.

Hepatobiliary Ultrasonography

Ultrasound Technique

The location of the liver within the costal arch limits the availability of acoustic windows from which the liver can be evaluated without interference from the ribcage. The use of a transducer with a relatively small contact area is therefore recommended; a curvilinear or microconvex probe operating at frequencies of 5–12 MHz is ideal, with the higher frequencies being used for cats and small-to-medium dogs and the lower frequencies for large- and giant-breed dogs.

Careful patient preparation is important in optimizing image quality. An overnight fast is strongly recommended, as the presence of gas and ingesta within the stomach lumen often reflects and/or attenuates the sound waves, hindering detailed examination. Although not always necessary, sedation will usually facilitate an easier and more thorough examination, especially in deep-chested or tense patients who may resent the firm pressure of an ultrasound probe around their ribcage. A clipped area extending cranially to the level of the xiphisternum and extending dorsally two-thirds of the way up the abdominal wall on either side is required, together with the generous application and reapplication of ultrasound gel to optimize acoustic transmission.

The liver is fixed within the costal arch by a number of ligamentous attachments. This fixed location facilitates a systematic approach to the ultrasound examination. In cats and small-to-medium dogs, it is often possible to examine the entire liver from a subcostal window, usually with the patient in right lateral or dorsal recumbency: the ultrasound probe is placed in the midline just caudal to the xiphisternum and the ultrasound beam is "swept" through the liver in both sagittal and transverse planes. In patients where the liver lies well within the costal margins (typically deep-chested patients and those with a small liver), it can be challenging to get a good image from a subcostal window, and it is often easier to examine each side of the liver by obtaining dorsal and transverse plane images through the adjacent intercostal spaces. The gallbladder, common bile duct, and caudal vena cava all lie to the right of midline; for this reason, evaluation of the biliary tract and screening for possible portosystemic shunts are often performed with the transducer positioned on the right side, either just caudal to the costal arch or within the caudal intercostal spaces.

Recognizing Artifacts

Several artifacts are commonly encountered during hepatic ultrasound. The "mirror-image" artifact (Figure 61.5) is seen as a reflection of the liver beyond the diaphragm, and is caused by the highly reflective interface between the liver and lung. "Acoustic enhancement" is caused by the fact that fluid results in less attenuation of the ultrasound beam than soft tissues, and is recognized as the tissues deep to a fluid-filled structure, such as the gallbladder, appearing artificially echogenic relative to the adjacent tissues.

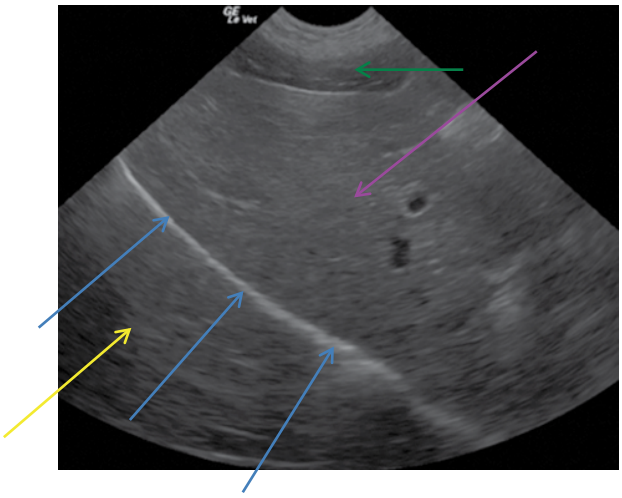

Figure 61.5 A sagittal plane ultrasound image of a normal canine liver. The diaphragm is seen as a curved hyperechoic line (*blue arrows*) demarcating the cranial hepatic margin. The normal hepatic parenchyma (*pink arrow*) is of medium echogenicity with a coarse but even echotexture. In the near field, the ventral border of the liver is separated from the coarser appearing falciform fat (*green arrow*) by a fine hyperechoic line representing the hepatic capsule. A "mirror-image" of the liver is seen beyond the diaphragm (*yellow arrow*).

"Acoustic shadowing" occurs when highly attenuating structures (such as bone and calculi) leave the deeper tissues relatively devoid of echoes, appearing artificially hypoechoic or anechoic. In the normal liver, acoustic shadowing may be recognized deep to the ribs when scanning through an intercostal space. "Reverberation" is recognized as a closely spaced series of parallel hyperechoic bands running across the screen and is caused by sound waves reverberating between the transducer and a very reflective gas interface. When examining the liver, this artifact is most frequently identified deep to a gas-filled stomach.

Ultrasound Evaluation

A consistent, logical approach to ultrasound evaluation is recommended, with an initial assessment being made of the position, size, and shape of the liver, followed by more detailed evaluation of the parenchymal structure, vasculature, biliary system, and lymph nodes.

The *position* of the liver is most easily evaluated relative to the position of the surrounding organs. The diaphragm should be seen as a curved hyperechoic line on the cranial aspect of the liver, demarcating the interface between liver and air-filled lung, with a mirror-image artifact sometimes seen beyond the diaphragm. Caudally, the normal liver is in contact with the spleen on the left, the stomach centrally and the right kidney on the right. Changes in position are more commonly encountered due to changes in the adjacent organs or structures (e.g., rupture of the diaphragm) than due to abnormalities of the liver itself.

Although radiography is usually more useful in evaluating the overall *size* and *shape* of the liver, caudal extension of the liver beyond the costal arch and rounding of the normally sharply pointed caudoventral margin in patients with generalized hepatomegaly may also be identified on ultrasound. Localized hepatomegaly is usually easier to identify with ultrasound than with radiography, and is recognized by distortion and/or bulging of the hepatic margins, often together with a localized change in the appearance of the hepatic parenchyma.

Parenchymal Structure

The normal liver (see Figure 61.5) is of medium echogenicity with a slightly coarse but uniform echotexture, interrupted only by the hepatic vasculature and gallbladder. Although the hepatic margins are generally well defined, the liver lobes are not usually individually identified unless they are separated out by the presence of free abdominal fluid. The liver is bordered on the ventral aspect by variable amounts of falciform fat. This fat is coarser in appearance than the normal hepatic parenchyma and is usually demarcated from the liver by the fine hyperechoic line of the hepatic capsule; however, in some patients the demarcation between fat and liver is not as clear and the falciform fat may be misdiagnosed as hepatomegaly.

Biliary System

The normal gallbladder is seen just to the right of midline as a rounded fluid-filled structure with a thin well-defined echogenic wall. Normal gallbladder size varies widely and is larger in fasted or anorexic patients. The normal gallbladder wall measures up to 1 mm across in cats and up to 2–3 mm in dogs. Gallbladder sludge is a common and often incidental finding, recognized as echogenic, non-shadowing material settled dependently within the gallbladder lumen. The normal intrahepatic biliary tree cannot be identified, although in some patients, especially cats, it is possible to identify the normal common bile duct leaving the porta hepatis ventral to the hepatic portal vein and entering the proximal duodenum at the major duodenal papilla.

Vasculature

Normal hepatic arteries are not identified on ultrasound. The hepatic portal vein enters the liver at the porta hepatis before branching into left and right portal veins and arborizing throughout the liver. The portal vasculature is seen as branching, tapering anechoic tubes with characteristically echogenic walls. The caudal cava enters the liver dorsal to the portal vein, receiving venous drainage via the hepatic veins as it crosses the right side of the liver. Unlike the portal veins, the walls of the hepatic veins cannot usually be seen.

Hepatic Lymph Nodes

The hepatic and splenic lymph nodes receive the majority of lymphatic drainage from the liver and are located respectively at the porta hepatis and along the course of the splenic vein. The normal lymph nodes are small, ovoid, isoechoic to the surrounding mesentery and usually not identified. Enlarged lymph nodes are typically hypoechoic and rounded or irregular.

Imaging Features of Hepatobiliary Disease

Parenchymal Disease

Conditions classified as parenchymal disorders include vacuolar diseases (e.g., steroid hepatopathy, hepatic lipidosis), amyloidosis, acute and chronic hepatitis, cirrhosis, hepatic abscessation, granulomatous disease, and hepatic necrosis (e.g., due to toxic, ischemic or immune-mediated disease).

The radiologic assessment of hepatic parenchymal disease is limited to the evaluation of overall hepatic size and shape; ultrasound assessment provides additional valuable information about parenchymal echotexture and echogenicity and is therefore more sensitive in the detection of parenchymal abnormalities. Hepatic parenchymal disease may be described as diffuse, focal or multifocal, depending on the distribution of changes identified on ultrasound.

Diffuse Parenchymal Disease

Diffuse parenchymal pathology is usually due to generalized infiltrative disease, typically affecting all liver lobes. Unless the disease process results in a fairly marked change in liver size and/or shape, the liver may appear normal on abdominal radiographs. However, in many cases, changes in hepatic echogenicity and/or echotexture can be identified on ultrasound.

Accurate evaluation of hepatic echogenicity is challenging, as apparent echogenicity is influenced by machine settings and transducer choice; this makes the identification of uniform alterations in hepatic echogenicity especially difficult. Comparison of the liver with adjacent organs imaged at the same depth is useful: the normal canine liver is coarser than and hypoechoic to the spleen, but usually isoechoic, or slightly hyperechoic, to the kidneys. A diffusely hyperechoic liver is likely to be similar in echogenicity to the spleen, with decreased contrast between abnormally hyperechoic parenchyma and the hyperechoic portal vessel walls blurring the normally clear definition of these walls. A diffusely hypoechoic liver may be recognized by the unusual prominence of the portal vessel walls, which become highlighted by the abnormally hypoechoic background. Diffuse parenchymal disease may also be seen as an abnormally heterogenous liver of mixed hyper- and hypoechogenicity. This can be difficult to differentiate from a poorly defined multifocal disease process. It is also important to remember that it is possible for significant infiltrative disease to be present without any obvious abnormalities identified on ultrasound examination. Due to the nonspecific nature of the imaging findings, cytologic and/or histopathologic evaluation of tissue will almost always be required to provide a definitive diagnosis.

Vacuolar Disease

Vacuolar hepatopathy (Figure 61.6) is most commonly associated with steroid hepatopathy and hepatic lipidosis.

The liver typically appears diffusely enlarged, with caudal extension of a rounded caudoventral hepatic margin recognized on both abdominal radiography and ultrasound. On ultrasound, the liver is typically hyperechoic and hyperattenuating, with increased attenuation of the ultrasound waves as they pass into the patient resulting in the deeper areas of the liver appearing unexpectedly dark relative to the more superficial areas.

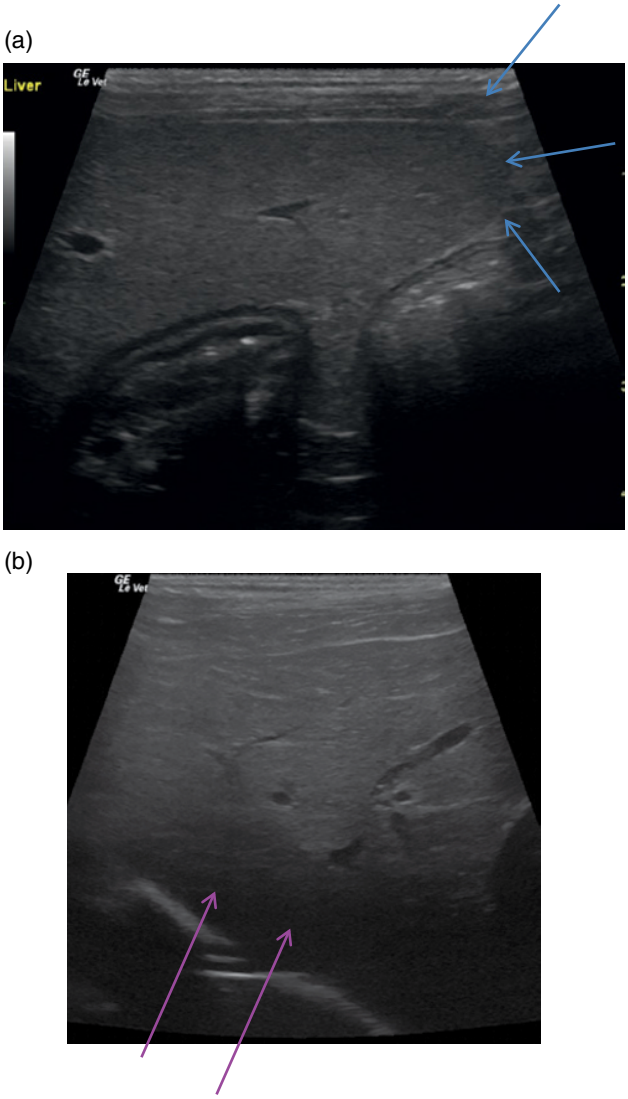

Figure 61.6 Sagittal plane ultrasound images showing the liver of a patient with vacuolar hepatopathy secondary to hyperadrenocorticism. (a) Marked rounding of the caudoventral hepatic margin (*blue arrows*). (b) Hyperattenuation of the hepatic parenchyma, with the deeper areas of the liver appearing unexpectedly hypoechoic (*pink arrows*).

Amyloidosis

Amyloidosis may cause hepatomegaly, with diffusely heterogenous hepatic parenchyma characterized by mixed hyperechoic and hypoechoic foci described in cats. Spontaneous hepatic rupture may occur in patients with severe amyloidosis, resulting in hemabdomen. This would be recognized on abdominal radiographs as loss

of normal serosal detail and on ultrasound as the presence of free abdominal fluid. A breed predisposition to amyloidosis is reported in Shar Peis, Abyssinian and Siamese cats.

Acute Hepatitis

Although acute hepatitis may cause diffuse hepatic enlargement, this is often not obvious on abdominal radiography or ultrasound. A diffusely hypoechoic liver with unusually prominent portal vessel walls may be recognized but in some patients the liver may appear ultrasonographically unremarkable. In cats, there may be evidence of concurrent biliary tract disease (see later).

Chronic Hepatitis and Cirrhosis

Chronic hepatitis (Figure 61.7) is usually associated with a mixed pattern of hepatic fibrosis, inflammation, and hyperplasia; this appears on ultrasound as heterogenous hepatic parenchyma of mixed echogenicity.

Cirrhosis is the end-stage of chronic hepatitis; a small, irregularly marginated liver may be identified on both abdominal radiography and ultrasound; extensive hepatic fibrosis may result in diffusely increased hepatic echogenicity, often with hypoechoic regenerative nodules scattered throughout the parenchyma and bulging from the hepatic margins. Portal hypertension is a common sequel to hepatic fibrosis, resulting in abdominal ascites and the development of acquired portosystemic shunts.

Hepatocutaneous Syndrome

Hepatocutaneous syndrome (Figure 61.8), also known as superficial necrolytic dermatitis, is occasionally seen in older dogs, where it is associated with ulcerative skin lesions.

The hepatic parenchymal lesions are seen as multiple hypoechoic nodules, giving the liver a "honeycomb" appearance. There are no marked changes in hepatic size or shape, making this condition impossible to diagnose from abdominal radiographs.

Focal or Multifocal Parenchymal Disease

Focal or multifocal parenchymal lesions are more easily recognized than diffuse parenchymal infiltration on ultrasound examination and are typically seen as areas of altered echogenicity and/or echotexture that are highlighted by the surrounding normal parenchyma. Large or peripheral lesions may be identified on abdominal radiographs if they result in localized hepatomegaly or distortion of the hepatic margins. The imaging features described are not specific and it is not possible to accurately differentiate the different lesions on imaging appearance alone.

Hepatic Abscesses

Hepatic abscesses are rare in cats and dogs. Although multiple lesions may be seen, solitary lesions, often at least 3 cm in diameter, are more common. On ultrasound, the typical appearance is of a rounded or irregular cavitated lesion, with a relatively echogenic and variably thick capsule around a hypoechoic central area. There

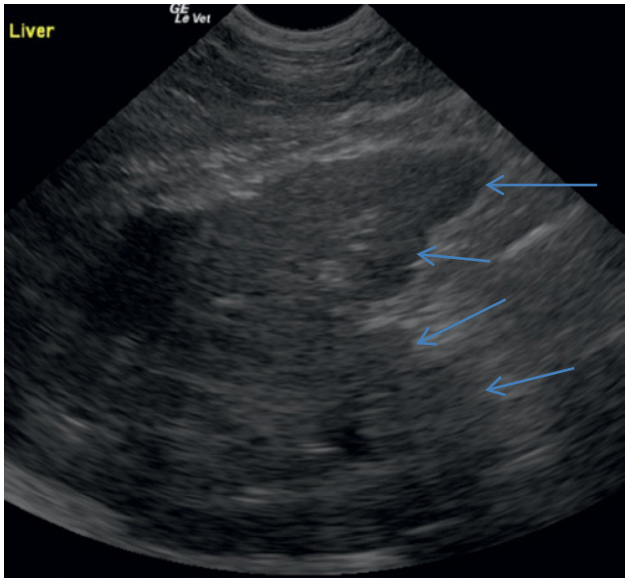

Figure 61.7 Sagittal plane ultrasound image showing the liver of a patient with chronic hepatitis. The liver is small and irregularly marginated (*blue arrows*).

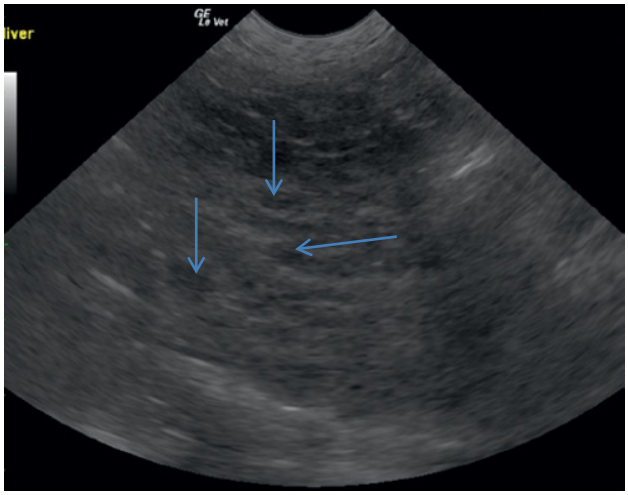

Figure 61.8 Sagittal plane ultrasound image showing the liver of a Cavalier King Charles spaniel presented with ulcerative skin lesions. Multiple poorly defined hypoechoic nodules are seen throughout the hepatic parenchyma (*blue arrows*); hepatocutaneous syndrome was diagnosed from a liver biopsy.

may be acoustic enhancement deep to fluid content, with occasional gas bubbles recognized as brightly echogenic foci with distal reverberation artifact. Mineralization of the abscess capsule may result in echogenic foci with distal acoustic shadowing. Most hepatic abscesses will not be radiographically apparent; however, lesions bulging from the liver surface and lesions with mineralization of the capsule and/or gas within the abscess cavity may be identified. Concurrent hepatic lymphadenopathy, abnormally hyperechoic local mesentery, and free abdominal fluid may be seen in some patients; radiographically, these features would be recognized as a progressive loss of serosal detail.

Cystic Lesions

Hepatic cysts are recognized as well-circumscribed, single or multiple, uni- or multilocular, thin-walled structures, with anechoic contents and distal acoustic enhancement. Congenital cystic diseases of the dog and cat are occasionally seen and may be associated with polycystic kidney disease. These congenital cysts typically arise from congenital dilation of the intrahepatic bile ducts, and strictly speaking should be classified as a biliary disorder. Differential diagnoses include parasitic cysts, focal areas of necrosis, and cystic tumors (e.g., biliary cystadenoma). Cystic lesions that do not distort the hepatic margins will not be recognized on abdominal radiographs.

Hepatic Granulomas and Hematomas

Hepatic granulomas and hematomas are uncommon. Granulomas are occasionally identified in association with *Mycobacterium tuberculosis*, fungal diseases, migrating parasites and, in cats, feline infectious peritonitis. They are usually multifocal and typically appear hyperechoic and well marginated on ultrasound. Abdominal radiographs are often unremarkable but may occasionally show evidence of dystrophic mineralization, with hepatomegaly and possible distortion of the normally smooth hepatic margins seen in patients with extensive disease. Hematomas may be seen following trauma or biopsy procedures, typically appearing anechoic or hypoechoic on ultrasound until an echogenic clot has formed. The subsequent retraction and lysis of the clot results in a variable pattern of mixed echogenicity whose appearance cannot be differentiated from an abscess or necrotic tumor.

Liver Lobe Torsion

Liver lobe torsion is a rare cause of acute abdominal pain and abdominal effusion in the dog. On ultrasound, the affected lobe is typically seen as a hypoechoic mass, often surrounded by free fluid, with color Doppler demonstrating reduced or no blood flow into the area. A loss of serosal detail will be seen on abdominal radiographs due to the presence of free fluid. Depending on the volume of fluid, it may also be possible to appreciate alteration of the normal hepatic shape.

Neoplastic Disease

The WSAVA classification of neoplastic disorders includes primary neoplasia, usually arising from the hepatocytes (hepatocellular adenoma/carcinoma) and/or the biliary system (e.g. cholangiocellular adenoma/carcinoma), primary vascular neoplasia (most commonly hemanigosarcoma), diffusely infiltrative hematopoietic neoplasia (e.g., lymphoma, malignant histiocytosis, and malignant mastocytosis) and metastatic neoplasia. Although benign, nodular hyperplasia, commonly seen in older dogs but less frequently identified in cats, is also included in the classification of neoplastic disease.

Primary Focal Neoplasia

Primary liver tumors arising from the hepatocytes or the biliary system are typically seen as focal, or occasionally multifocal, masses. A wide variety of imaging features may be recognized and it is not possible to differentiate between benign and malignant lesions or between tumor types based on imaging appearance. On ultrasound, lesions are variably well defined and vary in size, shape, and echogenicity (Figure 61.9).

Biliary cystadenomas are uncommon benign tumors of older cats. These lesions, which have a wide range of possible sizes and may be solitary or multifocal, are characterized by the presence of a variable cystic component (Figure 61.10).

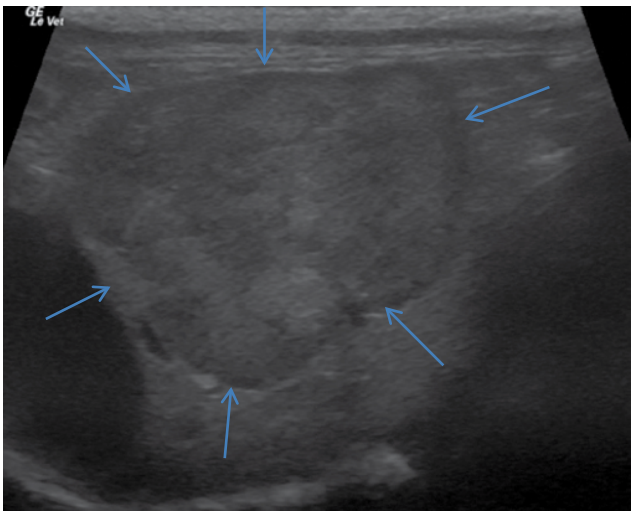

Figure 61.9 Sagittal plane ultrasound image demonstrating a well-defined heterogenous mass in a 10-year-old FN DSH (*blue arrows*). The cytologic diagnosis was hepatocellular carcinoma.

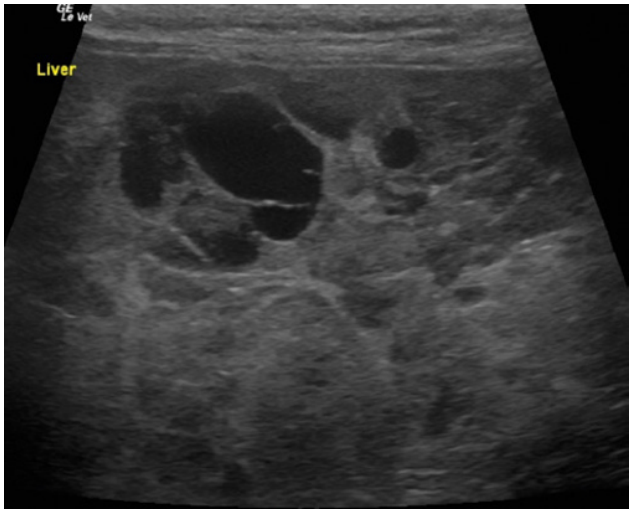

Figure 61.10 Sagittal plane ultrasound image showing a multiloculated cystic hepatic lesion diagnosed as a biliary cystadenoma in a 12-year-old FN DSH.

Hepatic hemangiosarcomas often also have a cystic component and, in cases of rupture, will be accompanied by the presence of free abdominal fluid. Liver tumors will only be recognized radiographically where they cause localized hepatomegaly and/or distortion of the normal hepatic shape (see Figure 61.3). The oral administration of barium may be useful in determining the location of the gastric axis in cases with suspected localized hepatomegaly. Pedunculated liver tumors can be confusing and may be seen as a cranioventral soft tissue abdominal mass, which is not obviously connected to the liver. In patients with tumor rupture and subsequent hemoperitoneum, abdominal radiographs will show loss of serosal detail.

Infiltrative Neoplasia

Lymphoma, histiocytic tumors, and mast cell tumors are typically diffusely infiltrative. On ultrasound, these tumors are most commonly recognized as diffusely hypoechoic or heterogenous hepatic parenchyma, or as multifocal parenchymal nodules or masses. Less commonly, the hepatic parenchyma appears diffusely hyperechoic or, occasionally, ultrasonographically normal. Evaluation of the area around the porta hepatis is important for the identification of hepatic lymphadenopathy, which is often identified in association with infiltrative hepatic neoplasia. Diffuse neoplastic infiltration often results in generalized hepatomegaly, which may be apparent on abdominal radiographs.

Metastatic Neoplasia

Metastatic hepatic disease is most likely to be recognized on ultrasound as multifocal nodules or masses. Although a wide variety of imaging features may be seen, the identification of "target lesions," seen as hypoechoic nodules with a hyperechoic center, is commonly associated with (but not pathognomonic for) metastasis (Figure 61.11).

An important differential diagnosis for multifocal nodules is benign nodular hyperplasia. Unless the metastatic lesions are large enough to cause localized or generalized hepatomegaly, metastatic hepatic disease is unlikely to be identified on abdominal radiographs.

Benign Nodular Hyperplasia

Benign nodular hyperplasia, also referred to as regenerative nodular hyperplasia, appears on ultrasound as multiple nodules of variable size, shape, echogenicity, and definition. It is not possible to distinguish between benign nodular hyperplasia and primary or metastatic neoplasia from the ultrasound appearance. Mild generalized hepatomegaly may occasionally be radiographically apparent in patients with benign nodular hyperplasia.

Disease of the Biliary System

Important disorders of the biliary tract include cholestasis, due to either primary liver disease or obstruction of the (usually extrahepatic) biliary tract, and cholangitis (most commonly neutrophilic or lymphocytic). Diseases affecting the gallbladder include gallbladder mucoceles and cholecystitis (frequently seen in cats, sometimes in association with neutrophilic cholangitis).

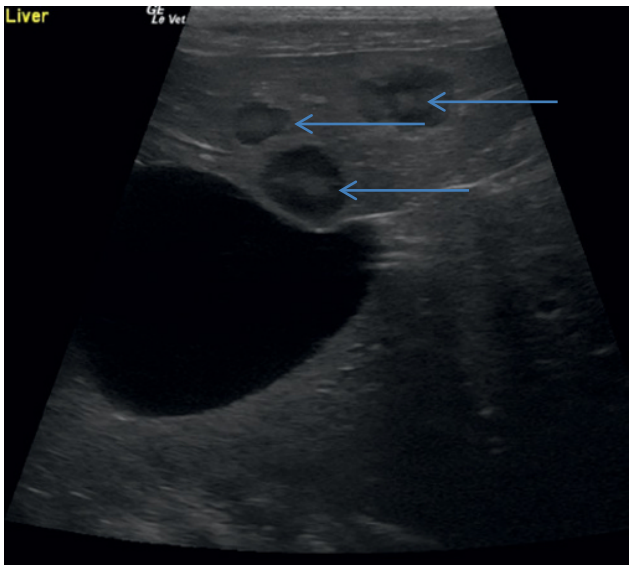

Figure 61.11 Sagittal plane ultrasound images showing target lesions (*blue arrows*) consistent with metastatic liver disease in a 9-year-old JRT with an insulinoma.

Extrahepatic Cholestasis

Causes of extrahepatic biliary obstruction (EHBO) include inflammation or neoplasia of the common bile duct, pancreas or duodenum and obstruction of the duct lumen by choleliths (choledocholithiasis). Dilation of the common bile duct (>5 mm in cats and >4 mm in dogs) is the most consistent ultrasound finding in acute EHBO (Figure 61.12).

Dilation of the extrahepatic and intrahepatic bile ducts may be seen in patients with obstruction of at least 5–7 days duration; these dilated ducts are recognized as the presence of multiple slightly tortuous anechoic tubes with hyperechoic walls, which do not show any evidence of flow on Doppler. Dilation of the gallbladder is an inconsistent finding and the absence of a distended gallbladder does not exclude the possibility of EHBO. Detailed evaluation of the common bile duct is required to identify possible causes of obstruction; obstructive choleliths are most commonly located in the distal common bile duct, highlighted by the dilated bile duct proximal to the obstruction, with an empty bile duct seen distally. In patients with inflammatory or neoplastic disease, an extraluminal mass may be identified causing obstruction; however, it is not possible to determine the nature of the mass (inflammatory or neoplastic) from the ultrasound appearance. Although mineralized choleliths may be identified on abdominal radiographs, EHBO will not be seen.

Cholangitis

Inflammatory liver disease is classified according to the histopathologic features of the disease. Neutrophilic and lymphocytic cholangitis are both commonly diagnosed in cats, but less frequently reported in dogs. On ultrasound, cholangitis is most commonly recognized as diffusely hypoechoic hepatic parenchyma, which highlights the echogenic walls of the portal vasculature (Figure 61.13).

These changes are nonspecific, and it is not possible to make a definitive diagnosis or to distinguish between neutrophilic and lymphocytic disease without tissue sampling. Cholangitis cannot be diagnosed from abdominal radiographs. Concurrent cholecystitis (see later) is identified in a significant number of cats and occasionally dogs with cholangitis.

Gallbladder Mucocele

Gallbladder mucoceles occur in dogs and are caused by an abnormal accumulation of inspissated mucus and bile within the gallbladder lumen, leading to progressive luminal distension and potentially to necrosis and ultimately rupture of the gallbladder wall. Typical mucoceles have a distinctive ultrasound appearance, described as "kiwi-like" or "stellate," with immobile hyperechoic striations seen radiating from a central point (Figure 61.14).

Variations in the appearance include a "mosaic-like" pattern of mixed echogenicity; unlike gallbladder sludge, which is a common and often incidental finding, the contents of a gallbladder mucocele are immobile and do not move with gravity when the patient changes position. Gallbladder wall thickness is variable, although inflammation and/or necrosis may result in wall thickening. Gallbladder rupture may be recognized as discontinuity within the gallbladder wall, together with a localized

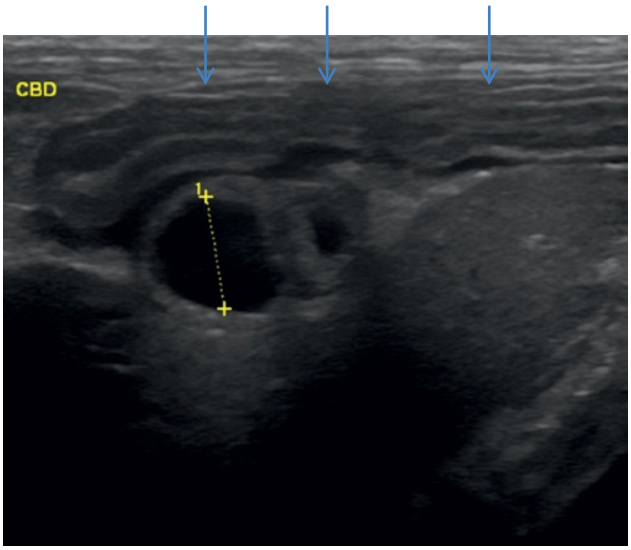

Figure 61.12 Ultrasound image of a 14-year-old MN Siamese showing moderate dilation (7 mm) of the distal common bile duct (*yellow cursors*) just proximal to its termination. The duodenum is seen in the near field of the image (*blue arrows*).

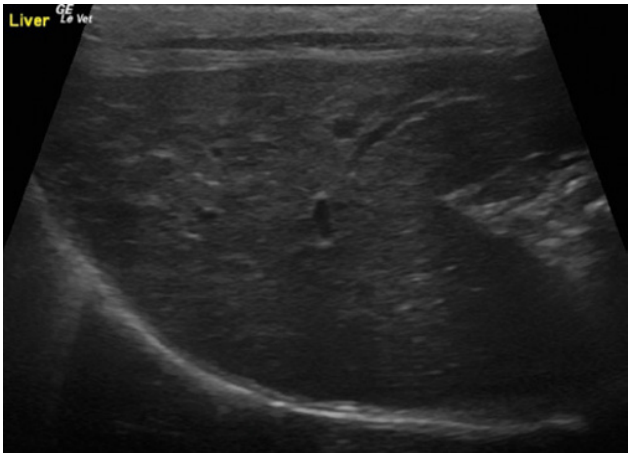

Figure 61.13 Sagittal plane ultrasound image showing the liver of a jaundiced 11-year-old MN DSH. The diffusely hypoechoic hepatic parenchyma highlights the echogenic walls of the portal vasculature. A histopathologic diagnosis of neutrophilic cholangitis was made on examination of an ultrasound-guided tissue-core biopsy.

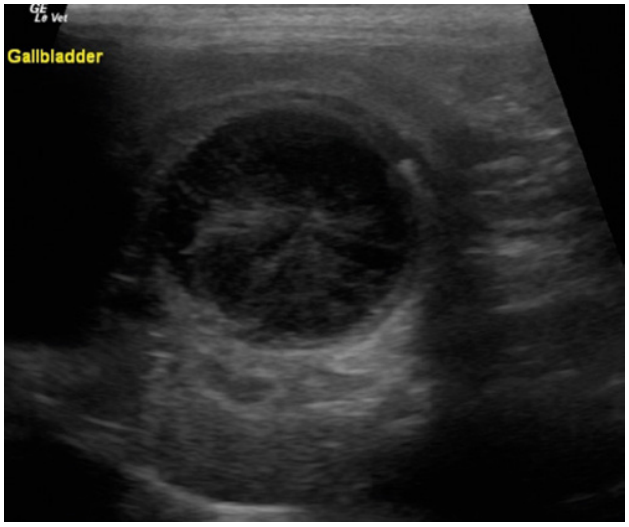

Figure 61.14 Ultrasound image showing the typical "kiwi-like" appearance of a gallbladder mucocele in a 5-year-old FN Chihuahua.

collection of free fluid and abnormally hyperechoic fat around the periphery of the gallbladder.

Cholecystitis

Cholecystitis is more commonly identified in cats than dogs, and is usually associated with bacterial infection. Typical ultrasound features of acute cholecystitis include gallbladder wall thickening (Figure 61.15) (>1 mm in cats, >2–3 mm in dogs), together with thickening of the wall of the common bile duct.

The thickened gallbladder wall may be diffusely hyperechoic or may have a layered appearance, with a hypoechoic central layer sandwiched between hyperechoic layers. Differential diagnoses for gallbladder wall thickening include acute cholecystitis, edema (e.g., in patients with hypoalbuminemia or portal hypertension), cystic mucinous hyperplasia and, rarely, neoplasia. Although commonly considered to be an incidental finding, biliary sludge, sludge balls, and choleliths may be associated with cholecystitis, especially in cats. Biliary sludge is recognized as mobile echogenic nonshadowing debris within the gallbladder lumen. Sludge balls are mobile, rounded, echogenic, nonshadowing luminal structures composed of thick bile. Choleliths are seen as hyperechoic foci of variable size, shape, and number, often casting an acoustic shadow. Ultrasound-guided aspiration of bile (cholecystocentesis) is useful in providing material for bacterial culture in patients with suspected cholecystitis.

Radiographic abnormalities associated with cholecystitis are unusual; however, choleliths may occasionally be identified as small mineralized foci in the area of the gallbladder and/or common bile duct and, rarely, patches

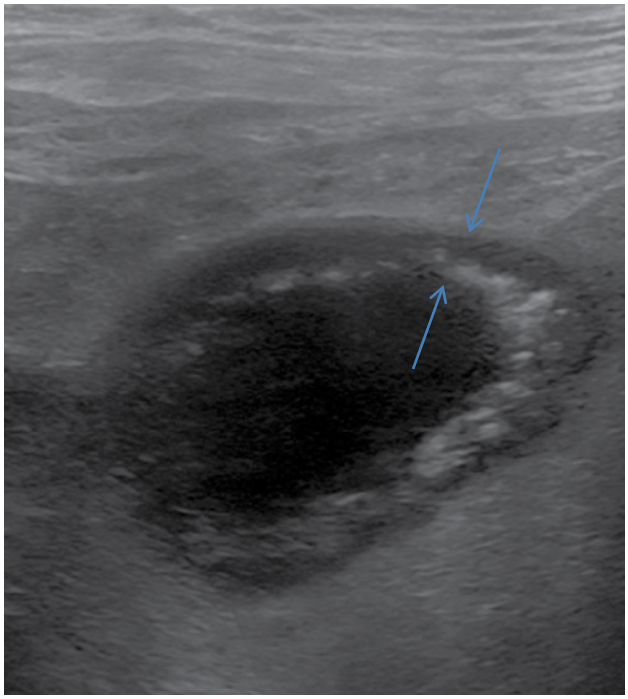

Figure 61.15 Ultrasound image showing thickening of the gallbladder wall (*blue arrows*) in a 10-year-old ME cross-bred dog diagnosed with cholecystitis.

and streaks of gas opacity may be seen in patients with emphysematous cholecystitis.

Hepatic Vascular Disorders

The largest group of hepatic vascular disorders consists of the circulatory disorders, which are subdivided into congenital portosystemic shunts, hepatic congestion due to outflow disturbances, and disorders due to portal hypertension. Other vascular disorders include peliosis hepatis and portal vein thrombophlebitis.

Congenital Portosystemic Shunts (CPSS)

Congenital portosystemic shunting occurs due to an anomalous connection between the portal vasculature and systemic venous system, which allows blood to bypass the hepatic sinusoids. CPSS are usually described according to their location (extrahepatic or intrahepatic) and can be further classified by their anatomic configuration. Extrahepatic CPSS are most commonly identified in smaller breed dogs and in cats, while intrahepatic CPSS are most commonly identified in larger breed dogs. Although studies have demonstrated more than 90% accuracy for experienced operators, the identification of CPSS with ultrasound is challenging.

In addition to evaluating the liver from the standard subcostal acoustic window, the use of a high right dorsal

acoustic window, located just cranial to the right kidney, with the patient positioned in left lateral recumbency, is recommended for visualization of the caudal vena cava (CVC) and the hepatic portal vein (HPV) as they enter the liver; in most patients with an extrahepatic CPSS, this window allows identification of the shunting vessel itself. Subcostal, right dorsal intercostal, and left ventral intercostal windows are all recommended for evaluation of the liver in patients with a suspected intrahepatic CPSS. In anesthetized patients with a very small liver, positive pressure ventilation may be useful in improving visualization by displacing the liver caudally. Although not essential, color and spectral Doppler allow the determination of flow direction, the identification of turbulence and the measurement of hepatic portal velocity, and are therefore very useful in the ultrasound assessment of patients with suspected CPSS.

The majority of extrahepatic CPSS in dogs originate from the splenic or left gastric veins and terminate in the caudal vena cava (usually at the level of the epiploic foramen), the left phrenic vein (at the level of the oesophageal hiatus) or, less commonly, in the azygos vein. In cats, portocaval shunting via the left gastric vein is most frequently reported but cats also appear to have a higher incidence of more unusual shunting loops, which may arise caudal to the confluence of the mesenteric veins. Regardless of the precise anatomy, the ultrasound appearance of an extrahepatic CPSS is usually of a relatively short, dilated and sometimes tortuous vessel, diverting blood away from the hepatic portal vein (Figure 61.16).

Comparison of the diameter of the portal vein at the porta hepatis with the diameter of the aorta and caudal vena cava at the same level is very useful; a portal vein:aortic ratio ≤0.65 is predictive for the presence of an extrahepatic shunt. Conversely, an extrahepatic shunt is considered unlikely with a portal vein:aortic ratio >0.8 and a portal vein:caval ratio >0.75.

Intrahepatic CPSS may be classified as left, central or right divisional. The left divisional shunt, which represents a patent ductus venosus and joins the left portal branch to the intrahepatic caudal vena cava, is the most common (Figure 61.17).

Both right and central divisional shunts arise from the right portal branch; right divisional shunts are long shunts, whereas the central divisional shunt is usually a short aneurysm-like dilation joining the right portal branch with the intrahepatic caudal vena cava.

Microhepatica is common in dogs with both extrahepatic and intrahepatic CPSS, but is less commonly reported in cats. Urolithiasis and mild renomegaly are also fairly common in dogs, but infrequently identified in cats.

Potential abnormalities identified on survey radiographs of patients with CPSS include microhepatica, renomegaly, and limited serosal detail due to poor body condition. In cases with portoazygos shunting, a dilated azygos vein is occasionally recognized as a soft tissue band crossing the thorax adjacent to the aorta. Although hematogenous osteomyelitis of the lumbar vertebrae has occasionally been reported in patients with CPSS, this is not a common finding. The uroliths associated with CPSS are ammonium biurate and are typically radiolucent.

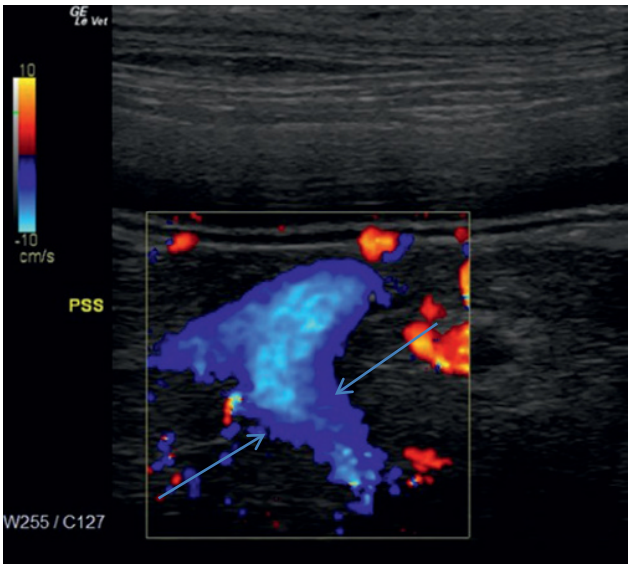

Figure 61.16 Color Doppler ultrasound image showing an extrahepatic portocaval shunt (*blue arrows*) in a 6-month-old ME Bichon × Yorkshire terrier. The blue color indicates that the direction of blood flow is away from the hepatic portal vein.

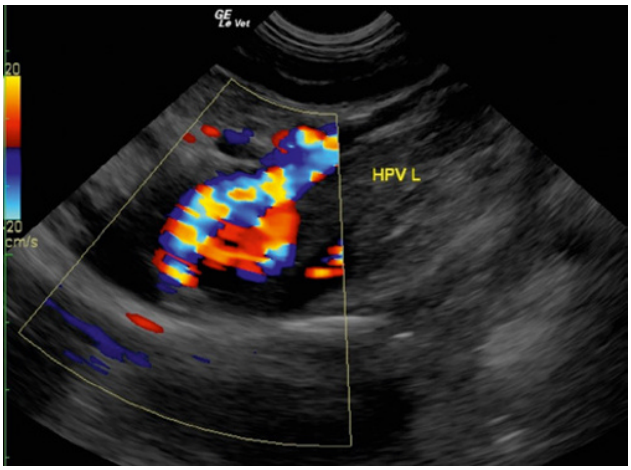

Figure 61.17 Color Doppler ultrasound image showing a left divisional intrahepatic portocaval shunt in a 6-month-old FE golden retriever. The mosaic pattern of the color Doppler indicates turbulence at the point that the shunt joins the intrahepatic caudal vena cava.

Historically, mesenteric portovenography was widely used for the definitive confirmation of a suspected portosystemic shunt and for the differentiation between intra and extrahepatic shunts. The most popular technique for portovenography is the intravenous injection of nonionic iodinated contrast media through a catheter preplaced into a mesenteric vein. This involves a laparotomy and is an invasive procedure. Alternative and potentially less invasive, but less commonly used, techniques for contrast administration include percutaneous ultrasound-guided catheterization of the splenic vein, catheterization of the cranial mesenteric artery via the femoral artery and transvenous retrograde portography. In many cases, mesenteric portovenography has been superseded by contrast Computed Tomographic examination. However, during surgical occlusion of a shunt, portovenography is still used to verify that the correct vessel has been occluded, to check that there are no additional shunting vessels and to assess the degree of portal vascularization post-ligation. Fluoroscopic imaging of the contrast injection provides useful real time information (Fig 61.18): if this is not available, then standard radiographic views (ideally both lateral and VD views, each exposed at the end of a separate contrast injection) should be taken.

Hepatic Congestion

Disturbance of the normal venous outflow results in passive hepatic congestion. Causes include right-sided heart failure and obstruction or compression of the cranial part of the caudal vena cava (between the hepatic veins and right atrium), for example by thrombosis, neoplasia or inflammation. Ultrasound findings include hepatomegaly, reduced hepatic echogenicity, dilation of the hepatic veins and caudal vena cava and, in some cases, the presence of free abdominal (+/– pleural) fluid. Radiographs may show hepatomegaly and loss of serosal detail in patients with ascites, possibly with evidence of a pleural effusion and cardiomegaly in patients with right-sided heart failure.

Portal Hypertension

Chronic portal hypertension resulting in the development of portosystemic collaterals (acquired portosystemic shunts) is relatively common in dogs, but rarely identified in cats. Causes of portal hypertension include advanced chronic liver disease (cirrhosis), intrahepatic arterioportal fistulae, congenital hypoplasia of the portal vein and portal vein obstruction. Ultrasound evaluation of patients with portal hypertension will typically demonstrate ascites, often with edema of the gallbladder wall and pancreas. Spectral Doppler is useful in measuring portal velocity; the identification of reduced flow velocity (from a normal velocity of approximately 17+/-5cm/s to <10 cm/s in the dog), and occasionally reversed portal flow, is very suggestive of portal hypertension. The portosystemic collaterals open in response to sustained portal hypertension and connect the portal system directly to the systemic circulation. These acquired shunting vessels can be challenging to identify on ultra-

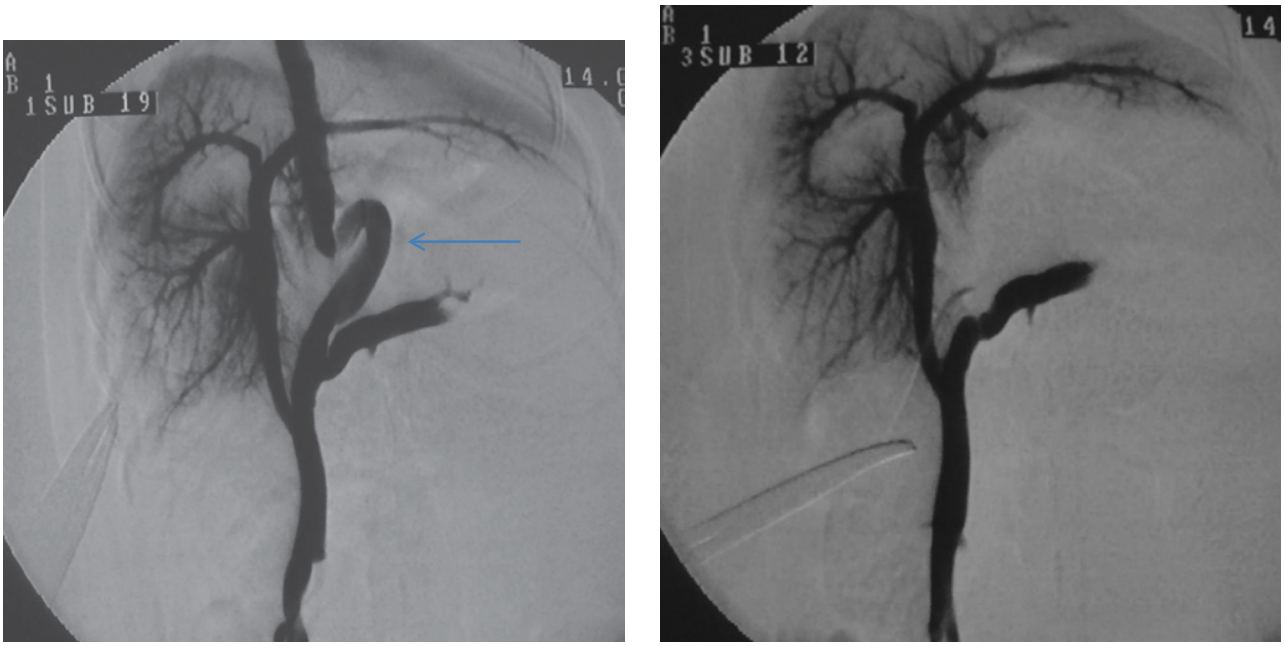

Figure 61.18 Ventrodorsal intraoperative fluoroscopic image acquired immediately after the administration of nonionic contrast medium into a mesenteric vein. The contrast highlights a left gastro-azygos extrahepatic portosystemic shunt (blue arrow). *Source:* Rob White, School of Veterinary Medicine and Science, University of Nottingham

sound; in dogs, the opening of splenorenal collaterals, with enlargement of the left gonadal vein and development of a complicated plexus of vessels adjacent to the left kidney, has been most commonly documented.

Ultrasound examination may be useful in documenting the cause of portal hypertension. A small, hyperechoic, irregular liver with multiple hypoechoic regeneration nodules may be identified in patients with *cirrhosis*. Intrahepatic *arterioportal fistulae* are direct connections between the hepatic arteries and the portal vessels. These vascular anomalies may be congenital or acquired and may be seen on ultrasound as distended, tortuous intrahepatic vessels. The high arterial pressure results in portal hypertension and dramatic ascites, with spectral Doppler demonstrating reversed, often pulsatile flow within an enlarged hepatic portal vein. *Congenital hypoplasia* of the hepatic portal vein is thought to affect both extrahepatic and intrahepatic portal vasculature and includes the condition of portal vein hypoperfusion previously referred to as microvascular dysplasia.

Although hypoplasia of the extrahepatic portal vein may be seen as a reduction in vessel diameter, the lack of objective measurement criteria makes this difficult to identify definitively. A small liver may be identified in patients with mild portal vein hypoplasia; ultrasound examination is often otherwise unremarkable. However, evidence of portal hypertension and acquired portosystemic shunting may be identified in patients with more severe changes. The most common cause of portal vein obstruction is *portal thrombosis*, which may occur secondary to hypercoagulability, vascular stasis or damage to the vascular endothelium (for example, due to local neoplasia or inflammation). Portal thrombosis is recognized as an intraluminal immobile echogenic structure, with color Doppler highlighting the thrombus as filling defects in the normal pattern of flow (Figure 61.19).

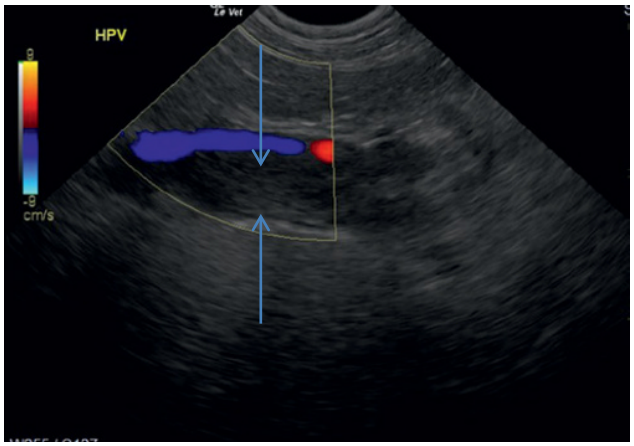

Figure 61.19 Color Doppler ultrasound image highlighting a portal thrombus as a filling defect within the hepatic portal vein (*blue arrows*).

Larger thrombi can extend from the extrahepatic portal vein into the portal branches, resulting in portal hypertension and acquired shunting.

Radiographic examination of patients with portal hypertension is often unrewarding. Many will have evidence of ascites, obscuring the serosal detail of the abdomen. In patients with chronic liver disease, it may be possible to identify microhepatica, even in the presence of ascites, by the cranial displacement and clockwise rotation of the gastric axis.

Peliosis Hepatis

Peliosis hepatis is seen as randomly distributed cystic and blood-filled spaces within the liver, thought to be formed due to either focal hepatocytic necrosis or local obstruction of small portal branches with hepatic atrophy and subsequent sinusoidal dilation. The condition is rare in dogs and more commonly identified in older cats. On ultrasound, the the abnormal sinusoidal dilation may be seen as multiple cystic lesions that may mimic vascular tumors, such as hemangioma or hemangiosarcoma.

Advanced Imaging Techniques

Contrast-Enhanced Ultrasound

Contrast-enhanced ultrasound is a non-invasive imaging technique that enables the functional assessment of organ perfusion patterns. The contrast media consist of microscopic (2–6 μm) inert gas-filled microbubbles that are injected intravenously. When subjected to ultrasound waves, these bubbles respond with a nonlinear oscillation, generating strong harmonic frequencies that can be detected using specialized transducers and dedicated contrast imaging software. In the liver, two phases of contrast enhancement may be recognized: the early phase of enhancement is equivalent to the blood pool phase and is composed of arterial (wash-in) and portal (wash-out) stages, with the enhancement peaking at the same time as peak portal blood flow (typically 15–60 seconds in dogs), and disappearing by 150–200 seconds in most dogs. This early phase allows the detection of hepatic arteries and small vessels that would not be apparent with conventional gray-scale B-mode imaging. The late phase is only recognized with contrast media that are able to leave the blood pool; this phase corresponds to intracellular contrast uptake and enables the assessment of parenchymal perfusion.

Contrast-enhanced ultrasound has been demonstrated as a safe and accurate technique for differentiating between benign and malignant liver lesions. Malignant lesions do not have a portal venous supply and are perfused only via the hepatic arterial supply. At peak

(portal) early phase enhancement, malignant nodules therefore appear show hypoenhancement in comparison to the surrounding liver, while benign nodules typically show isoenhancement or slight hyperenhancement. A similar pattern is reported during late-phase enhancement, with most malignant lesions appearing relatively hypoechoic.

Nuclear Scintigraphy

Although nuclear scintigraphy is a well-established imaging technique, its availability is limited by the strict regulation of radiopharmaceuticals. Nuclear medicine is most widely used as a very sensitive and minimally invasive technique for the diagnosis of PSS. The best documented protocol involves the per-rectal administration of ^{99m}technetium pertechnetate (^{99m}Tc), which is rapidly absorbed from the colonic mucosa. The ^{99m}Tc subsequently enters the mesenteric vessels, from where it should pass through the hepatic portal vein into the hepatic parenchyma before filtering through the hepatic microcirculation to enter the hepatic caudal vena cava and then the heart. In a patient with a PSS, the ^{99m}Tc bypasses the liver and is delivered directly to the heart. Regions of interest (ROIs) drawn over the heart and liver are used to calculate the shunt fraction by comparing the intensity of radioactive counts over the heart with the intensity of counts over the liver.

$$\text{Shunt fraction} = \frac{\text{Total heart counts over first 12 seconds}}{\left[\text{Total heart and liver counts over first 12 seconds}\right]}$$

A normal shunt fraction is less than 15%. In dogs with PSS (extra- or intrahepatic), shunt fractions of 80%+ have been reported; lower shunt fractions (approximately 50%) have been reported in cats with PSS. Unfortunately, there does not appear to be a good correlation between the calculated shunt fraction and the physical size of the shunt. Direct ultrasound-guided injection of the ^{99m}Tc into the splenic parenchymahas been described as an alternative to per-rectal administration; this results in significantly decreased radiation exposure and provides superior image quality, in many cases allowing the differentiation between single congenital and multiple acquired shunts. Although useful both in confirming the presence of a PSS and identifying the presence of continued shunting after an unsuccessful or partial surgical ligation, disadvantages of nuclear scintigraphy include the lack of specific anatomic information (especially with per-rectal scintigraphy), as well as the potential inconvenience and hazards of working with radioactive isotopes. Portal vein hypoplasia (microvascular dysplasia) will not be identified with nuclear scintigraphy.

Following the intravenous administration of the radiopharmaceutical ^{99m}Tc-mebrofenin, hepatobiliary scintigraphy may also used for the evaluation of liver function, detection of cholestasis and biliary tract obstruction, and diagnosis of cholecystitis. In the normal patient ^{99m}Tc-mebrofenin is extracted from the blood pool by the liver, with peak liver radioactivity observed 6–8 minutes after injection. The hepatic extraction fraction (HEF) is used as a measure of hepatocyte function. Following extraction by the hepatocytes, the radiopharmaceutical is excreted into the biliary tree with a half-life of 19 minutes, resulting in detectable radioactivity in the gallbladder and small intestines within one hour of injection. A prolonged clearance time indicates extrahepatic biliary obstruction and in dogs may allow the detection of abnormalities before any ultrasound changes are identified.

Computed Tomography

Computed tomography (CT) is an increasingly widely available, rapid and noninvasive diagnostic imaging technique that is especially useful in the evaluation of hepatic vascular abnormalities and hepatic mass lesions. Multidetector row CT angiography enables very detailed anatomic evaluation of the hepatic arterial, portal and venous architecture and should facilitate the identification of both intra- and extrahepatic portosystemic shunts, arterioportal fistulae, and portal vein obstruction. Using three-dimensional reconstructions, it should be possible to accurately identify and trace the hepatic portal vein and its tributaries and to accurately identify the origin and termination of both intra- and extrahepatic shunts.

In patients with hepatic masses, CT provides important information about the exact size and extension of a mass, allows identification of significant vascular involvement, and facilitates evaluation of the rest of the abdomen and the thorax for the presence of metastatic disease; this information is invaluable both in determining the feasibility of surgical resection and in planning surgical margins. More recently, the use of dynamic contrast CT in dogs has shown potential in the differentiation of benign and malignant hepatic masses.

Disadvantages of CT include its relatively limited availability, the requirement for general anesthesia, and the relatively high doses of ionizing radiation involved.

Magnetic Resonance Imaging

Contrast-enhanced magnetic resonance imaging (MRI), usually referred to as magnetic resonance angiography (MRA), is routinely used in humans for imaging the portal venous system. Although the acquisition of good-quality images is technically difficult and accurate interpretation of the images requires experience, this

technique is being successfully used in dogs and cats and can provide a rapid and accurate diagnosis with excellent anatomic resolution. In dogs with liver masses, MR imaging findings have also been successful in differentiating benign and hepatic lesions.

Image-Guided Sampling

Although diagnostic imaging provides useful information, the imaging features of canine and feline hepatobiliary disease are rarely specific for a single disease process. Despite the potential offered by newer techniques such as contrast-enhanced ultrasound, CT and MRI, in most cases it is still not possible to definitively characterize the underlying disease process or to differentiate benign from malignant disease from the imaging appearance alone. Obtaining samples of material for cytology and/or histopathology is therefore important in providing additional information and, in many cases, a definitive diagnosis.

The most commonly used image-guided sampling techniques are percutaneous ultrasound-guided aspiration and tissue-core biopsy. These well-established techniques are routinely used in dogs and cats, and are considered safe and minimally invasive. Fine needle aspiration (FNA) is cheaper, easier and has fewer potential complications than tissue-core biopsy. However, cytopathologic (FNA) and histopathologic (core biopsy) diagnoses from the same tissue do not always agree. FNAs inevitably result in disruption of the normal structural relationship between cells within a tissue and are therefore most useful in diagnosing diseases that can be identified from individual cells (e.g., lymphoma) and in differentiating between inflammatory, neoplastic, and degenerative/necrotic change. In conditions where preservation of tissue architecture is more important, for example vascular disorders and chronic hepatopathies, a tissue-core biopsy is more likely to provide useful diagnostic information.

When obtaining samples, the most important guidelines are to use the *shortest distance* and the *safest path* to reach the site of interest. The needle should not pass through more than one body cavity or more than one organ and for both FNA and tissue-core samples, it is important to visualize the needle tip as it is advanced into the tissue, keeping the entire needle length visible within the plane of the ultrasound beam. Accurate needle placement is usually easier using a curvilinear (or micro-convex) transducer. For superficial lesions, linear transducers have the advantage of superior near-field resolution, but needle placement may be more challenging. 1" or 1.5" 20–22 ga standard injection needles are most commonly used for FNA, with 2.5" or 3.5" spinal needles occasionally used for sampling deeper lesions. For tissue-core biopsies, either manual or automated biopsy devices may be used. A 14, 16 or 18 ga needle (depending on the size of the patient and of the liver) and a 2 cm tissue sample notch are usually selected. Depending on the patient's clinical status and the tissue being sampled, a coagulation profile is not usually required before obtaining FNAs; however, it is strongly recommended prior to tissue-core biopsy.

Although many conscious patients will tolerate ultrasound-guided FNAs, sedation is recommended and general anesthesia is indicated for patients undergoing tissue-core biopsy. When obtaining FNAs, the skin overlying the aspiration site should be clipped and cleaned prior to sampling; ultrasound gel can confuse the cytologic interpretation and should be avoided. For a tissue-core biopsy, aseptic preparation is required. Ultrasound gel may be used, but should be sterile.

Serious complications associated with FNAs are rare, but include hemorrhage, tumor seeding, and, following gallbladder aspiration, bile leakage and potential peritonitis. The risk of hemorrhage is increased with tissue-core biopsy; however, although small amounts of free fluid are not uncommon post biopsy, in patients with normal coagulation status any bleeding should be self-limiting.

Metabolic, Toxic, and Neoplastic Diseases of the Liver

Jan Rothuizen, DVM, PhD, Dip ECVIM-CA

Department of Clinical Science of Companion Animals, Utrecht University, Utrecht, The Netherlands

Metabolic Diseases

The liver displays a multitude of metabolic functions, which may fail when the liver becomes diseased. The most important functions which may cause immediate clinical signs with a failing, diseased liver are bilirubin metabolism and metabolism of neurotransmitter precursors. Failing liver function may then lead to hyperbilirubinemia with icterus, and hepatic encephalopathy, respectively. Furthermore, the liver is involved in many metabolic and detoxification processes, and may therefore be the principal organ to develop secondary damage. The most important examples are secondary nonspecific (reactive) hepatitis, steroid or vacuolar hepatopathy, and hepatotoxicity of drugs such as acetaminophen, carprofen, and sulfonamides. Hepatic lipidosis (steatosis) in cats deserves specific mention, as this is the most common metabolic disorder of the liver in cats. The final group of metabolic liver diseases are the inherited metabolic diseases. Some are very frequent, such as copper storage diseases in many dog breeds, while others are rare (amyloidosis) or very rare (lipoprotein lipase deficiency, lysosomal storage diseases).

Vacuolar Hepatopathy, and Liver Changes in Cushing Disease

Etiology/Pathophysiology

Both spontaneous hyperadrenocorticism (Cushing disease) and the administration of glucocorticoids cause specific abnormalities in the liver. A similar hepatic change may occur without any known cause. There is glycogen accumulation in the hepatocytes that results in large vacuoles (ballooning). This leads to varying degrees of hepatomegaly. These changes can cause elevation of the plasma levels of liver enzymes, mainly alkaline phosphatase (ALP), and bile acids. Alanine aminotransferase (ALT) may be elevated but usually much less than the cholestasis indicators. Increased ALP is caused not only by hepatocellular damage but also by induction of an isoenzyme of ALP by glucocorticoids.

History and Clinical Signs

The clinical signs are those of Cushing disease if this is the underlying cause. Steroid hormones other than cortisol may also cause these liver effects. The above-mentioned changes in the liver can result in hepatomegaly, which may be detectable by abdominal palpation. The histologic changes occur long before signs suggestive of Cushing disease, as do the elevations of ALP and ALT. It is important to remember that a number of signs that occur in Cushing disease also occur in primary liver diseases: lethargy, exercise intolerance, polydipsia, hepatomegaly, and elevated ALP, ALT, and bile acids.

Diagnosis

It is important to know whether elevated liver enzyme levels and bile acids are due to exogenous corticosteroid use or Cushing disease. The typical liver changes can always be determined by histologic examination of a liver biopsy; the histologic changes are specific. These diffuse changes are also detectable in cytologic smears taken by way of fine needle aspiration. The corticosteroid-induced ALP isoenzyme can be distinguished because most of it is still active after heating the plasma to 65° for 2 minutes. Readers are referred elsewhere for discussions on the diagnosis and management of Cushing disease.

Therapy

The glucocorticoid-induced changes in the liver are reversible within a few weeks to months after removing the cause. However, in other cases, the prognosis depends

on the cause of the glucocorticoid excess. In cases in which it is not possible to identify the cause of glucocorticoid excess, over time fibrosis may develop, leading to worsening liver disease.

Hepatic Lipidosis Secondary to Diabetes Mellitus

Etiology/Pathophysiology

The liver plays a central role in fat metabolism. In diabetes mellitus, there is increased lipolysis in adipose tissue and therefore increased delivery of fatty acids to the liver, while the production of triglycerides is also increased. Fat accumulates in the liver cells and in the dog it is microvesicular, mainly caused by accumulation of triglycerides. This fatty change begins around the central veins and progresses toward the periphery of the lobule. This results in the development of hepatomegaly. Sometimes there is cholestasis, which can be quite severe. There is much more severe liver dysfunction with fatty change than with glycogen accumulation. In humans, the chronic fatty change that occurs in diabetes mellitus can lead to hypertrophic liver cirrhosis, but in dogs and cats this is very rare.

History and Clinical Signs

Fatty change in the liver is usually present in diabetes mellitus and it can occur without causing clinical signs. It can also cause mild to severe intrahepatic cholestasis. In this case, physical examination reveals hepatomegaly and icterus. All of the liver enzymes can be mildly to severely increased. The clinical signs are those related to diabetes mellitus, namely polyuria, polydipsia, weight loss, and an increased appetite.

Diagnosis

Liver histology demonstrates the fatty change, which is confirmed in combination with the diagnosis of diabetes mellitus (persistent hyperglycemia, glucosuria).

Therapy

Therapy of fatty change in the liver of dogs is not necessary. Regulation of the diabetes mellitus leads to a gradual disappearance of the fatty change.

The Liver in Hyperthyroidism

Hyperthyroidism is associated with fatty infiltration of the hepatocytes. This does not cause clinical signs of liver dysfunction, but in many cases the liver enzymes and bile acid levels are abnormally high. The fatty changes are not severe and there is no liver enlargement. A number of clinical signs associated with hyperthyroidism mimic those of primary liver diseases: polyuria, vomiting, diarrhea, and weight loss.

Hepatic Lipidosis (Steatosis) in Cats

Etiology/Pathophysiology

One important difference between dogs and cats is the relatively low capacity of the liver enzymes responsible for conjugation of cholephilic substances, used to make them more polar prior to biliary or urinary excretion, in the cat. The low hepatic glucuronyl transferase capacity is important for the metabolism of endogenous products such as bilirubin and exogenous compounds, either drugs or toxins. The elimination of drugs like chloramphenicol, nonsteroidal antiinflammatory drugs and anticonvulsants depends on this function. Hence, toxic side-effects develop much more easily in cats in cases of overdosage or reduced liver function.

Cats also have different amino acid requirements from dogs, as they cannot synthesize a sufficient number of the essential amino acids (arginine, taurine, and carnitine). Arginine is an important intermediate metabolite in the hepatic urea cycle in which ammonia is being converted into urea. This causes a relatively high susceptibility to develop hyperammonemia and hepatic encephalopathy in cases of inadequate protein intake, for example anorexia. Cats, unlike dogs, may have hepatic encephalopathy with parenchymal liver disease without portosystemic collateral circulation. Arginine and taurine are involved in the hepatic production of apoproteins, which are used to form the very low-density lipoproteins. These lipoproteins are the form in which the liver can secrete triglycerides into the circulation for further metabolism. Insufficient availability of arginine and taurine may lead to accumulation of triglycerides in the liver, for example in the case of fasting. Taurine also plays a role in detoxification, as it is used by the liver as a conjugating group to make substances such as bile acids more hydrophilic. Taurine is also involved in glutathione metabolism, which is one of the major routes of hepatic detoxification. Carnitine is an intermediate enabling beta-oxidation of long chain fatty acids in mitochondria, and this function may be impaired in anorexia.

Fat accumulation in the liver occurs in different species, as a result of metabolic conditions in which there is increased deposition or impaired removal of triglycerides in the liver. Clinically, this may be of importance in diabetes mellitus as discussed for dogs. Subclinical fat accumulation, only detectable with histologic examination of the liver, occurs in many other conditions such as high intake of calories, hypoxia of the liver and induction by a number of toxic substances. Cats, however, display an idiopathic form of hepatic lipidosis that may become life-threatening. Accumulation of triglycerides is the result of a disturbed balance between triglyceride uptake by the liver and their removal. The latter is normally achieved by formation of lipoproteins (especially very

low-density lipoproteins, VLDL), which allows for secretion of fatty acids into the circulation for further metabolism in other tissues. Another route for the liver to metabolize fatty acids is via beta-oxidation.

Fat cats seem to be predisposed, but lean cats may also develop lipidosis. It is generally appreciated that prolonged fasting is the most important factor inducing lipidosis. Fasting may affect hepatic fatty acid metabolism in three ways. First, fasting induces peripheral lipolysis and increased delivery of fatty acids to the liver. The intake of essential amino acids may also become inadequate. Deficiency of arginine and taurine may inhibit the apoprotein formation necessary to form resulting in the accumulation of triglycerides. Finally, carnitine deficiency may result in impairment of beta-oxidation, which is a major pathway for hepatic fatty acid catabolism.

Most cats with lipidosis have slight hyperglycemia as a result of impaired glucose tolerance. It is not known what underlying mechanism leads to deranged glucose metabolism. There is no tendency to develop overt diabetes mellitus. There is no consistency with respect to the level of insulin and glucagon; both high and low values have been reported. In cats with concurrent diabetes mellitus, very high doses of insulin are required to lower the blood glucose in these cats, suggesting insulin resistance. We have measured high growth hormone concentrations in a few patients, which could explain insulin resistance, but this could not be related to progestin administration or other factors known to induce growth hormone excess. Whatever the cause, hyperglycemia is a possible factor further contributing to accumulation of triglycerides.

Lipidosis results in hepatomegaly with yellow discoloration and a friable texture. As in all types of hepatomegaly, the margins of the lobes become rounded. Accumulated fat is concentrated in micro- or macrovesicular vacuoles in the hepatic cytoplasm. Swelling of cells can easily produce intrahepatic cholestasis. Reduced liver function and fasting may trigger hepatic encephalopathy.

Signalment

Lipidosis may occur at any age in both males and females, although there seems to be an increased incidence in middle-aged cats. There appear to be individual differences in susceptibility; some cats sustain prolonged fasting without developing lipidosis, and others develop recurrence with every episode of prolonged fasting. It is interesting to note that hepatic lipidosis occurs regularly in the United States but less frequently in Europe, and is very uncommon in the United Kingdom. It is not known whether these regional differences reflect variations in genetic make-up of the populations or differences in composition of cat food.

History and Clinical Signs

Cats often present with anorexia and lethargy. There may be occasional vomiting, and icterus is a common finding. Clinical signs consistent with hepatic encephalopathy may also occur. Clinical signs related to an underlying disease resulting in anorexia may also be present.

Diagnosis

The clinical signs and findings on physical examination (icterus and hepatomegaly) are not specific, and neither are elevated serum bile acids and liver enzymes. Slight or moderate hyperglycemia is often present but this is not diagnostic. Remember that stress during blood sampling often results in hyperglycemia in cats. On ultrasonographic examination, an enlarged and obviously hyperechoic liver is commonly seen. The diagnosis can only be made by evaluation of liver tissue. However, due to the diffuse nature of the disease, fine needle aspiration cytology is usually diagnostic.

Therapy

The most important management strategy is to get the cat out of the catabolic condition, and to supply the amino acids essential to prevent further fat accumulation and development of hepatic encephalopathy. Forced feeding of semiliquid food may be required, and this can be achieved in most cases by slow oral feedings with a syringe. However, this method of feeding is unsuitable for the long term and can be very difficult in some cats. Other forms of enteral feeding are therefore preferred, and esophagostomy or gastrostomy tubes are sensible first choices. These feeding tubes can be left *in situ* for prolonged periods, and also enable sufficient calories to be fed to meet the cat's daily need. Alternatively, a nasoesophageal feeding tube can usually be placed with relative ease, although these are not suitable for the long term, nor adequate for meeting the daily nutritional requirements.

Since protein is the most important component in the treatment of the metabolic derangements leading to lipidosis, 30–40% of the total calories should be administered as protein. Moreover, diets should contain the essential amino acids arginine and taurine. Recovery formula commercial diets are available to meet these requirements. It may be advisable to give vitamin B12 supplementation as well. There is little indication for the use of glucose as an energy source, since cats tend to have glucose intolerance and cannot adequately utilize it. So-called lipotrophic compounds, such as methionine, are also not recommended. It also is not recommended to administer insulin, because of the risk of life-threatening hypoglycemia, whereas hyperglycemia appears to be a secondary instead of a primary phenomenon.

Supportive care includes restoration of the fluid and electrolyte balance. Ammonia (if available), electrolytes (sodium and especially potassium), and pH should be monitored to permit supportive care directed at hepatic encephalopathy if indicated.

Prognosis

Owners need to be warned that the prognosis is generally guarded, with roughly half of cats surviving. Moreover, therapy can be prolonged, sometimes consisting of several weeks to months of enteral nutrition. The prognosis is quite good if the condition is diagnosed and treated early. However, cats with severe hepatic encephalopathy have a worse prognosis.

Liver Changes Due to Anemia and Shock (Acute Hypoperfusion)

Etiology/Pathophysiology

Liver degeneration or necrosis can occur with acute hypoxia of the liver. In this context, it is important to remember that the blood supply of the liver is predominantly venous and therefore any adaptation to hypoxia requires time. Possible causes for such lesions are acute hemolysis or massive blood loss. Histologically, there is necrosis of the centrilobular zone 3 (the oxygen-poor part of the liver lobule). Extensive necrosis may occur in rare cases with confluent and bridging necrosis, forming connections between necrotic centrilobular areas. Necrosis induces a secondary inflammatory reaction of polymorphonuclear cells, and there is usually widespread cholestasis. In cases of hemolysis, there is erythrophagocytosis and/or accumulation of iron pigment in the reticuloendothelial system, and sometimes extramedullary hematopoiesis is seen. In addition to the general illness and icterus, hepatic encephalopathy can also occur in severely affected cases.

These changes explain why hemolytic anemia is so often accompanied by an increase in conjugated bilirubin, and this is sometimes marked. It is the cholestasis, rather than the hemolysis, that determines the degree of icterus. Hence, bilirubin is predominantly the conjugated direct reacting type. ALT, AST, ALP, and gamma-glutamyl transferase (GGT) can be severely elevated. Sometimes, the liver dysfunction is so severe that, in spite of adequate treatment of the hemolysis, it leads to death.

History and Clinical Signs

Clinical signs are usually acute in onset, and a history of recent shock may be present. In hemolytic anemia, the mucous membranes may be jaundiced and are usually pale. Clinical signs are in part those of anemia, namely lethargy and exercise intolerance. Subsequent signs resulting from liver dysfunction depend on the extent of liver necrosis, and vary from general illness and lethargy to hepatic encephalopathy. Anorexia and vomiting may occur as a result of impaired detoxifying function of the liver.

Diagnosis

The presence and severity of any liver changes can only be confirmed by histologic examination of a liver biopsy. These changes are specific and therefore confirmatory. An impression of the severity and course of the liver necrosis is provided by measurements of the liver enzymes and bile acids in serum, but they may also be elevated in any other hepatobiliary disease and are by no means specific. The diagnosis of the underlying disease causing anemia or shock is not discussed here.

Therapy

Management primarily involves treatment of the underlying cause of hypoxia. There is no specific treatment possible for the hepatic lesions, and the liver will recover spontaneously in most cases after resolution of the underlying condition. In cases of severe damage, the impaired liver function may become life-threatening. Only symptomatic supportive therapy for liver dysfunction can be given, to allow time for the liver to regenerate. Specific measures to prevent or reduce hepatic encephalopathy may be important. Remember that the course of liver regeneration cannot be evaluated by the degree of icterus.

Prognosis

The prognosis is very variable and primarily depends on the underlying cause of hypoxia. If the underlying cause can be addressed, hepatic changes are likely to be reversible.

Amyloidosis

Etiology/Pathophysiology

Amyloidosis of the liver is very rare in dogs or cats. Amyloidosis is often a systemic disease involving a number of organs. In cases of generalized amyloidosis, there is usually also deposition of amyloid in the liver and kidneys, but this seldom leads to clinical signs relevant to the liver. The severe glomerular damage leading to urinary protein loss is almost always the most important clinical phenomenon. In the liver, deposits of amyloid are visible as amorphous hyaline and eosinophilic material in the space of Disse when Congo red staining is used. Depending on the amount of amyloid, the liver may be enlarged on abdominal palpation. However, it is often a normal size. Liver enzymes and bile acids may be increased, although sometimes they are within the normal reference interval.

Signalment

Amyloidosis is frequently identified in the shar-pei dog, although other breeds can be affected. In cats, the Siamese, Oriental shorthair, Devon Rex and Burmese are predisposed.

History and Clinical Signs

Overt liver dysfunction is rare in amyloidosis, even when the liver is grossly enlarged. Nephrotic syndrome is the most common finding in these patients due to severe and prolonged proteinuria resulting from renal amyloidosis. Other possible signs of renal dysfunction are vomiting, anorexia, and polyuria. Spontaneous rupture of the liver may occur in severe cases, resulting in acute blood loss, shock, and death.

Diagnosis

The deposition of amyloid can only be detected by cytologic or histologic examination of relevant biopsy material (liver or kidney). Taking biopsies is not without risk as the liver may rupture, resulting in severe abdominal hemorrhage.

Therapy

There is no specific treatment available for amyloidosis. The deposition of amyloid is progressive and in animals with end-stage disease, the prognosis is very poor.

Copper Storage Diseases Leading to Chronic Hepatitis and Cirrhosis

The accumulation of copper in liver tissue has been described in several breeds of dog. Excessive accumulation includes that seen in true "copper storage" disease, where the primary initiating event is a defect in copper excretion leading to secondary hepatocyte damage, and "copper-associated" disease, in which copper accumulates secondary to an underlying inflammatory liver disease.

Copper storage diseases probably occur in several breeds of dog, although there appear to be differences in prevalence between countries. Copper storage disease was suspected in about 30% of all dogs with hepatitis in one study from The Netherlands, but is relatively uncommon in the UK. The Bedlington terrier, Labrador retriever, Dalmatian, Anatolian shepherd, Airedale terrier, and spaniel breeds appear to be predisposed.

In primary copper storage disease, copper accumulates in the liver when the excretion of excessive copper into the bile is deficient. This is a gradual process and usually toxic levels leading to chronic hepatitis and cirrhosis are reached at an age of 4–7 years. Copper first accumulates in the centrolobular region of the liver (zone 3 around the central vein); in later stages, zone 2 and zone 1 (periportal zone) may also become gradually affected. This differs from copper-associated disease, which is the predominant form in all dogs, in which cholestasis causes periportal copper accumulation (zone 1), with copper later accumulating in zones 2 and 3.

Copper Storage-Induced Hepatitis and Cirrhosis in the Bedlington Terrier

Etiology/Pathophysiology

This disease occurs in Bedlington terriers, resulting in an accumulation of copper in the liver, usually due to an autosomal recessive mode of inheritance. In many affected dogs, the disease is caused by a deletion in the COMMD1 gene, resulting in lack of production of a specific protein. This protein is an important chaperone for the copper-transporting protein ATPase 2, encoded by the human Wilson disease gene ATP7B, the principal hepatocyte exporter of copper into bile. Only homozygotes become ill; heterozygotes have a normal liver.

Normally, some of the copper ingested is absorbed in the intestine and transported to the liver in the portal blood, where it is loosely bound to albumin. Most of this is taken up by the hepatocytes and excreted in the bile via the liver cell lysosomes. A small part is incorporated in ceruloplasmin in the liver, and copper incorporated in this protein is released in the plasma. Copper in ceruloplasmin is used for incorporation in a number of enzymes and proteins, essential for normal function. Most of the copper is bound to the protein metallothionein. Copper then moves to the lysosomes of the hepatocytes and is excreted into the bile bound to an unidentified protein. In this form, it leaves the body in the feces. In Bedlington terriers with copper storage disease, the hepatocytes are almost completely unable to excrete copper in the bile and hence there is an increasing accumulation of copper in the liver. The exact nature of the defect is not known, but it is a lysosomal disorder. Because the copper accumulation begins gradually, the clinical signs usually only begin to appear after around 4 years of age. The increased copper concentration in the liver can be confirmed after 1 year of age; before then, some dogs with the disease have not yet stored sufficient copper to distinguish them from normal animals.

There is a chronic form in which the copper accumulation leads to liver cell necrosis and secondary hepatitis, cumulating in cirrhosis. Some dogs also have an acute form of copper storage disease, with a hemolytic crisis. The hemolysis is probably the result of a sudden release of a large amount of copper from hepatocytes into the blood. The mechanism for this is not clear. The sudden increase in blood copper concentration causes acute hemolysis, and because liver function is already reduced, this leads to severe icterus. Tubulonephrosis may occur and can lead to uremia. The hemolysis in turn results in

centrilobular liver necrosis as a result of hypoxic damage. In dogs surviving the hemolytic crisis, cirrhosis occurs much more often than in other animals.

History and Clinical Signs

With chronic copper accumulation, the clinical signs are those of chronic hepatitis or cirrhosis. The reader is therefore referred to the relevant sections for further details. In the acute form there is acute hemolysis, anemia, severe icterus, and sometimes uremia. The acute form is often lethal within a few days.

Diagnosis

Laboratory examination may reveal any of the changes seen in chronic hepatitis and cirrhosis, such as increased ALT, ALP, GGT, bile acids, and bilirubin. Hypoalbuminemia and hepatic encephalopathy with increased ammonia concentrations occur only in late stages. There are no specific laboratory parameters that are specific for copper accumulation. Ceruloplasmin and free copper concentrations are not different from healthy dogs, whereas Wilson disease in humans is associated with decreased ceruloplasmin levels.

On the basis of the clinical examination and result of blood tests, it is not possible to differentiate copper storage disease from chronic hepatitis or cirrhosis. The diagnosis can only be made by demonstrating increased copper accumulation in a liver biopsy in animals older than 1 year. Histologically, copper in a liver biopsy may be detected with specific stains such as rubeanic acid. The same staining may be used on cytologic preparations collected by fine needle aspiration. Copper accumulation begins in hepatocytes around the central veins (zone 3) and gradually spreads outwards toward the portal areas. The copper is stored in the hepatic lysosomes. The copper-induced liver cell damage only occurs when a certain level is exceeded. The damage leads to ongoing liver cell necrosis and secondary inflammation that can eventually result in fibrosis and cirrhosis. The normal concentration of copper in the canine liver is between 50 and 300 µg/g dry weight. Dogs with copper accumulation have levels exceeding 1000 µg/g dry weight at 1 year of age, but most cases have higher concentrations. With time, levels of 12 000 µg/g dry weight may be reached. At 1 year of age, a few dogs have concentrations between 300 and 1000 µg/g dry weight, and most of them appear not to accumulate when reexamined later.

A genetic test for the mutated COMMD1 gene is available, although not all dogs with the disease have this defect. However, heterozygote carriers cannot be distinguished from homozygote healthy animals. A few decades ago, the incidence of the disease in Bedlington terriers was about 30–50%. However, with the availability of a reliable genetic test, the incidence of the disease has dramatically declined, with clinical cases becoming quite rare.

Therapy

Once signs of chronic hepatitis or cirrhosis are present, or those of an acute hemolytic crisis have developed, specific therapy is usually not possible. Symptomatic and supportive care is therefore important. In chronic hepatitis or cirrhosis, management of hepatic encephalopathy, portal hypertension, and ascites is vital. Readers are referred to Chapter 65 for further details regarding therapy.

Hemolytic crisis is a very serious event. Administration of penicillamine, which is a chelating drug that binds metals, preferentially copper, is indicated. The penicillamine–copper complex is excreted from the kidneys into urine, resulting in free copper being removed from the circulation. Intravenous infusion of fluids with diuresis may also be helpful to enhance urinary copper excretion.

It is important to try to prevent the development of clinical signs in dogs at risk for copper storage disease. Hence, asymptomatic dogs should be examined at a young age, and if there is copper accumulation, life-long medication with drugs that prevent further accumulation of copper is essential. There are two drugs available, and both are given orally in a capsulated form. Penicillamine may be given 30 minutes before each meal at a total daily dose of 25 mg/kg. Penicillamine binds copper in the circulation and the bound complex is excreted in the urine. Another drug is zinc, which may be given as zinc gluconate at a dosage of 30 mg/kg/day in divided doses immediately before each meal. The action of zinc is at the level of the intestinal mucosa, as it induces the formation of copper-binding metallothionein, thus preventing the absorption of copper. The two drugs should not be combined since they form complexes and inactivate each other. These medications are unable to reduce hepatic copper levels in most cases, but they prevent further accumulation and development of the symptomatic stage. Another measure to prevent further accumulation is to reduce the copper content of the food. Commercial foods have been developed to treat and prevent copper storage diseases, and have been proven to be very effective. These are veterinary-formulated liver diets containing low copper and high zinc.

Copper Storage-Associated Hepatitis and Cirrhosis in Labrador Retrievers

Since 2006, Labrador retrievers have been reported to have a form of copper storage disease causing hepatitis, which if untreated results in cirrhosis. Much of the description pertaining to the Bedlington terrier applies to the disease in Labradors. Like all forms of copper storage, the disease develops gradually due to the slow accumulation of copper in the centrilobular area of the liver. Therefore, the typical age of onset of clinical signs in this

breed is also 4–7 years. The copper concentrations in Labrador retrievers remain much lower than in Bedlington terriers (by a factor of 10), and liver samples from Labrador retrievers usually do not exceed 2000 µg/g dry weight, whereas Bedlington terriers may have concentrations exceeding 15000 µg/g dry weight. Another difference is that Labrador retrievers do not develop a hemolytic crisis as easily as Bedlington terriers. The hepatitis may remain "hidden" for a long period since the most sensitive marker, ALT, may stay within normal limits for years, even when copper accumulation and hepatitis are already present. In more advanced cases, fibrosis and cirrhosis may develop, similar to other breeds with copper storage disease.

The diagnosis is made in the same way as the Bedlington terrier, and prevention and therapy are also comparable. Commercial hepatic diet has proven very effective in this breed. Although it is a proven genetic disease, it appears to be much more complex than in the Bedlington terrier, and as such a reliable genetic test is not yet available. Due to the complexity of the disease, it is difficult to give good advice to breeders to aid in prevention of the disease.

Toxic Diseases

Nonspecific Reactive Hepatitis Due to Endotoxins

Etiology/Pathophysiology

Nonspecific reactive hepatitis is a diffuse or focal liver disease with secondary inflammatory reaction resulting from toxemia or sepsis. Reactive hepatitis can occur with every toxemia, sepsis, inflammation, and necrotizing process (including necrosis in tumors). When the process is in tissues drained by the portal system, toxins are transported exclusively to the liver. Toxins and bacteria from processes elsewhere are first diluted in the general circulation before reaching the liver. It is therefore logical that reactive hepatitis is most often caused by processes within the abdomen.

Reactive hepatitis develops in most cases of gastroenteritis and extensive gastric or intestinal tumours (e.g., lymphoma), as a result of increased endotoxin absorption. It also develops in peritonitis, including local peritonitis resulting from abdominal surgery, and in other inflammatory processes in the organs drained by the portal vein. Reactive hepatitis is thus most often caused by gastrointestinal disorders. On the other hand, vomiting and/or diarrhea often occur with primary liver disorders. Hence, when a patient with gastrointestinal problems is found to have high liver enzyme levels, the classic chicken-or-egg situation is encountered, and this problem may only be solved with liver histopathology. However, the reaction pattern in the liver to endotoxins primarily involves the development of canalicular cholestasis, and therefore the cholestatic enzymes ALP, GGT, and bile acids are the most important markers. In many primary liver diseases, the hepatocellular enzymes ALT and AST are the predominant markers, with cholestatic markers less affected. However, there are many exceptions to this general rule.

The circulating toxins, inflammatory mediators, and microbes cause reticuloendothelial proliferation and infiltration of neutrophils into the liver. There can also be focal liver necrosis. In chronic cases, there is also lymphocytic and plasmacytic inflammation. There can be mild to severe cholestasis in the canaliculi. In some cases associated with sepsis, there are diffuse foci of necrosis, microabscesses, or granulomas (e.g., infection with *Herpes canis*, toxoplasmosis, brucellosis, tuberculosis, *E. coli* and migrating larvae of *Toxocara canis*).

Hepatocellular functions usually remain intact in this group of secondary liver diseases. Therefore, hypoalbuminemia, coagulopathies and hepatic encephalopathy are not seen in animals with nonspecific reactive hepatitis.

History and Clinical Signs

The clinical signs are often determined by the primary disorder. Hence, there is often vomiting and/or diarrhea, and sometimes fever. When reactive hepatitis is severe, there can be icterus, general lethargy, and sometimes reduced exercise intolerance.

Diagnosis

Differentiation between primary liver diseases and reactive hepatitis is only possible by histologic examination of a liver biopsy. The abnormalities described under pathogenesis are characteristic. Once the diagnosis of reactive hepatitis is made, it can be very difficult to localize the primary process. Further examination and investigation of the gastrointestinal system are usually therefore indicated.

Therapy

Therapy and prognosis depend on the primary disorder. Reactive hepatitis itself requires no treatment, since it resolves spontaneously after removal of the cause. The underlying, likely gastrointestinal disease should therefore be treated.

Drug Toxicity

Many toxins and drugs are concentrated in the liver and may cause direct toxic damage (intrinsic toxicity), and rarely cause idiosyncratic (very acute and severe) toxicity. Direct toxic damage may primarily involve the hepatocytes, causing necrosis and/or steatosis, or bile canaliculi, causing intrahepatic canalicular cholestasis. In veterinary medicine, documented idiosyncratic liver toxicity is

restricted to sulfonamides causing severe intrahepatic bile duct necrosis and irreparable cholestasis. Anecdotally, although not well documented, liver toxicity has also been reported for azathioprine, ketoconazole, fen/oxibendazole, phenobarbital, halothane, methoxyflurane, cephalexin, amoxicillin, oxacillin, nafcillin, erythromycin, clindamycin, and several other drugs. The hepatic lesions may include canalicular cholestasis and/or liver cell vacuolization and in severe cases liver cell necrosis. There are no large studies to document the true risk and toxicity of these drugs. Relatively well-documented toxicity is reported for diazepam (cats), acetaminophen (paracetamol) in dogs and cats, and carprofen in dogs.

Specific Toxins

Diazepam Toxicity in Cats

This toxicity has all the features of an idiosyncratic reaction, and has only been reported in cats receiving several doses of diazepam. Toxicity results in severe necrosis of the entire liver lobule, leading to fulminant liver failure and severe signs including inappetence, vomiting, severe lethargy, hepatic encephalopathy, coagulopathy, and jaundice. Liver enzymes, including the transaminases ALT/AST, and also ALP and bile acids are significantly elevated. Only symptomatic treatment is possible and the prognosis is poor in most cases.

Acetaminophen (Paracetamol) Toxicity in Dogs and Cats

Too high a dose of acetaminophen may cause severe oxidative hepatic damage. The result is hepatocellular necrosis which, depending on the dose, may involve the entire liver lobule and cause complete liver failure. Acetaminophen has been used as an experimental drug to induce reproducible acute liver failure in dog models, and it is one of the most used suicide drugs in humans.

If acetaminophen toxicity is suspected, antioxidative drugs such as SAM-e and N-acetylcysteine are advised. However, the proven effect of these drugs was tested in experimental situations in which the drug was given together or before the toxic drug. Treatment after the occurrence of the toxicity, as occurs naturally, may be less successful. The most important treatment is immediate gastric lavage. Supportive care with intravenous fluids and enteral feeding may also be required. If hepatic encephalopathy with severe hyperammonemia is present, the prognosis is often very poor.

Carprofen Toxicity in Dogs

This nonsteroidal antiinflammatory drug (NSAID) may cause idiosyncratic hepatic toxicity. The toxicity usually occurs after prolonged or repeated treatments, and may cause very severe liver damage. Immediate drug withdrawal and supportive care, with intravenous fluids and intensive therapy, result in a favorable outcome for most cases, although several weeks of treatment may be required. Carprofen may also cause simultaneous renal toxicity. Carprofen toxicity causes marked elevation of all liver enzymes, bile acids, and bilirubin. It is not known if other NSAIDs can cause similar hepatotoxicity.

Sulfonamide Toxicity in Dogs and Cats

Repeated or prolonged treatment with sulfonamides (including trimethoprim/sulfa) may occasionally lead to an idiosyncratic toxicity of the liver in both dogs and cats. The intrahepatic bile ducts appear to be targeted, especially the collecting bile ducts receiving bile from the smaller liver lobules. In most cases, these intrahepatic components of the biliary tree undergo complete necrosis, leading to very severe intrahepatic cholestasis. The degree of cholestasis is comparable to that of complete extrahepatic bile duct obstruction. Clinical signs include a sudden onset of anorexia, depression, vomiting, polyuria, and occasionally acholic stool, in combination with marked icterus. Sometimes the liver is moderately enlarged. The resulting clinical signs are those of severe cholestasis with preservation of liver function. At ultrasonography, the gallbladder may be entirely empty. The diagnosis requires careful histologic examination of the liver, since the lesions have a specific pattern. Management includes immediate withdrawal of the drug, and therapy with the choleretic drug ursodeoxycholic acid. Complete recovery has never been documented and surviving cases need to be treated lifelong with ursodeoxycholic acid.

Biologic Toxins

Amanita mushrooms and blue algae are the two important producers of biologic toxins, which may cause very severe liver damage. Both toxic mushrooms and blue algae cause severe necrosis of hepatocytes, and this is dose dependent. In most cases, the damage is very severe and associated with complete liver necrosis (fulminant hepatitis). This leads to massive increases of all liver parameters (enzymes, bile acids, ammonia, etc.). Clinical signs are comparable to those of the drug toxicities, and may include hepatic encephalopathy, jaundice, spontaneous bleeding, and severe lethargy. Therapy is supportive, with antiemetics and intravenous fluid administration, and normalization of blood pH and electrolytes. Forced diuresis may help to relieve the signs of hepatic encephalopathy.

Neoplasia

Primary Tumors

Hepatocellular Carcinoma

Etiology/Pathophysiology

Among epithelial tumors, hepatocellular carcinoma (HCC) occurs more frequently than hepatocellular adenoma. Both tumors are usually solitary and can become

very large, leading to focal enlargement of a liver lobe. Hepatocellular carcinomas do not commonly metastasize and they grow slowly. They seldom lead to reduced liver function as they only arise from one liver lobe, leaving the rest of the liver intact. Hepatocellular carcinoma is associated with chronic hepatitis and cirrhosis in humans, but such a relation does not appear to exist in dogs though they appear to occur more frequently in Scottish terriers with hyperphosphatemia.

Signalment

Hepatocellular carcinomas are generally seen in older dogs, and some studies have shown a breed predisposition in the poodle, fox and Scottish terrier, and Labrador retriever.

History and Clinical Signs

Hepatocellular carcinomas lead to the development of clinical signs only when they have attained a significant size, at which time they may be palpable. With increasing size, they can also displace the stomach and cause vomiting. Abdominal palpation reveals a mass in the cranial abdomen in most cases, and the tumor may be so big that the abdomen is distended. It may be difficult to distinguish such masses from those arising from the spleen.

Hypoglycaemia occurs relatively commonly (about 50% of cases), and may be a paraneoplastic phenomenon due to tumor production of insulin-like peptides (IGF-2). In some cases, hypoglycemia induces exercise intolerance or episodic weakness.

Diagnosis

The liver enzymes are variably elevated, and sometimes may be within the reference interval. Focal enlargement of the liver, often combined with displacement of the stomach, can often be identified on plain abdominal radiographs. Ultrasonography reveals a mass with an echogenicity similar to that of normal liver, although sometimes echogenicity is abnormal. Histology of a liver biopsy may be diagnostic, but sometimes these tumors are well differentiated and may be very hard to distinguish from normal liver or an adenoma. Cytologic diagnosis is therefore impossible in most cases.

Therapy

Surgical removal of the affected liver lobe is the only definite treatment. This may be successful if the tumor is not located near the hilus, the large hepatic vessels or major bile ducts. Peripherally located carcinomas are resectable, and in most cases, resection is curative. It is important to monitor the blood glucose concentration during or directly following surgery. Moreover, no anticancer chemotherapeutic drugs have been shown to be effective in the management of this tumor type although tyrosine kinsase inhibitors are being investigated.

Bile Duct Carcinoma

Etiology/Pathophysiology

This is a relatively infrequent primary tumor of the biliary epithelium. In the dog, it usually arises from intrahepatic bile ducts and readily metastasizes to the liver parenchyma and other organs. The multiple metastases throughout the biliary system often lead to signs of cholestasis. In the cat, bile duct carcinomas occur more often in the large bile ducts and result in obstruction. The disease tends to be rapidly progressive.

History and Clinical Signs

Icterus is a common clinical sign. Other clinical signs depend on the amount of hepatic involvement, and signs may be those of acute or chronic liver disease. There is often widespread infiltration of the tumor in the liver and thus hepatomegaly.

Diagnosis

Physical examination and laboratory findings usually only indicate extrahepatic cholestasis. Fine needle aspiration cytology is generally not useful for diagnosis. Bile duct carcinoma is best diagnosed by liver biopsy, either under ultrasound guidance or at laparotomy/laparoscopy.

Therapy

The tumor usually is usually very infiltrative. However, if localized to a single liver lobe, lobectomy of that lobe can be curative. In most cases, no treatment is possible by the time clinical signs occur. Moreover, no anticancer chemotherapeutic drugs have been shown to be effective in the management of this tumor type.

Hemangiosarcoma

Etiology/Pathophysiology

This is the only common mesenchymal type of hepatic tumor. They are usually smaller (up to a few centimeters) and multiple. Because they occur as multiple masses, their presence often results in more extensive hepatic dysfunction and cholestasis than are seen with epithelial tumors. Apart from being primary liver tumors, they may also be metastatic from other organs such as the spleen, kidneys, and skin.

Signalment

Hemangiosarcomas usually occur in older dogs and there appears to be a breed predisposition in the German shepherd dog, golden retriever, boxer, Great Dane and English setter.

History and Clinical Signs

Mesenchymal tumors usually have a severe and rapid course, with anorexia, vomiting, weight loss, and sometimes icterus. Abdominal distension and hemorrhagic ascites due to ruptures of the tumor may be present.

Diagnosis

There may be palpable liver enlargement but this is not always the case. Biochemical examination usually reveals high liver enzymes and bile acids but this is nonspecific. Ultrasonography allows visualization of any tumors, and these appear as dark hypoechogenic masses due to their rich vascularization. The diagnosis may also be confirmed by laparoscopy/laparotomy. Ultrasound-guided biopsy can be used in diagnosis, although there is a risk of bleeding and also tumor seeding. Fine needle aspiration cytology is not recommended for diagnosis.

Therapy

Mesenchymal tumors are usually inoperable and rapidly progressive. See discussion of hemangiosarcoma in Chapter XX. Survival times are usually in the area of weeks to months, and the owner should be warned about the risk of acute bleeding into the abdomen.

Secondary Tumors (Metastatic)

Etiology/Pathophysiology

Tumors of organs in the portal drainage area usually metastasize to the liver in the course of the disease. Hemangiosarcomas of the spleen are by far the most frequent, followed by pancreatic carcinomas and gastrointestinal tumors. Tumors from outside the portal drainage area can also metastasize to the liver. Tumor metastases are almost always multiple and distributed throughout the liver. Depending on their number and size, there can be varying amounts of liver damage.

History and Clinical Signs

The clinical signs may originate chiefly from the primary organ: vomiting in the case of gastric tumors, extrahepatic cholestasis with pancreas tumors, and ascites resulting from hemorrhage from splenic hemangiosarcoma. The main clinical signs caused by liver damage from metastatic disease include lethargy, anorexia, vomiting, and icterus. There may also be palpable hepatomegaly, although this depends on the number and size of masses.

Diagnosis

Physical and laboratory signs of liver damage and/or cholestasis are not specific. The diagnosis is made by histologic examination, although this may be missed by a percutaneous liver biopsy. The chances of a representative liver biopsy are increased when this procedure is performed under ultrasound guidance.

Therapy

Because of the multiple sites of metastases, surgery is virtually never possible and the prognosis is extremely guarded.

Generalized Systemic Tumors: Malignant Lymphoma

Etiology/Pathophysiology

Hepatic lymphoma is relatively commonly seen in dogs and cats, usually as part of a generalized disease. However, in some cases lymphoma may only be present in the liver. Infiltration of tumor cells causes hepatomegaly, and intrahepatic cholestasis can also occur. Because the liver damage is diffuse and widespread, there is often severe liver dysfunction. The tumor infiltration is usually more severe in the portal areas and around the central veins, which sometimes causes severe portal hypertension. Portal hypertension then results in the development of ascites and acquired portosystemic shunting vessels. In such cases, hepatic encephalopathy may develop.

History and Clinical Signs

The signs are highly variable, depending on the organ systems involved. With respect to the liver, clinical signs of icterus, lethargy, anorexia, and vomiting may occur. Sometimes there is ascites and hepatic encephalopathy. Hepatomegaly and splenomegaly may result in abdominal distension.

Diagnosis

The diagnosis can always be confirmed by a percutaneous liver biopsy. The diffuse hepatic involvement also means that the diagnosis can usually be made by fine needle aspiration cytology; this is one of the few indications for performing this test for the diagnosis of liver disease.

Therapy

A variety of anticancer chemotherapy protocols for lymphoma are available, and the reader is referred to Chapter 134 for details of these.

Feline Inflammatory Liver Disease

Nicki Reed, BVM&S, Cert VR, DSAM (Feline), DECVIM-CA, MRCVS

VeterinarySpecialists, Scotland 1Deer Park Road Livingston West Lothian

Etiology/Pathophysiology

Inflammation of the liver in cats may occur with infectious diseases such as feline infectious peritonitis, toxoplasmosis or bartonellosis although other systems may be more significantly affected than the liver. Hepatitis may also be seen in association with toxic damage from drugs such as diazepam, paracetamol (acetaminophen), methimazole and carbimazole, potentiated sulfonamides, tetracyclines, griseofulvin, and phenobarbitone.

Most commonly, however, feline inflammatory liver disease refers to the cholangitis/cholangiohepatitis complex, which is primarily an inflammatory disease of the biliary system. When the inflammation breaches the fibrous tissue of the periportal limiting plate, the term *cholangiohepatitis* may be used. However, as this is uncommon, cholangitis is usually the more correct term.

Cholangitis may be further classified, according to the WSAVA Liver Standardisation Group, into neutrophilic cholangitis (NC), lymphocytic cholangitis (LC), and chronic cholangitis associated with liver fluke infestation. The last of these is due to ingestion of raw fish containing metacercariae of the family Opisthorchiidae, and is associated with mixed inflammation around dilated bile ducts and development of periductal and portal fibrosis.

Neutrophilic cholangitis is proposed to be due to bacteria ascending into the biliary system from the intestines, as common bacteria identified include *E.coli* and *Enterococcus*. Acute neutrophilic cholangitis (ANC) shows a predominantly neutrophilic infiltrate in the epithelium and lumen of the bile ducts, and edema may be present in the portal areas. In more severe cases, the inflammation extends into the hepatic parenchyma and may potentially lead to development of hepatic abscesses. In more chronic cases (chronic neutrophilic cholangitis – CNC), the infiltrate becomes more mixed in nature, comprising lymphocytes, plasma cells and fibrosis in addition to neutrophils.

Concurrent inflammation is commonly identified in other organs such as the pancreas (60%), intestines (50%), and kidneys (60%). The combination of cholangitis, pancreatitis, and inflammatory bowel disease is commonly known as triaditis, and occurs in approximately 25% of NC cases.

Lymphocytic cholangitis is attributed to an immune-mediated process although some authors have suggested that it may be a more chronic form of NC. The inflammatory infiltrate is predominantly T lymphocytes in the portal region, and in some cases the biliary ductular epithelium. With chronicity, portal bridging fibrosis can develop, severe forms of which have been referred to as sclerosing cholangitis. Proliferation of bile ducts or ductopenia can develop and ductopenia is also considered to reflect an immune-mediated process.

The pathogenesis of this disease complex is incompletely understood. Recent work has suggested that bacteria may play a role in LC, as bacterial DNA has been found in the bile of 38% of cats affected with LC. Although this may support the theory that this is a chronic form of NC, it could also be the consequence of the disease, with dilation of the bile ducts and decreased peristalsis permitting retrograde ascent of bacteria from the duodenum. Whether or not *Helicobacter* spp. play a role in triggering initiation of this disease also remains speculative. Another recent study has also documented bacteria within the hepatic parenchyma but not the bile ducts in cats with NC, questioning the traditional hypothesis of ascending infection and suggesting hematogenous entry via the portal vein.

Epidemiology

Cholangitis-cholangiohepatitis was first described in cats in the 1980s. It is the second most common feline hepatic disorder after hepatic lipidosis in the USA, with

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

hepatic lipidosis being diagnosed twice as often as cholangitis, although prevalence within a necropsy population is only documented at 0.86%. The prevalence of the different forms of cholangitis is difficult to establish, due to different classifications in older publications. In the UK, cholangitis anecdotally may be more common than hepatic lipidosis.

Signalment

Neutrophilic cholangitis has been reported in a wide age range, although most commonly young to middle-aged cats are affected and a recent study documented a median age at diagnosis of 110 months (9.2 years). No breed or sex predispositions are reported. LC was previously reported to affect primarily young cats, and Persians were suggested to be overrepresented. More recent studies, however, have suggested that this disease affects mainly middle-aged to older cats, with a median age of around 10.5–11 years. Again, no breed or sex predisposition has consistently been identified.

History and Clinical Signs

Cats suffering from NC often present more acutely ill with a shorter history than those with LC. Signs reported by owners include anorexia or inappetence, vomiting and/or diarrhea, lethargy, weight loss, and ptyalism (excessive production of saliva). Physical examination findings can include dehydration, icterus, hepatomegaly, abdominal pain, and pyrexia.

Cats suffering from LC often remain bright, and some may show polyphagia rather than anorexia, although either is possible. Vomiting and diarrhea tend to be more intermittent, hence a more insidious history prior to seeking veterinary attention. Acholic feces can occur in cats with biliary obstruction, for example from cholelithiasis or with ductopenia due to sclerosing cholangitis (Figure 63.1).

Pyrexia is less common on physical examination although hepatomegaly and, in advanced cases ascites can be present.

It is not possible to differentiate the two conditions based on history and physical examination findings alone, as there can be significant overlap in presentation.

Diagnosis

Routine hematology is often nonspecific. Neutrophilia may be more commonly seen with NC than LC, and neutrophils can have a toxic appearance. Lymphopenia is also a nonspecific finding. While significant (10–40× reference range) increases in alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and gamma-glutamyl transferase (GGT) can be seen, not all cases of cholangitis (NC or LC) will have elevated values. Hyperglobulinemia may be seen with LC. Electrolyte abnormalities, most commonly hypokalemia, may be present as a consequence of vomiting and/or diarrhea.

Bilirubin is frequently, but not always elevated. The effect on bile acids is likely to be similar to bilirubin, as both substances are excreted in bile and affected by cholestasis (see Figure 63.1). Intrahepatic cholestasis results with reduced flow of bilirubin from the hepatocytes into the bile canaliculus, as a result of periportal edema and inflammation. Obstruction of larger bile ducts due to inflammation or cholelithiasis also causes extrahepatic cholestasis.

Urinalysis should be performed to add further information. The specific gravity can be useful to assess for concurrent renal involvement if azotemia is identified. In acutely ill patients it is often high due to dehydration. The finding of bilirubinuria is abnormal in cats, so if identified, it reflects hyperbilirubinemia. It does not help differentiate between the causes of icterus, but if urobilinogen is absent, this may indicate abnormal enterohepatic recirculation, suggestive of extrahepatic bile duct obstruction (see Figure 63.1).

Although imaging can add further information, findings may be normal or nonspecific for cholangitis. Radiography can identify hepatic enlargement, and with chronic inflammatory changes, mineralization of the biliary system can be seen. Presence of ascitic fluid will reduce the utility of this imaging modality.

On ultrasonographic examination, the liver often appears normal although it may be enlarged and have a normal, hypoechoic or hyperechoic texture. Due to the potential for "triaditis," it is also important to evaluate the remainder of the abdomen fully, especially the pancreas, intestines, and kidneys. Free fluid may be sampled for biochemical analysis, cytology, and culture to rule out some other differential diagnoses such as feline infectious peritonitis or neoplasia.

The biliary system should be closely evaluated, although no differentiation can be made between NC and LC based on ultrasound findings. The gallbladder can contain echogenic debris, although this may be seen in normal cats as well. If the common bile duct is found to be distended (>4 mm), it should be checked closely for intraluminal (e.g., choleliths) or extraluminal (e.g., pancreatic mass effect) obstructive lesions that require surgical correction (Figure 63.2). Thickening of the gallbladder wall (>1 mm) is suggestive of cholecystitis.

Ultrasound guidance may be used to obtain bile for culture, although this can be problematic if the bile is

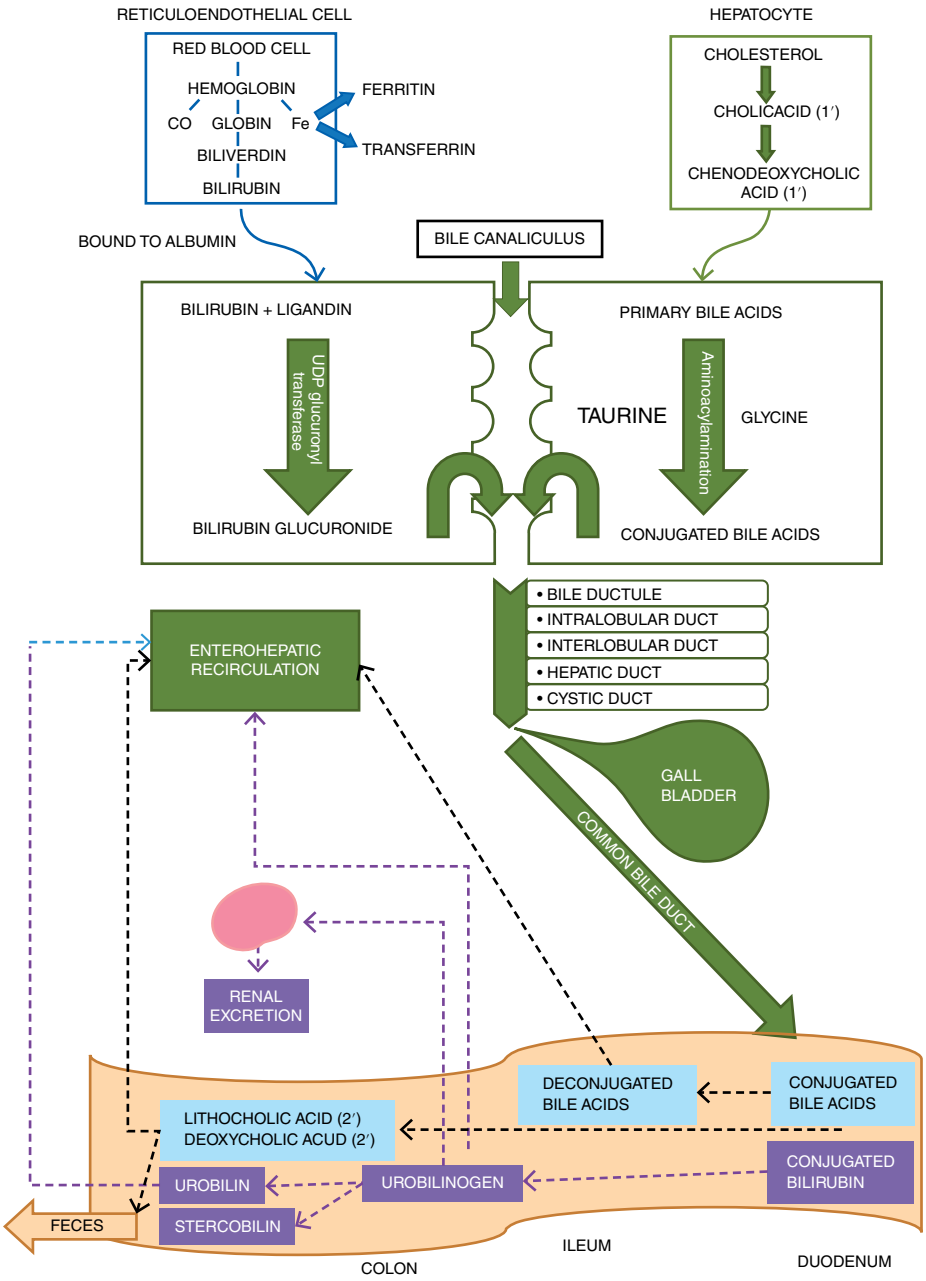

Figure 63.1 Diagrammatic representation of normal biliary physiology. Cholestasis results in hyperbilirubinemia and elevated bile acids. With complete obstruction of the biliary system, urobilinogen will not be available for urinary excretion, and stercobilin will not be present in the feces (acholic feces). Bacteria are responsible for deconjugation of bile acids and bilirubin, therefore these processes may also be affected by abnormal gut flora.

inspissated, requiring use of a larger gauge needle and hence potentially increased risk of bile peritonitis.

Coagulation times may be prolonged due to vitamin K deficiency, both as a result of anorexia but also because cholestasis reduces passage of bile acids into the intestine where they are required for absorption of this fat-soluble vitamin. Coagulation times should therefore always be evaluated prior to liver biopsy. Liver biopsy is required for a definitive diagnosis. Due to the patchy distribution of lesions, the larger samples obtained via laparoscopy or surgical wedge biopsies may be preferable to needle ("Tru-cut") biopsies. Ideally, both liver and bile should be cultured, as different organisms may be cultured from each site, although culture of bile yields higher recovery of organisms than culture of liver. Anaerobic as well as aerobic culture should be performed.

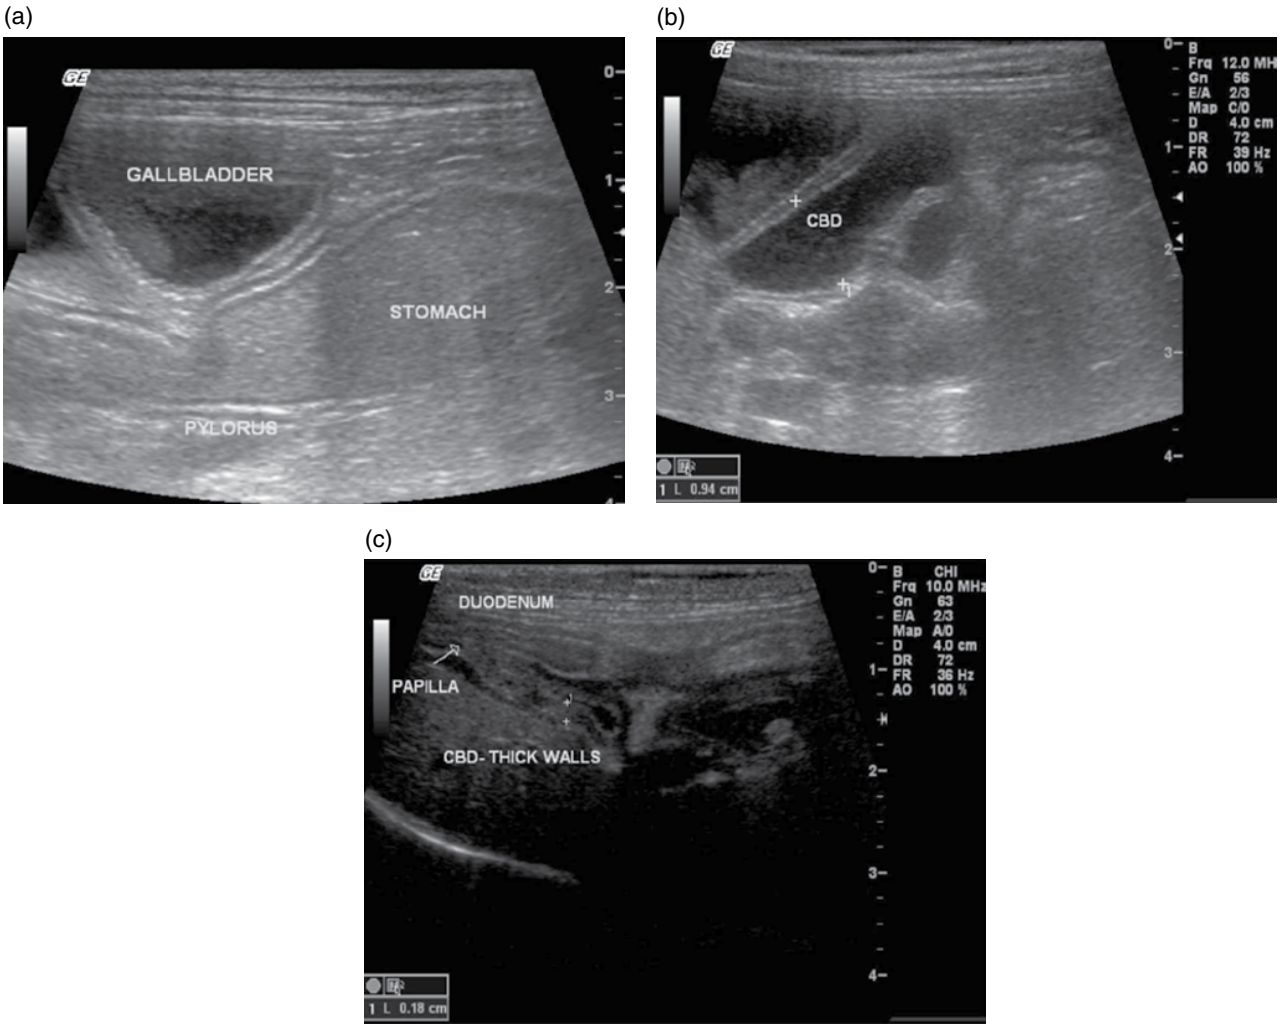

Figure 63.2 Ultrasound images from a cat diagnosed with neutrophilic cholangitis. Cytology of an aspirate of bile showed large numbers of predominantly degenerate neutrophils, many of which contained intracellular bacteria. A profuse growth of *E.coli* was cultured. (a) The gallbladder is distended and contains hyperechoic sludge. (b) The common bile duct is markedly dilated at 0.94 cm (normal <0.4 cm). (c) The walls of the common bile duct (CBD) are thickened.

Lymphocytic cholangitis needs to be differentiated from lymphoma, and immunophenotyping or T cell receptor polymerase chain reaction (PCR) for gene rearrangement may need to be considered if the diagnosis is in doubt.

Therapy

If chronic cholangitis is identified to be due to liver flukes, treatment involves the administration of praziquantel (30 mg/kg PO q24h for 5–10 days). Treatment of necroinflammatory hepatitis primarily involves withdrawal of any hepatotoxic drugs and use of supportive and hepatoprotective therapies as described later.

Patients with ANC can be seriously ill, potentially in septic shock from bacteremia. Fluid therapy should therefore be administered at rates appropriate to the degree of dehydration or shock present. Potassium supplementation at 20 mmol/L fluid is likely to prevent development of hypokalemia with rehydration; however, if hypokalemia is already documented, higher rates may be required.

Analgesia should be administered as abdominal pain is a common finding in these patients. Opioids are preferred over nonsteroidal antiinflammatories, especially in hypovolemic patients.

Antibacterial therapy should ideally be based on culture and sensitivity results, but pending these, empiric choices may be made based on the likely bacteria present (gram negative and anaerobes – see Table 63.1). Combination therapy may be required (e.g., fluoroquinolone plus metronidazole). Intravenous antibacterial therapy should be used initially in systemically ill patients. Antibacterial therapy is typically administered for a minimum of four weeks, or until values of hepatic

Table 63.1 Antibacterial agents used in the management of feline hepatobiliary disease

Drug	Dose	Comments
Amikacin	10–15 mg/kg IV, SC, IM q24h	Gram-negative bacteria. Nephrotoxic (less so than gentamicin), therefore only used if resistance patterns merit its use
Amoxicillin-clavulanate	12.5–25 mg/kg IV, PO q8–12h	Broad-spectrum antibacterial but may not be effective against *Pseudomonas* or *Klebsiella*. Oral absorption reduced in systemically ill patients
Cephalexin (first generation)	10–35 mg/kg PO q8–12h	May not be effective against *Pseudomonas* or *Proteus*. Poor efficacy against anaerobes
Cefotaxime (third generation)	20–40 mg/kg IV, SC q8–12h	More effective against gram-negative but less effective against gram-positive organisms than cephalexin. Variable activity against anaerobes
Cefovecin (third generation)	8 mg/kg SC q14 days	More effective against gram-negative but less effective against gram-positive organisms than cephalexin. Possibly better activity against anaerobes than cefotaxime
Cefuroxime (second generation)	10–15 mg/kg IV q8–12 h	More effective against gram negative but less effective against gram positive organisms than cephalexin, but not as effective as 3rd generation cephalosporins
Chloramphenicol	15–25 mg/kg PO, SC, IM, slow IV q12h	Good efficacy against gram-positive organisms and anaerobes. Moderate activity against gram-negative organisms. Not used routinely as cholestasis may increase risk of toxicity
Clindamycin	5.5–12 mg/kg PO q12h 10 mg/kg IV q12h	Effective against gram-positive organisms and anaerobes. Needs to be combined with drug effective against gram-negative organisms. Concentrated in the bile, but care with reduced liver function as excretion is via hepatic metabolism
Marbofloxacin	2 mg/kg PO, IV q24h	Good efficacy against gram-negative and some gram-positive organisms, but not effective against anaerobes. Preferred to enrofloxacin as decreased risk of retinal damage
Metronidazole	8–10 mg PO, IV q12h	Narrow spectrum against anaerobes. May cause nausea, vomiting, and neurologic signs. Intravenous infusions given over 20–30 minutes
Pradofloxacin	3 mg/kg PO q24h	Better efficacy against anaerobic organisms than marbofloxacin
Options pending culture results: Amoxicillin-clavulanate Cephalosporin + metronidazole Fluoroquinolone + clindamycin or metronidazole		

IM, intramuscular; IV, intravenous; PO, by mouth (*per os*); SC, subcutaneous.

enzymes return to normal. In some patients antibacterial therapy may need to be continued for 2–3 months, and repeat culture of bile may be warranted to assess response to therapy.

Surgery may be required to manage biliary obstruction, if identified. The above treatments should be initiated first to stabilize the patient as biliary surgery is complex and may require prolonged general anesthesia. Surgical procedures such as stenting of the bile duct, cholecystectomy, cholecystotomy or biliary bypass (cholecystoduodenostomy, cholecystojejunostomy) may be required.

Nutritional support is very important as, if hepatic lipidosis is not already present, these anorectic patients are at risk of developing it. Placement of a feeding tube is recommended. A nasoesophageal tube may be placed in the first instance, especially if prolonged clotting times are identified, but an esophagostomy tube is preferred. The wider bore of these tubes increases the range of diets that may be administered as well as enabling some medications to be given via this route. In addition, the chance of removal is reduced, and owners often can manage these tubes at home. Gastrostomy tubes may be placed at time of surgical intervention if required.

"Critical care" diets are generally appropriate as they are highly digestible, can be administered via feeding tubes and are supplemented with arginine, taurine, and antioxidants. Hepatic encephalopthy (HE) is usually a contraindication to feeding a high-protein diet but in this population of cats, signs of HE are generally attributable to arginine deficiency from anorexia and will correct with feeding protein. An exception to this is if HE is present due to development of acquired portosystemic shunts subsequent to severe fibrosis, although significant hepatic fibrosis is uncommon in cats. Longer term dietary management should consider the presence of concurrent diseases and be chosen accordingly. A diet for inflammatory bowel disease may be more appropriate than a "hepatic" diet, for example.

Table 63.2 Supportive therapies used in the management of feline hepatobiliary disease

Medication	Dose	Comments
Analgesia		
Buprenorphine	0.01–0.02 mg/kg SC, IV, IM q8h 0.02 mg/kg TM q8h	Partial mu agonist – may affect use of full mu agonist perioperatively. Can cause dysphoria
Fentanyl	2.5–10 µg/kg/h CRI 25 µg/h transdermal patch (>3 kg) 12.5 µg/h transdermal patch (<3 kg)	Full mu agonist. May be indicated with marked pain (e.g., bile duct obstruction or peritonitis)
Methadone	0.1–0.5 mg/kg IM or slow IV q4h 0.1 mg/kg/h CRI	Full mu agonist. May be indicated with marked pain (e.g., bile duct obstruction or peritonitis)
Morphine	0.1–0.4 mg/kg IM or slow IV q4h 0.1 mg/kg/h CRI	Full mu agonist. May be indicated with marked pain (e.g., bile duct obstruction or peritonitis)
Vitamins		
Cobalamin (vitamin B12)	0.125–0.25 mg/cat SC q7–14 days	Liver cobalamin stores may be depleted in the face of normal serum cobalamin; may help stimulate appetite
Vitamin K1	0.5–1.0 mg/kg SC, PO q12h for 3 doses	Given by SC injection using a 25 ga needle
Vitamin E	10 IU/kg PO q24h	Antioxidant often depleted with anorexia or malabsorption
Management of vomiting		
Cimetidine	2.5–5.0 mg/kg PO q12h	H2 receptor antagonist with weak antacid effects
Famotidine	0.5–1.0 mg/kg PO q12–24h	More potent H2 receptor blocker. Prokinetic effect unknown
Ranitidine	2 mg/kg PO, SC, slow IV q8–12h	Prokinetic effect may be beneficial in addition to H2 receptor blockade
Omeprazole	1 mg/kg PO, IV q12–24h	Antacid of choice; more potent thanthe H2 receptor blockers by causing complete blockade of the proton pump
Maropitant	0.5–1.0 mg/kg SC q24h	Antiemetic acting on NK1 receptors. May also provide some visceral analgesia
Metoclopramide	1 mg/kg/24h CRI	Central antiemetic effect in cats questionable due to lack of dopaminergic receptors, but peripheral prokinetic effects
Sucralfate	250 mg/cat PO q8–12h	Protects against esophageal, gastric, and duodenal ulceration
Hepatoprotection		
S-adenosyl-L-methionine (SAM-e)	20–40 mg/kg PO q24h 90 mg/cat/day	Nucleotide essential for major hepatic biochemical pathways with antioxidant and hepatoprotective properties. A higher dose is required if enteric-coated tablets are crushed for administration via feeding tube
Ursodeoxycholic acid (UDCA)	10–15 mg/kg PO q24h	Synthetic hydrophilic bile acids that aid bile flow. It has antiinflammatory, immunomodulatory, and antifibrotic activities, and is cytoprotective to hepatocytes
Milk thistle (common name for *Silybum marianum*)	20–50 mg/kg per day Optimal dosage unknown	Contains silibinin (sylibin/silymarin); may be useful for treatment of chronic and acute liver disease, and may modulate cirrhosis. Evidence base is limited
Immunomodulation		
Chlorambucil	2 mg/cat PO q48h (>4 kg) 2 mg/cat q72h (<4 kg)	Immunosuppressive effect is not well documented
Prednisolone	1–2 mg/kg PO q12h (LC) tapering to 0.5 mg/kg q24h 0.5 mg/kg PO q12–24h (NC)	Immunosuppressive doses used for LC; antiinflammatory doses used for NC

CRI, constant rate infusion; IM, intramuscular; IU, international units; IV, intravenous; LC, lymphocytic cholangitis; NC, neutrophilic cholangitis; PO, by mouth (*per os*); SC, subcutaneous; TM, transmucosal.

Vitamin supplementation is usually beneficial in anorectic cats. B vitamins become rapidly depleted and thiamine deficiency can contribute to neurologic signs, while cobalamin deficiency can exacerbate anorexia. Vitamin E is an antioxidant that also has antiinflammatory properties. Vitamin K supplementation may be required to correct coagulopathies (Table 63.2).

Symptomatic therapy can include antiemetics (e.g., metoclopramide or maropitant) and gastroprotectants (e.g., H2 blockers, proton pump inhibitors, sucralfate). Control of vomiting is important for patient comfort and to reduce the risk of feeding tubes becoming dislodged. Gastroprotectants may be beneficial due to the presence of concurrent inflammatory bowel disease and to address gastritis induced by persistent vomiting (see Table 63.2).

S-adenosyl-L-methionine (SAM-e) has a number of hepatoprotectant effects: it is a glutathione precursor (hence antioxidant properties), it stabilizes cell membranes, and it modulates inflammatory cytokines. As low glutathione levels are present in a high percentage of cats with hepatobiliary disease, administration of SAM-e should be beneficial, although no published data exist to support this claim (see Table 63.2).

Ursodeoxycholic acid (UDCA) is a hydrophilic bile acid that has a number of benefits: choloresis, that is, making the bile more liquid and promoting bile flow; replacement of more toxic, hydrophobic bile acids; antiapoptosis; antioxidant; and immunomodulation (see Table 63.2). It has been used as the sole therapy for treatment of primary sclerosing cholangitis in people, but its use as sole therapy for treatment of LC in cats did not compare favorably to prednisolone.

Immunosuppression is considered important for the management of LC, but should only be commenced once NC has been ruled out. Prednisolone is typically employed, starting at higher, immunosuppressive doses and tapering to as low a dose as possible once in remission (see Table 63.2). Some authors have also advocated the use of methotrexate or chlorambucil.

Development of fibrosis is seen with progression of the disease. While the use of colchicine to reduce fibrosis has previously been advocated in dogs, there are no studies to demonstrate benefit. Moreover, its use can be associated with significant side-effects. Current medical advice suggests that it not be recommended, although silymarin and UDCA may have potential antifibrotic effects.

Our poor understanding of the etiopathogenesis of the cholangitis-cholangiohepatitis complex, and lack of controlled clinical trials, combined with an inability on occasions to obtain diagnostic samples before antibacterial therapy, can often result in initiation of therapy with an antibacterial along with other supportive therapies as indicated. If a diagnosis of NC has been made, and improvement has plateaued, prednisolone at antiinflammatory doses could be introduced as this may be beneficial in attenuating the inflammatory response.

Prognosis

Prognosis will depend on the severity of the disease. Obstruction of the bile duct, necessitating surgical intervention, has a guarded prognosis, particularly where biliary diversion surgery is required. Cats with ascites similarly have a guarded prognosis as this is likely to represent the presence of significant fibrosis. However, cats that survive the initial acute phase of NC or that are diagnosed with LC often go on to live for several years. Relapses are possible, especially if there is a concurrent condition such as pancreatitis that may be difficult to control.

Lymphocytic cholangitis is likely a progressive disease, and dilation of the bile ducts may be irreversible. This has been proposed to increase the risk of these cats developing ascending infections and potentially cholecystitis, therefore although recurrence is not inevitable, periodic monitoring of liver parameters +/- ultrasonographic evaluation of the biliary system may be warranted.

Canine Inflammatory Liver Disease

Nick Bexfield, BVetMed, PhD, DSAM, DECVIM-CA, PGDipMEdSci, FHEA, MRCVS

Department of Veterinary Medicine, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, UK

The most frequently identified inflammatory liver diseases in dogs are nonspecific reactive hepatitis, acute hepatitis (AH), and chronic hepatitis (CH) and their histologic appearance has been standardized by the World Small Animal Veterinary Association's (WSAVA) Liver Standardization Group. Nonspecific reactive hepatitis represents a nonspecific response to a variety of extrahepatic disease processes, especially febrile illnesses and inflammation somewhere in the splanchnic bed. Histologically, it is characterized by an inflammatory infiltrate in portal areas, and sometimes in the parenchyma, without evidence of hepatocellular necrosis or apoptosis. It results from a disease occurring outside the liver, so will not be discussed further. AH is characterized by a combination of inflammation and hepatocellular apoptosis and necrosis, with the specific features varying according to the cause. The majority of AH cases occur as a result of toxin or drug ingestion, and are discussed further in Chapter 62.

Acute hepatitis can sometimes be caused by infection with certain bacteria or viruses, and these are detailed below. CH is defined histologically by the presence of hepatocellular apoptosis or necrosis, a variable mononuclear or mixed inflammatory cell infiltrate, regeneration, and fibrosis. It is the most frequently identified canine inflammatory liver disease and so will be the focus of most of this chapter.

Chronic Hepatitis

Etiology/Pathophysiology

The development of fibrosis is the key pathologic change that leads to the development of CH. The hepatic stellate cell, also known as the Ito cell or lipocyte, is central in the development of fibrosis in humans and rats, and evidence also suggests its involvement in the pathogenesis of hepatic fibrosis in dogs. Hepatic stellate cells reside in the space of Disse, between the sinusoidal endothelial cells and the hepatocytes. In the healthy liver, they are the major storage site of vitamin A, but in chronic liver injury they are stimulated to transform into collagen-secreting, activated cells that express smooth muscle-specific alpha-actin and secrete high-density matrix and collagen into the space of Disse. The secretion of collagen and formation of fibrous tissue from activated stellate cells are believed to be indirect via the release of cytokines from inflammatory cells, although some inflammatory mediators act on them directly. Fibrous tissue within the liver leads to the development of intrahepatic portal hypertension by altering sinusoidal tone and blood flow. The development of portal hypertension results in many of the complications of chronic liver disease such as ascites and gastrointestinal (GI) ulceration. The known or postulated causes of CH are listed below, although the majority of cases have no identifiable cause and thus are termed idiopathic.

Infectious Causes

Canine Acidophil Cell Hepatitis Virus

A potential viral cause of AH and CH was identified in 1985 and named "canine acidophil cell hepatitis virus" although no specific agent was isolated. Histopathologic examination revealed an inflammatory infiltrate with areas of hepatocyte necrosis and scattered numbers of large cells with acidophilic cytoplasm, termed "acidophil cells." When liver homogenate and serum from affected dogs were injected into naive animals, this resulted in the development of clinical and pathologic changes of AH that in some dogs progressed to CH. However, no further work to identify the potential transmissible hepatitis-causing agent was performed, nor have further reports emerged.

Canine Adenovirus-1

Adenoviruses are medium-sized viruses, two of which are known to infect dogs: canine adenovirus type 1 (CAV-1) and canine adenovirus type 2 (CAV-2). CAV-1 is well known as a cause of AH in nonimmune dogs, but CH has also been experimentally reproduced in partially immunized dogs challenged with CAV-1. However, several studies have failed to identify CAV-1 in liver tissue from large numbers of clinical cases of CH.

Canine Hepacivirus

A novel virus, canine hepacivirus (CHV), was recently identified in outbreaks of respiratory illness in dogs from animal shelters in the USA. CHV was also identified at low levels in hepatocytes dogs that died of "unexplained GI illness" although the results of liver histology were not reported. Despite CHV being identified in canine liver tissue, it is unclear if this virus is hepatotrophic or if it causes disease. However, in two recent studies, there was no evidence of exposure to, or a carrier state of, CHV in large cohorts of dogs with CH, suggesting that the virus is probably not associated with canine CH.

Hepatitis Viruses A, B, C, E, and GBV-C

Although hepatitis B (HBV) and C viruses (HCV) are by far the most frequent causes of human chronic viral hepatitis, several other viruses are implicated. The more frequently described include hepatitis A (HAV) and E viruses (HEV), and GB virus-C (GBV-C), although these are generally associated with the development of AH. However, previous attempts using polymerase chain reaction (PCR)-based approaches have failed to identify HAV, HBV, HCV, HEV, and GBV-C in liver tissue from large numbers of dogs with CH.

Bacteria

Infection with leptospires is a well-known cause of AH, as detailed later in this chapter. Infection with leptospires can also cause CH, with histologic changes consisting mainly of lymphoplasmacytic, portal and intralobular inflammation, hepatocyte necrosis, and biliary stasis. The organisms are relatively sparse and difficult to find with conventional staining techniques, so it is possible that CH associated with leptospirosis is underrecognized. Using nested PCR, a recent study failed to detect *Leptospira* spp. DNA in 98 dogs with CH.

Infection with other bacteria is a relatively uncommon cause of CH. Bacillus piliformis, Helicobacter canis, Ehrlichia canis and Bartonella spp have also been identified in dogs with CH, but causality has not been clearly established. Dogs do develop cholangitis or cholangiohepatitis, and this is covered in further detail in Chapter 67. Additionally, granulomatous hepatitis is an unusual presentation, in which the predominant cell type present is the macrophage. Lesions are usually multifocal and have been associated with numerous bacteria, including *Nocardia*, *Mycobacterium*, *Rhodococcus*, *Bartonella*, and *Borrelia*. Chronic hepatic leptospirosis is a particular concern in these cases and should be ruled out with fluorescent in situ hybridization (FISH). In addition, several fungi have been associated with this specific histologic diagnosis.

Autoimmunity

An immune-mediated aetiology to human liver disease is well recognised, and the criteria for its diagnosis are well established. Diagnosis is based on increased serum alanine aminotransferase (ALT) activity, presence of positive serum autoantibody titres, increased serum IgG concentration, characteristic histopathology findings, and exclusion of other aetiologies. However, there is only anecdotal evidence for an immune-mediated cause to canine CH. Circulating autoantibodies were present in the serum of dogs with a variety of liver diseases, and antiliver membrane protein antibodies have been identified in serum of dogs with CH. However, the question that remains from all these studies is whether these autoantibodies are the primary cause of the disease, i.e. suggestive of an autoimmune aetiology, or whether they are a secondary phenomenon. Peripheral blood mononuclear cell proliferation in response to liver membrane protein was also significantly higher in dogs with CH compared to control dogs. Moreover, high numbers of CD3+ lymphocytes are found in the liver of dogs with CH, again suggesting the involvement of the immune system in the etiology of the disease. An immune-mediated aetiology to CH in some dogs is also suggested by the fact that there is a female gender predilection, along with clearly defined breed predispositions. In addition, the association of certain susceptibility and resistance MHC class II haplotypes with CH indicates a role of the immune system in disease development, although this does not necessarily point to an autoimmune aetiology.

Copper

The accumulation of copper in liver tissue has been described in several breeds of dog. Excessive accumulation includes that seen in copper-associated hepatitis, sometimes known as true "copper storage" disease, where the primary initiating event is a defect in copper excretion leading to secondary hepatocyte damage, and the copper accumulation which occurs secondary to an underlying inflammatory liver disease. Copper-associated hepatitis was first described in the Bedlington terrier over three decades ago. Since then, many studies have detailed its clinical course and pathologic features,

including the progressive accumulation of copper in hepatocytes starting in zone 3 and leading to the development of CH. Copper-associated hepatopathies have been reported in several breeds of dog including the Dalmatian, Labrador retriever, Skye terrier, West Highland white terrier, and Doberman pinscher. These may not be true copper storage diseases as copper does not build up throughout life, and the amount of copper stored is often not correlated with the severity of the underlying disease. Although uncommon in the United Kingdom, copper-associated hepatopathy is increasingly seen in other countries, especially The Netherlands. Disorders associated with excess copper accumulation are covered in more detail in Chapter 62.

Epidemiology

Historically, the term *canine CH* was poorly defined and used to describe a variety of inflammatory liver diseases. The terms *chronic active hepatitis* and *chronic lobar hepatitis* were used early in the description of the disease, although these names have now largely been abandoned in favor of CH. Improvements in the classification of canine CH were brought about by the WSAVA Liver Standardization Group which established standardized histologic criteria for diagnosis. Since the publication of these criteria, one study has demonstrated a postmortem prevalence of 12% in a first opinion practice setting in the UK. Data to assess the prevalence of the disease in other countries are not available, although anecdotally CH appears to be the most frequently identified inflammatory liver disease in dogs worldwide.

Signalment

Chronic hepatitis typically affects middle-aged to older dogs, with the median age for all breeds in a recent study being 8 years (range, 7 months to 16 years). Females appear to be predisposed, with a female to male ratio of 1.5:1.0 in one study. Several reports detail breed predispositions to CH. The first of these was performed on a Swedish population of dogs, and demonstrated that the American and English cocker spaniel, West Highland white terrier, Labrador retriever, Doberman pinscher, and Scottish terrier had an increased risk for CH. In this study, the disease was reported to occur more commonly in middle-aged to older animals and there was a gender predisposition in male English and American cocker spaniels and female Labrador retrievers. A recent study performed in the UK assessed the breed distribution by comparing the signalment of 551 cases with a histologic diagnosis of CH to that of a large control population. From a total of 61 breeds, the American cocker spaniel, cairn terrier, Dalmatian, Doberman pinscher, English cocker spaniel, English springer spaniel, Great Dane, Labrador retriever, and Samoyed were found to be at increased risk for developing CH (Table 64.1).

Table 64.1 Age and gender data for breeds with an increased risk for developing canine chronic hepatitis

Breed	Median age at diagnosis (range)	Gender
American cocker spaniel	5 years 6 months (2 years to 11 years 3 months)	1F, 5M
Cairn terrier	10 years 2 months (7 years to 13 years 5 months)	4F, 5M
Dalmatian	4 years 7 months (3 years to 12 years)	9F, 1M
Doberman pinscher	5 years 4 months (2 years 6 months to 10 years)	16F, 8M
English cocker spaniel	8 years 9 months (1 year 3 months to 14 years)	34F, 19M
English springer spaniel	5 years (1 year 2 months to 11 years)	60F, 20M
Great Dane	6 years 2 months (1 year 2 months to 7 years 11 months)	3F, 3M
Labrador retriever	8 years 3 months (2 year 8 month to 13 years)	63F, 32M
Samoyed	10 years (3 years 1 month to 11 years)	2F, 3M

F, female; M, male.

History and Clinical Signs

Clinical signs in dogs with CH vary, and are usually nonspecific and insidious in onset. Sometimes another disease, stress or therapy causes sudden decompensation. The liver has tremendous functional and structural reserve, and a significant loss of normal hepatic tissue can occur with minimal or no change in clinical signs. In addition, the liver has a remarkable capacity to regenerate following hepatic injury, providing the damage is not too severe or ongoing. Overt liver failure does not develop until at least 70–80% of functional capacity is lost, so the development of clinical signs implies marked impairment of liver function. In addition, some dogs with advanced CH or cirrhosis can be asymptomatic, or alternatively may present with signs of "acute" liver disease.

The clinician should pay particular attention to subtle waxing and waning GI signs, depression, lethargy, anorexia, weight loss, and polyuria and polydipsia. Additional signs that may be more suggestive of CH, although still not specific, include jaundice, ascites, coagulopathy, and neurologic signs caused by hepatic encephalopathy.

Clinical signs of hepatic encephalopathy, which are often intermittent, include behavioral changes, hypersialism, head pressing, circling, ataxia, temporary blindness, seizures, and coma. In one study of 101 dogs with both AH and CH, the most commonly identified clinical signs were lethargy (56/101), anorexia (56/101), vomiting (48/101), polyuria and polydipsia (47/101), and weight loss (28/101).

Physical examination findings are generally relatively unremarkable. Poor body condition is often seen in animals with CH. With progressive disease and the further development of fibrosis, liver size reduces in dogs with CH. Ascites and icterus may also be seen with chronic disease.

Diagnosis

Clinical Pathology

Clinical pathology is usually the next step in the investigation of a dog with suspected CH. Sometimes, results of clinical pathology performed for another reason, for example as a preanesthetic blood screen, may fortuitously reveal the presence of CH. Clinical pathology findings include elevations of liver enzymes, especially hepatocellular enzymes released as a result of liver cell damage, namely ALT and aspartate aminotransferase (AST). Increased ALT activity is the primary clinical laboratory finding in dogs with CH, and is raised in over 90% of cases. In addition, the markers of cholestasis, alkaline phosphatase (ALP) and gamma-glutamyl transferase (GGT), are invariably elevated. It is important to remember that liver enzyme activity is not a test of liver function, and very occasionally a dog with advanced CH may have liver enzymes within the reference interval. In addition, elevations in liver enzymes are not an uncommon reaction to many other diseases and these elevations can sometimes be marked.

While liver enzymes do not give any indication of liver function, there are other tests on the biochemistry panel which provide some information about liver function. Due to the development of fibrosis, liver function in dogs with CH is progressively compromised, and so these markers are particularly useful in diagnosis. With progressive liver dysfunction, levels of albumin, urea, glucose and coagulation factors decrease, while the concentration of bile acids, ammonia, and bilirubin increases. Hypoalbuminemia occurs in about 40% of cases, although with advanced disease (cirrhosis), this increases to 75%. None of these tests are completely specific for liver disease, so they should always be interpreted in the light of other clinical and clinicopathologic findings.

Both qualitative and quantitative abnormalities in erythrocytes may also be present in dogs with CH, in combination with alterations in white cell and platelet numbers. The more frequently encountered abnormalities in dogs with CH include mild nonregenerative anemia of chronic disease, which is normocytic and normochromic. Sometimes abnormal red cells including acanthocytes (irregular large surface projections) and/or target cells (codocytes), which are dense-centered cells surrounded by a clear area, can be identified on a blood smear. Dogs with CH may have a neutrophilic leukocytosis, although this is a nonspecific change. Thrombocytopenia may develop due to platelet sequestration or increased destruction, and alterations in platelet function (thrombocytopathies) may also occur.

Abnormalities may be present in the urine of dogs with CH, including a low specific gravity (<1.030), bilirubinuria, increased urobilinogen, urate crystals, and occasionally urate calculi. Approximately 10% and 60% of dogs have prolonged prothrombin time (PT) and partial thromboplastin time (PTT) respectively.

Diagnostic Imaging

Diagnostic imaging is usually the next step after clinical pathology in the assessment of the dog with suspected CH. Abdominal radiography can be used to assess liver size, as dogs with CH may have a reduced liver size. However, the liver may appear normal on routine radiographic evaluation, even when severely diseased. Ultrasonography is the preferred imaging modality for the investigation of liver disease. In one study of 67 dogs with CH, only 15 had no identifiable ultrasonographic abnormalities. Hepatic size was assessed as normal in 26, enlarged in eight and small in 26. Hepatic structure was found to be normal in 27, irregular in 31, and 11 had increased echogenicity. Nodular processes were observed in 16 dogs and ascites was present in 18. The reader is referred to Chapter 61 for further details on diagnostic imaging in the investigation of liver disease.

Liver Biopsy

It is not possible to make a definitive diagnosis of CH from the results of clinical pathology or diagnostic imaging. In some cases, a tentative diagnosis can be made but definitive diagnosis ultimately relies on histologic examination of liver tissue. Moreover, descriptors of severity of inflammation and the amount of fibrosis are provided, and these can be used prognostically and therapeutically. Liver histology will give vital information to help establish the most appropriate therapy. Without a biopsy, therapy of CH will be at best nonspecific and at worst counterproductive. Many methods are available for collection of liver tissue, and the method used will depend on clinician preference, availability of equipment, technical skill, type of lesion present, location, and clinical stability of the patient. Further details about the methods for collection of liver tissue are detailed in Chapter 60. The recently published ACVIM Consensus statement on the diagnosis and treatment of chronic hepatitis in dogs, recommends a wedge

biopsy taken at laparoscopy or laparotomy because trucut biopsies produce misleading results 50% of the time and also carry an increased risk of haemorrhage. Needle aspiration cytology is not reliable for the diagnosis of CH and is therefore not recommended.

The only real absolute contraindication for liver biopsy is severe coagulopathy. Prior to biopsy, coagulation status should be checked, by way of platelet count, measurement of PT, PTT, and ideally thromboelastography. In humans, thromboelastography can predict bleeding tendencies in cirrhotic patients, but data does not exist in dogs to determine how reliable this is as an assessment of bleeding tendencies. However, assessment of coagulation status should not be a substitute for proper technique and adequate postoperative care. If coagulation times are prolonged, vitamin K can be given by injection 24 hours prior to biopsy and then coagulation times retested. An alternative approach, if available, is the use of fresh-frozen plasma to assist in replenishing deficient coagulation factors. All animals should be hospitalised and monitored carefully for signs of hemorrhage for at least 12 hours after biopsy.

As detailed previously, standardized criteria for the histologic diagnosis of CH exist. The standard histochemical stain used in the assessment of liver tissue is hematoxylin and eosin, but consideration should be given to the use of additional stains for specific features such as reticulin (connective tissue), Perls' Prussian blue (ferritin), Fouchet's (bile pigments) and periodic acid–Schiff (polysaccharides). In addition, specific histochemical stains for copper, such as rubeanic acid or rhodanine, should be consider in at-risk breeds (see earlier) (Figure 64.1).

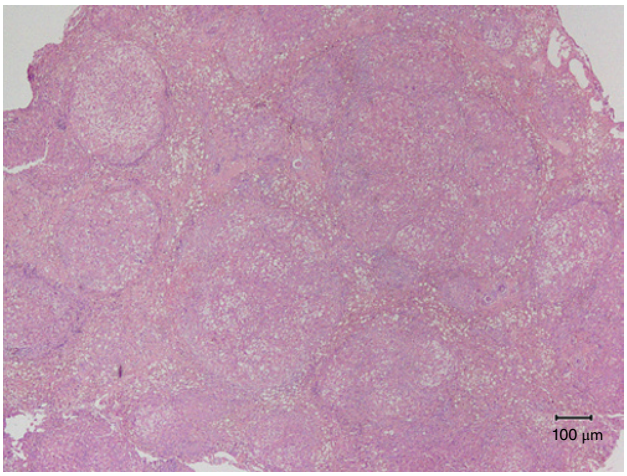

Figure 64.1 Low-power photomicrograph of liver tissue from an English springer spaniel demonstrating disruption to the normal architecture by a marked and generalized infiltrate of inflammatory cells and also bundles of fibrous tissue. Hematoxylin and eosin. Original magnification ×40.

Therapy

Therapy for CH is aimed at the underlying cause, if known. However, as the etiology of most cases is currently not understood, specific therapies are usually not possible. Hepatocytes have a remarkable capacity for regeneration, which means that early diagnosis and therapy have the potential to reverse disease mechanisms. It is also important to initiate therapy as early as possible in an attempt to inhibit fibrosis, which will ultimately lead to functional impairment. Therapy aimed at addressing clinical signs of liver disease, including ascites, GI ulceration leading to melena, and hepatic encephalopathy, is also an important part of therapy of the dog with CH. Copper chelators are important in dogs with copper-associated hepatitis. Careful dietary management to support the liver is essential too. Unfortunately, in veterinary medicine there is a lack of controlled studies on clinical efficacy and pharmacokinetics of the drugs commonly used in canine CH. As a result, many of our current therapeutic protocols are either derived from human hepatology or anecdotal reports or originate from low-quality veterinary clinical studies. The following refers to the recommended therapy of a dog with CH.

Corticosteroids

Corticosteroids have antiinflammatory, immune-modulating, and antifibrotic properties. They have a potent indirect antifibrotic action via reducing prostaglandin and leukotriene production from inflammatory cells, and a weak direct antifibrotic action by inhibiting mRNA and enzymes. Corticosteroids are indicated in the therapy of CH where there is biopsy evidence of ongoing inflammation, when there is mild to moderate fibrosis associated with an inflammatory infiltrate, and when infectious causes have been ruled out as far as possible. However, steroids are not without adverse effects, and these can be very severe and potentially life-threatening in some dogs with CH. Adverse effects include increased protein catabolism, fluid retention, GI ulceration, and risk of infections. Their use in humans with ascites, GI ulceration, and encephalopathy has been shown to decrease survival time, and the same is likely to be true in dogs. These are patients with portal hypertension. As advanced bridging fibrosis or cirrhosis is likely to be associated with portal hypertension, corticosteroids are therefore contraindicated if there is biopsy evidence of these changes. Dexamethasone tends to cause more adverse effects than prednisolone and should be avoided.

There have been limited numbers of studies evaluating the use of corticosteroids in dogs with CH. In an early study, prednisolone was used in 151 dogs at a dose of 2.2 mg/kg/day for 7–14 days, and resulted in increased

survival from a median of ten months to thirty months, and complete remission was reported in some dogs with no relapse. However, the diagnosis of CH was not made according to our current histologic criteria. In a more recent study of 36 dogs with idiopathic CH treated with prednisolone at 1 mg/kg/day for at least six weeks, at follow-up 11 dogs were in complete remission, eight dogs had recurrent clinical signs, and 17 had residual disease. In a prospective study of CH in English Springer spaniels, 14 dogs were treated with prednisolone at a mean dose of 1.2mg/kg/day. These dogs all demonstrated improved survival over a historical control group, and there was improvement in liver enzyme activity and bilirubin in all. Finally, a retrospective study demonstrated that when 13 Cocker spaniels were treated with prednisolone 0.5-1.25mg/kg/day, in combination with azathioprine, there was a longer survival than a historical control group. . In these reports, some dogs with CH demonstrate an improvement in clinical signs, laboratory data or histopathology, inferring an immunomodulatory or anti-inflammatory benefit. However, limited conclusions can be drawn from most of these studies, as the underlying cause of CH wasn't often known. In addition, variable doses of immunosuppressive drugs were used, and dogs usually received concurrent therapies. If there is strong evidence for an immune-mediated causes to CH (see earlier), the clinical should consider using an immunosuppressive dose of corticosteroids. However, if infectious causes have not been ruled out, and especially if hepatic histology is not typical for an immune-mediated aetiology, a lower dose should be used.

The duration of corticosteroid therapy, or method of dose reduction in dogs with CH is also not known. In human patients, corticosteroids are continued for at least six months beyond remission, and in some cases life-long. It is often difficult to assess remission in dogs, particularly as corticosteroids induce hepatic enzymes and so confuse attempts to follow the disease clinicopathologically. Repeat liver biopsy can be very useful, although sometimes results are nonrepresentative if the disease is patchy in distribution. The length of therapy therefore remains empiric and some animals remain on life-long therapy. In this situation the aim is to use a low alternate-day dose. Using an additional immunosuppressive alongside corticosteroids may enable a more rapid tapering of the corticosteroid.

Ciclosporin has also been used as an additional, or alternative, immune-modulating drug in canine CH. . In a retrospective study 48 dogs with suspected idiopathic CH were treated with 5.0mg/kg BID cyclosporine; 79% of dogs achieved biochemical remission, although no follow-up biopsies were taken to determine the effects of therapy on hepatic histology.

Antifibrotics

Progressive fibrosis in CH ultimately leads to reduced function and many of the clinical consequences of advanced liver disease. The most effective 'anti-fibrotic' in chronic liver disease is to remove the underlying cause. In addition to the antifibrotic action of corticosteroids, more specific antifibrotics exist. Colchicine, an alkaloid that binds tubulin, may be useful in some dogs with CH and moderate to marked fibrosis on biopsy, although it is not licensed for use in animals. Although it may improve survival in some human patients with advanced fibrosis, there are very limited reports of its use in dogs. If used, care should be exercised as adverse effects, including marrow suppression, anorexia and diarrhea, are seen relatively commonly. Again, it is very difficult to judge how long to treat for and a follow-up liver biopsy is necessary to assess response. The author does not use colchicine.

Cholerectics and Bile Acid Modifiers

Ursodeoxycholic acid (ursodiol, UDCA) is a hydrophilic bile acid that displaces toxic hydrophobic bile acids and also stimulates bile flow (it is a cholerectic). These two actions reduce cell damage and oxidative stress resulting from retention of bile acids in the liver. It has also been shown to have immunomodulatory actions by reducing immunoglobulin and interleukin production and expression of MHC-1 on hepatocytes. Recent studies show an additional antioxidant activity with a synergistic action with S-adenosyl-L-methionine (SAM-e) and vitamin E. No data on its use in canine CH are available, although because biliary stasis is invariably present, it is probably indicated in all cases. It also appears to be well tolerated with no significant adverse effects reported to date.

Antibiotics

The majority of dogs with CH do not appear to have an underlying bacterial etiology, and so do not require antibiotics. Having said that, due to compromised reticuloendothelial function, bacterial infections may be a secondary complication of many liver diseases, including CH, and so their use may be justified. Moreover, antibiotics should also be used if the patient has signs of hepatic encephalopathy. Because of their efficacy against enteric organisms and ability to concentrate in bile, suitable antibiotics include ampicillin, amoxicillin, cephalexin, fluoroquinolones, and metronidazole. Note that, because of its reliance of hepatic clearance, metronidazole should be used at half the routine dose in dogs with liver disease to avoid toxic adverse effects. The use of antibiotics in dogs with bacterial cholangitits/cholangiohepatitis is discussed in Chapter 67.

Antioxidants

These include vitamin E, zinc, silymarin (milk thistle), and SAM-e. Oxidant stress is likely to be increased due

to the effects of inflammation, reduced blood flow, and mitochondrial damage by refluxed bile acids. Oxidation is a significant mechanism of hepatic damage, therefore antioxidant therapy is reasonable. SAM-e increases hepatic and red blood cell levels of glutathione, a potent antioxidant, and is also a critical enzyme in transmethylation, transsulfuration, and aminopropylation pathways. As part of these pathways, SAM-e is essential to all cells and is particularly important in hepatocytes because of their central role in metabolism. It is widely available as a neutraceutical for dogs, sometimes in combination with silymarin. Although no experimental data exist, antioxidants are likely of benefit in CH. However, not all antioxidants are necessarily innocuous in liver disease; for example, ascorbate may increase liver damage by accumulating iron, so it is best to avoid supplementing vitamin C.

Copper Chelators

Copper chelators include 2,3,2-tetramine tetrahydrochloride (2,3,2-T), 2,2,2-tetramine tetrahydrochloride (2,2,2-T), penicillamine, and zinc. 2,3,2-T is the more potent chelator but is not widely available in a drug formulation. Penicillamine is an alternative copper chelator, but significant adverse effects can be associated with its use. Copper chelators should be reserved for dogs in which significant copper accumulation has been identified in liver tissues, primarily those animals with copper storage disease. Zinc is used as prophylaxis in dogs with copper storage disease, and commercially produced hepatic support diets often contain increased zinc for this reason. The use of copper chelators for the management of copper-associated hepatitis is discussed in Chapter 62.

Diuretics

Ascites in CH is usually due to portal hypertension, although in some animals hypoalbuminemia may contribute to the pathogenesis. If blood albumin is normal or near normal in the ascitic dog, portal hypertension is likely to exist. Portal hypertension leads to splanchnic pooling of blood with subsequent reduction in systemic arterial pressure and activation of the renin-angiotensin-aldosterone system (RAAS). RAAS activation then leads to further fluid retention and more ascites. Spironolactone, an aldosterone antagonist, is therefore the drug of choice in ascitic patients with portal hypertension, although it can take 2–3 days to work. For this reason, spironolactone combined with a thiazide diuretic or furosemide can be used in an attempt to increase its speed of action. Spironolactone also has the advantage that it does not induce hypokalemia, which can precipitate hepatic encephalopathy (HE) (hypokalemia allows ammonia to enter cells more easily).

Gastroprotectives

Portal hypertension is common in dogs with CH and leads to gut wall edema and potentially ulceration. This is one of the most common causes of death in dogs with chronic portal hypertension. Sudden GI bleeding can precipitate an acute encephalopathic crisis due to the high protein content of blood. An important way to reduce the incidence of GI tract ulceration is to ensure adequate enteral nutrition (see later), as anorexia predisposes to GI ulceration. H2 receptor antagonists, or proton pump inhibitors, are often used in the prevention and therapy of ulceration. However, there is some evidence that gastric pH is actually elevated in human CH, and, moreover, many ulcers are duodenal rather than gastric, so the rationale for these drugs is unclear. Traditionally, ranitidine is preferred as an H2 receptor antagonist in liver disease as it does not affect the cytochrome P450 system, and sucralfate should probably be used also.

Dietary Management

Appropriate dietary management is as important as drug therapy in the dog with CH. Each case is individual and the diet should be adjusted accordingly, so clinicians should resist the temptation to think that "one diet fits all." In particular, many dogs with CH are fed diets with inappropriate and excessive protein restriction, which may restrict hepatic regeneration and result in protein-calorie malnutrition. Specific recommendations include the following.

- Feed a palatable diet little and often (4–6 times a day) as many dogs with CH may be inappetent. Frequent feeding also reduces the development of HE.
- Feed highly digestible, high-quality protein in normal amounts whenever possible. Good-quality commercial diets are acceptable. Examples of high-quality proteins include soya and these can be supplemented if weight or blood albumin decreases. If signs of HE are suspected, feeding a normal amount of high quality digestible protein little and often is recommended. Excessive protein restriction may result in protein-calorie malnutrition and the breakdown of highly ammoniagenic endogenous proteins.
- Dogs with CH may have impaired carbohydrate metabolism, so a diet containing highly digestible, complex carbohydrates should be fed.
- Normal amounts of fat should be fed, although fat can be restricted if steatorrhea develops.
- Fermentable fiber is helpful in dogs with HE as it acidifies the colon and traps ammonia. It also increases nitrogen incorporation into bacteria and reduces bacterial ammonia production. Nonfermentable fiber is helpful in preventing constipation, a predisposing factor for hepatic encephalopathy.

- Zinc deficiency is common in human CH and is thought to also occur in dogs with CH. Supplementation reduces HE and decreases copper absorption from the GI tract and copper availability in the liver. Zinc may also have antiinflammatory, antifibrotic, and antioxidant effects.
- In dogs with excessive hepatic copper accumulation, primarily those with a primary copper storage disease, copper intake should be restricted. This includes not providing water from copper pipes in soft water areas.
- Fat-soluble vitamins include A, D, E, and K. Vitamin E is an antioxidant and can be supplemented in dogs with CH. Vitamin K supplementation may occasionally be necessary if clotting times are prolonged, especially preceding biopsy. Vitamins A and D should not be supplemented as vitamin A can cause hepatic damage and vitamin D can cause calcification in tissues.
- Vitamin B, a water-soluble vitamin, can also be supplemented, as there may be increased loss associated with polyuria.

The effectiveness of dietary therapy should be monitored by the assessment of clinical signs and making sure that the patient maintains body weight and blood protein levels. Consideration should also be given to the use of enteral feeding methods in the anorexic dog with CH.

Prognosis

The prognosis for CH is variable, and likely dependent on multiple factors, especially the underlying etiology and stage of disease. The presence of advanced fibrosis and cirrhosis is strongly associated with a reduced survival time in humans with CH, and the same appears to be true in dogs. In one study, the median survival time of a variety of breeds of dogs with CH was 18.3 months. Other studies have demonstrated mean survival times of approximately 18 months and 16 months, again in a variety of breeds of dog with CH. In Labrador retrievers with CH, the median survival was 374 days (range, 1–2645 days), whereas in English springer spaniels it was 189 days (range, 1–1211 days).

One of the most important individual prognostic indictors in CH appears to be the presence of ascites; the time from onset of clinical signs to death was two months for dogs with ascites, compared to 33 months for those without. Total serum bilirubin has also been shown to be significantly negatively correlated with a reduced survival time in dogs with CH. Other parameters associated with a shorter survival time in dogs with CH include anorexia, prolonged prothrombin time, prolonged partial thromboplastin time, thrombocytopenia, hypoalbuminemia, and hyperglobulinemia. Caution should, however, be employed when interpreting these data in the individual dog with CH, as prognosis is likely dependent on multiple variables.

Acute Hepatitis

Etiology/Pathophysiology

The majority of cases of AH are idiopathic. Of the known causes, toxin or drug ingestion is thought to be most common, and is discussed further in Chapter 62. Other causes of AH are discussed here.

As detailed previously, a potential viral cause of AH and CH was identified some 30 years ago and named "canine acidophil cell hepatitis virus." However, no specific agent was isolated, nor have further reports emerged. CAV-1 is probably the best known infectious cause of AH, particularly in non-Immune dogs, but it can occasionally cause disease in partially immune dogs. However, the use of widespread vaccination against this disease has significantly reduced its incidence, so cases of clinical disease are now uncommon.

Probably the most frequently implicated infectious cause of AH is due to *Leptospira* spp. The characteristic hepatic lesions in acutely infected dogs include edema and sinusoidal congestion, perivascular inflammation, hepatocyte necrosis, and cholestasis. Some animals also present with signs of renal dysfunction. Widespread vaccination has significantly reduced the incidence of disease although, at least in the UK, the majority of dogs are only vaccinated against two serovars. Clinical cases of leptospirosis due to infection with other serovars occur, so the use of vaccines providing protection against these additional serovars is recommended. Infection with other bacteria is a relatively uncommon cause of canine AH, although dogs do develop cholangitis or cholangiohepatitis.

Defects in copper metabolism leading to the development of AH have also been described in several breeds of dog. In one study of 21 dogs with AH, five had histologic evidence of increased copper accumulation and were diagnosed with copper-associated hepatopathy.

Epidemiology

Few data exist to determine the prevalence of AH in dogs. In part, this likely represents the failure to achieve a histologic diagnosis in many animals. In one study of 101 cases of primary hepatitis, AH was diagnosed in 21 dogs and CH in 67. Improvements in histologic classification of canine liver diseases, including that of AH, may therefore result in future prevalence studies.

Signalment

Acute hepatitis, like CH, typically affects middle-aged to older dogs, and females appear to be predisposed. In a study of 21 dogs diagnosed with AH, the mean age of

affected dogs was 7.8 +/– 4.1 years, with a range of 2.4–14.5 years. No comprehensive study has been performed to determine the breed predispositions to AH, although in this same study, Jack Russell terriers may have been at increased risk.

History and Clinical Signs

Clinical signs in dogs with AH are usually nonspecific and similar to those described for CH. Interestingly, in one study of dogs with AH, clinical signs had been present for 10.0 weeks (range, 0.5–52 weeks) before diagnosis. Again, the clinician should pay particular attention to subtle waxing and waning GI signs, depression, lethargy, anorexia, weight loss, and polyuria and polydipsia. Clinical signs of HE may also occur in the patient with AH. Physical examination findings are generally unremarkable, although the liver is occasionally palpably enlarged in the dog with AH. Dogs with an infectious etiology may also be pyrexic and show other signs of systemic disease.

Diagnosis

As discussed earlier, clinical pathology is usually the next step in the investigation of a dog with suspected AH. Clinical pathology findings include elevations of liver enzymes, including ALT, AST, ALP, and GGT. In one study, there was no significant difference in any routine biochemical or hematologic variable between dogs with AH and CH. However, if liver function is assessed, it is more likely to be within the reference range in dogs with AH.

Diagnostic imaging is often performed after clinical pathology in the assessment of the dog with suspected AH. Abdominal radiography can be used to assess liver size, although as detailed earlier, ultrasonography is the preferred imaging modality for the investigation of liver disease. In one study of 21 dogs with a histologic diagnosis of AH, all apart from two had abnormalities detected on ultrasonographic examination of the liver. Hepatic size was assessed as normal in seven dogs, enlarged in eight, and small in six. The hepatic parenchyma was found to be normal in seven dogs, irregular in 11, and to have increased echogenicity in three. Interestingly, three dogs with AH had evidence of ascites on ultrasonographic examination.

It is not possible to make a definitive diagnosis of AH based on results of clinical pathology or diagnostic imaging. Definitive diagnosis ultimately relies on histologic examination of liver tissue. However, as animals with AH may be systemically unwell, liver biopsy is often not performed in the acute setting, with patient treatment based on a tentative diagnosis. Fine needle aspiration cytology is not reliable for the diagnosis of AH, and is not recommended.

Therapy

Therapy for AH is aimed at the underlying cause, if known. However, as the etiology of most cases is currently not understood, treatment is generally symptomatic and supportive. In one retrospective study, dogs with AH were treated with antibiotics (5/16), hepatic support diet and ursodeoxycholic acid (7/16), and 5/16 dogs were not treated. Due to the potential for an underlying infectious cause, corticosteroids are usually avoided in dogs with AH . The use of antiviral drugs in dogs with CAV-1 infection has not been studied. Fluid therapy is required if the dog is anorexic, and short-term nutritional support by methods of assisted enteral nutrition is sometimes also required.

Prognosis

The prognosis for AH is variable, and likely dependent on multiple factors, such as the etiology, severity of disease, and how early treatment is instigated. In a previous study, the median survival time of dogs with AH was 34.9 months. It is also possible that AH progresses to CH in some dogs. For instance, in a study of 12 dogs with AH that had a repeat liver biopsy performed after approximately six weeks, histopathology revealed complete remission of inflammatory and degenerative changes in six dogs, no changes in one dog, and progression from AH to CH in five dogs.

Cirrhosis and its Consequences

Katherine Scott, DVM, DACVIM (SAIM)

VCA Alameda East, 9770 East Alameda Ave, Denver, CO, USA

Etiology/Pathophysiology

Cirrhosis

Development of hepatic fibrosis and subsequent cirrhosis is a common complication of chronic hepatitis (CH). Cirrhosis is defined histologically by the presence of diffuse bridging fibrosis and regenerative hepatic nodules. CH can be caused by a variety of different initial insults that include toxins or drugs, breed-associated metabolic errors, including disorders of copper metabolism, and infections, although the majority of cases are idiopathic. Regardless of the underlying cause, fibrosis may develop when CH is severe and/or is present for an extended period of time.

Fibrosis develops when hepatic myofibroblast-like cells become activated secondary to hepatic injury. These cells produce factors including transforming growth factor-beta (TGF-beta), which upregulate hepatic extracellular matrix components such as collagen and glycoaminoglycans. TGF-beta also upregulates inhibitors of metalloproteinases, resulting in decreased extracellular matrix breakdown. In CH, these changes result in progressive accumulation of extracellular matrix in the liver. Cirrhosis develops with the diffuse accumulation of fibrous tissue in the liver, resulting in conversion of normal hepatic architecture into structurally abnormal hepatic nodules (Figure 65.1). With the development of cirrhosis, a variety of adverse consequences develop, and these are predominantly related to the development of portal hypertension and progression of hepatic dysfunction.

Portal Hypertension

Portal hypertension (PH) is an increase in blood pressure within the portal vasculature, the vessels responsible for providing venous drainage to the intestines and spleen. The hypertension can be caused by any disease that results in obstruction of venous return of portal blood. PH can be classified according to location of the increase in blood pressure, including prehepatic, intrahepatic, or posthepatic causes. The type of portal hypertension caused by cirrhosis is an intrahepatic form of PH, as opposed to prehepatic PH that occurs in disorders of the portal vein itself, or posthepatic PH that occurs with right-sided heart failure or caudal vena cava disorders. With cirrhosis, hepatic sinusoidal endothelial cells have lost normal fenestrae and acquired a collagenous basement membrane in their place. This change, as well as other remodeling changes in the liver such as regenerative nodules and microthrombi, results in distortion of sinusoids and increases intrahepatic venous resistance, with resultant PH.

Ascites

Once PH is present, ascites may also develop as, according to Starling's law, the increased venous resistance and increase in portal venous hydrostatic pressure drive fluid out of the vasculature and into the interstitial space. Lymphatic drainage of the interstitial space may be able to deal with this extra fluid for some time, but when the regional lymphatics become overwhelmed and unable to control this increase in interstitial fluid, ascites will develop.

Additionally, ascites may develop as a result of hypoalbuminemia secondary to severe liver disease. Albumin is a plasma protein normally produced by the liver, and significant hepatic dysfunction may result in a clinically important decrease in albumin concentration. Albumin is the most important blood protein responsible for maintenance of normal plasma colloid oncotic pressure. If serum albumin levels decrease to less than approximately 1.6 g/dL, plasma colloid oncotic pressure will become too low to maintain intravascular volume and fluid will enter the interstitial space. Animals with cirrhosis will often develop both portal hypertension and

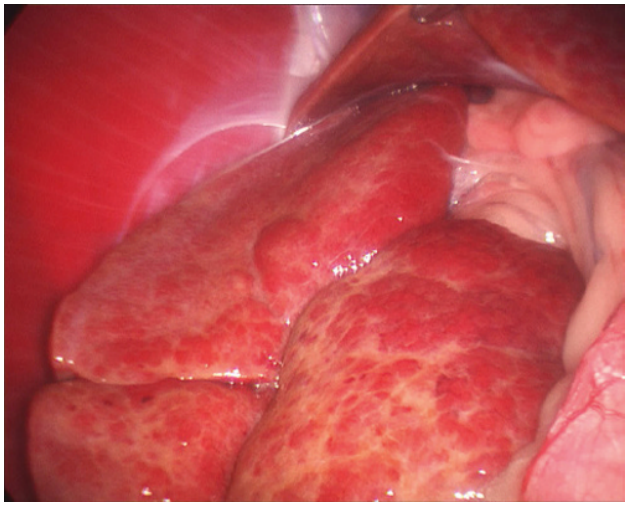

Figure 65.1 Laparoscopic view of a cirrhotic liver secondary to toxin insult from cycad ingestion. Note the pale and undulating appearance of the hepatic tissue.

hypoalbuminemia concurrently, further increasing the risk of development of ascites.

Acquired Portosystemic Shunts

Portosystemic shunts are anomalous venous vessels that join the portal blood with the systemic vasculature, while bypassing the liver. They can be congenital in origin or acquired secondary to cirrhosis/fibrosis or other causes of PH. If PH develops and does not resolve quickly, the development of multiple acquired portosystemic shunts (aPSS) may occur. Acquired shunts are thought to develop in an attempt to decrease PH. Experimentally, it takes 5–14 weeks of PH before acquired shunts develop. This continued increase in hepatic venous portal pressure results in the opening of embryonic vessels that arise between the portal vasculature and the cranial and caudal vena cava, resulting in the formation of multiple aPSS. These shunts vary in anatomic location, but are most commonly visualized as a plexus of small vessels found caudodorsal to the left kidney. They connect the portal vasculature with the vena cava, allowing for venous blood to bypass the liver. This blood remains unfiltered and enters the systemic circulation.

Hepatic Encephalopathy

One of the most important consequences in the development of aPSS is hepatic encephalopathy (HE). In the presence of aPSS, toxins normally filtered by the liver are transported from the gastrointestinal (GI) tract to the rest of the systemic circulation, including the central nervous system (CNS). While many toxins are involved in this process, ammonia is thought to be one of the most important and the only currently measurable encephalotoxin. Ammonia is a breakdown product of ingested proteins, and is normally absorbed by the GI tract, transported to the liver, and metabolized into urea. If aPSS are present, ammonia remains intact and is transported across the blood–brain barrier, resulting in neuronal dysfunction and alterations in neurotransmission. HE may result in increased activation of neuronal gamma-aminobutyric acid (GABA)/benzodiazepine receptors, which are responsible for neuronal suppression.

Gastrointestinal Ulceration

Gastrointestinal ulceration is another possible complication of severe hepatic disease or cirrhosis. In humans, GI ulceration is thought to be related to impaired gastric mucosal defense secondary to alterations in GI motility and circulation, and bile acid secretion. While this condition has been described in people, the etiology has not been evaluated in dogs and cats. Portal hypertension also likely contributes to the development of GI ulceration. Regardless of cause, GI ulceration is a recognized complication of liver disease in animals. If GI bleeding occurs as a result of ulceration, this can acutely increase the risk of HE. Blood is a highly ammoniagenic protein, and may result in a rapid increase of serum ammonia levels when absorbed following the digestion of blood. This rapid increase in ammonia may cause a sudden onset of signs related to HE.

Coagulation Disturbances

The liver is responsible for the production of coagulation factors, recycling and activation of vitamin K-dependent factors and protein C, production of thrombopoietin, and removal of clotting factors from the circulation. In a liver which is severely diseased from cirrhosis, coagulation abnormalities are likely to be present to some degree. Studies have shown that anywhere from 57–93% of dogs, and 82–98% of cats with liver disease have at least one alteration in coagulation parameters. Decreased factor production appears to play the most significant role in secondary hemostatic abnormalities, but consumption of factors due to disseminated intravascular coagulation (DIC) may also occur.

Thrombocytopenia may also occur secondary to liver disease in dogs, but is uncommon in cats. Thrombocytopenia is usually mild, and may occur secondary to decreased thrombopoietin production by the liver, increased sequestration in the spleen as a result of splenic congestion secondary to liver disease, increased consumption from low-grade DIC, and increased destruction due to autoantibodies.

Signalment

Signalment of an animal with cirrhosis largely depends on the underlying cause of liver disease, but cirrhosis is much more common in dogs than in cats. This may be due to a slower accumulation of fibrosis in cats, or development of more severe complications of hepatic failure before advanced fibrosis occurs. Males and females are likely to be equally affected, and dogs with breed-related risk of CH are more likely to be affected. For further details of dog breed predilections to CH, the reader if referred to Chapter 62. Dogs with idiopathic CH and copper-associated CH are often middle-aged to older, while dogs with lobar-dissecting hepatitis are usually young, around 2 years of age. Dogs or cats with a history of hepatotoxicity secondary to environmental toxins or drugs may be of any age.

History and Clinical Signs

The presenting clinical signs in chronic liver disease are often vague in nature, and include a history of inappetence, lethargy, vomiting, polyuria/polydipsia, weight loss, and/or diarrhea. Melena may be observed if GI ulceration is present. Ascites and icterus are more specific clinical signs that may be noted. Neurologic abnormalities such as depressed mentation, circling, ptyalism in cats, star-gazing, seizures, stupor or coma may also occur secondary to HE. These neurologic changes may be intermittent in nature, and frequently occur shortly following ingestion of a meal containing protein. Signs have usually been present for weeks to months, and are often progressive in nature.

Physical examination findings are also often nonspecific, and may only include weight loss or muscle wasting. If ascites is present, abdominal distension and a palpable fluid wave may be apparent. Splenomegaly may also occur in the presence of PH and pooling of blood in the spleen. Icterus may be visualized on the skin, sclera, or mucous membranes as a result of accumulation of bilirubin. Less commonly, petechiae or ecchymosis may be observed on the skin or mucous membranes secondary to thrombocytopenia or thrombocytopathy. Melena may be observed on rectal examination. If HE is present, neurologic examination abnormalities localizing to the forebrain may be present.

Diagnosis

Laboratory Testing

The most common laboratory abnormalities in patients with cirrhosis are alterations of liver-related enzymes. Patients with cirrhosis will often have a known history of elevated liver enzymes, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and gamma-glutamyl transpeptidase (GGT). However, in occasional cases of severe hepatocellular loss, liver enzymes may be within normal limits simply due to the low number of remaining hepatocytes. Liver pseudofunction tests may also be abnormal, and suggest some degree of liver dysfunction. It is estimated that a reduction of approximately 70–80% of overall hepatic function must be present before these alterations occur. Pseudofunction tests include decreased albumin, BUN, cholesterol, and/or glucose, and an increase in bilirubin. All of these pseudofunction compounds are produced or metabolized normally by the liver, and will be altered in states of liver dysfunction.

On a complete blood count, microcytosis may be noted in patients with acquired or congenital PSS, secondary to a deficiency in mobilization of iron stores. Anemia may occur from GI ulceration and blood loss or bleeding secondary to coagulopathy. Mild thrombocytopenia may be present due to decrease in hepatic synthesis of thrombopoietin. Leukocytosis is nonspecific, but may occur secondary to stress, inflammation, or infection.

Urinalysis is often normal in patients with cirrhosis, but may demonstrate dilute urine as a result of decreased BUN concentration. Urea is a major component of the renal medullary concentration gradient, and, when decreased, may lead to the development of dilute urine. Bilirubinuria may be observed, and is always significant in the cat, and if 2+ or greater is also significant in the dog. Urate crystals may be observed in as many as 40–70% of dogs with canine PSS, and secondary urinary tract infections are possible as a result of dilute urine.

Coagulation testing should be undertaken if hepatic biopsy is to be performed, or if any clinical signs of bleeding are observed. Prothrombin time (PT) and partial thromboplastin time (PTT) may be increased, and antithrombin, fibrinogen, and protein C levels are decreased in dogs and cats with cirrhosis due to poor production of coagulation factors and/or decreased recycling of vitamin K. Vitamin K deficiency may be especially important in cats with severe liver disease. Evaluation of platelet function testing via buccal mucosal bleeding time may also be abnormal secondary to a thrombocytopathy.

Hepatic function testing can be performed by measuring pre- and postprandial bile acid concentrations or blood ammonia levels. Both tests may be elevated in the face of significant liver dysfunction or aPSS secondary to cirrhosis. Postprandial bile acids are considered to be more sensitive for detection of PSS but elevated ammonia may be more specific. Additionally, ammonia is currently the only measureable HE toxin, so the finding of hyperammonemia may also suggest a higher risk of clinical signs related to HE. However, ammonia sam-

ples are labile, and must be placed on ice and analyzed within 30 minutes to ensure accurate results. Hepatic function tests are commonly altered in dogs with cirrhosis, but as cats uncommonly develop significant fibrosis, function can remain normal in this species.

For further details of laboratory testing in patients with liver disease, the reader is referred to Chapter 60.

Imaging

Imaging modalities most commonly utilized for further evaluation of cirrhosis and its complications include abdominal radiographs and abdominal ultrasound. Abdominal radiographs are the most commonly available imaging modality, but are relatively nonspecific for hepatic disease. Cirrhosis may result in microhepatica, which can be visualized on abdominal radiographs. However, this is a change that may be seen in other hepatic diseases such as congenital PSS. Ascites secondary to PH or hypoalbuminemia may be visible radiographically as loss of abdominal serosal detail.

Abdominal ultrasound is a very useful noninvasive imaging modality that can be utilized to further diagnose liver disease and its complications (Figure 65.2). Ultrasound can evaluate hepatic parenchymal echogenicity and uniformity, overall hepatic size, biliary structures, hepatic and portal vessels, and identify very small volumes of ascites that might not be visible radiographically. It can also be utilized to identify multiple aPSS. Ultrasound is also useful in guiding safe collection of samples of ascites or bile for fluid analysis, or ultrasound-guided "Tru-Cut" biopsies.

Unfortunately, while ultrasound is a very useful noninvasive test, it does not identify changes pathognomonic for a specific liver disease, and should never be used to rule out the possibility of liver disease. Many dogs and possibly cats without sonographic abnormalities may still have important liver abnormalities on histopathology. Ultrasound is also not a reliable method to diagnose cirrhosis. In a study evaluating ultrasound findings with histopathologic diagnoses, there were no sonographic features significantly associated with cirrhosis, and it was concluded that ultrasound could not reliably be used to detect the presence, absence, or severity of fibrosis. In fact some animals with cirrhosis had ultrasonographically normal appearing livers. But sonographic findings may still be useful in suggesting the possibility of cirrhosis and its consequences. Findings that would be most suggestive of cirrhosis and subsequent PH include identification of multiple aPSS, a small liver with irregular margins, presence of ascites, and a hyperechoic echotexture. But ultimately, biopsy and histopathology are required to obtain a definitive diagnosis of cirrhosis.

Figure 65.2 Ultrasonographic image of a cirrhotic liver. Note the presence of large-volume ascites, a small liver with irregular hepatic margination, and mottled echogenicity.

Other imaging modalities may also be useful in diagnosing the cause or complications of cirrhosis. Computed tomography (CT) and magnetic resonance imaging (MRI) may provide a more complete evaluation of hepatic vasculature than abdominal ultrasound. When utilized with contrast, CT and MRI may also provide further evaluation regarding location of neoplasia and possible metastasis. Rectal or transsplenic nuclear scintigraphy can be useful in the diagnosis of PSS, when ultrasound is inconclusive, although scintigraphy may not be able to distinguish congenital versus aPSS. Further details of diagnostic imaging in the investigation of cirrhosis and its complications can be found in Chapter 61.

Cytology and Fluid Analysis

Fine needle aspiration cytology is an inadequate method to diagnose cirrhosis. While cytology may help identify the underlying cause of cirrhosis, it cannot confirm the presence or absence of fibrous tissue

Cytology of ascitic fluid may be utilized when attempting to identify whether the ascites is caused by PH, infectious disease, or neoplastic disease. Typically, ascites secondary to PH is a modified transudate (also refereed to as a protein-rich transudate), or possibly a pure transudate. PH ascites is nonneoplastic, and noninflammatory in origin. Cytology and culture of bile may also be important in diagnosing the underlying cause of cirrhosis. Biliary cultures have been shown to yield a significantly higher rate of positive growth than hepatic tissue cultures.

Histopathology

The gold standard diagnosis of cirrhosis is liver biopsy with histopathology that identifies the presence and extent of fibrosis. Not only is it important to document

the presence and severity of cirrhosis, but it is crucial to attempt to identify the underlying disease that has resulted in the development of fibrosis/cirrhosis. This will allow for specific treatment to be directed at the underlying cause.

Due to the risk of coagulopathy in dogs with hepatic disease, coagulation testing including PT, PTT, platelet count, and possibly buccal mucosal bleeding time (BMBT) should always be performed prior to liver biopsy. Interestingly, results of these parameters do not consistently predict risk of bleeding after liver biopsy in human patients with chronic liver disease. Fibrinogen concentration should also be evaluated if possible, as it may be decreased in cirrhosis. In humans, thromboelastography (TEG) analysis can predict bleeding tendencies in cirrhotic patients, but the value of TEG in predicting bleeding in our canine and feline patients with liver disease is unknown. In cases of hypofibrinogenemia or other coagulopathy, transfusion with cryoprecipitate or fresh frozen plasma should be performed prior to biopsy. Vitamin K1 therapy (1–1.5 mg/kg q12–24h for three doses) prior to biopsy may also be necessary, especially in cats.Assessment of coagulation status should, however, not be a substitute for proper technique and adequate post-operative care.

Biopsy may be obtained through ultrasound-guided "Tru-Cut" needles, laparoscopically, or via exploratory laparotomy. Each method has practical advantages and disadvantages when it comes to cost, time involved, invasiveness, and availability. But collection of a wedge biopsy via laparoscopy or exploratory laparotomy is generally considered to be a superior method of sample collection. It has been shown that morphologic diagnosis of needle biopsy specimens and wedge biopsies (considered the gold standard) only agreed in 40% of animals with liver disease. If the "Tru-Cut" biopsy method is utilized, two or more samples should be collected to minimize sampling error. Further details on the methods to collect liver tissue can be found in Chapter 60.

Treatment

Cirrhosis is considered irreversible. Therefore, the most important aspect of treatment is addressing the underlying cause of liver disease as early as possible to prevent further development of fibrosis/cirrhosis, and to minimize the risk of cirrhosis-associated complications. Corticosteroids have been shown to have positive long-term effects in the treatment of idiopathic chronic hepatitis, and may have minor antifibrotic properties (see Chapter 62). Copper-chelating medications such as D-penicillamine or trientine should be utilized in cases where primary copper-associated chronic hepatitis is diagnosed. In cases of previous toxic hepatopathy or idiopathic disease, specific treatment may not be possible. In all cases of cirrhosis, treatment must also include management of any important complications of cirrhosis.

Colchicine (0.03 mg/kg/day) is the only specific drug in veterinary medicine currently used to stop the formation of fibrosis. It is thought to stimulate collagenase activity, increasing the breakdown and decreasing the formation of collagen. Colchicine is reported to have important and common side-effects, including vomiting, diarrhea, and neurologic signs. Additionally, there are no large studies that have shown positive benefit from this medication, it has not been evaluated in cats, and it is currently cost-prohibitive for many pet owners. As a result of these problems, most clinicians do not currently recommend its use, even in documented cases of hepatic cirrhosis.

Glucocorticoids may be beneficial in some cases of cirrhosis. Steroids interact with TGF-beta signaling pathways and may reduce fibrotic progression, although this effect may be relatively weak. More importantly, prednisone/prednisolone (1 mg/kg/day) may be useful in inhibiting hepatic inflammation, if present. This decrease in inflammation will result in decreased activity of hepatic stellate cells, responsible for formation of further fibrosis. Glucocorticoids may be most beneficial for treatment of dogs and cats with active hepatic inflammation that have not yet developed fibrosis/cirrhosis. Evidence supporting use of glucocorticoids in the absence of hepatic inflammation is lacking, so their use may or may not provide additional benefit in treatment of cirrhosis alone. Moreover, the adverse effects of steroids in animals with advanced fibrosis can be very significant. Due to their ability to cause gastric ulceration, they should be used with extreme caution in animals with , as these animals already have a compromised GI tract blood flow. Steroids cause muscle breakdown so may also potentiate HE.Further details on the use of corticosteroids in dogs with chronic liver disease can be found in Chapter 62.

Losartan is another medication that shows promise for fibrosis/cirrhosis but has not yet been evaluated for this purpose in small animals. Losartan is an angiotensin II receptor antagonist that has been shown in rodent models to inhibit hepatic stellate cell activation and attenuate hepatic fibrosis. It is currently utilized in veterinary medicine for its effects on proteinuria. No studies have shown if losartan may be an effective therapy in preventing fibrosis development in dogs or cats.

Ascites

Ascites may spontaneously improve with specific treatment of the underlying liver disease. Reducing hepatic inflammation, when present, may decrease PH

and therefore decrease the volume of ascites. If this is ineffective, treatment with diuretics is indicated. Spironolactone is the drug of choice in these cases due to its sodium-wasting but potassium-sparing effects, with a starting dose of 1–2 mg/kg/day. Aldactazide, a combination of spironolactone and hydrochlorothiazide, may also be administered. Low-dose furosemide (1-2 mg/kg PO q12h) can also be utilized, but carries a risk of worsening HE due to its acidifying effects. Therefore, it should only be added to therapy when other diuretics fail to fully control the ascites. Dietary sodium restriction may also be beneficial to help decrease volume of ascites. Diets with <0.05 g/100 kcal of sodium have been recommended. It is important to monitor electrolytes and renal values while on these medications, and taper to lowest effective dose to control clinical signs of ascites.

Abdominocentesis may be performed when necessary for severe abdominal distension resulting in patient discomfort or respiratory difficulties. Removing large volumes of ascites may result in cardiovascular collapse and poor perfusion, in addition to lowering body protein levels, so it is recommended to only remove 20–50% of the total volume of effusion in one procedure.

Hepatic Encephalopathy

In treating HE, efforts are classically focused on lowering the amount of encephalopathic toxins in the colon. This can be performed by both dietary changes and administration of lactulose and/or antibiotic therapy. Because ammonia is derived from protein sources, historically a protein-restricted diet with reduction in aromatic amino acids has been recommended in dogs with HE secondary to cirrhosis. However, protein restriction is controversial, and evidence from human medicine actually suggests that patients with cirrhosis require additional, not reduced, amounts of protein. What is probably more important is to ensure that the protein content of the diet is highly digestible and is fed little and often. Dairy and soy proteins have been found to promote less HE compared to meat protein. Commercial hepatic diets are available for dogs, although in some dogs the protein level may be too low, and muscle catabolism may occur. In these dogs, supplementation with highly digestible, high-quality protein in limited amounts may be necessary.

Lactulose is a nonabsorbable disaccharide that acidifies the colonic lumen, converting ammonia (NH_3) into ammonium (NH_{4+}). The positively charged ammonium is membrane impermeable, compared to the neutral charge of ammonia. Lactulose is also a cathartic, decreasing GI transit time for production and absorption of ammonia. Lactulose dosing starts at 0.25 mL/kg PO q8–12h, with adjustments in dose as needed to achieve a goal of 2–3 soft, but formed stools daily.

Antibiotics have also been used for HE in an effort to decrease the volume of colonic urease-producing bacteria responsible for production of ammonia. The two most commonly utilized antibiotics are neomycin (22 mg/kg q8h) and metronidazole (7.5 mg/kg q12h). Neomycin is an oral aminoglycoside. Aminoglycosides are very poorly absorbed by the GI tract, so it is thought that the effects will usually remain within the GI tract. However, neomycin carries a risk of nephrotoxicity and ototoxicity, even when given orally, so acute kidney injury can occur. Metronidazole may result in vomiting, diarrhea, or neurotoxicity, especially when administered at high doses or chronically. Alternatively, amoxicillin/clavulanic acid can be used at standard doses to decrease in the patient with HE.

Emerging evidence also suggests that inflammatory cytokines are synergistic with ammonia in precipitating HE. Treating concurrent inflammatory and infectious disease in other organs is therefore an important part of managing the patient with HE.

Emergency treatment of HE is warranted if a patient presents with seizures or coma, or otherwise is severely neurologic and unable to safely receive oral medications. A warm water cleansing enema (10–15 mL/kg water) should be given to remove fecal material and allow for a retention enema with lactulose. Lactulose (5–10 mL/kg) should then be infused at a 30% dilution and allowed to remain in the colon for 10–15 minutes. Flumazenil is an antagonist for benzodiazepine receptors and is used as a reversal agent for benzodiazepines. Because HE may cause stimulation of GABA/benzodiazepine receptors, flumazenil (0.01–0.02 mg/kg IV) may also provide acute improvement in neurologic depression in cases of HE.

If seizures are present, diazepam or other benzodiazepine medications should not be administered as these may increase the stimulation of GABA/benzodiazepine receptors and risk worsening neurologic depression. Instead, levetiracetam (20 mg/kg) may be given IV for acute seizure control. Phenobarbital may also be utilized. If prolonged seizure activity has been present or there are clinical signs of cerebral edema, mannitol infusion may also be necessary.

Gastrointestinal Ulceration

Gastrointestinal ulceration and bleeding can increase the risk of HE due to digestion of blood proteins and absorption of ammonia. Therefore, aggressive treatment is warranted in cases of GI ulceration. Proton pump inhibitors such as omeprazole (1 mg/kg q12–24h) have

been proven to have superior acid-blocking effects compared to H2 blockers in dogs and should be utilized in these cases. Sucralfate may also be of benefit in rapid healing and prevention of continued bleeding.

Coagulation Disturbances

Disturbances in coagulation will usually only need to be treated in the face of active bleeding, or if a biopsy is to be pursued. Vitamin K1 therapy may also be beneficial either for acute hemorrhage or prior to biopsy, especially in cats. For active bleeding, cryoprecipitate (1 unit/10 kg) should be administered for hypofibrinogenemia, as it provides the most concentrated source of fibrinogen. Fresh-frozen plasma (10–20 mL/kg) may also be utilized for fibrinogen and other factor replacement.

Hepatoprotectants

The evidence regarding hepatoprotectant therapy in veterinary medicine is generally lacking. It is unclear when and which hepatoprotectant might be most beneficial for specific hepatic diseases in dogs and cats. Therefore, it is difficult to make recommendations regarding their use in animals with cirrhosis. However, the use of ursodeoxycholic acid, S-adenosyl-L-methionine (SAM-e), silymarin, N-acteylcysteine, and vitamin E have all been anecdotally or experimentally recommended as potentially beneficial in the treatment of severe liver disease.

One of the more promising hepatoprotectant medications is ursodeoxycholic acid (ursodiol, UDCA). Ursodeoxycholic acid is a synthetic hydrophilic bile acid that is thought to provide a cholerhetic effect, decreasing levels of more "toxic" hydrophobic bile acids. It is also thought to have immunomodulatory and antioxidant effects. It has been advocated for use in CH and gallbladder mucoceles. Its utility in the treatment of cirrhosis is unknown.

S-adenosyl-L-methionine has also been advocated for use in cases of hepatic disease. It is thought to increase available levels of glutathione, an important antioxidant of the liver, by increasing levels of the glutathione precursor methionine. Glutathione production may become inadequate in cases of chronic inflammation and continuous oxidative stress. SAM-e was reported to be effective in veterinary medicine in a case of acetaminophen toxicity, and may provide protection against steroid hepatopathy. It is unknown if it provides benefit in cases of cirrhosis.

Silymarin, silybinin, or milk thistle, is another antioxidant and free radical scavenger that increases levels of superoxide dismutase (SOD). It has proven efficacy in veterinary medicine against hepatic toxicity from *Amanita* mushroom and acetaminophen toxicity. It was also shown to decrease CCNU-induced hepatotoxicity when used in combination with SAM-e. Again, its use for treatment of cirrhosis has not been evaluated.Further details on the use of hepatoprotectants in dogs with chronic liver disease can be found in Chapter 62.

Monitoring

The frequency of monitoring depends on the severity of illness and the underlying disease. Rechecking electrolytes and renal parameters is of the utmost importance when utilizing and adjusting doses of diuretic therapy. Liver enzymes, most importantly ALT, should be evaluated every 2–4 weeks in animals being treated with glucocorticoids for inflammatory liver disease. If HE is present, monitoring fasting ammonia levels may provide useful information regarding response to HE treatment.

Prognosis

Prognosis for cirrhosis is generally guarded, as cirrhosis is an irreversible condition. Prognosis may also vary widely based on whether or not the underlying hepatic disease is treatable, and the severity of cirrhotic complications such as HE and PH. One study evaluated dogs diagnosed with CH with and without cirrhosis, and found that noncirrhotic dogs with CH had a median survival time (MST) of 33 months, compared to cirrhotic dogs MST of only 1.3 months. Ascites has been reported to be a negative prognostic indicator in dogs with CH, with survival time from onset of clinical signs to death of only two months, when compared to dogs with CH and no ascites.

Conclusion

Cirrhosis is a severe, irreversible condition that occurs as a consequence of underlying liver disease. It often leads to additional complications including portal hypertension, ascites, multiple aPSS , HE, gastric ulcers, and coagulopathy. Early recognition and diagnosis of liver disease followed by specific treatment are always warranted to prevent the development of cirrhosis. Once cirrhosis and its complications are present, supportive care is the only treatment option and prognosis is guarded to poor.

Portosystemic Shunts and Microvascular Dysplasia

Geraldine Hunt, BVSc, MVetClinStud, PhD, FACVSc

School of Veterinary Medicine, University of California Davis, Davis, CA, USA

Etiology

Portosystemic shunting refers to a condition where blood bypasses the liver and travels from the hepatic portal circulation to the systemic circulation through one or more connections that can occur at a microvascular or macrovascular level.

Congenital portosystemic shunts (CPSS) occur as a result of an error in embryonic development where primordial vessels either develop abnormal connections or fail to undergo atresia. This has been shown to have a genetic basis in some breeds, including the Maltese, Irish wolfhound, and Cairn terrier. Inheritance, as assessed by pedigree analysis and test-mating, appears to be complex – either digenic or polygenic with variable expression.

Rarely, intrahepatic shunts may result from failure of the ductus venosus to close. This is most commonly reported in Irish wolfhounds (considered to be digenic in this breed). Left-divisional shunts may be encountered in any breed, but it is unclear how often these represent failure of the ductus venosus to close, versus other vascular malformations.

Acquired shunts develop as a result of increased vascular resistance within the portal system, the hepatic sinusoids or the hepatic veins (in the face of normal central venous pressure). The most common cause is hepatic fibrosis/cirrhosis, although other conditions such as portal vein thrombosis, periportal neoplasia, hepatic arteriovenous fistula, and dynamic hepatic vascular occlusion are sometimes encountered.

Microvascular dysplasia (MVD, which has more recently been termed portal vein hypoplasia (PVH) without portal hypertension, refers to abnormal development or absence of the portal microvasculature within the liver. As different authors use different terminology, this spectrum of conditions will be referred to henceforth as PVH-MVD. PVH-MVD may occur with or without CPSS. Dogs and cats with primary PVH-MVD (but no CPSS) may develop acquired shunts within the first few years of life due to chronic portal hypertension, in which case they fall into a category termed "noncirrhotic portal hypertension."

Classification and Anatomy

Portosystemic shunts are classified according to three criteria:

- congenital versus acquired
- single versus multiple
- macroscopic versus microscopic.

Congential portosystemic shunts are further classified according to their point of origin as either extrahepatic (originating from the hepatic portal vein or one of its source vessels) or intrahepatic (originating from one of the hepatic branches of the portal vein). Extrahepatic shunts are described by their origin and insertion (e.g., portocaval, splenoazygous). A subset of extrahepatic shunts that insert into the phrenic or hepatic vein has recently been characterized in various countries. Intrahepatic shunts are typically described according to the division of the portal vein from which they arise (left, central, and right-divisional).

A subset of dogs with CPSS have portal aplasia and no demonstrable portal circulation to their liver. In these cases, the shunt represents the only outlet from the portal circulation, inserting directly into the systemic venous circulation. Unfortunately, there is no surgical option for these patients. This anatomic variant may be associated with other malformations such as interruption of the caudal vena cava with azygous continuation, abdominal situs inversus, and segmentation of the spleen.

Acquired shunts are usually multiple and generally extrahepatic. Multiple intrahepatic shunts have been identified in patients following thrombogenic coil occlusion of intrahepatic shunts but it is not yet known

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

whether they represent preexisting or acquired vascular communications.

Traditional acquired shunts may occur between any branch of the portal and systemic vasculature, but they are typically small and tortuous and cluster around the cranial and caudal aspects of the kidneys, especially the left kidney. Communications with the remnant ovarian veins may occur in spayed females; these single vessels may become particularly large and noticeable, especially in cats.

In PVH-MVD , shunts are considered to be microscopic, occurring between the hepatic portal and hepatic venous systems, thereby bypassing the sinusoids.

Pathophysiology

Dogs and cats with portosystemic shunting usually have low functional hepatic mass. The liver either fails to grow normally as it is deprived of its normal blood supply, trophic factors (such as insulin and hepatic growth factor) and nutrients, or liver function is impaired as a result of a primary hepatopathy (in cases with acquired portosystemic shunts).

The major clinical signs associated with portosystemic shunting result from failure of the liver to metabolize substances being absorbed from the gastrointestinal tract, receive pancreatic hormones, and metabolize other circulating hormones. There is deranged nitrogen metabolism and the capacity of the liver to produce urea is diminished, leading to elevated levels of circulating ammonia and low blood urea nitrogen (BUN) levels. Serum bile acids, which normally undergo almost complete enterohepatic circulation, are also elevated in systemic samples. Abnormal filtering or metabolism of a variety of other substances absorbed into the portal venous blood (branched chain and aromatic amino acids, bacteria and bacterial toxins) is responsible for the cardinal clinical signs of portosystemic shunting (Table 66.1).

Neurologic perturbations caused by the liver dysfunction resulting from portosystemic shunting leading to neurologic abnormalities are termed hepatic encephalopathy (HE) (see description later).

It is becoming increasingly recognized that infection and inflammation also play a role in development of encephalopathy in laboratory animals and humans. Circulating blood levels of C-reactive protein (a marker of inflammation) have relatively recently been shown to be elevated in dogs with HE, suggesting that this is also likely to be an important mechanism in dogs. HE may be complicated by hypoglycemia in patients that are inappetent or being fasted, as a result of low hepatic glycogen reserves in the hypoplastic or damaged liver.

Circulating levels of these substances will fluctuate according to whether the animal has eaten, the diet, and other factors affecting gastrointestinal transit time, bacterial flora or the production of ammonia within the gut. Gastrointestinal hemorrhage is a known risk factor for development of HE, and can be a particular problem in patients with end-stage liver disease and portal hypertension, or dogs with CPSS that develop gastrointestinal ulceration (see later).

Deranged nitrogen metabolism causes a tendency for urinary ammonium biurate crystalluria and calculus formation, which may lead to irritation of the renal pelvis with hematuria, ureteral obstruction or (more commonly) urethral obstruction.

Polyuria and polydipsia are common in patients with portosystemic shunts. The mechanism is not completely understood but is probably multifactorial. Contributing factors include low plasma BUN and poor renal concentrating ability, and increased thirst resulting from systemic inflammation and fever.

Abnormal blood flow within the hepatic sinusoids results in impairment of delivery of vital substances to

Table 66.1 Clinical and diagnostic features of different conditions causing biochemical evidence of hepatopathy

	Age	HE	Ascites	Jaundice	Diarrhea	Elevated shunt fraction
CPS	Younger	Yes	Rare*	No	Rare	Yes
PVH-MVD	Any age	No	No	No	No	No
Noncirrhotic PH	Young to middle-aged	Yes#	Yes	No	Yes	Yes#
Cirrhotic PH	Older	Yes#	Yes	Yes	Yes	Yes#

* Possible in patients with very low serum albumin.
# Once acquired shunts have developed.

the hepatocytes, eventually resulting in cell damage and death. Cell damage is followed by accumulation of lipid within the hepatocytes, cell death and phagocytosis by macrophages, which then coalesce to form lipogranulomas. Interstitial fibrosis eventually leading to cirrhosis has been observed in some patients with CPSS, but is far more likely to be seen in patients with acquired portosystemic shunts resulting from end-stage hepatopathy of another etiology.

Pathophysiology of Portal Hypertension

Portal hypertension (leading to acquired portosystemic shunts) is by definition an increase in portal venous pressure above the expected normal of 8–12 mmHg (note that patients with CPSS will usually have portal pressures comparable or slightly higher than central venous pressure (typically 4–8 mmHg). Portal hypertension occurs when the resistance to vascular flow within the hepatic portal vein or sinusoids increases, causing sequestration of blood within the viscera. Reduction in the arterial to venous pressure gradient across the capillary beds of the gut causes reduced blood flow and hence reduced oxygen delivery to tissues. Alteration of hydrostatic pressure, often accompanied by reduced plasma oncotic pressure resulting from the patient's underlying liver disease, allows fluid to leak from the capillaries into both the intestinal lumen and the peritoneal cavity, resulting in ascites and diarrhea. In acute, severe portal hypertension, frank blood may leak into the lumen of the bowel, resulting in hematemesis and hematochezia. Edema and swelling of the intraabdominal organs causes stretching of the capsules and peritoneum, and hence this condition can be quite painful.

Reduction in blood flow through the hepatic sinusoids results in lower venous return to the right atrium, with a resultant fall in cardiac output and the compensatory changes of tachycardia and reduced stroke volume. Hypovolemic shock will eventuate if the compensatory mechanisms are not sufficient to assure adequate tissue oxygen delivery, or if ongoing fluid losses into the bowel and peritoneal cavity cannot be replaced.

In patients that are able to compensate for mild to moderate portal hypertension, small veno-venous communications open within a few days. These take the path of least resistance from the portal circulation into a nearby branch of the systemic venous system, and therefore tend to occur where the vascular systems are in closest proximity to one another (root of the mesentery, esophageal hiatus, perianal region). These vessels are thin-walled and tortuous and usually cluster in plexi.

Although congestive heart failure or caudal vena caval obstruction causes hepatic venous distension, this does not result in acquired portosystemic shunting because the hydrostatic pressure is increased within the caudal vena cava as well as the hepatic sinusoids and there is hence no hydrostatic drive for the portosystemic shunts to occur.

Ascites resulting from increased hydrostatic pressure within the caudal vena cava (caval tumors, right-sided congestive heart failure) tends to be a modified transudate due to leakage of protein-rich hepatic lymph, whereas ascites resulting from mild to moderate portal hypertension tends to be a transudate. Ascites occurring in fulminant portal hypertension may also be sanguinous if the capillaries or splenic capsule rupture. Portal hypertension is likely to result in splenomegaly, with a normal to small-sized liver, unless the obstruction occurs at the level of the hepatic venules or hepatic veins (Budd–Chiari syndrome).

Epidemiology

Signalment

Acquired shunts may be seen in any species or breed of patient in which diseases causing hepatic fibrosis or cirrhosis occur. A good example of such a disease in dogs is chronic hepatitis. A subset of patients with acquired shunts resulting from portal hypertension caused by congenital PVH-MVD will present before the age of 3 years and may be indistinguishable from patients with CPSS (see further discussion in Diagnosis section).

Congenital shunts are seen most commonly in purebreed dogs, or cross-bred dogs with parents of breeds that are overrepresented amongst the shunt population. Many breeds have been reported as predisposed around the world, the most notable being a number of terriers (Yorkshire, cairn, Maltese, Jack Russell), Chihuahuas, miniature schnauzers, pugs, toy poodles, Australian cattle dogs, Labrador and golden retrievers, and Irish wolfhounds.

In general, extrahepatic shunts are more common in terriers and other small-breed dogs, whereas intrahepatic shunts are more common in medium- to large-breed dogs. However, exceptions occur (e.g., toy and miniature poodles) and some form of shunt imaging is recommended prior to surgical exploration. Patients from breeds that are not known to be predisposed to CPSS are more likely to "break the rules" and should be evaluated especially carefully.

PVH-MVD tends to occur in similar breeds to those affected with CPSS, and has been best characterized in the terrier-type breeds such as Maltese, Yorkshire and cairn terriers.

History and Clinical Signs

Patients with portal vascular abnormalities may be clinically asymptomatic (abnormality detected after routine wellness screening, or preanesthetic blood testing), display vague and self-limiting clinical signs, or present with severe neurologic abnormalities associated with HE.

Common clinical signs include a picky appetite or pica, failure to thrive, hypersialism (most evident in cats), sporadic vomiting, polyuria and polydipsia, urinary irritation and obstruction caused by ammonium biurate calculi, episodes of abnormal mentation accompanied by ataxia, and amauratic (apparent) blindness. Cats with CPSS may have copper-colored irises, although this is not always the case, and it is not pathognomonic .

Dogs with CPSS sometimes present with a history of generalized motor seizures, although in a subset of cases the seizures are caused by a co-morbidity such as idiopathic epilepsy or granulomatous meningoencephalitis (more recently referred to as meningoencephalitis of unknown etiology), rather than the shunt itself (see Prognosis section). Behavior changes including aggression may occasionally prompt presentation. Dogs with CPSS may have other intermittent problems that seem to result from systemic debility, such as coughing, ocular discharge, and urinary tract infection.

Ascites is very uncommonly seen in dogs with CPSS unless they have been on a restricted protein diet for an extended period of time. Ascites is more common in cases of portal hypertension accompanying end-stage liver disease or portal venous hypertension/dysplasia.

Diagnosis

There are a number of diagnostic methods, including demonstration of liver dysfunction, confirmation of portosystemic shunting, imaging of the shunt, and histologic evaluation of the liver.

Clinical Pathology

Biochemical abnormalities typically include low to low-normal BUN, cholesterol, albumin, glucose and protein C, andelevatedliverenzymes(alanineaminotransferase[ALT], alkaline phosphatase[ALP]). Serum bile acid activity is measured before (resting) and after eating (post prandial), to gauge the degree to which bile acids leak into the systemic circulation from the portal vein, rather than being extracted by enterohepatic circulation. Serum bile acid activity should be elevated in animals with portosystemic shunts, and the post prandial sample is more frequently abnormal than the resting sample. Plasma ammonia levels can also be measured before and after administration of an ammonium chloride solution per rectum (ammonia tolerance test). Ammonia is labile in serum, and the ammonia tolerance test is somewhat more invasive and can be very dangerous, and thus serum bile acids are preferred over ammonia as a clinical screening test. Hematologic abnormalities include anemia with microcytosis and often a mature neutrophilia.

Confirmation of Portosystemic Shunting

This is most easily done using nuclear scintigraphy; imaging the patient following rectal or transsplenic administration of technetium pertechnetate. Contrast portography, following injection of radiographic contrast agent through a catheter placed in the jejunal vein or percutaneously by means of splenic injection (splenoportography), provides another mechanism for confirmation that portal blood is passing directly into the caudal vena cava and bypassing the liver. Contrast portography also provides a mechanism for determining the anatomy of the portosystemic shunt, if a good-quality study is achieved. Chapter 61 provides further details on the methods to image the animal with a portosystemic shunt.

Imaging of the Portal Vasculature

Abdominal sonography is the least expensive and invasive modality, but confidently finding a portosystemic shunt can be difficult in very small dogs, dogs with intestinal gas or ingesta, or with shunts that are in unusual locations. Even in the hands of an experienced sonographer, shunts may not be located in up to 25% of patients. Even when the vessel is not identified, circumstantial evidence for CPSS may include turbulence within the prehepatic caudal vena cava, renomegaly, microhepatica, and urinary calculi.

Three-dimensional imaging using computed tomography (CT) or magnetic resonance imaging (MRI) is becoming the “gold standard” of diagnosis. Dual-phase CT angiography (DPCTA) allows confirmation of portosystemic shunting, clarification of the exact shunt anatomy, identification of other congenital abnormalities, calculation of liver volume, assessment of hepatic perfusion in both the arterial and venous phase, and identification of urinary calculi. DPCTA is essential for planning transvenous coil embolization.

Differentiating CPS from PVH-MVD

Dogs with these two conditions may present in exactly the same way, although dogs with PVH-MVD are less likely to demonstrate overt signs of HE. Confirmation by nuclear scintigraphy, or advanced imaging, that there is no macroscopic shunt, and identification of the histologic

features on liver biopsy in the absence of another hepatopathy that could explain the biochemical perturbations are required for definitive diagnosis of PVH-MVD.

Therapy

Medical Therapy

Medical therapy is aimed at ameliorating the signs of HE by reducing the amount of ammonia (and other substances) produced in the gut, and the degree to which they are absorbed. Medical management is often employed in those animals that show few clinical signs on presentations, are older, in which financial or owner-lead reasons limit surgery, or which have a shunt that is not amenable to ligation. The main aims of therapy are to decrease the formation of gut derived encephalotoxins, especially ammonia. Therefore the mainstays of current therapy are a combination of dietary alterations, oral antibiotics to suppress bacterial populations that produce encephalopathic toxins and local acting agents to reduce gastrointestinal uptake of ammonia (e.g. lactulose). Controlled trials have not been performed in animals to determine the optimal treatment for HE and so current recommendations are based on anecdotal evidence.

Feeding a high-quality digestible diet is the mainstay of management of the stable patient. Protein restriction is controversial, and generally not recommended, as some authorities report that dogs with CPSS actually have normal to increased requirements. If protein restriction is required, a commercial restricted protein diet is the easiest to prescribe. For clients who wish to formulate their own diet, protein sources should be easily digestible and metabolizable. Vegetable and dairy proteins tend to be better tolerated than meat-based ones, with cottage cheese being a palatable option for many patients. Cats have more stringent dietary requirements than dogs, and this should be taken into account when choosing a diet. Patients with reduced hepatic mass will have poor glycogen reserves and a tendency toward hypoglycemia, so meals should be given frequently.

Lactulose is prescribed for symptomatic patients, with the goal of reducing intestinal pH and thereby trapping ammonia within the gut, and by virtue of its action as an osmotic cathartic, hastening intestinal transit time and reducing the time available for absorption of ammonia. In patients that are actively encephalopathic and unable to tolerate oral medication, lactulose may be administered rectally.

Antibiotics may also be prescribed, with a view to reducing the intestinal bacterial population and thus reducing ammonia production. Further details about medical management of the patient with liver disease can be found in Chapter 65.

There is evidence that patients with liver disease are at increased risk for gastrointestinal ulceration, and anecdotal reports of this being a particular problem in dogs with intrahepatic shunts. Therefore, many clinicians include some type of antacid medication (H2 receptor antagonist or protein pump inhibitor such as famotidine or omeprazole) as part of the standard medical management protocol. Finally, emerging evidence also suggests that inflammatory cytokines are synergistic with ammonia in precipitating HE and that controlling inflammation in other organs is an important part of managing the patient with HE.

Surgical Therapy

Surgical therapy is indicated for patients with CPSS, or hepatic arteriovenous fistulae, where the primary problem can be resolved. Patients with acquired shunts secondary to end-stage liver disease or PVH are unlikely to benefit from surgical attenuation of their shunts as the shunts are providing a mechanism for decompressing the portal system and reducing portal hypertension. Dogs with PVH-MVD, and those with portal vein aplasia, are also not candidates for surgical intervention. However, the results of liver biopsy may inform medical management in patients with acquired liver disease, and this often provides justification for surgical exploration.

Surgical therapy for CPSS is aimed at identifying the shunt and attenuating it. As most patients have poorly developed hepatic portal circulation and relatively high portal vascular resistance, total immediate occlusion of the shunt is highly likely to result in life-threatening portal hypertension. Therefore, surgical methods aim either to provide partial occlusion (which may be increased in stages by subsequent procedures) or application of a device to promote slow occlusion. The goal of slow or staged occlusion is to allow the intrahepatic portal circulation time to regenerate, with reduction in vascular resistance, at the same time as the shunt is being slowly or incrementally occluded.

The main techniques used for slow occlusion of extrahepatic shunts are cellophane bands and ameroid constrictors. Cellophane bands promote occlusion by stimulating a foreign body reaction and fibrosis between the band and the shunt wall. Ameroid constrictors produce some mechanical occlusion as the ameroid clay takes up fluid, but also cause local inflammation with fibrosis and thrombosis of the shunt vessel. More recent reports have described the use of a variety of other clear films for shunt occlusion in dogs and cats, including polypropylene and polyethylene. These seem to be as effective as cellophane, probably due to the chemicals incorporated during the manufacturing process.

Intrahepatic shunts were historically addressed by surgical attenuation using either extravascular dissection or a transvenous approach under partial venous inflow occlusion. In recent years, minimally invasive procedures have become more common, with an expanding body of international experience in interventional techniques such as percutaneous thrombogenic coil embolization (PTCE). This technique results in much less morbidity. The downsides are the need for advanced equipment (including fluoroscopy) and expertise, and the likelihood that repeated procedures will be required for complete shunt occlusion (see Prognosis section).

Surgical Attenuation

Surgical exploration is performed through a ventral midline celiotomy, which may be extended cranially by transdiaphragmatic incision or median sternotomy. Combination of a paracostal incision with a ventral midline celiotomy is also an effective way of exposing the craniodorsal abdomen, but is rarely required for shunt surgery. A standard exploration should be performed to evaluate the portal vasculature and identify the portosystemic shunt. If present, acquired shunts will usually be visible around the cranial aspect of the left kidney.

Perioperative Monitoring and Treatment

Serum glucose concentration should be monitored regularly due to the tendency for hypoglycemia. Albumin levels may drop markedly when intravenous crystalloid is administered at surgical rates, and plasma transfusion is sometimes required. However, serum albumin increases relatively little following plasma transfusion, and therefore human albumin solutions are an alternatively way to increase serum albumin. Hemodynamic parameters should be measured regularly during and following surgery to gauge trends and allow early detection of developing portal hypertension. Patients can be severely polyuric prior to surgery and may require increased fluid rates to avoid dehydration postoperatively. Potassium supplementation may be required.

Complications of Surgery

A large range of complications have been reported following surgery for CPSS. Anesthetic-related complications include hypotension (mainly in cats), hypothermia due to small body size and poor body condition, and hypoglycemia for reasons previously described. Intraoperative hemorrhage is not usually a major issue unless tearing of the vessels occurs during dissection. This is more likely during treatment of intrahepatic shunts, but unlikely if careful technique is used when dissecting extrahepatic vessels. Although some perturbations in coagulation parameters have been reported in dogs with CPSS, most patients do not experience clinically significant problems with coagulation. This is much more likely to be a problem in patients with end-stage liver disease.

The major life-threatening complications that occur perioperatively are portal hypertension and postligation neurologic dysfunction. The incidence of portal hypertension has been greatly reduced by adoption of the slow occlusion techniques, and publication of guidelines for safe shunt attenuation. Mild to moderate portal hypertension may not cause life-threatening problems; affected patients may have inappetence or diarrhea for a short period of time, or develop ascites. Assuming they are able to compensate hemodynamically for the reduced central venous return, and the bowel does not become critically hypoxic, they will eventually develop acquired shunts and a consequent return of portal pressure towards normal. Early published reports suggested that up to 20% of patients can be expected to develop acquired shunts but more recent studies, in which patients underwent postoperative evaluation using DPCTA, showed that the incidence is probably less than 10%, with an additional 10% of patients experiencing ongoing shunting as a result of misplacement or failure of the attenuating device to promote complete occlusion.

Postoperative neurologic sequelae range from blindness or muscle twitching, through disorientation, to generalized motor seizures and status epilepticus. Hypoglycemia and HE may also produce signs that can be difficult to distinguish from true postligation neurologic dysfunction . In addition, patients experiencing seizures preoperatively may continue to have seizures postoperatively if the seizures were caused by something other than their CPS.

Hypoglycemia, HE, and the seizures of idiopathic epilepsy should be manageable by evaluating the patient and relevant bloodwork, and treating accordingly. Postligation neurologic dysfunction seizures and status epilepticus constitute a much more serious problem with a guarded prognosis. The cause of these seizures is still not well understood, but may include factors such as imbalance of neurotransmitters, cerebral edema, and derangements in cerebral blood flow. Historically, seizures were considered to occur acutely, with patients found when they were already in status epilepticus. Closer observation of patients following surgery has shown that in many cases, the condition is progressive. Patients start behaving abnormally, vocalizing and showing signs of disorientation and inappropriate mentation. They do not interact appropriately when being handled. They are ataxic and often display compulsive movements. Left untreated, they will develop facial twitches that progress to generalized motor seizures and status epilepticus. Several studies have shown an incidence of seizures in up to 5% of dogs following surgery for CPSS.

Anecdotal experiences suggest that older dogs and pugs may be at greater risk for seizures, but this has not been definitively proven. Cats seem at greater risk for neurologic sequelae, including blindness and twitching, in addition to seizures. Preoperative treatment with phenobarbitol and levetiracetam (Keppra®) has been shown to significantly reduce the incidence of seizures, although published reports and anecdotal experience suggest that the risk is not completely abolished.

Therapeutic Decision Making

In light of the fact that many patients have mild clinical signs, and surgical shunt attenuation has a significant morbidity/mortality rate, owners are sometimes faced with a difficult choice between long-term medical management and surgical correction. Some dogs live apparently normal lives with no management at all, whereas others develop severe clinical signs within the first few months of life. On risk–benefit analysis, a young puppy with obvious HE is more clearly a candidate for surgery than an 8-year-old dog in which CPSS is detected on a routine wellness check. An exception would be the older male dog in which CPSS is diagnosed following urethral obstruction with ammonium urate calculi. Medical management in these patients may not control stone formation, and as urethral obstruction is, in itself, potentially life-threatening, many owners will opt for surgical correction of the CPSS. Likewise, patients with severe polyuria/polydipsia may be generally happy but present unacceptable management issues, making surgery an attractive option.

Many dogs with severe clinical signs will become near-normal on medical management, prompting the owners to question the necessity for surgery. The choice then is between lifelong dietary management and other therapies, weighed against a high probability for return of liver function to normal following CPSS attenuation.

Ongoing Evaluation

There are two main factors that should be considered when determining a patient's progress, either with medical or surgical management: liver function and the presence and degree of portosystemic shunting.

Biochemical Evaluation

Liver function is usually monitored indirectly by measuring blood levels of the products of hepatic metabolism including albumin, cholesterol and BUN . Return of cholesterol and BUN to reference levels is a good indicator that liver function is returning to normal. Serum bile acid levels are a sensitive indicator of macroscopic or microscopic portosystemic shunting. Postoperatively, patients may have normal serum biochemistry and a normal technetium scan in the face of continuing mild elevations in serum bile acids. The significance of these mild elevations to long-term prognosis is not yet known. Protein C has been proposed as a useful monitoring tool but the assay is not offered widely, and results from different laboratories may differ, making interpretation of single results difficult.

Nuclear Scintigraphy

Per rectal scintigraphy provides an estimate of shunt fraction and is helpful in determining the degree of shunt closure following surgery. It does have some interobserver variation, and we reported some dogs with normal technetium scans following surgery that had persistent shunting through small tributary vessels. Therefore, the results of scintigraphy should be interpreted in the context of other measures such as serum biochemistry and imaging. Percutaneous transsplenic scintigraphy is more accurate and may provide information about shunt anatomy in the hands of an experienced operator, but is more invasive and not yet performed routinely.

Abdominal Sonography

Assuming that the shunt was sonographically visible before surgery, postoperative sonography is a mechanism for confirming closure of the shunt, increase in liver volume, and decrease in kidney size. It is also useful for identifying or monitoring development of urinary calculi.

Computed Tomography

Dual-phase CT angiography is emerging as the most reliable way to evaluate patients postoperatively, allowing calculation of liver volume and perfusion, and evaluation of shunt anatomy, presence of persistent shunting through the original shunt or acquired vessels.

Interpretation of Surgical Outcomes

Historically, patients have undergone minimal objective follow-up after surgical attenuation, making interpretation of published outcomes difficult. Patients with persistently abnormal blood values may have persistent shunting, acquired shunts, PVH-MVD, or some other hepatopathy. Persistently abnormal technetium scans are now recognized to occur in a variety of scenarios, including failure of the occlusion device to promote complete occlusion, malpositioning of the occlusion device, and development of acquired shunting. Clearly, neither of these techniques is able to identify the etiology for the abnormal result, and thus inform the most appropriate management plan.

Imaging using sonography may be helpful if the abnormal vessel(s) are visible. The ideal strategy for evaluation would include serial serum biochemistry including

serum bile acids and protein C, nuclear scintigraphy, and DPCTA. This battery of tests should be used as the gold standard for future research studies attempting to evaluate surgical outcomes, but is not realistic for clinical patients, many of whom have shown resolution of their clinical signs and for whom the risk of anesthesia and contrast imaging is not warranted. Advanced imaging should, however, be considered for patients displaying persistent biochemical or scintigraphic abnormalities six months following surgery.

Prognosis

While medical management can be successful for a prolonged period in many patients, the published literature suggests that outcomes following surgery are better, as long as the surgery is performed before severe secondary changes in liver function occur. A more recent study has shown that those undergoing surgical ligation of the shunting vessel have a longer median survival time, and a lower frequency of ongoing clinical signs. The mortality rate following correction of CPSS (including PTCE) is less than 5%. Up to 80% of patients receiving slow occlusion devices for extrahepatic CPS can be expected to regain normal liver function, with a median survival of 152 months. The mortality and morbidity rates are higher for surgical correction of intrahepatic shunts, and for cats with CPSS of any anatomic type, and the chance of return to liver function is lower than for dogs with extrahepatic CPSS.

The prognosis for patients undergoing PTCE has not yet been established definitively. However, early reports suggest that the mortality and morbidity rates are low, and patients are highly likely to show substantial clinical improvement, although complete closure of the shunt is unlikely.

Regardless of the technique used, the clinical impact of residual flow through the original shunt has yet to be determined. Intuitively, a reduction in shunt fraction should improve hepatic function, but the actual shunt fraction at which a patient might resume a normal diet and not show clinical signs is not known.

Approximately 10% of patients will never return to normal liver function even following complete shunt occlusion and will likely require lifetime medical management, although interestingly, they are often less severely affected clinically once acquired shunts have developed than they were with a single shunt.

Diseases of the Gallbladder and Extrahepatic Biliary Ducts

Ben Harris, MA, VetMB, CertSAM, MRCVS

Northwest Veterinary Specialists, Sutton Weaver, Cheshire, UK

The gallbladder is a bladder-like organ possessing a thin, mucosa-lined wall with a muscular layer and an outer serosal layer. Its function is to store, modify, and secrete bile, which is synthesized in the hepatocytes and reaches the gallbladder via bile canaliculi, lobar bile ducts, and eventually the cystic bile duct. During its time stored in the gallbladder, bile becomes concentrated (up to 10 times) and mildly acidified. Gallbladder contraction propels bile into the common bile duct (CBD) and then via the sphincter of Oddi into the proximal duodenum at the major duodenal papilla. Gallbladder contraction is stimulated by cholecystokinin, gastrin, and motilin, which in turn are released in response to fatty acids, peptides, and amino acids in the stomach and duodenum.

In cats, the CBD joins the pancreatic duct, sharing a common opening into the duodenum at the duodenal papilla. In dogs, the pancreatic and CBD meet only at the papilla; in many dogs, an additional separate pancreatic duct enters the duodenum more distal to the papilla.

Etiology/Pathophysiology

Disorders of the canine and feline biliary tract are more frequently acquired than congenital, although congenital biliary cysts, malformations, and biliary atresia have been reported. The flow of bile from the gallbladder to the duodenal papilla, as well as the chemical character of bile and the mucosal immunity (secretory IgA and mucosal mononuclear cells), serves to reduce the risk of biliary bacterial infection. *In vivo* studies and molecular techniques have detected transitory bacteria in bile of normal dogs. Interruption or obstruction to flow may allow these transitory bacteria to colonize the tract, causing bacterial cholangitis.

Trematode infections (*Platynosomum fastosum* and other *Platynosomum* spp.) of the biliary tract are found occasionally in cats in the southern USA, in South America and Asia, with clinical disease ranging from asymptomatic to severe obstructive cholangitis or subsequent neoplastic transformation to cholangiocarcinoma.

Mucosal resistance to the extreme chemical nature of bile is afforded by secretion of mucin from mucous glands within the biliary tract. Hypersecretion, possibly as a result of inflammatory stimuli or transporter defects (ABCB4 phosphatidylcholine translocator mutation in Shetland sheepdogs), may result in accumulation of mucin within the gallbladder in dogs, leading to the formation of a biliary mucocele (Figure 67.1). Untreated biliary mucoceles may rupture, as the gallbladder wall becomes necrotic under pressure from the accumulating concretion of mucus. Bile is a highly irritating substance, so leakage into the abdomen results in a chemical peritonitis ("bile peritonitis"). Cholecystocentesis is contraindicated in biliary mucocele patients because of the risk of gallbladder rupture.

Biliary obstruction may be either intrinsic to the biliary tract or outside it. Blockage of biliary flow results in posthepatic jaundice. One of the more common causes of biliary obstruction is acute pancreatitis. This occurs due to the intimate association of the body of the pancreas with the CBD near the duodenal papilla – the point of entry of the CBD into the small intestine. Pancreatic carcinoma or biliary carcinoma similarly may result in complete bile duct obstruction. Inflammation or neoplastic infiltration of and around the duodenal papilla (e.g., duodenal lymphoma, carcinoma) is an occasional cause of jaundice.

Choleliths are uncommon in cats and dogs but may cause bile duct obstruction or rupture. Most canine and feline choleliths contain some bile pigments, rather than being pure cholesterol liths such as those commonly found in humans. A predisposition to cholelithiasis may occur due to gallbladder motility disorders, endocrine disease, cholestasis, cholangitis or supersaturation of the components of bile (cholesterol, pigments).

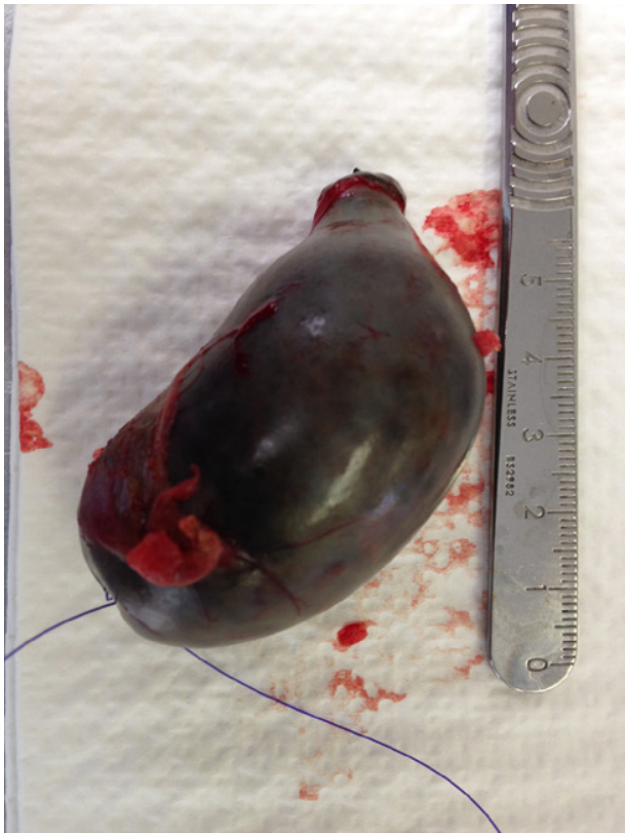

Figure 67.1 A distended gallbladder removed from a dog with a mucocele.

Primary biliary neoplasia ranges from benign choledochal cysts and biliary cystadenoma to biliary carcinoma, which may originate in the intrahepatic or extrahepatic biliary system. Biliary neoplasia occurs more commonly in cats. The gallbladder is susceptible to infarction if the cystic artery – the sole arterial blood supply to the organ – is compromised by trauma or thrombosis.

Bacterial cholangitis may occur due to ascending bacterial infection from the gastrointestinal tract, hematogenous spread or colonization by the aforementioned transitory bacteria.

Epidemiology

Arguably, the most common disorders predisposing to biliary tract disease are endocrine diseases such as hyperadrenocorticism, diabetes mellitus, and hypothyroidism. Of these, hyperadrenocorticism increases risk of gallbladder mucocele by up to 29 times; the association with hypothyroidism and diabetes mellitus is less concrete.

Inflammatory bowel disease (IBD) is a common comorbidity with cats with cholangitis, just as there is a strong association of IBD with primary sclerosing cholangitis in humans. Although such a strong association is not reported in dogs, inflammation around the duodenal papilla can alter bile flow and may encourage bacterial colonization of the biliary tract. Likewise, intestinal motility disorders or small intestinal bacterial overgrowth may augment infection risk by increasing numbers of potentially pathogenic bacteria that may ascend the biliary tract.

Biliary flukes are not prevalent in Europe, but are more commonly found in the southern USA, South America, and Asia. Infection requires ingestion of a secondary intermediate host such as a frog or lizard.

Signalment

Particular species and breed associations are found for certain biliary disorders. Neoplasia occurs more commonly in middle-aged to older cats and dogs, but benign and cystic disorders may be acquired even in individuals less than 2 years of age. Biliary flukes are reported in cats but are far less common in dogs. Mucocele formation is more common in Shetland sheepdogs, border terriers, miniature schnauzers and cocker spaniels and become increasingly common in dogs beyond middle age. Mutation of a phosphatidylcholine translocator (ABCB4) has been identified in affected Shetland sheepdogs. Choleliths are more commonly found in miniature schnauzers and miniature poodles, particularly in older females.

Pancreatic neoplasia does not have a strong breed predisposition, but pancreatitis is more commonly associated with cocker spaniels and miniature schnauzers. Of note is the often marked inflammatory swelling of the pancreas in cocker spaniels with pancreatitis, which may be erroneously described as a pancreatic tumor based on diagnostic imaging findings. Those breeds with predispositions towards endocrine disease (e.g., hypothyroidism, hyperadrenocorticism) may be more commonly affected by bile stasis, cholangitis, and biliary mucocele.

History and Clinical Signs

Nonobstructive biliary tract disease may be insidious in onset, with vague clinical signs such as lethargy, pyrexia, anorexia, and vomiting. Pyrexia is more likely to be present with florid inflammation, bile peritonitis or bacterial biliary infection but can also be seen with cholelithiasis, presumably due to secondary bacterial infection. Clinical signs may be mild and therefore present for weeks or months before veterinary attention is sought.

Vomiting may be a clinical sign associated with biliary disease itself or caused by an underlying associated problem such as pancreatitis. A history of dietary indiscretion or ingestion of fatty foods may be relevant in cases of acute pancreatitis. Abdominal pain may result from the obstruction or distension of the bile ducts or gallbladder or from inflammation of the biliary tract and surrounding area (e.g., local peritonitis). Patients with biliary mucocele may also exhibit abdominal pain and, if significantly obstructive, may become jaundiced. Jaundice (icterus) becomes clinically evident as yellow discoloration of the mucus membranes, skin, and sclera when the serum bilirubin exceeds around 2 mg/dL. The exact concentration at which icterus becomes clinically visible will depend upon the patient's own pigmentation and hemoglobin concentration (mucous membrane pallor makes icterus more evident). Total biliary obstruction prevents pigmentation of the feces, resulting in pale "acholic" feces.

Diagnosis

Clinical Examination

It should be apparent from clinical examination if the patient is jaundiced, but jaundice is only clinically evident when serum bilirubin levels exceed 2 mg/dL. As previously mentioned, how evident hyperbilirubinemia is will depend upon multiple factors. Examination of the sclera or internal aspect of the pinna (the latter particularly in cats) may display more obvious evidence of icterus.

Cranial abdominal pain may manifest as a hunched posture, "prayer posture" or via the patient's response to palpation. Once again, how evident this subjective finding is will depend upon patient factors and also concurrent problems such as pancreatitis. Pancreatic pain usually localizes to the right cranial abdominal quadrant, but may be more diffuse. In some patients, pancreatic pain does not manifest until pressure is placed directly upon the pancreas during ultrasonography. A very distended gallbladder might be palpable beyond the hepatic margin in some patients, but this is unusual. If rupture of the biliary tract has occurred then an abdominal effusion may be present, potentially resulting in a fluid wave on ballottement. Often, however, patients with bile peritonitis have tensed abdominal muscles, because of the associated pain, which limits clinical examination.

Blood Chemistry

Following centrifugation, the plasma or serum of a jaundiced patient's blood will appear deep yellow (icteric). This interferes with some colorimetric blood biochemistry tests.

Blood biochemistry in biliary tract disease varies depending upon the degree of biliary obstruction as well as the accompanying hepatic and pancreatic disease.

In an icteric patient, total bilirubin will be increased. If the patient has significant cholestasis, then bile acids will also be increased. If total bilirubin is increased then nothing additional may be inferred from measurement of bile acids or performing a bile acid stimulation test – the patient has either significant hepatic functional compromise or bile duct obstruction.

Increases of the concentration of biliary canalicular enzymes in the blood are expected (alkaline phosphatase [ALP], gamma-glutamyl transferase [GGT]) with cholestasis or biliary tract inflammation. Bile acids are toxic to hepatocytes, so it is extremely common for animals with bile stasis to have elevation in hepatocellular enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST]). Patients with concurrent hepatic parenchymal disease may also have increased hepatocellular enzymes. If hepatic disease is advanced enough to impair hepatic function, then urea and albumin may be reduced due to poor hepatic synthesis and conversion. Similarly, coagulation factors may be depleted due to reduced recycling of the vitamin K-dependent factors (II, VII, IX, X), resulting in prolonged coagulation times (prothrombin time, activated partial thromboplastin time).

The inflammatory response may cause increased synthesis of globulins. Pancreatitis may be reflected by elevations of amylase and lipase, due to leakage from the pancreas, but these enzymes have poor specificity and may be spuriously elevated in hemoconcentrated patients and patients with other diseases. Amylase and lipase are even less sensitive and specific in cats than in dogs. Pancreatic species-specific lipase is a more sensitive and specific test, but it must be remembered that a positive result does not necessarily indicate that pancreatitis is the primary problem as gastrointestinal disease, peritonitis, or pancreatic neoplasia can also result in increased pancreatic specific lipase. Additonally, a normal value does not exclude pancreatitis as a possible differential diagnosis.

Hematology

The complete blood count can reflect the inflammatory disease by revealing increased numbers of neutrophils which, in marked inflammation or infection, may exhibit a left shift or toxic changes.

Urinalysis

Icteric patients are, by definition, hyperbilirubinemic, which results in bilirubinuria, imparting a deep yellow color to the urine. On microscopic examination of urine sediment, bilirubin crystals may be evident.

Diagnostic Imaging

Radiography

Radiography may give an overall impression of the size of the liver but usually does not give information regarding structure. It may identify the presence of radiodense choleliths within the biliary tree or gallbladder. Rarely, the gallbladder may be visible as a "porcelain gallbladder" with a fine mineral opacity delineating the gallbladder wall. This may be caused by dystrophic mineralization due to neoplasia of the gallbladder. If peritonitis has developed subsequent to biliary rupture, then effusion will cause loss of radiologic contrast in the cranial abdomen or a "ground glass" appearance.

Ultrasonography

Transcutaneous abdominal ultrasonography is the mainstay of imaging of the biliary tract. It affords assessment of the bile ducts within and outside the liver, ensuring that the ducts are patent and not distended. The gallbladder may be examined and measured, noting any material within the lumen as well as the wall thickness. The common bile duct should be followed from the gallbladder to the point of entry into the duodenum at the major duodenal papilla. Intestinal gas may impede this examination. The normal common duct may measure 3 mm diameter in dogs or up to 4 mm diameter in cats.

Choleliths appear as hyperechoic structures with distal acoustic shadowing. If a cholelith is causing complete obstruction then the bile duct may appear dilated proximally. Choleliths do not commonly cause obstruction, but may be associated with nonobstructive bile duct dilation. In humans and most likely in dogs, such nonobstructive dilation may be associated with bacterial infection of the bile duct. In this circumstance, it is difficult to determine whether the cholelithiasis is the cause or the consequence of cholangitis.

Complete bile duct obstruction does not necessarily result in gallbladder distension but often causes dilation of the major bile ducts, sometimes giving a very tortuous appearance on ultrasonography.

Echogenic sediment or "sludge" is a normal finding in many dogs and cats but should be dependent (i.e., affected by gravity) and not obscuring the lumen. "Sludge balls" are echogenic, roughly spherical accumulations of bile and mucus that move depending upon patient position. They may pose a risk for bile duct obstruction.

Gallbladder mucoceles classically have a hyperechoic stellate appearance on ultrasound, with strands of the echogenic material extending to the gallbladder wall. Early or incipient mucoceles may have a more subtle appearance, but the main feature is of immobile nondependent sludging occupying the majority of the gallbladder.

Advanced Imaging

Computed tomography and magnetic resonance imaging may yield more detailed information about the extrahepatic biliary ducts and gallbladder. They can be useful for detecting neoplasia, characterizing anatomic anomalies and detecting choleliths. The main advantage of advanced imaging above abdominal ultrasound is that regions of the abdomen are usually not missed on advanced imaging, though methodical radiologic review is essential and time-consuming. Whereas gastrointestinal gas may obscure the bile ducts by reflecting ultrasound, this is not a problem with advanced imaging. When assessing the abdomen for neoplasia on computed tomography, the thorax may also be scanned to assess for possible metastasis. Intravenous contrast may be used to assess the vascularity of a structure to assist in diagnosis. The requirement for sedation, anesthesia, and exposure to ionizing radiation must be considered.

Endoscopy

The duodenal papilla may be assessed during endoscopy, which affords the opportunity for gastrointestinal biopsies. Some small studies of endoscopic retrograde cholangiography and cholangiopancreatography in cats and dogs have documented that this procedure is feasible, but there is no tangible benefit over advanced imaging. Cholangiopancreatography has been used historically to induce pancreatitis for experimental purposes in dogs – this in itself casts doubt over its diagnostic utility and safety. Using a similar procedure employing a side-angled endoscope, it is feasible to cannulate and therefore stent the common bile duct in the case of functional obstruction (e.g., acute pancreatitis, pancreatic mass).

Cholecentesis

If inflammatory or bacterial cholangitis is suspected then bile sampling is indicated. This may be performed under ultrasound guidance or during a laparotomy or laparoscopy. While potential complications include bile leakage and subsequent peritonitis and vagal-induced arrhythmias, most samples taken in this way do not cause complications. The gallbladder should be emptied as much as possible during the procedure to reduce the pressure of the residual contents and the risk of leakage. Bile obtained should be examined cytologically and should also be submitted for gram staining and bacterial culture and sensitivity (the author prefers to submit two transport charcoal swabs of bile – one for aerobic and one for anaerobic culture conditions). Ideally, both aerobic and anaerobic culture should be performed. In a study of patients with hepatic inflammation, nearly one

quarter had positive bile culture whereas 6% had positive culture of liver tissue. In patients with confirmed cholecystitis, more than half had a positive bile culture.

Laparotomy and Laparoscopy

Direct examination of the extrahepatic biliary system and gallbladder affords an opportunity for biopsy, cytology, and potentially palliative and curative surgical intervention. Complete bile duct obstruction is an indication for surgical intervention. Bile ducts may be stented for short- or long-term management of obstruction, to allow resolution of the underlying disorder (e.g., acute pancreatitis causing complete extrahepatic bile duct obstruction).

Surgical exploration may be done via laparotomy or laparoscopy. Whichever technique is adopted, the opportunity should be taken for biopsy of the liver and pancreas, cholecentesis, and possibly intestinal biopsy. Surgery is required for assessment and potentially repair of the biliary tract in cases of bile peritonitis. Cholecystectomy is indicated in the case of gallbladder mucocele.

Cytology

Fine needle aspirates may be taken, under ultrasound guidance, from the liver, pancreas, and associated lymph nodes. Similarly, cholecentesis and abdominocentesis may be performed to investigate potential inflammatory or infectious processes. As previously mentioned, cholecentesis is contraindicated if biliary mucocele is suspected – diagnosis may be confirmed at surgery.

Therapy

Surgery

The patient should be stabilized first as biliary surgery is complex and may require prolonged general anesthesia. As detailed above, dogs with gallbladder mucoceles are treated surgically by way of cholecystectomy with or without biliary bypass (cholecystoduodenostomy, cholecystojejunostomy). Surgery is often required for animals with extrahepatic bile duct obstruction, especially if this is complete or persistent. Rupture of the biliary tract, resulting in bile peritonitis, is another indication for surgical intervention.

Antibiotics

Antibiotic choice for biliary infections should be ideally based upon results of culture and sensitivity. A 4–6-week course is advisable in the absence of a nidus for infection (e.g., cholelith). One large retrospective study of bile and liver culture in dogs and cats with hepatobiliary disease found that *Escherichia coli*, *Enterococcus* spp., *Bacteroides* spp., *Streptococcus* spp., and *Clostridium* spp. were the most common isolates. This study suggests that empirical antibiotic choice for hepatobiliary infection could include a fluoroquinolone for gram-negative cover alongside a penicillin or metronidazole for gram-positive and anaerobic organisms. It cannot be stressed enough, however, that responsible antibiotic usage demands culture and sensitivity testing, particularly before employing antibiotics such as fluoroquinolones. Repeating bile culture to monitor response to treatment should be considered, as significant antibiotic resistance can develop during the course of treatment.

Cholerectics

Sludging and stasis of bile promote biliary inflammation and infection. Additionally, hydrophobic bile acids are cytotoxic and damage cell membranes. Ursodeoxycholic acid (ursodiol, UDCA) is a hydrophilic bile acid, which exerts cytoprotective and antioxidant effects and induces choleresis (increased bile flow). The recommended dose is 10–15 mg/kg once daily. In addition to using this drug in cholangitis, it may have some efficacy in treating early mucoid bile accumulation (early gallbladder mucocele). Ursodeoxycholic acid is contraindicated in complete bile duct obstruction and is not an alternative to surgery for gallbladder mucocele.

Antioxidants

In addition to the antioxidant effects of ursodeoxycholic acid, other antioxidant drugs are commonly used in hepatobiliary disease. S-adenosyl-L-methionine (SAM-e) increases glutathione production in cat and dog livers, assisting conjugation and acting as an antioxidant. SAM-e has been shown to reduce hepatotoxicity following acetaminophen administration. Milk thistle-derived silymarin has strong antioxidant properties and has been shown to exert hepatoprotective effects when administered alongside some chemotherapy drugs. Those formulations which complex silymarin with phosphatidylcholine have much improved bioavailability. Vitamin E is a widely available antioxidant that also reduces transcription of proinflammatory cytokines.

Parasiticides

Praziquantel or fenbendazole may be used as flukicidal therapy.

Prognosis

Biliary neoplasia bears a grave prognosis as resection is rarely achieved and metastasis is common. Stenting of the bile duct may be of palliative use and can be performed at endoscopy, laparotomy or as a laparoscopy-assisted procedure. Bacterial cholecystitis and cholangitis bear a favorable prognosis if the infection is identified and treated. Gallbladder mucocele has an excellent prognosis following successful surgery, but the perioperative period carries risks such as bile peritonitis and inducing pancreatitis. Rupture of the biliary tract of any cause bears a guarded prognosis, particularly if bacterial infection is present. There is a broad spectrum of prognoses with pancreatitis with extrahepatic bile duct obstruction, depending upon the severity and complications. Acute pancreatitis carries a guarded prognosis, but may reach a successful outcome in a good proportion of cases with intensive management.

The Neurologic Examination

Alexander de Lahunta, DVM, PhD, DACVIM (Neurology), DACVP

College of Veterinary Medicine, Cornell University, Ithaca, NY, USA

Anatomic Diagnosis

What is the most important first step in evaluating a patient presented for a neurologic disorder? It is making the anatomic diagnosis based on the results of your neurologic examination. Did you ever think about who first made these correlations between the neurologic signs exhibited by a patient and the location of the lesions responsible for these clinical signs? Based on textbook publications that were available to me, you have to credit the keen observations of two veterinary pathologists for this: Jack McGrath at the University of Pennsylvania School of Veterinary Medicine and Anthony Palmer at the Cambridge University School of Veterinary Medicine. These two astute veterinarians both published a textbook in 1956 and 1965 respectively that recorded their observations of the location and character of nervous system lesions with the clinical observations supplied to them by the clinicians that examined the patient prior to its death. Thus began the concept of an anatomic diagnosis.

I was a veterinary student at the College of Veterinary Medicine at Cornell University from 1954 to 1958. The majority of my clinical neurology education took place in a course in Applied Anatomy in my third year of college. This course taught the clinical signs associated with cranial nerve abnormalities and the effects of specific nerve dysfunction on the gait of the animal. I joined the faculty of the Department of Anatomy at this college in 1963 and was given the responsibility of teaching the new course in neuroanatomy to first-year veterinary students in their second semester. As a rule, veterinary students have a need to understand the reason why they must study a subject. When a course in clinical neurology does not exist or is a brief exposure in the third year, most students will find it difficult to concentrate on neuroanatomy in their first year. If you agree with this, then you will understand that combining the teaching of neuroanatomy and clinical neurology in one course is the solution and the foundation for making an appropriate anatomic diagnosis. The first-year student is readily able to handle this. Now, in the 21st century, when the need for teaching time is so critical, it should be recognized that the most effective teaching of neuroanatomy and clinical neurology is as a vertically integrated course taught by a board-certified veterinary neurologist ideally in the first year of the curriculum. Most veterinary neuroanatomy courses are taught by nonveterinarians and as a result there is no correlation to clinical disorders.

As an example of how far we have come, consider this. Prior to the mid-1960s, there was no understanding of the pathogenesis of what was known as coonhound paralysis then and is now known as polyradiculoneuritis. There had been a few case studies published that suggested that these dogs became paralyzed following the trauma to their cervical spinal cord caused by their continual jumping up on the trees where they had followed a raccoon. Now, you should recognize the fallacy of this observation because you understand that a cervical spinal cord lesion cannot cause the diffuse lower motor neuron disorder that is present in these paralyzed dogs. Hopefully, your education has taught you how to distinguish tetraplegia caused by a lower motor neuron disorder from one caused by an upper motor neuron disorder.

Fifty years ago, we were just learning the importance of making an anatomic diagnosis and how to do it. Now, we are faced with how to select the most useful diagnostic procedure to support our most presumptive clinical diagnosis from a plethora of diagnostic instruments. Issues of expense and patient safety are most prevalent. However, all of these ancillary procedures are meaningless without an accurate anatomic diagnosis.

I was asked to write about the approach to a neurologic patient. This must be a compassionate hands-on approach that requires your utmost patience as well as that of your patient so that a thorough physical neurologic examination can be performed. An accurate anatomic diagnosis will be dependent on this cooperation between you and

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

your patient. It is perfectly appropriate to make a fool of yourself as you attempt to gain the cooperation needed from your patient. When you think about this, you are asking this patient to perform movements never asked of it before. It is really remarkable how well most of them cooperate. The reward will be as accurate an anatomic diagnosis as possible.

Examination of a patient with signs of a neurologic disorder should include a review of the history, a complete physical examination, a neurologic examination, and appropriate ancillary procedures. The purpose of the neurologic examination is to determine the neurologic abnormalities and, based on that, the location of the lesion or lesions in the nervous system responsible for causing these abnormalities. The location is the anatomic diagnosis. The continual use of a routine systematic procedure will provide you with the experience and confidence to make an accurate anatomic diagnosis.

The differential diagnosis must be based on the anatomic diagnosis, and the order of significance of these disorders will depend on your evaluation of the signalment and history. Be sure to consider all five major kinds of lesions in your differential diagnosis or a list of these with which you are comfortable. My list includes malformation, injury, inflammation, neoplasia, and degeneration (MIIND). Your experience with the anatomic diagnosis together with the signalment and history will often lead to a presumptive clinical diagnosis. Further examination of the patient with ancillary procedures must depend on your differential diagnosis and what you consider to be the most likely clinical diagnosis. Many factors will be considered in this selection, including the cost to the owner.

Be sure to record carefully all your observations from the neurologic examination, and never rely on your memory. Many forms are available for recording your observations. Some of these forms list in detail every possible response that is present or absent, with numbers to estimate the level of response. The considerable variation between individual patients of the same species makes the recording of the degree of a response less reliable and often misleading. I prefer a less time-consuming form that is easier to follow and adaptable to all species. An example of this follows.

NEUROLOGIC EXAMINATION

PATIENT IDENTIFICATION: _____
SIGNALMENT:_____
HISTORY:_____
MENTAL STATUS:_____
GAIT AND POSTURE:_____

CRANIAL NERVES:

ANATOMIC DIAGNOSIS:

DIFFERENTIAL DIAGNOSIS:

Examination

The neurologic examination can be divided into five parts.

1) Sensorium – mental attitude
2) Gait and posture
3) Postural reactions
4) Muscle tone, size, and spinal nerve reflexes
5) Cranial nerves

The order in which these parts are performed is usually determined by the degree of patient cooperation and your preference. We usually perform the examination in the order listed. However, if the patient is resting comfortably in its cage, performing the cranial nerve examination first may be preferable. If the patient is excited or apprehensive, performing the cranial nerve examination may be more convenient after the patient has been handled for the examination of its gait, postural reactions, and spinal nerve reflexes.

Sensorium – Mental Attitude

An assessment should be made and recorded of the patient's sensorium, its mental attitude and response to the immediate environment, and attitude to being handled by you. The owner is the best judge of subtle changes in the patient's behavior in its normal environment. Be sure to explore this issue when you obtain the history. Considerable patient variation exists in how alert and responsive the patient may be in the examination room of a veterinary hospital. Do not mistake a very laidback behavior for depression. Descriptive terms for this portion of your examination include alert and responsive, depressed, lethargic, obtunded, semicoma (stupor), and coma. Other descriptions include acting vague, disoriented, hyperactive, propulsive, and aggressive.

As a rule, alterations in the patient's normal sensorium reflect disturbances in the ascending reticular activating system (ARAS) and limbic system components of the cerebrum or rostral brainstem. Be sure to evaluate the sensorium of a recumbent patient thoroughly. Recumbency from diffuse neuromuscular disease or focal cervical spinal cord disease will not alter the patient's sensorium. A dog that is recumbent with polyradiculoneuritis may appear to be severely depressed or lethargic because it has no voluntary movement to show a response. The quality of the tetraparesis or tetraplegia with a cervical spinal cord lesion is the same as that caused by a mid- to caudal brainstem lesion, but the latter circumstance will often alter the patient's level of response to its environment.

Gait and Posture

Examination of the gait should be performed in a place where the patient can be walked with a leash and where the surface is not slippery. Most hospital floors have a very slippery surface, which facilitates cleaning but is poor for evaluating a gait disorder and can be dangerous if the patient slips and falls. A washable carpet is very useful for small animals and can be rolled up between examinations. If you are constructing a small animal hospital, you should consider having a covered area with a specialized surface used in playgrounds that is relatively soft, provides excellent traction for the patient, and is easily cleaned. The material is called Vitriturf® and is available from Hanover Specialties, Inc., Hauppauge, New York.

Observe the patient while it is standing for a head tilt, lowered position of the neck, trembling, degree of tarsal extension, and tail position. You should evaluate the gait both as you lead the patient and as an assistant leads the patient. Most deficits are best seen during a slow walk and as it turns. Walk the animal back and forth in a straight line and in circles in each direction. Observe the patient from all directions. In our opinion, most abnormalities are best seen from a side view. Be aware of breed characteristics that influence the posture and gait. The overflexed tarsus in German shepherd dogs is an example.

Is your patient unwilling or unable to move normally? When you see a gait disorder, this question is the first one that you need to answer. This circumstance is especially true when the patient is short strided or does not support weight well on one or more limbs. A loss of support from a femoral or radial nerve disorder will mimic a severe painful disorder causing a reluctance to bear weight.

Pattern recognition is critical in evaluating gait disorders. With experience, clinicians recognize specific patterns in abnormal gaits that suggest an anatomic diagnosis. These patterns can be described but observing them on videos is the best way to learn them. See www.neurovideos.vet.cornell.edu. These patterns have five components, consisting of two qualities of paresis and three qualities of ataxia.

Paresis is defined as "weakness" in the dictionary, but in clinical neurology, it is defined as "a deficiency in the generation of the gait or the ability to support weight." This definition includes the two qualities of paresis, which are lower motor neuron (neuromuscular) and upper motor neuron. Lower motor neuron (LMN) paresis reflects degrees of difficulty in supporting weight and varies from a short stride that is easily mistaken for a musculoskeletal lameness to complete inability to support weight, causing collapse of the limb whenever

weight is placed on it. Animals with LMN disorders affecting both pelvic limbs will occasionally use them simultaneously. This action is described as *bunny hopping*. Be aware that bunny hopping can also be seen in orthopedic disorders, as well as spinal cord dysplasias. Upper motor neuron (UMN) paresis causes a delay in the onset of protraction, which is the swing phase of the gait. The stride will usually be longer than normal. Stiffness and spasticity may be apparent in the stride. Most of the UMN pathways necessary for gait generation are anatomically adjacent to the pathways of the general proprioceptive (GP) sensory system, and lesions usually affect both simultaneously. Therefore, the gait that reflects UMN paresis also reflects ataxia caused by dysfunction in the GP system. It is unnecessary to recognize the separate clinical signs of dysfunction of these two systems. Therefore, we recognize a pattern that reflects the combined dysfunction of UMN paresis and GP ataxia. As you observe the gait of a dog with UMN paresis and GP ataxia, you have the sense that the patient does not know where its limbs are located. This is never a concern with LMN paresis.

Ataxia is a synonym for incoordination, and we recognize three qualities of ataxia: (1) GP, (2) vestibular (special proprioception [SP]), and (3) cerebellar. GP ataxia reflects the lack of information reaching the central nervous system (CNS) that informs the CNS of where the neck, trunk, and limbs are in space and the state of muscle contraction at any time. Without this GP information, the onset of protraction of a limb may be delayed, and the stride may be lengthened. During protraction, the limb may swing to the side (abduct) or swing under the body (adduct), overextend during protraction, scuff or drag one or more digits, and in the support phase, stand on the dorsal aspect of the digits. Remember that these clinical signs overlap with those caused by dysfunction of the UMN. The gait pattern of a patient with a focal cervical spinal cord lesion between the C1 and C5 segments reflects dysfunction of the UMN and GP systems and is observed as spastic tetraparesis and ataxia. This cervical spinal cord pattern is often recognized by the overextension of the thoracic limbs creating an overreaching or floating action. This clinical sign can be augmented by holding the head and neck extended as the patient is led. This unique form of hypermetria must not be confused with cerebellar ataxia in which the limb is overflexed on protraction. At no time do we try to differentiate between conscious (cerebral) and unconscious (cerebellar) GP pathways! No examination will clearly differentiate these two pathways from each other or from the UMN pathways. No pure conscious proprioceptive deficit exists. This term should be dropped from the clinician's vocabulary.

Vestibular ataxia reflects the loss of orientation of the head with the eyes, neck, trunk, and limbs, which results in a loss of balance. Lesions limited to this system cause the patient to lean, drift, or fall to one side. However, the patient's strength and awareness of where its limbs are in space are normal with lesions confined to this system. This ataxia is usually accompanied by a head tilt and sometimes abnormal nystagmus. We will occasionally blindfold our patients with bandage material which will exacerbate the vestibular ataxia.

Cerebellar ataxia most commonly causes hypermetric ataxia characterized by sudden bursts of motor activity with a marked overflexion of the limbs on protraction. Vestibular system components exist in the cerebellum that, if dysfunctional, may cause loss of balance, head tilt, and abnormal nystagmus. As a rule, hypertonia accompanies cerebellar ataxia.

Postural Reactions

Remember that spinal nerve reflexes require only the specific nerves that innervate the area being tested and the spinal cord segments with which they connect. Postural reactions depend on the same components as the spinal nerve reflexes plus the cranial projecting pathways in the spinal cord white matter to the brainstem, cerebellum, and frontoparietal portion of the cerebral hemisphere and the caudal-projecting UMN pathways that return from the cerebrum and brainstem and comprise tracts in the white matter of the spinal cord that terminate in the cervical and lumbosacral intumescences. These postural reactions test the integrity of nearly the entire peripheral and central nervous systems. By themselves, the postural reactions are relatively less reliable for lesion location.

The degree of functional limb deficit will determine the need for postural reaction testing. In a patient that is recumbent with tetraplegia or is paraplegic, you need not perform postural reactions in the affected limbs. However, in the paraplegic patient, you must test the thoracic limb postural reactions so as to avoid overlooking a focal cranial thoracic lesion or a multifocal disorder.

In small animals, we evaluate muscle size and tone just before our evaluation of the postural reactions. Be sure to talk to your patient continually, and use its name to gain its cooperation. Stand over the patient with both of you facing in the same direction. Simultaneously palpate the muscles of the neck and both thoracic limbs from proximal to distal for any evidence of atrophy. Flex and extend each limb for range of motion and to determine the degree of muscle tone. A short stride or stiffness in the gait may be caused by a joint disorder, limiting the range of motion. When you place the limb back on the ground surface, turn the paw over so that its dorsal surface bears the weight of the limb to determine how

rapidly the paw is replaced. Most normal small animals immediately return the paw to its normal position. This response is known as the paw replacement reaction that requires many peripheral and central components to be normal. This test is not just for conscious perception of GP and should not be called the CP test. This term is a misnomer that we are well aware will be difficult to eliminate from the clinical language of veterinarians, even boarded veterinary neurologists.

Moving on, palpate the thoracolumbar epaxial muscles and then the muscles of both pelvic limbs followed by flexing and extending those limbs for tone and range of motion and checking for paw replacement. Check for the degree of tail tone, and while extending the tail, evaluate the anal tone.

Hopping responses, in our opinion, are the most reliable of the postural reactions that we test. While still straddling the patient, move back to the thoracic limbs and elevate the abdomen with one hand so that the pelvic limbs are not bearing any weight. With your other hand, pick up the thoracic limb on that side. With all the weight supported on that thoracic limb, hop the patient laterally. Go as far as you can without moving your pelvic limbs. Then, switch hands and hop the patient back on the other thoracic limb. Repeat this test many times until you are sure the thoracic limbs are normal or abnormal. Only evaluate hopping in the lateral direction. As you stand over your patient and look down the lateral aspect of the limb that is being hopped, the limb should move as soon as you move the shoulder region laterally over the paw. Any delay in this response is abnormal. The hopping movements should be smooth and fairly rapid and not irregular or excessive. The paw should never drag or land on its dorsal surface. Carefully compare one thoracic limb with the other.

To test the hopping responses in the pelvic limbs, stand beside the patient, and place your forelimb that is closest to the patient's head between its thoracic limbs with your hand on its sternum. Lift up on the thorax just enough to take the weight off the thoracic limbs. With the other hand, pick up the pelvic limb on the side where you are standing and push the patient toward the pelvic limb that is bearing the weight. This action will force the patient to hop laterally on that pelvic limb in a direction away from you. After a few hops, switch sides, and hop the patient back on the other pelvic limb. Keep repeating this test until you have determined that the response is normal or abnormal. The responses should be brisk and smooth but will not be quite as rapid as in the thoracic limbs. While you are hopping the patient, you will also be aware of the degree of tone in the limb that is bearing all the weight.

In large dogs that are too heavy to lift for this testing, the same observations can be made while the patient is walked on one side (hemiwalking). Hemiwalking is performed by standing on one side of the patient. Grasp each limb on that side and lift the limbs off the ground and push the patient toward its opposite side. The patient will hop with both limbs on that side. Switch sides and repeat the hemiwalking performance on the opposite limbs. Be sure to compare one thoracic limb with the other and one pelvic limb with the opposite pelvic limb.

In small animals in which the hopping responses are equivocal or difficult to interpret, testing the placing responses may be useful. Pick up the patient and bring its thoracic limbs to the edge of a shelf, table, or chair so that the dorsal surface of the paw contacts the front surface of the object. The normal patient will immediately place its paws on the horizontal surface of the object. Test both thoracic limbs while holding the patient from both sides. For some unknown reason, occasionally the normal patient will not respond on the side on which it is being held. Blocking the vision of the patient while conducting this test may also be useful. Do this by extending its head and neck so that it cannot see the protruding surface of the shelf, table, or chair. Whether the lack of vision or the position of the head and neck helps exacerbate the placing deficits is unclear.

In cooperative patients in which you are not sure of the thoracic limb function, you can wheelbarrow the patient while holding its head and neck in extension. With one of your forelimbs, elevate the abdomen of your patient, and with the other hand, hold the head and neck in extension and force the patient to walk forward. With this posture, vision is compromised, and the need for GP is increased.

Remember that patients with LMN disease that still have some voluntary movements will hop or circle rapidly if their weight is supported because their GP is unaffected. This observation may help distinguish between subtle UMN and LMN paresis. When we are presented with a patient that we suspect has LMN paresis, we will hop the patient with and without supporting all the weight on the affected limb or limbs. As already stated, the patient with LMN paresis should know exactly where the limb is located during these postural reactions.

When presented with a recumbent patient, you should pick it up and hold it in a standing position. Get help if the patient is too large for you to handle alone. By holding it in this position and lifting it up and down, you can readily determine the quality of the muscle tone, whether they are hypotonic-flaccid from LMN disease, or hypertonic from spasticity of UMN disease. You can determine whether any voluntary movements are present in the limbs, and while supporting the patient, you can determine the presence and quality of the hopping responses.

One might conclude that these postural reactions are relatively nonspecific. This conclusion is absolutely

correct. Why then are they useful? First, testing postural reactions acts as a screen for detecting abnormalities in the nervous system. Abnormal responses will be the first clinical sign of any progressive lesion in any part of the central or peripheral nervous system that is involved in limb movement. One or more of these postural reactions may be abnormal before any detectable abnormality in the gait is observed. Second, their importance in localizing lesions is dependent on the results of the rest of the neurologic examination. If the gait is normal in the environment of your examination and one or more of the postural reactions are abnormal in the limbs on one side of the body, a contralateral prosencephalic lesion is strongly suggested. This test is the most useful of the three clinical tests that we use for prosencephalic disorders. If you have a patient with clinical signs of a unilateral vestibular system disorder with a normal gait but the postural reactions are abnormal, then the lesion is in the central components of the vestibular system.

Remember to use terminology that all clinicians can understand. Lesions that affect the UMN pathways also affect the GP pathways; thus when you describe a gait abnormality as paraparesis, also include pelvic limb ataxia. Use tetraparesis and ataxia for C1–C5 spinal cord lesions and hemiparesis and ataxia for unilateral C1–C5 spinal cord lesions that affect the gait. If the gait is normal and the postural reactions are abnormal on one side, describe it that way, and do not refer to this abnormality as hemiparesis. Be sure your reader can clearly understand what you have observed.

Muscle Tone and Size, and Spinal Reflexes

In small animals, examination of these features is performed in the recumbent patient that is gently restrained by an assistant. You can conduct this test unassisted in a cooperative patient by gently kneeling on the patient's neck to hold it in lateral recumbency. For cats, toy breeds, and puppies, you might want to sit on the floor with your back against a wall and your knees held together and flexed. Place the patient with its back resting against your thighs. This position is also useful for the cranial nerve examination.

Flex and extend the limbs on the nonrecumbent side to assess muscle tone, and palpate the muscles again for any indication of atrophy. For the patellar reflex, hold the pelvic limb in partial flexion, and, with the limb as relaxed as possible, lightly strike the patellar ligament with a human pediatric patellar hammer or any blunt instrument. The response is a brisk extension of the stifle. This response can be graded as 2 for normal, 1 for depressed, and 0 for absent; grade 3 is hyperactive, and grade 4 is clonic. A clonic reflex is one in which, after the response to a single stimulus, the stifle repeatedly rapidly relaxes and extends for a brief period, creating a tremor. Grades 2, 3, and 4 occur with UMN lesions. This is the most reliable tendon reflex and determines the integrity of the femoral nerve and the L4, L5, and L6 spinal cord segments. Always check the patellar reflexes in both limbs while in both recumbencies because, in normal dogs, it will occasionally be absent in one position and not the other. We have no explanation for this phenomenon. Also recall that, in dogs 10 years of age or older, one or both patellar reflexes may be absent with no other neurologic signs present. The presence of normal tone and the lack of any atrophy suggest that the basis for this sign is on the sensory side of the reflex arc, which may involve an age-related sensory neuropathy. However, this suggestion has not been proven. The patellar reflex is the most reliable tendon reflex in our examination of a patient.

Other tendon or muscle reflexes elicited by striking the tendon (gastrocnemius muscle – tibial nerve) or muscle (cranial tibial muscle – fibular nerve) are of limited use because they are not present in all normal small animals and some occur in denervated muscle. I do not consistently perform these reflexes. Be sure to test the patellar reflexes before the withdrawal reflexes because the latter require a noxious stimulus that may upset your patient.

The withdrawal-flexor reflex is evaluated in both pelvic limbs. This reflex requires an adequate noxious stimulus that differs between individual patients. A pin may be adequate in many cats but not in many dogs. I prefer using tissue forceps because the degree of compression can be adjusted to the individual patient. Compress the skin at the base of the third phalanx of a digit with enough pressure to elicit the reflex and usually a slight conscious response in a normal patient. By increasing the compression of the digit, the stimulus becomes sufficiently noxious to elicit nociception. Your digital pressure is sometimes sufficient, but a pair of tissue forceps is usually more reliable. Remember that this noxious stimulus tests both the spinal nerve reflex and the pathways in the CNS for nociception. You can have a reflex loss without loss of nociception; therefore you must use care in the amount of pressure you apply to avoid excessive discomfort to the patient and injury to you by the patient.

This withdrawal reflex is a more complex reflex. The sensory neurons tested depend on the digit being tested or the autonomous or cutaneous zone that you select for this noxious stimulus. Compression of the first digit stimulates receptors innervated by the saphenous nerve (femoral nerve, spinal cord segments L4–L6). Compression of digits 2–5 stimulates receptors innervated by the sciatic nerve (tibial nerve on the plantar surface and fibular nerve on the dorsal surface). The motor response involves primarily the sciatic nerve in the pelvic limb, with caudal thigh muscular branches responsible for

stifle flexion, the fibular nerve branch for tarsal flexion, and the tibial nerve branch for digital flexion. Be aware that the flexion of the hip is the responsibility of motor neurons in the femoral nerve and the ventral branches of all the lumbar spinal nerves that innervate the psoas major muscle. An animal with a complete dysfunction of its sciatic nerve can still flex the hip when the medial side of the crus or metatarsus is stimulated. The latter receives sensory innervation from the saphenous nerve branch of the femoral nerve. The spinal cord segments associated with the sciatic nerve are L6, L7, and S1. As you increase the forceps compression, nociceptors will be stimulated and voluntary effort will be added to the reflex you are testing if the pathway is normal. Remember that these reflexes will still be intact with a transverse lesion cranial to the L4 spinal cord segment, but nociception will be lost in the pelvic limbs.

Lesions of nerves cause both reflex loss and hypalgesia or analgesia. Lesions of the spinal cord tracts cause hypalgesia or analgesia but will spare the reflexes in the limbs caudal to the lesion. As you perform this reflex and observe flexion of the limb that is stimulated, watch the opposite pelvic limb. In some animals with severe UMN dysfunction, you may observe extension of the opposite limb. This reaction is called *cross-extension* and is a clinical sign of release from inhibition and is an abnormal response. In the dog with severe diffuse LMN paralysis caused by polyradiculoneuritis, the only evidence of nociception will be movements of the jaw as the dog attempts to vocalize and movements of the eyes.

In the thoracic limb, only the withdrawal reflex is reliable. The biceps (musculocutaneous nerve) and triceps (radial nerve) tendon reflexes are not consistently elicited in normal animals. For the biceps reflex, place your finger on the distal portion of the muscle at the elbow, and lightly strike your finger with the hammer and feel the muscle contract or observe a brief elbow flexion. Striking the triceps tendon may elicit a brief elbow extension. Striking the extensor carpi radialis muscle (radial nerve) may elicit a brief carpal extension. Because of the numerous muscles and nerves involved with the withdrawal response from a noxious stimulus of a thoracic limb digit, this evaluation method is a crude test for the entire brachial plexus and the cervical intumescence. The sensory nerve or nerves tested depend on the autonomous or cutaneous zones selected. In small animals, compression of the digits 1–5 stimulates the sensory components of the radial nerve dorsally and the median and ulnar nerves on the palmar surface. The motor neurons involved are in the axillary nerve (shoulder flexion), musculocutaneous nerve (elbow flexion), and the median and ulnar nerves (carpal and digital flexion).

With your patient still being restrained in lateral recumbency, evaluate the tail and anal tone, and gently pinch the skin of the perineum and observe for a tightening of the anus. This response is the perineal reflex (pudendal nerve, sacral spinal nerves, and sacral spinal cord segments). This reflex is often accompanied by tail flexion (caudal nerves and segments).

When this testing is completed, return your patient to a standing position, and perform the cutaneous trunci reflex evaluation. Using your tissue forceps and starting at the level of the sacrum, pinch the skin on the dorsal midline or on either side of the trunk and look for truncal skin movement due to reflex contraction of the cutaneous trunci muscle. In normal animals, this response will usually be bilateral. Progress cranially with your midline stimulus until a response is elicited or until you determine that it is absent. Some variation exists on where you will first elicit a muscle contraction in normal animals. In most dogs, this contraction will occur by approximately the midlumbar level. Sometimes the contraction cannot be elicited in some normal dogs and cats. The forceps compression stimulates the sensory neurons in the dorsal branches of the spinal nerves that innervate the area of skin stimulated. Because of the short caudal distribution of these dorsal branches, each spinal nerve innervates the skin for a distance of approximately two vertebrae caudal to the intervertebral foramen where the spinal nerve emerges from the vertebral canal. The general somatic afferent (GSA) neurons that are stimulated synapse in the respective dorsal gray column on long interneurons, the axons of which enter the adjacent fasciculus proprius bilaterally with a predominance on the contralateral side. Here, these axons course cranially to the C8 and T1 spinal cord segments to terminate in the ventral gray columns by synapsing on the general somatic efferent (GSE) neurons that innervate the cutaneous trunci via the brachial plexus and the lateral thoracic nerve. This reflex is absent in injuries that cause an avulsion of the roots of the brachial plexus. In these patients, this reflex will be present only on the side opposite to the injury. This reflex may help locate a transverse thoracolumbar spinal cord lesion where it will be absent when the stimulus is applied caudal to a line that is approximately two vertebrae caudal to the lesion.

At this point in your neurologic examination, if any indication exists of a possible spinal cord dysfunction, carefully palpate the vertebral column for any location of discomfort.

Cranial Nerves

The cranial nerve examination should be performed when the patient is the most relaxed. In most cooperative patients, this examination is performed after the examination of the gait and spinal nerve reflexes. With very young animals, the examination is often performed

before you handle them at all. The less restraint you use, the better your examination will be. As soon as you try to restrain young small animals, the ensuing struggle will make the cranial nerve evaluation very difficult. Puppies and kittens may be wrapped in a towel and placed between your thighs when you sit on the floor with your back against the wall and your knees flexed. This same floor position can be used for toy breeds. For all other small animals, we examine the cranial nerves while standing over the standing patient facing the same way as the patient, similar to when we performed the postural reactions. The cranial nerve examination can be performed by the numbers I–XII or by regions. We prefer the latter method, starting with the eyes, where either part or all of cranial nerves II–VIII are evaluated.

Vision – Menace and Pupils

We always start with the menace response. Cover one eye with your hand. In small patients, use the hand that is holding the head to cover one eye and menace the opposite eye. This reaction is a learned response that may not be developed until 10–12 weeks in puppies and kittens. Before this age, you may be able to assess vision by determining their ability to follow objects moving in their environment. The menace response requires normally functioning eyes, the optic nerves (cranial nerve II), and the visual pathway to the visual cortex in the occipital lobe via the lateral geniculate nucleus. The efferent response involves association axons from the occipital cortex to the motor cortex and then an UMN pathway to the brainstem terminating in the contralateral facial nucleus in the medulla. This pathway may include a connection through the cerebellum via the pontine nuclei. The majority of this central visual pathway caudal to the optic chiasm is contralateral to the eye being menaced. Some normal patients need a mild stimulus to get a response. I usually tap their orbital or frontal bone region with my hand to arouse their attention and to observe for an intact palpebral reflex to be sure the facial nerve is functioning. In the normal menace response, the menacing gesture elicits closure of the palpebral fissure. This closure is dependent on normal facial nerve innervation of the orbicularis oculi. Be careful to avoid touching any part of the face, especially the hair of the eyelids or the long vibrissae (whiskers), and to avoid creating a sudden air movement that might stimulate the hair or skin of the face. This action creates a cranial nerve V–VII reflex.

If the menace response is absent, we immediately touch the eyelid to be sure the facial nerve innervation is intact to cause palpebral fissure closure. If facial paralysis is present, then we look for eyeball retraction and third eyelid elevation or head retraction movements to determine if vision is present. Setting up a maze of objects in the patient's environment is sometimes necessary to determine if the animal can see and avoid these objects when walking around them.

Immediately after the menace test, the pupil size and response to light should be evaluated. Most patients have a dark-colored iris, which makes seeing the border of the pupil difficult without some light assistance. Cats with a yellow iris are an exception. You need a bright source of light such as that from a Welch Allyn halogen pen light or an Energizer pen light.

Initially, hold the light on the midline over the nose just close enough so that you can see the margin of the pupils and determine their size and if any anisocoria is present. Then bring the light source as close as possible to one eye without touching the patient's face. If no response occurs, move the light so that it shines on all aspects of the ocular fundus. Quickly swing the light into the opposite eye and observe what happens to that pupil. Then quickly return the light source to the original eye. Keep repeating this swinging light action until you are comfortable with your findings, and record them accurately. To prevent confusion, record what happens in each eye when the light is directed into one eye, and perform this maneuver for both eyes. See how this pupillary light reflex is recorded on the neurologic examination form in this chapter. In the normal patient, the pupil will rapidly constrict when the light is directed into it (the direct response), and the opposite pupil will also constrict without moving the light (the indirect or consensual response). Because of the major axonal crossing that occurs at the optic chiasm and at the level of the pretectal nuclei, light directed into one eye will cause a stimulus that will reach both oculomotor nuclei. When you swing the light to the opposite eye, the pupil has already constricted from the light directed into the first eye, and it stays constricted. As you repeatedly swing the light back and forth between the eyes, the pupils remain constricted in the normal animal.

The process I have described here is the way in which I observe the direct and indirect (consensual) pupillary light responses, but avoid using these terms, which can be confusing to students and clinicians alike. I will sometimes evaluate pupil size in a darkened room to help determine the origin of anisocoria.

Test yourself on the anatomic diagnosis of the following examples of eye examinations. (OS is oculus sinister and refers to the left eye. OD is oculus dextra and refers to the right eye. OU is oculi uterque and refers to both eyes.)

- A patient has no menace response in OS with a normal palpebral reflex. No anisocoria is observed. Light directed into OS causes no response OU. Light directed into OD causes a normal response OU. As you swing

the light from OD where the pupil is constricted back to OS, the OS pupil that was constricted from stimulation of OD is now dilating back to its original size. This asymmetry is repeated as you swing the light back and forth between the two eyes. When you cover OD with your hand, the OS pupil fully dilates. *Anatomic diagnosis*: in OS or the left optic nerve. In most cases with this anatomic diagnosis, room light entering the normal eye is sufficient to keep the pupil in the affected eye constricted. Occasionally, the pupil on the affected side will be slightly larger than the pupil on the unaffected side in room light.

- A patient has normal menace responses. Anisocoria is present with the pupil in OD widely dilated. Light directed into OD causes the pupil to constrict only in OS. Light directed into OS causes only the OS pupil to constrict. *Anatomic diagnosis*: right oculomotor nerve general visceral efferent (GVE) component, ciliary ganglion, ciliary nerves. Be aware that this reaction may be the first clinical sign of an extraparenchymal mass lesion ventral to the diencephalon compressing the oculomotor nerve and causing a loss of function of the GVE preganglionic neurons, which may precede the loss of function in the GSE neurons. This disparity between the altered pupil size without ptosis or strabismus is useful in making an anatomic diagnosis of the different components of the oculomotor nerve.
- A patient has no menace response OD with a normal palpebral reflex. Anisocoria is present with the OD pupil widely dilated. Light directed into OD causes no response OU. Light directed into OS causes only the OS pupil to constrict. *Anatomic diagnosis*: right optic nerve and the GVE neurons of the right oculomotor nerve, ciliary ganglion, ciliary nerves. A retrobulbar neoplasm or abscess might produce this result.
- A patient acts blind and has no menace response OU with normal palpebral reflexes. In room light, the pupils are mildly dilated. Light directed into OS causes the pupils to constrict OU. Light directed into OD causes the pupils to constrict OU. This dog's sensorium is normal. *Anatomic diagnosis*: both eyeballs, optic nerves, optic chiasm, or optic tracts.

Patients with lesions in the retina (retinal degeneration, sudden acquired retinal degeneration) or optic nerves (optic neuritis) OU often lose their vision and are clinically blind but still have light-responsive pupils when a bright light is directed into the eyes. However, room light is insufficient to cause normal constriction, and the pupils will appear mildly dilated. This response can be explained by the disease process sparing the retinal neurons involved with these light responses or, more likely, with progressive loss of function of retinal neurons, the threshold for loss of vision is lower than that for pupillary constriction to light. In other words, the pupillary light reflex neurons are the last to lose function when lesions disrupt the retina or optic nerve.

The anisocoria of Horner syndrome has no effect on the menace response and both pupils will respond to light directed into either eye. The pupil asymmetry with Horner syndrome will be more obvious in a dark room where the absence of room light will further dilate the normal pupil.

Anisocoria may result from many intraocular disorders. Iris atrophy is fairly common in older dogs and creates dilated unresponsive pupils with no interference with vision. Be sure to evaluate the iris thoroughly with your bright light source. Neurologic causes of anisocoria include disturbances to cranial nerves II and III and the sympathetic ocular innervation. Examination of the patient in a darkened room may help determine the cause of anisocoria in your patient.

Palpebral Fissure and Third Eyelid

Observe the size of the palpebral fissures and their symmetry. In small animals, the fissure will be smaller with oculomotor nerve dysfunction (loss of function of the levator palpebrae superioris muscle causing ptosis), sympathetic innervation dysfunction (loss of the orbitalis smooth muscle function in the orbit), and secondary to atrophy of the muscles of mastication from dysfunction of the mandibular nerve from the trigeminal nerve or chronic myositis. An elevated third eyelid will be apparent with sympathetic denervation, as well as secondary to atrophy of the muscles of mastication. The third eyelid elevates in tetanus secondary to the tetanus of the extraocular muscles that results in retraction of the eyeball and in animals with a facial paralysis when they are menaced.

Strabismus

Strabismus is an abnormal position of the eyeball. While examining the eyes, you can appreciate whether they are normally positioned in the orbits. Normal ocular position is dependent on the innervation of the extraocular muscles by cranial nerves III, IV, and VI and the normal function of the vestibular system. Repeatedly move the head in a horizontal (dorsal) plane from one side to the other. Watch the excursions of the eyeballs. The degree of adduction (medial rectus, cranial nerve III) should be the same as the abduction (lateral rectus, cranial nerve VI). This is normal physiologic nystagmus and requires a normal vestibular system as well as normal oculomotor and abducent nerve function. In some cats, you will only see this response at the end of the head movement. A ventrolateral strabismus occurs with oculomotor nerve dysfunction, a medial strabismus with abducent nerve dysfunction, and an ocular extorsion with trochlear

nerve dysfunction. The last of these abnormalities causes the dorsal aspect of the pupil to rotate laterally in cats. In dogs, in which the pupil is round, a fundic examination will show a lateral deviation of the retinal vein that emerges from the superior edge of the optic disk and normally courses in a superior direction. A vestibular strabismus is usually ventrolateral and is present only in some positions of the head.

Nystagmus

Nystagmus is an involuntary oscillation of the eyeballs. In normal animals, a jerk nystagmus occurs when the head is moved rapidly. This normal physiologic nystagmus was observed when the eyes were examined for the function of cranial nerves III and VI. Abnormal nystagmus occurs with dysfunction of the vestibular system. In severe cases, it is continual and is observed when the head is resting in its normal posture, as well as in any change of the head position. This disorder is a resting or spontaneous nystagmus. In less severe and chronic disorders, the abnormal nystagmus may be seen only when the head is held in different positions. This disorder is called a positional nystagmus.

While you are holding the head in its normal resting position, look at the eyes for any resting nystagmus. To facilitate this, use one hand to pull the facial muscles caudally enough so that the retraction of the eyelids will expose the limbus of the eye to better observe it for any abnormal nystagmus. Move the head laterally to one side, hold it there, and observe for any development of a positional nystagmus. Repeat this maneuver on holding the head directed to the opposite side. Then hold the head and neck in extension and observe for any positional nystagmus. If you are suspicious of subtle vestibular system dysfunction and you have not observed any abnormal nystagmus with the head held in a laterally flexed or dorsally extended position, place the patient on its back in dorsal recumbency. Extend the patient's head and neck, and look for any positional nystagmus. Be sure to record the direction of the abnormal nystagmus, as well as the plane of rotation. The direction is defined as the direction of the quick phase of the jerk nystagmus. The plane of rotation may be horizontal, rotatory, or vertical. As a rule, a consistently vertical nystagmus with no rotatory component usually indicates involvement of the central components of the vestibular system. Look for possible change in this direction with different positions of the head. With peripheral vestibular system disorders, the jerk phase of the nystagmus is always directed away from the side of the lesion and is either in a horizontal plane or is rotatory. If the direction of the nystagmus changes with different head positions, then a disorder of the central components of the vestibular system is present.

When you have the head and neck in extension, look at the position of the eyeballs, without retracting the eyelids, to observe in small animals that both eyeballs have also elevated and are still centered in the palpebral fissure and no sclera is exposed dorsal to the limbus. Sclera that is exposed dorsally indicates inadequate elevation of the eyeball and either an oculomotor nerve dysfunction or a vestibular system dysfunction; the latter disorder is a vestibular strabismus. With vestibular strabismus, this eyeball deviation is present only in some head positions, and the eyeball adducts normally when physiologic nystagmus is examined.

On rare occasions, a rapid resting pendular nystagmus is present at all times and in all positions of the head. The eyeball excursions are rapid and to the same degree in both directions. This ocular tremor is congenital and associated with anomalies of the retina or the decussation of the optic axons at the optic chiasm. Vision is normal. This is most common in Siamese cats.

Facial and Trigeminal Neurons

Up to this point in your cranial nerve examination, all of your evaluations have been directed at the eyes and orbital structures. Some of these evaluations have involved part of the innervation that is dependent on normal facial and trigeminal nerve function. At this point, I reevaluate all of the facial and trigeminal nerve functions that are practical.

For the facial nerve, repeat the palpebral reflex (cranial nerves V and VII) by touching both corners of the eyelids for each eye. The sensory nerves are branches of both the ophthalmic and maxillary nerves from the trigeminal nerve and the closure of the fissure is a function of the palpebral branch of the facial nerve. Observe the symmetry of the face and the position of the ears. The erect ears of all cats, some breeds of dogs, and those dogs that have had ear crop surgery will not droop with facial paralysis because of the rigidity of the auricular cartilage. You will feel atonia when you palpate the ear, and the ear will not move when the skin of the ear canal is stimulated with your forceps or by blowing in the ear. You may be able to palpate the loss of tone in the lips, and, in many patients, you may observe a droop of the lips. Elevate the head and observe the lips at the angle of the mouth. More lip mucosa may be exposed on the denervated side (VII), and the animal may tend to drool on that side. Facial paralysis does not cause a deviation of the philtrum in dogs and cats. Be aware that a deviated philtrum in a dog is most likely the result of tetany of the facial muscles on the side to which the philtrum is directed. This hemifacial tetany can be confirmed by its disappearance with local or general anesthesia. In older literature, this observation is known as hemifacial spasm, which is a misnomer.

For the trigeminal nerve, palpate the muscles of mastication for any denervation atrophy caused by dysfunction of the mandibular nerve from the trigeminal nerve. The only evidence of unilateral loss of function of the mandibular nerve will be unilateral atrophy of the muscles of mastication. Be sure to palpate for this atrophy because you will not see it in breeds with a thick hair coat, such as an old English sheepdog. No clinical evidence of any loss of jaw function will be observed; they can still bite vigorously. A dropped jaw that the patient cannot move requires dysfunction of both mandibular nerves. The observation of a dropped jaw is sometimes aided by holding only the superior jaw and associated lips elevated and observing the gap created by the inability to elevate the inferior jaw to close the mouth. Place the blunt end of your tissue forceps against the nasal septum. The normal patient will immediately move its head away from the stimulus. This action tests two anatomic pathways. One is the integrity of the ipsilateral branch of the ophthalmic nerve from the trigeminal nerve that innervates the mucosa of the nasal septum. The other is the nociceptive pathway that projects predominantly to the opposite side of the rostral brainstem and the somesthetic cortex of the opposite cerebral hemisphere. This evaluation is one of the three clinical examinations that we routinely use for prosencephalic dysfunction. We do not routinely check the autonomous zones of the other two branches of the trigeminal nerve.

Cranial Nerves IX, X, and XII

Cranial nerves IX, X, and XII are examined together with the so-called gag reflex. This examination is performed rapidly because the patient usually objects to the manipulation that is necessary, especially cats.

Grasp the superior jaw with one hand and pull down on the inferior jaw with the other hand to open the mouth. The resistance felt is the result of the function of the masticatory muscles that close the mouth and are innervated by the mandibular nerves from the trigeminal nerves. Quickly look at the surface of the tongue for its size and any movement that is present. Push the tongue with your finger and observe for any movement. This maneuver evaluates the sensory branches of the trigeminal nerves (V) and the motor neurons in the hypoglossal nerves (XII). Then insert your finger through the oral cavity into the oropharynx and laryngopharynx. Feel for the muscle tone and evaluate the patient's sensory response to this maneuver. This response is the gag reflex. The sensory nerves stimulated include the trigeminal branches to the tongue surface and oropharyngeal surface of the soft palate and both the sensory and motor neurons in the glossopharyngeal (IX) and vagal (X) nerves. This assessment of the gag reflex is difficult to evaluate and is usually quite subjective. A more reliable indication of dysphagia usually comes in the form of a complaint by the owner as they watch their animal eating and drinking. These functions can also be assessed by watching the patient prehend and swallow food.

I do not routinely test for olfaction or hearing because they are difficult to evaluate objectively, especially when they are incomplete. The owner's observation of their animal's behavior is more reliable for disorders of these functions. Brainstem auditory-evoked potential (BAER) testing is the most reliable way to evaluate hearing function, especially with unilateral disorders. Tests for olfaction have been described.

Spinal Trauma

Traumatic spinal cord injury (SCI) is a devastating disease in human and veterinary medicine. The majority of SCIs result from vehicle-related accidents but other important causes include gunshots, dog fights, falls, accidental owner-induced injuries, and falling objects.

Pathophysiology of Spinal Cord Injury

The normal spinal cord is a stable structure throughout life, but it exhibits modest decrements in myelinated axon and neuron numbers with advancing age. Its complexity greatly exceeds that of other tissues, and its thin cellular processes can extend long distances, thereby increasing their vulnerability. It has unique vascular barriers and fluid compartments. Its cellular components and the tissues that they form are highly susceptible to injury. Together with the brain, this organ has the least ability to undergo self-repair. Increasing evidence indicates that the spinal cord also has distinct differences from the brain in its injury responses.

The pathophysiology of SCI can be divided into two phases: the initial primary injury and subsequent secondary injury.

- *Primary injury* refers to the initial traumatic insult to the spinal cord, which results in immediate severing of axons and death of spinal cord cells.
- *Secondary injury* invariably follows and leads to progressive tissue damage for weeks after the initial insult. It results from a complex series of related events on a number of physiologic levels. Hypotension and hypoxia are important preventable causes of secondary injury at a clinical level and must be recognized and either prevented or treated proactively. Numerous secondary injury mechanisms also occur on the cellular level, and although their delayed time course theoretically provides a window for therapeutic intervention, we are currently less capable of halting these processes, which include vasospasm and localized ischemia, delayed cell damage and apoptosis, ion-mediated cell damage and excitotoxicity, and neuroinflammation, as well as mitochondrial dysfunction and oxidative cell damage.

Clinical signs associated with spinal trauma are caused by injury to the spinal cord, the spinal nerves as they exit the vertebral canal, and the vertebral column itself. The different injuries resulting from trauma include vertebral fractures, subluxations and luxations, flexion/extension injuries, and traumatic disk herniations. Subluxation and luxation can occur in combination with a vertebral fracture or due to soft tissue disruption only, without evidence of vertebral injury. These injuries occur most frequently at the lumbosacral, thoracolumbar, and atlantoaxial junctions. Cats are more likely to suffer sacrocaudal fractures than dogs, and typically have a combination of fracture and luxation, whereas approximately 20% of dogs suffer a luxation only.

These events can cause spinal cord contusion and laceration, and can result in compression by bone, soft tissue or blood (hematomas). Ongoing instability can result in repeated contusive injuries, additional laceration of the cord, and increasing severity of compression. Compression of the spinal cord reduces perfusion, potentially causing neuronal and glial cell death by the secondary injury mechanisms described above. Demyelination is a common finding histopathologically, as a result of both direct damage to myelin and death of oligodendrocytes. Physical deformation of axons can cause failure of ion channels, changing membrane permeability and producing conduction block that rapidly reverses when decompressed. Ongoing spinal cord compression can also cause development of syringohydromyelia cranial to the compression site, potentially causing neuropathic pain in addition to further neurologic deterioration.

Spinal Cord Instability

Instability of the vertebral column can have devastating consequences for the patient.

Sudden luxation of an unstable vertebral unit can cause spinal cord transection, contusion, and compression. Sometimes apparently stable fracture/luxations have just enough movement to cause repeated small spinal cord contusions, producing deterioration in neurologic status. Stability is produced by the interaction of the vertebrae with each other via intervertebral disks and synovial joints at the articular facets. The dorsal and ventral longitudinal ligaments, interarcuate ligaments, and spinal musculature provide further support.

While there are different methods of predicting instability, the most commonly used method divides the spine into three compartments (Figure 69.1). Compartment 1 contains the ventral three-quarters of the vertebral body and disk, and the ventral longitudinal ligament; the second consists of the dorsal one-quarter of the vertebral body, the disk and the dorsal longitudinal ligament; and the third compartment includes the articular facets, lateral pedicles, dorsal laminae, interarcuate ligaments, and dorsal spinous processes. Disruption of any two of the three compartments is suggestive of instability. Sometimes muscle spasm or impaction of fracture fragments into each other renders a potentially unstable injury stable for practical purposes. It is also important to remember that disruption of the soft tissues of the intervertebral disk, dorsal and ventral longitudinal ligaments, and synovium of the articular processes disrupts all the compartments and causes instability.

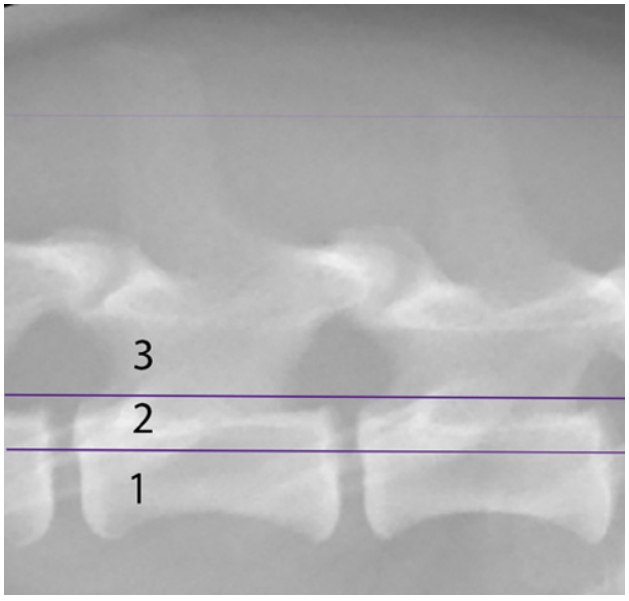

Figure 69.1 A lateral radiograph of the lumbar vertebrae illustrating the three compartments used to determine vertebral stability after a fracture.

Clinical Assessment of the Spinal Injury Patient

Once systemic assessment and stabilization has been completed, attention shifts to more directly assessing and treating the injured spinal cord. A detailed neurologic examination is imperative to establish baseline function and becomes the baseline against which subsequent examinations and clinical progression are judged. The neurologic examination should be aimed at localizing the lesion and determining its severity.

Special attention should be paid to determining the presence of voluntary motor function and nociception in each limb. In cases of suspected sacrocaudal fracture or luxation, nociception in the tail base and perineal region should be assessed. It is not unusual for there to be more than one site of injury and so neurologic signs can be multifocal and peripheral nerve injury such as brachial plexus avulsion can complicate the clinical assessment. A full neurologic assessment should be performed cautiously, as clinical deterioration is possible due to vertebral instability. Such a deterioration can be catastrophic, particularly in patients that have suffered an atlantoaxial injury.

Patients who have suffered trauma can have other soft tissue injuries. It is not uncommon for spinal trauma victims to have significant thoracic trauma causing pneumothorax, pulmonary contusions, and traumatic myocarditis with their attendant signs. In addition, cervical spinal cord injury may affect motor control of intercostal and diaphragmatic muscles. The ability to ventilate should therefore be assessed carefully. Abdominal trauma can result in a ruptured bladder, splenic and hepatic injury. Finally, neurologic signs can be masked by appendicular fractures, and complicated by head injury.

Thoracolumbar spinal cord injury severity is commonly graded as follows.

- 0 – Normal
- 1 – Painful
- 2 – Conscious proprioceptive deficits, ataxia and paraparesis
- 3 – Nonambulatory paraparesis
- 4 – Paraplegia with nociception intact
- 5 – Paraplegia with loss of nociception

Lack of nociception is not as relevant in tetraparesis, but special attention should be paid to the respiratory rate and pattern in any nonambulatory tetraparetic or tetraplegic patient with a view to detecting hypoventilation.

Imaging of the Spinal Cord Injury Patient

When SCI is present, imaging is used to confirm the injury and delineate the anatomy of the lesion.

Survey Radiography

Thoracic radiographs should be evaluated after a significant trauma, looking for pleural effusions, contusions, pneumomediastinum, and pneumothorax as well as the possibility of pericardial effusion and diaphragmatic herniation. If a vertebral injury is suspected, it is recommended that survey lateral radiographs are taken of the entire spine prior to additional manipulation of the animal (Figure 69.2). Sites particularly predisposed to fracture and luxation include the atlantoaxial junction, the thoracolumbar junction, and the lumbar and lumbosacral spine.

As some fractures can be subtle, good-quality and well-positioned radiographs from orthogonal planes are necessary. This may be accomplished with the animal awake and immobilized; analgesia may be required. Poor radiographic technique resulting in rotation of the spine (especially in the cervical area) can make assessment for unstable and malaligned vertebral segments difficult. Extreme care should be taken in positioning the animal for ventrodorsal views; horizontal beam radiographs can be obtained if the equipment is available.

Sedation may be necessary to achieve accurate positioning for radiography in some animals. This should not be performed if the examiner is unsure of the physical diagnosis, as sedation often influences the results of the neurologic examination. Additionally, sedation or anesthesia results in the loss of voluntary paraspinal muscle contraction, and unstable vertebral segments may be more likely to subluxate.

It is important to remember that radiographs provide a static record of the location of the vertebrae at the time of the study but they do not allow for assessment of how extensive the displacement of the vertebrae was at the time of the injury and prior to radiology. As a result of the strong paraspinal musculature, vertebrae can be significantly displaced acutely at the time of injury but then subsequently pulled back into a more normal position.

Advanced Imaging

Advanced imaging such as computed tomography (CT) or magnetic resonance imaging (MRI) is needed to evaluate spinal cord compression and to ensure that additional lesions unidentifiable on survey radiographs are not present. CT is invaluable in identifying bone defects that may not be apparent on survey radiography (Figure 69.3). Three-dimensional reconstruction from CT images may provide additional anatomic information regarding bone contour for surgical planning (Figure 69.4).

Magnetic resonance imaging is optimal for delineating the soft tissues involved in the injury as well as identifying spinal cord compression, spinal cord swelling, disk herniations, and the presence of intraparenchymal

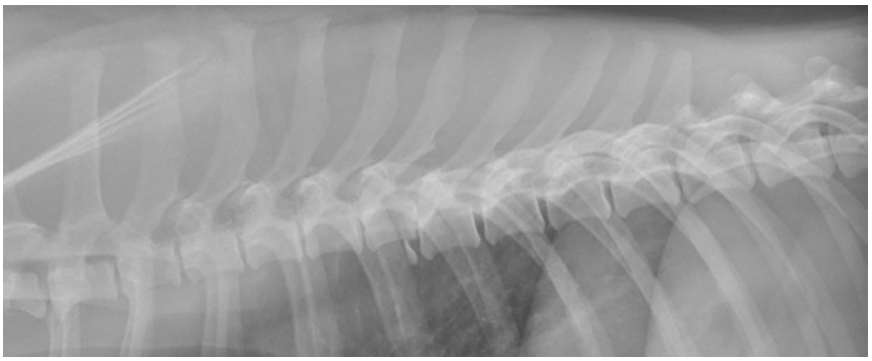

Figure 69.2 A lateral radiograph of the thoracic vertebrae confirms a fracture luxation affecting T6–T7.

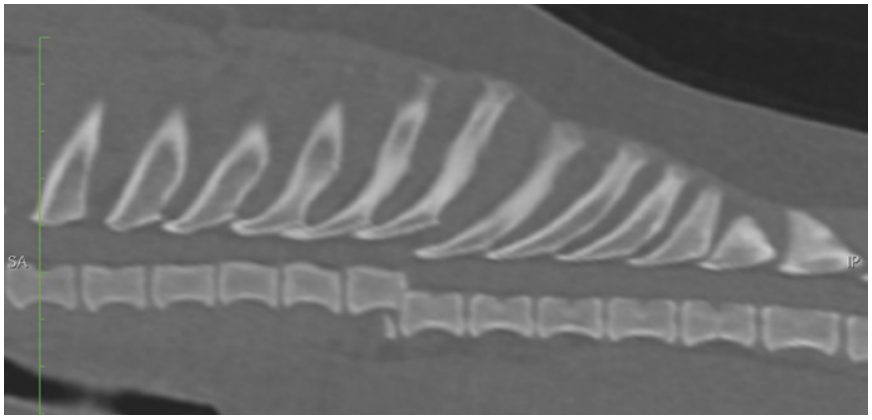

Figure 69.3 A sagittal reconstructed CT scan of the thoracic vertebrae of the case seen in Fig. 69.2. Although the spinal cord cannot be seen in detail, compression of the cord can be inferred from the stenosis of the canal seen with this image at the site of the luxation.

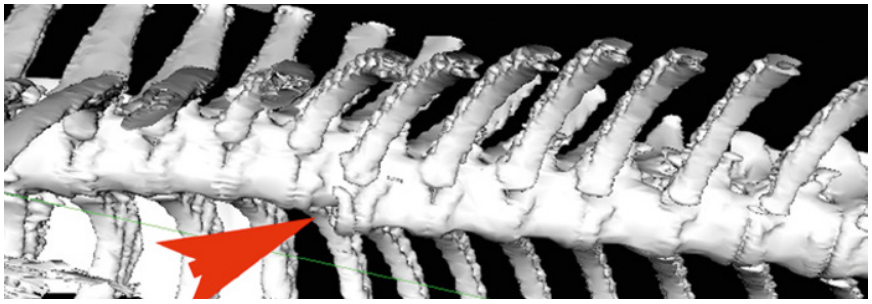

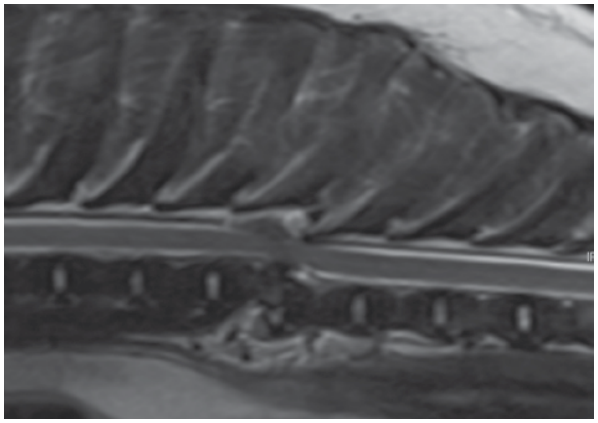

Figure 69.4 A 3D CT reconstruction of the thoracic vertebrae of the case seen in Fig. 69.2. This ventral view of the spinal column assists in the understanding of the vertebral fracture (*arrowhead*).

(b)

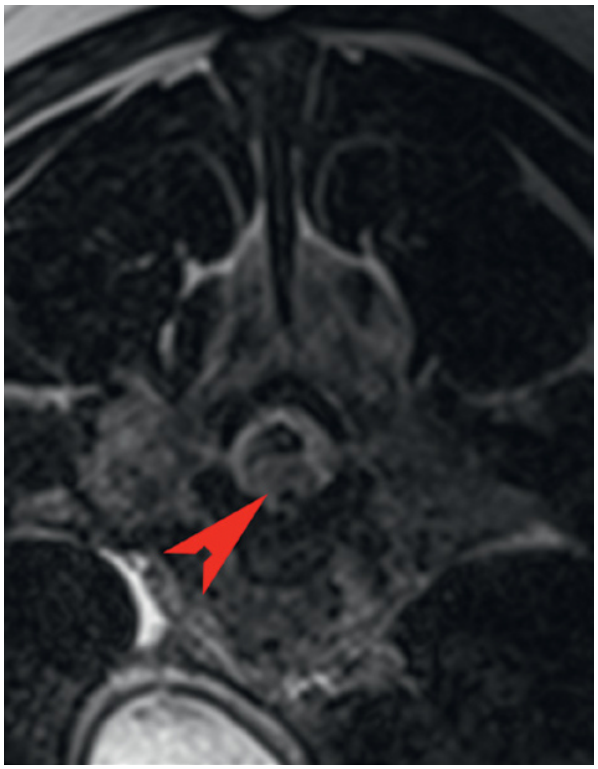

Figure 69.5 A sagittal (a) and transverse (b) T2-weighted MRI of the case seen in Fig. 69.2. The spinal cord can be seen in detail at the site of the injury with the cord compressed by hemorrhage within the canal (*arrowhead*).

hyperintensity and/or hemorrhage, which may assist in the prediction of adverse neurologic outcomes after SCI (Figure 69.5).

Both CT and MRI are useful to measure vertebral body size from the transverse views, essential when considering the maximum depth of surgical implants to be used.

Urinary Tract Assessment

In addition to blood urea and creatinine values and urine specific gravity levels, urethral catheterization may be required in patients that have undergone a severe concurrent abdominal or pelvic trauma in order that urine production may be assessed over the subsequent 72 hours. This will also be of value in those patients with systemic shock due to the traumatic event. Abdominal ultrasonography may be required to evaluate the bladder wall and kidneys, and to detect the presence of free abdominal fluid; contrast-enhanced imaging of the urinary tract may provide further information on the function and form of the individual structures.

Current Treatment Options for Spinal Cord Injury

The standard of care in veterinary medicine remains to stabilize the patient physically and medically and decompress the spinal cord, although the evidence for early decompression in dogs has not yet been clearly demonstrated in a prospective manner. However, there is evidence in humans that early decompressive surgery may reduce hospitalization time and, hence, complications, and improve the neurologic outcome in some. Spinal column surgery is a rapidly changing field but although operative nuances have seen dramatic change, the reality is that decompression, realignment, and stabilization remain the primary offerings of the spine surgeon for the acute SCI patient.

Initial Management

The top priority in managing acute SCI secondary to exogenous trauma is assessment and stabilization of vital signs, with strict adherence to a life support protocol.

Figure 69.6 Securing a dog or cat to a board in lateral recumbency can reduce vertebral movement prior to external or internal stabilization of a fracture luxation.

At the time of stabilization, patients with SCI should be immobilized by stabilizing *both* the body and head using a rigid spine board (Figure 69.6).

Airway

Although airway and spine protection share top priority, airway management takes precedence; risking iatrogenic SCI is justified in exceptional circumstance when required to secure or protect the airway.

Breathing

Respiratory insufficiency can be an important cause of early mortality after SCI. Cervical injuries can paralyze the diaphragm and cause respiratory arrest. Lower cervical injuries can affect the intercostal muscles, causing a paradoxical breathing pattern. Paralysis of the intercostal musculature is associated with a decrease in forced vital capacity and maximal inspiratory force because inspiration can cause chest wall collapse. Patients who compensate initially can fatigue rapidly, and indeed, many patients with cervical injuries can require intubation in the first 24 hours. It is thus useful to monitor vital capacity in such patients where possible; intubation should be considered in patients whose vital capacity is markedly reduced. Hypoxia is an important cause of secondary SCI and must be avoided.

Circulation

It is essential to avoid hypotension of any kind in patients with SCI given its contribution to secondary injury. Care must be taken to ensure that hypotension from other causes is excluded, especially that attributable to occult hemorrhage, which can be challenging to detect in patients with sensorimotor deficits.

Fluid administration is generally considered first-line therapy in this situation; however, a restricted heart rate makes these patients susceptible to fluid overload. Early consideration of vasoactive agents is recommended in people and so should be considered in veterinary patients where appropriate.

Specific Management Considerations

Medical Therapy

Pain Management Analgesic therapy is essential in the management of the neurotrauma patient. The degree of analgesia and sedation must be balanced with preservation of blood pressure and ventilatory status, as depression of each of these parameters can contribute to secondary injury, and if possible should not impede reassessment of neurologic status.

Opioids are the analgesic drugs of choice in critical care medicine, because of their ease of reversal and relative safety when titrated to effect. Several studies suggest that bolus infusion of opioids should be avoided, and constant-rate infusions (CRIs) are preferred. Because of the ease of reversal, it is recommended that full agonist opioids be used.

Table 69.1 lists the recommended analgesics and their respective doses.

Corticosteroids The use of corticosteroids in the treatment of acute SCI remains controversial despite extensive clinical investigation. Proposed mechanisms supporting the use of corticosteroids in SCI include free radical scavenging, antiinflammatory effects, and improved local blood flow. Unfortunately, there are no studies demonstrating a benefit of steroids in improving outcome after SCI in humans or veterinary patients. Given the potential for significant adverse side-effects, such as gastrointestinal ulceration, immunosuppression, and compromise of renal perfusion in hypovolemic patients, the routine administration of high-dose corticosteroids in the acute phase of injury is not recommended.

Table 69.1 Analgesic drugs suggested for use in patients with spinal cord injury

Analgesic	Recommended dose
Fentanyl	Dogs: 2 µg/kg, then constant-rate infusion (CRI) at 2–5 µg/kg/h Cats: 1 µg/kg, then CRI at 1–2 µg/kg/h
Morphine	Dogs: 0.15–0.5 mg/kg slow, then CRI at 0.1–1 mg/kg/h
Ketamine	0.1–1 mg/kg, then CRI at 2–10 µg/kg/min
Lidocaine	Dogs: 1–2 mg/kg, then CRI at 25–80 µg/kg/min
Dexmedetomidine	0.5–1 µg/kg/h

Cellular Transplantation Therapy Intraspinal olfactory glial cell transplantation in dogs with thoracolumbar SCI has been shown to have promise with respect to improved functional outcome. The rationale for this approach stems from the unique ability of these cells to promote regeneration in experimentally induced injured spinal cord and foster a more hospitable environment for axonal growth, increase tissue sparing after SCI, increase tissue bridging and reduce cavity formation following experimental SCI, and improve angiogenesis within the injured spinal cord. Olfactory ensheathing glia can be harvested from the olfactory epithelium and transplanted in the same animal, thereby minimizing the likelihood of rejection. Autologous bone marrow stromal cell transplantation has been evaluated in dogs with vertebral fracture luxation and found to be feasible and safe, with no complications noted.

Although such techniques are currently in the early stages of development, they may represent the future for patients with acute SCI.

Surgical Therapy

A significant body of animal research has demonstrated neurologic benefit from early decompression of the injured spinal cord; however, such benefit is less clear in polytrauma patients, who are often medically unstable in the acute postinjury phase. Despite the fact that early spine surgery appears to be safe in polytrauma patients, the question of whether early decompression for acute SCI is or is not beneficial for neurologic recovery remains incompletely answered. Cord compression can be due to displaced vertebral fragments, herniated intervertebral disk or hematomas. Decompression may be achieved by realignment of vertebrae alone; a laminectomy or hemilaminectomy may be necessary to remove material from the vertebral canal. Decompressive procedures could produce or exacerbate instability in the injured spine, thus requiring surgical stabilization.

Instability can be addressed surgically, by placement of an external splint, or simply by cage rest (Table 69.2). Surgical stabilization is the most effective method of stabilizing an unstable spine, but is associated with significant surgical risks. A variety of different techniques are used; in one of the most easily adaptable techniques, screws or pins are placed in the vertebral bodies adjacent to the injury and cement is applied to hold the structure in alignment (Figure 69.7). Another popular technique, sometimes known as "spinal stapling" or "segmental stabilization," uses pins wired to articular facets and dorsal spinous processes to stabilize dorsally. Different plates can be used; difficulty contouring plates to the vertebral bodies limits options, but more recently locking plates such as the string of pearls (SOP) plate have been described which can offer more flexibility.

Sacrocaudal luxations in cats are typically addressed by amputation of the tail if the tail is paralyzed and has no nociception. Prompt removal of the tail may limit

Table 69.2 Advantages and disadvantages of different stabilization techniques

Technique	Advantages	Disadvantages	Indications
Cage rest	• Inexpensive • No anesthetic or surgical risk	• No stability provided • No decompression	• Stable fracture (articular facet, dorsal spinous and transverse processes) • No spinal cord compression • Mild neurologic deficits
External splint	• Inexpensive • No anesthetic or surgical risk	• Splint complications • Limited protection against axial or rotational forces • No decompression	• Unstable fracture • Limited spinal cord compression • Mild neurologic deficits
Screws/pins and PMMA; plates	• Excellent stabilization • Can combine with decompression	• Cost • Risk of iatrogenic injury during implant placement • Infection • Implant failure	• Unstable fractures
Segmental stabilization	• Good stabilization against flexion and extension. • Reduced risk of iatrogenic injury. • Readily applied in the lumbosacral region	• Suboptimal protection against rotational and axial forces • Implant failure/migration • Infection	• Unstable lumbosacral/caudal lumbar fractures

PMMA, polymethylmethacrylate cement.

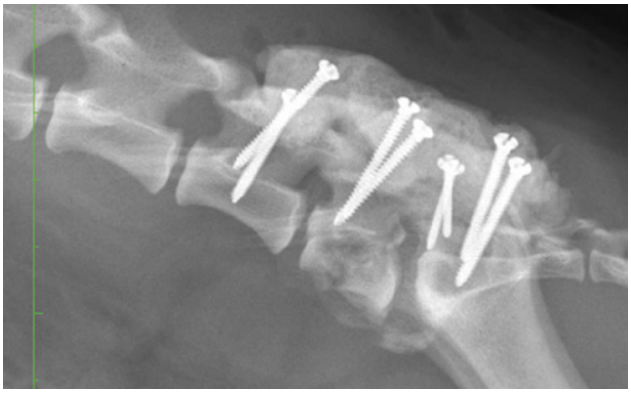

Figure 69.7 Multiple internal fixation materials and methods exist to stabilize vertebral fractures and luxations. This lateral radiograph demonstrates the use of screws and polymethylmethacrylate to stabilize a lumbosacral vertebral fracture luxation.

ongoing damage to the sacral nerve roots that could result from inadvertent movement of the tail.

Surgical complications from any spinal stabilization procedure can be serious and include iatrogenic injury to the spinal cord, damage to the vasculature immediately ventral to the vertebral column, failure of the fixation (Figure 69.8), and infection.

Placement of the splint is achieved by wrapping the appropriate part of the body in cast padding and then forming the splint from a material such as Vetcast® (3M) to cover the dorsal aspect of the thoracolumbar spine or the ventral aspect of the neck (from below the chin to the sternum). Following padding of the splint to ensure that there are no sharp edges, it is incorporated into the bandage with a cover of bandaging material such as Vetwrap®. Pressure points, particularly between thoracic and pelvic limbs, should be checked and padded carefully. The patient should always be hospitalized overnight after the first placement of a splint to ensure that the splint is tolerated, and to allow adjustment for any splint movement that occurs in the first 24 hours. Splints should be checked daily by the owner for development of decubital ulcers and should be checked and potentially changed by the veterinarian after the first 3–5 days and then on a weekly basis for six weeks. Splints do not protect from compressive loading of the spine, and offer poor protection against rotatory forces. In addition, it is not possible to stabilize the lumbosacral spine with an external splint. Splints are inappropriate if there are open wounds affecting areas that would be incorporated into the bandage.

Bladder Management

Urinary tract infections (UTI) in dogs being treated for SCI should be considered. Female dogs, dogs that cannot ambulate or voluntarily void urine, dogs which are not given antimicrobials during surgery, and dogs whose body temperature falls below 35 °C during surgical decompression of the spinal cord all have an increased likelihood of developing a UTI. The frequency of UTIs in dogs with an indwelling urinary catheter may approach 50%. Indiscriminate antimicrobial use for animals with an indwelling catheter should be avoided, though intraoperative antimicrobials should be administered at the time of surgical decompression of the spinal cord.

If the patient is unable to urinate, the owner must be able to express or catheterize their pet three times a day. Addition of phenoxybenzamine (0.25–0.5 mg/kg orally q8–12h) or prazosin (dog: 1 mg if less than 15 kg body weight or 2 mg if over 15 kg PO q8–12h; cat: 0.25–0.5 mg PO q12–24h) and diazepam (0.5 mg/kg orally 20 min prior to expression) may help to reduce urethral sphincter tone and facilitate expression. Since marked hypotension can result from prazosin, patients should be monitored for lethargy, collapse, pallor, syncope or seizures. Skin should be kept clean and dry and checked regularly for development of decubital ulcers over pressure points, or urine scald.

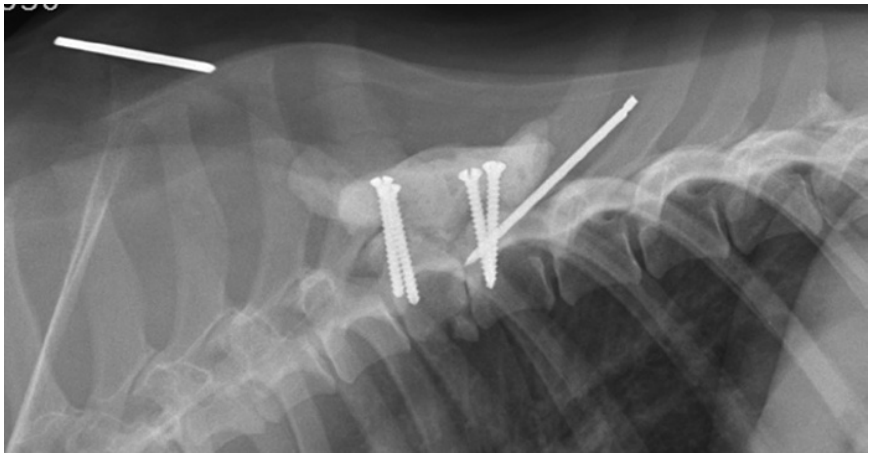

Figure 69.8 Fixation failure can be due to breakage or migration of the implants as can be seen to have occurred with these transarticular pins which needed to be removed.

Prognosis for Animals with Spinal Trauma

Prognosis associated with SCI is influenced by the severity of cord injury and the presence of injuries to other organs (e.g., lungs, heart, and bladder). The form of treatment (surgical versus conservative) does not appear to influence outcome, although in published case series, the more severely affected patients tend to be treated surgically, and so a true comparison is difficult. Prognostic indicators based on the neurologic examination are somewhat different for different regions of the spine.

- Thoracolumbar injuries carry a guarded to grave prognosis for recovery of pelvic limb function and fecal and urinary continence if the animal is paraplegic with loss of nociception to its pelvic limbs. If nociception is still present, these animals do have a good chance of recovery.
- Cervical injuries are associated with a guarded to grave prognosis if the animal is tetraplegic and unable to ventilate adequately. If treated surgically, the risk of perioperative death can be as high as 36% in cervical injuries. Note that it is extremely unusual to see tetraplegic animals that lack nociception because cervical spinal cord transection usually causes death by respiratory failure and bradyarrhythmias. Delaying referral, diagnosis, and treatment does worsen the prognosis. Less severe injuries carry a much better prognosis, with the majority of cases making a recovery if managed appropriately.
- The prognosis for recovery of fecal and urinary continence in lumbosacral and sacrocaudal fractures is approximately 50% if there is absent anal tone and no nociception in the perineal region or the tail at the time of presentation. Positive tail base sensation is useful to identify cases that will recover within 30 days of the injury, but it is not very useful to discriminate the cases that will recover despite not having tail base sensation. Because the cauda equina is largely composed of peripheral nerves, displacement of fracture fragments is less likely to cause complete transection but severe pain due to nerve root entrapment is common and can be a reason for euthanasia.

Head Trauma

Traumatic brain injury in veterinary patients occurs most commonly secondary to automobile accidents. Other common causes of traumatic brain injury include kicks to the head, falls, gunshot wounds, and animal bites. Immediate and appropriate treatment is critical to potentiate an acceptable recovery. Although treatment recommendations remain controversial, there are several guidelines for head trauma management. Accurate and frequent assessment of both systemic and neurologic injuries can allow for a successful outcome. Additionally, treatment strategies should remain flexible, adjusting to the patient's needs and changes in neurologic status. A complete understanding of intracranial physiology and the effects of injury will aid in the management of dogs and cats with head trauma.

Injury-Related Intracranial Physiology

Following injury, cerebral blood flow is often significantly reduced due to associated elevations of intracranial pressure (ICP) (>/= (greater than or = to)12–20 mmHg). Specific factors that decrease cerebral blood flow (CBF) include the presence of edema, hematomas, compression of vessels from mass effect, and vasospasm. Additionally, trauma significant enough to cause brain injury likely causes some degree of systemic shock and hypotension. The presence of hypotension further reduces cerebral blood flow.

Reduction of CBF due to elevation of ICP can lead to brain ischemia. A series of physiologic responses are in place to try to prevent this when CBF declines. Reduced blood flow to the vasomotor centers in the brainstem leads to reduced carbon dioxide removal. A subsequent elevation in local carbon dioxide concentrations stimulates the sympathetic nervous system to increase mean arterial pressure. The result is systemic hypertension in an effort to maintain blood flow to the brain. However, as the baroreceptors located in the aorta and carotid sinus both detect systemic hypertension, a signal is sent to the vagal centers of the brainstem. A reflex bradycardia occurs as a consequence. This phenomenon is referred to as the Cushing reflex. Therefore, concurrent systemic hypertension and bradycardia can indicate elevated ICP in head trauma patients.

Additionally, an elevation in ICP and the subsequent reduction of cerebral perfusion pressure (CPP) stimulates the release of catecholamines. This catecholamine surge can lead to the brain–heart syndrome, which causes arrhythmias and myocardial ischemia.

Pathophysiology of Brain Injury

After trauma, the brain parenchyma is susceptible to two types of injury: primary injury and secondary injury.

Primary or Biomechanical Injury

This is injury to the brain tissue from direct trauma and the forces applied to the brain at impact. An impact to the skull exerts the following forces on the brain: acceleration, deceleration, and rotational forces. The brain is unable to tolerate these forces because of its composition and lack of internal support. The superficial gray matter is most susceptible to the forces of acceleration, leading

to hemorrhage or contusion and tearing of neuronal tissue. The rotational forces have more of an impact on the deeper white matter of the brain, causing concussive injuries and axonal damage. The spherical shape of the skull and the propagation of rotational forces after injury direct these forces into the deeper tissues of the brain.

Additionally, penetrating injuries can cause direct damage to the brain parenchyma, fractures, and hemorrhage.

Skull Fractures

Skull fractures are described based on pattern (depressed, comminuted, linear), location, and type (open vs closed). A depressed fracture is one where the inner shelf of bone is driven into the brain to a depth equivalent to the width of the skull. Depressed fractures are most common on the dorsal and lateral aspects of the skull. Fractures may also occur at the base of the skull, middle ear, and temporomandibular joint; however, fractures in these locations are difficult to evaluate. Bullae fractures can result in neurologic signs such as vestibular syndrome, facial paresis/paralysis, and Horner syndrome on the side of the fracture. Fractures of the temporomandibular joint, mandible, and zygomatic arch may require additional treatment, but are unlikely to cause neurologic signs alone.

Brain Hemorrhage

Hemorrhage following trauma may be located in an extraparenchymal or intraparenchymal location. Extraparenchymal hemorrhage may occur in the epidural, subarachnoid, or subdural space. The most common location of hemorrhage following trauma is within the brain parenchyma (intraaxial) or subarachnoid space. Epidural hemorrhage is frequently secondary to bleeding from meningeal arteries, resulting in blood between the skull and dura. Hematomas located in the subdural space (between the arachnoid and dura) are typically secondary to venous bleeding, resulting in slow accumulation of blood.

Hemorrhage into the cranial cavity has several deleterious effects. The presence of hematomas contributes to elevations in ICP and reduction of CBF. Additionally, hemorrhage provides a substrate for oxygen free radical formation and promotes inflammation. Finally, hemorrhage promotes the release of excitatory amino acids exacerbating secondary brain injury.

Secondary Injury

After impact, a cascade of biomolecular events occurs causing continued and progressive brain pathology. The presence of hematomas and edema from the primary injury distorts normal brain parenchyma, and decreases CBF. Additionally, a series of cellular reactions begins at the time of impact and continues after the injury. This secondary brain injury has a significant effect on outcome and can lead to continued death of neurons and glial cells. The primary mediators involved in secondary brain injury include oxygen free radicals, excitatory amino acids (i.e., glutamate), and nitric oxide.

Cerebral Edema

Edema develops after primary brain injury and continues to develop as secondary brain injury ensues. Typically, brain edema is most severe 24–48 hours after injury. There are two main types of edema: vasogenic and cytotoxic (intracellular).

- *Vasogenic* edema occurs secondary to failure of the blood–brain barrier and vasodilation. Vasodilation is frequently secondary to hypercapnia, which is often associated with head injury. Initially, the brain is able to compensate for this increase in fluid through the compliance strategies discussed earlier.
- *Cytotoxic* edema occurs secondary to failure of cellular ion pumps and damage to cellular membranes. Cytotoxic edema can lead to cellular death.

Intracranial Pressure

The brain is protected within the bony confines of the skull, where it exists in equilibrium with cerebrospinal fluid (CSF) and blood. The pressure exerted between the brain and the skull is the ICP, which is normally 5–12 mmHg in dogs and cats. The skull is relatively inelastic, limiting the volume that can exist within the cranial cavity. The space within the cranial vault is occupied primarily by three components: brain parenchyma, CSF, and blood.

The Monro–Kellie hypothesis describes the relationship between these compartments and their ability to compensate for increases in volume within the cranial cavity. After head trauma, the volume of the intracranial contents within the skull may increase due to hemorrhage, edema, or CSF accumulation. The brain has the capacity to tolerate small increases in volume by adjusting the size of one of the three components, primarily the CSF compartment. Shunting CSF to the spinal subarachnoid space, decreasing CSF production, and increasing CSF absorption can rapidly decrease the CSF compartment. CSF production does not typically affect elevations in ICP unless its drainage is obstructed, leading to obstructive hydrocephalus. Additionally, venous blood can be redirected out of the cranial cavity and cerebral blood flow will decrease to compensate for ICP elevation. The ability of the brain to adjust for increases in intracranial pressure by decreasing the volume of CSF and blood is called compliance. During this time of compensation, the patient's clinical signs will remain relatively normal, unless the trauma primarily injured the parenchyma via laceration, puncture wounds, etc. Once

compliance is exhausted, small increases in volume will result in dramatic elevations in ICP, which will be accompanied by a rapid decline in the patient's neurologic status.

This ability to compensate is more effective if the increase in volume occurs slowly. With continued elevation of ICP, brain herniation can result. There are four types of brain herniation.

- *Falcine herniation*: herniation of one cerebral hemisphere ventral to the falx cerebri.
- *Transtentorial herniation*: herniation of the parahippocampal gyrus below the tentorium cerebelli which causes compression of the midbrain, leading to mydriatic, unresponsive pupils, loss of consciousness, and subsequent failure of the cardiorespiratory centers. A sign of developing transtentorial herniation is asymmetric mydriasis followed by symmetric mydriasis as the parasympathetic portion of the cranial nerve III nucleus is compressed. Transtentorial herniation can be life-threatening, leading to sudden cardiopulmonary arrest.
- *Foramenal herniation*: cerebellar herniation into the foramen magnum (see Figure 69.9). This is frequently fatal, causing respiratory arrest by compressing the respiratory centers of the medulla.
- *Calvarial herniation*: the brain can also herniate through a defect in the skull.

Clinical Assessment

The ability to recognize signs consistent with elevated ICP or a declining neurologic status is critical in the management of dogs and cats following head trauma. Trauma significant enough to cause brain injury will have systemic effects, which may be life-threatening. Additionally, systemic injuries and shock will cause continued decline in the head trauma patient. Therefore, a complete systemic evaluation and stabilization is required in addition to a thorough neurologic assessment (Table 69.3).

Systemic Assessment

Initial assessment should involve evaluation of the patient's respiratory and cardiovascular system. An airway must be established, if necessary through endotracheal intubation. Breathing patterns may be affected by thoracic trauma, but may also be secondary to brain injury. Auscultation of the thorax may detect pulmonary pathology or cardiac arrhythmias. Oxygen support should be given as necessary and mechanical or manual ventilation may be required with severe pulmonary injuries. Traumatic pneumothorax may require thoracocentesis or chest tube placement to allow proper ventilation. The cardiovascular system should be evaluated by monitoring heart rate, blood pressure, and electrocardiography. An electrocardiogram may demonstrate cardiac arrhythmias secondary to traumatic myocarditis, systemic shock, or brain injury. Arterial blood analysis and lactate concentrations may provide additional information regarding systemic perfusion and respiratory function.

Temperature assessment on a frequent basis is important in all patients. Cerebral metabolic rate is proportional to body temperature and increases 5–7% per degree centigrade. Hyperthermia should be avoided in all patients and cooling techniques should be considered if this is noted. Hypothermia reduces the cerebral metabolic rate and although this may be advantageous to the injured brain, it also increases the risk of cardiac abnormalities.

Once the patient is stable, CT or radiographs of the chest and abdomen are recommended to evaluate for pulmonary

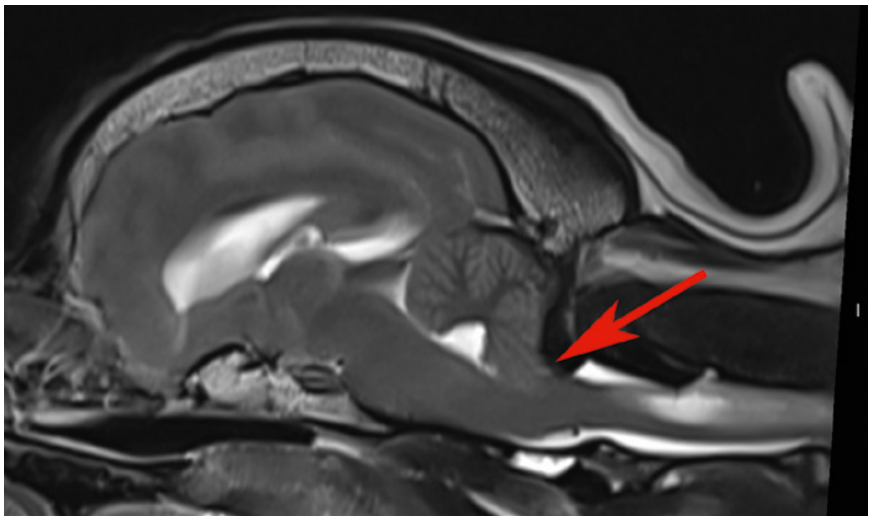

Figure 69.9 A sagittal T2-weighted MRI confirms cerebellar vermal herniation through the foramen (*arrow*).

Table 69.3 Monitoring parameters for the cat and dog following head trauma

Monitoring parameters	Suggested goal	Suggested treatment
Neurologic examination	MGCS >15	Ensure head elevation (30°) Ensure all points below are addressed Consider mannitol (see below) Consider surgery (see text)
Blood pressure	MAP 80–120 mmHg	Adjust fluid therapy Pressor support (dopamine 2–10 μg/kg/min)
Blood gases	PaO_2 >/=90 mmHg $PaCO_2$ <35–40 mmHg	Oxygen supplementation Consider active ventilation
Pulse oximetry (SpO_2)	SpO_2 >/=95%	Oxygen supplementation Consider active ventilation
Heart rate and rhythm	Avoid tachy- and bradycardias Avoid arrhythmias	Adjust fluid therapy Treat for pain Address ICP Treat arrhythmias specifically
Central venous pressure	5–12 cmH_2O	Adjust fluid therapy
Respiratory rate and rhythm	10–25/min	Ventilate if necessary
Body temperature	37–38.5 °C	Passive warming or cooling NSAIDs if hyperthermic
Electrolytes	See individual laboratory normal values	Adjust fluid therapy
Blood glucose	4–6 mmol/L	Adjust fluid therapy Consider dextrose administration
Intracranial pressure	5–12 mmHg	As for MGCS abnormalities

ICP, intracranial pressure; MAP, mean arterial pressure; MGCS, Modified Glasgow Coma Scale; NSAID, nonsteroidal antiinflammatory drug.

contusions, pneumothorax, and abdominal injuries. Pulmonary contusions are common following trauma and may not be most severe until 24 hours after injury. Trauma can also result in injury to abdominal organs. The abdomen should be evaluated with CT or radiography and ultrasonography for the presence of free fluid, blood, or urine, which may require additional therapy. Radiographs of the cervical vertebrae should also be considered as head trauma can often be accompanied by fractures and luxations of these bones.

Neurologic Assessment

Neurologic assessment should be undertaken on any animal which has experienced a trauma. Assessment of neurologic status in a patient after head trauma should initially be performed every 30–60 minutes. Frequent assessment allows for monitoring the efficacy of treatment and early recognition of deteriorating status. Primarily, neurologic evaluation of the patient serves to determine whether there are deficits suggesting structural neurologic lesions, where the lesions are located (i.e., at least intracranial, spinal, and peripheral nerve), and the severity of the lesion(s). Detection of a spinal and/or peripheral nerve (e.g., brachial plexus) lesion can affect the prognosis of any patient with head trauma. Without any extracranial lesions, the prognosis associated with head trauma is dependent on the location and severity of the parenchymal lesions.

The assessment should include evaluation of state of consciousness, motor function and reflexes, pupil size and responsiveness, position and movement of the eyes, and breathing pattern. The evaluation of pupil and eye function is the most accurate manner in which brainstem function can be assessed and this is the most important part of the examination prognostically. A scoring system has been developed in veterinary patients to provide an objective assessment and allow for rational diagnostic and treatment decisions.

Modified Glasgow Coma Scale

The Glasgow Coma Scale (GCS) is used in human medicine to assess head trauma patients by evaluating eye, verbal, and motor responses. This scale has been modified and applied to veterinary patients. The Modified Glasgow Coma Scale (MGCS) evaluates motor activity, brainstem reflexes, and level of consciousness in veterinary patients, enabling initial and serial monitoring following injury. The three categories evaluated using the MGCS provide objective standards for scoring a patient between 1 and 6, with lower scores assigned to

Table 69.4 Modified Glasgow Coma Scale

	Score
Motor activity	
Normal gait, normal spinal reflexes	6
Hemiparesis, tetraparesis	5
Recumbent, intermittent extensor rigidity	4
Recumbent, constant extensor rigidity	3
Recumbent, constant extensor rigidity with opisthotonus	2
Recumbent, hypotonia of muscles, depressed or absent spinal reflexes	1
Brainstem reflexes	
Normal pupillary light reflexes and oculocephalic reflexes	6
Slow pupillary light reflexes and normal to reduced oculocephalic reflexes	5
Bilateral unresponsive miosis with normal to reduced oculocephalic reflexes	4
Pinpoint pupils with reduced to absent oculocephalic reflexes	3
Unilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes	2
Bilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes	1
Level of consciousness	
Occasional periods of alertness and responsive to environment	6
Depression or delirium, capable of responding but response may be inappropriate	5
Semicomatose, responsive to visual stimuli	4
Semicomatose, responsive to auditory stimuli	3
Semicomatose, responsive only to repeated noxious stimuli	2
Comatose, unresponsive to repeated noxious stimuli	1

more severe clinical signs (Table 69.4). The score from each category is added together to determine a patient's coma score ranging from 3 to 18, which may be used to guide treatment decisions and prognosis.

Assessment of Limb Function The first category of the MGCS describes a patient's motor activity, limb tone, and posture. Voluntary motor activity is characterized as normal, paretic, or recumbent. Patients typically maintain some degree of voluntary motor activity even in altered states of consciousness unless they are comatose. Abnormal motor function usually reflects either brainstem injury or spinal cord injury; the latter may complicate the assessment of head trauma

Tone is evaluated by placing the limbs through passive range of motion. Increased tone can be seen following cranial trauma, as CNS inhibitory modulation to the lower motor neurons is lost. However, severe brain injury leading to coma will be associated with decreased tone in all limbs. Spinal reflexes are evaluated to primarily assess nerve function, but may provide some information regarding cerebral activity. Animals may have exaggerated reflexes following cerebral injury and absent reflexes when comatose.

An animal's posture after head trauma can also provide information about location and degree of brain injury. Decerebrate rigidity can occur following cerebral trauma and suggests severe brain injury and a poor prognosis as this posture reflects loss of communication between the cerebrum and the brainstem. Animals with decerebrate rigidity have opisthotonus with hyperextension of all four limbs and are stuporous or comatose, with abnormal pupillary light reactions (Figure 69.10). Decerebellate rigidity suggests acute cerebellar damage and may cause either flexion or extension of the pelvic limbs; however, consciousness may be normal.

Assessment of Brainstem Reflexes Pupil size, the pupillary light reflex, and the oculocephalic reflex should all be immediately evaluated in all head trauma patients. Pupil size, symmetry, and reactivity can provide valuable information about severity of brain injury and prognosis. These parameters should be frequently assessed as they can signal a deteriorating neurologic status. Response of the pupils to a bright light indicates sufficient function of

Figure 69.10 Extensor rigidity of the limbs as seen in this cat can be compatible with severe brain injury following trauma.

the retina, optic nerves, optic chiasm, and rostral brainstem. The presence of miosis may indicate a lesion in the diencephalon, as the sympathetic innervation to the eye originates in the hypothalamus. The peripheral sympathetic innervation to the eye can also be affected by injury anywhere along its pathway through the brachial plexus, anterior mediastinum, cervical soft tissues, and tympanic bulla which often causes concurrent third eyelid elevation, enophthalmos, and ptosis as part of a Horner syndrome. A miotic pupil may also be seen with ocular injury and spasm of the ciliary muscles of the iris; therefore, an ocular cause of miosis should be investigated.

Bilateral mydriasis that is unresponsive to light can indicate permanent midbrain damage or brain herniation and a poor prognosis. Other causes of mydriasis include decreased cerebral perfusion, postictal changes, trauma to the iris or retina, periorbital trauma or hematoma and previous ocular abnormalities.

Progression from miosis to mydriasis indicates a deteriorating neurologic status and is an indication for immediate, aggressive therapy. Unilateral changes in pupil size may be seen early in deterioration. Paralysis of cranial nerve (CN) III can lead to mydriasis, loss of direct pupillary light reflex, ptosis, and ventrolateral strabismus. The CN III nucleus is located in the midbrain so damage to this nucleus can be seen as a result of midbrain injury or compression secondary to transtentorial herniation.

The oculocephalic reflex (physiologic nystagmus) is tested by moving the animal's head in vertical and horizontal planes to assess brainstem function and function of the cranial nerve nuclei innervating the extraocular eye muscles. If the animal's head cannot be moved without risk, a visual stimulus such as food or the owner should move around the animal. Absence of the oculocephalic reflex reflects injury to the brainstem. This reflex may also be delayed with cerebral injuries.

Assessment of Consciousness

A patient's level of consciousness provides information regarding function of the cerebral cortex and the ascending reticular activating system (ARAS) of the brainstem. Consciousness can be described as normal, depressed or obtunded, stuporous, or comatose. An animal in a stupor is partially or completely unconscious, but will respond to noxious stimuli. A patient in a coma is unconscious and cannot be roused with noxious stimuli. Coma typically indicates severe cerebral injury or brainstem damage, which carries a guarded prognosis. These terms describe different levels or "quantities" of consciousness and provide information regarding degree of cerebral impairment. The quality of consciousness may be more difficult to objectively evaluate. Inappropriate activity suggesting confused or exaggerated responses to routine stimuli often confirms prosencephalon damage. It is important to note that the patient's blood pressure, oxygenation status, and temperature may all affect its level of consciousness and so the latter should be reevaluated after correction of the former vital parameters.

After evaluation, the patient should be assigned a score for each category to determine its overall coma score. This score can be used to monitor for improvement or deterioration of neurologic status, guide diagnosis and treatment decisions (see later), and provide information about prognosis.

Confirmation of Injury and Diagnosis

A diagnosis of head trauma is based primarily on a compatible history and clinical signs of intracranial neurologic dysfunction. However, additional tests can be used to confirm location and extent of injury. It is important to understand that advanced imaging of the brain (computed tomography and magnetic resonance imaging) should be reserved for patients that do not respond to initial treatment or who deteriorate despite aggressive therapy. Both of these imaging modalities require anesthesia, which can destabilize the head trauma patient, unless the patient is in a coma on presentation.

Significant injury to the brain can occur, leading to neurologic signs without causing skull fractures or hematoma formation. Advanced imaging of the brain may be performed to evaluate for fractures, hemorrhage, or parenchymal lesions; however, changes may not be seen even in a patient with severe neurologic deficits. Imaging modalities available include skull radiography, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). Advanced imaging can be helpful in identification of hematomas (extraaxial vs intraaxial), calvarial fractures, edema, and parenchymal contusions.

Skull Radiographs

Skull radiography may reveal calvarial fractures, but provides no information regarding the brain parenchyma (Figure 69.11). Radiographs of the skull can be difficult to interpret due to the irregularity of the skull bones and require anesthesia for accurate positioning, which may be contraindicated in the acutely injured patient. Radiography should not be limited to the skull following head trauma. Radiographs of the vertebral column, thorax, and abdomen are indicated to evaluate for evidence of other injuries.

Advanced Imaging

Computed tomography allows superior evaluation of bony structures and is preferred over conventional

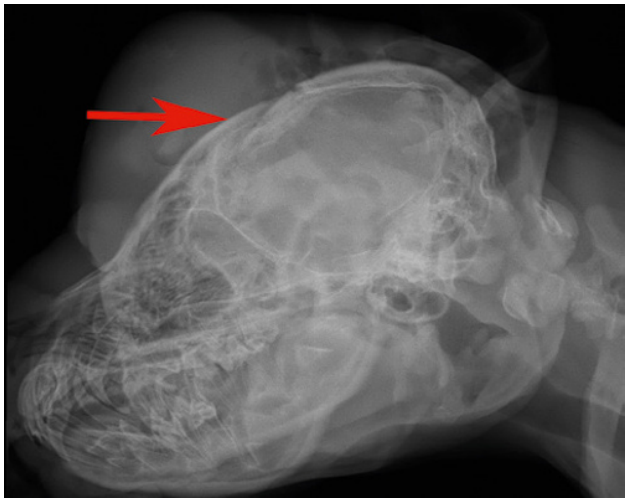

Figure 69.11 A lateral skull radiograph shows a frontal bone fracture (*arrow*) in this dog after being bitten by another dog.

Figure 69.12 A transverse bone windowed CT scan of the dog in Fig. 69.11 confirms a comminuted frontal bone fracture associated with soft tissue damage and air pockets dorsal to the skull.

radiography, especially considering the 3D reconstruction capabilities (Figure 69.12). Additionally, CT can be used to diagnose intracranial hemorrhage, alterations in ventricular size or shape, midline shift of the falx cerebri, and edema. CT does not provide good soft tissue detail of the brain parenchyma, but is frequently the preferred modality for evaluation of human head trauma patients for surgical intervention because of the speed of image acquisition. Typically, hemorrhage is hyperattenuating (hyperdense) on a CT in the acute stages. Over time, the

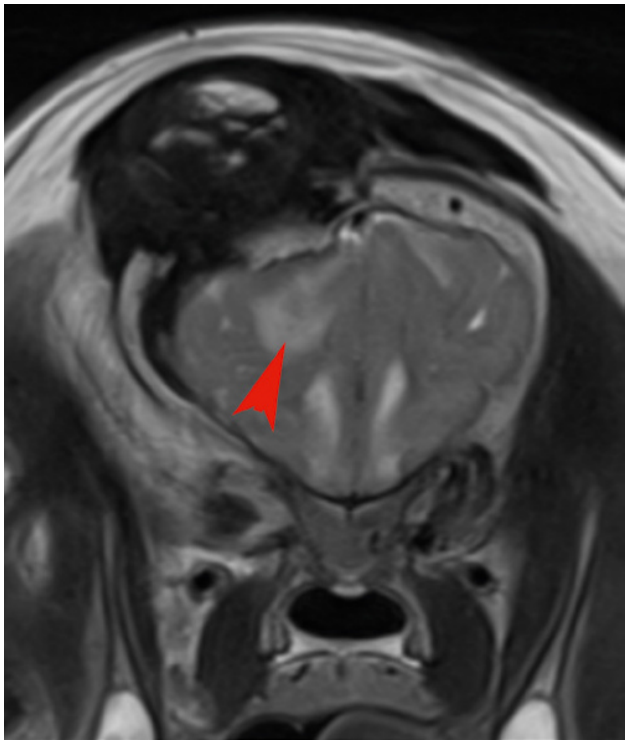

Figure 69.13 A transverse T2-weighted MRI of the dog in Fig. 69.11 confirms the extent of the soft tissue injury associated with frontal bone fractures. Hyperintensity seen in the brain (*arrow*) is compatible with edema secondary to the bite injury.

density decreases, with clot resorption creating a hypoattenuating lesion similar to edema. A CT can provide images for surgical planning, but should only be pursued in patients who are severely affected or deteriorating requiring surgical intervention.

Magnetic resonance imaging allows superior soft tissue detail and is preferred for evaluation of the brain, especially the caudal fossa which does not image well with CT (Figure 69.13). MRI can detect more subtle parenchymal changes that may be missed on a CT and may provide information about prognosis. Hematomas or hemorrhage, parenchymal contusions, and edema are readily apparent on MRI images. Although CT is preferred for evaluation of bony structures, fractures can also be identified on an MRI, most proficiently using STIR and gradient echo sequences.

Typically, CT and MRI are only pursued in patients who fail to respond to aggressive medical therapy or who deteriorate and may require surgical intervention. Both MRI and CT findings were recently correlated with prognosis in veterinary head trauma patients so their use may be of specific additional benefit.

Intracranial Pressure Monitoring

Intracranial pressure may be monitored through placement of a pressure transducer or fiberoptic transducer

into the epidural, intraaxial, or intraventricular space. ICP monitoring is frequently pursued in human head trauma patients, but may have its limitations in veterinary patients. ICP monitoring is not without risks and may lead to development of edema, hemorrhage, parenchymal damage, and infection.

Treatment of Head Trauma Patients

Treatment strategies should be directed toward both systemic and neurologic stabilization in an effort to minimize secondary damage. Several aspects of treatment exist. Systemic stabilization involves correction of systemic shock and respiratory abnormalities with fluid therapy and oxygen therapy/management of ventilation respectively. The second aspect of treatment involves measures to reduce elevations in intracranial pressure and cerebral metabolic rate. Finally, some animals require surgical intervention because of lack of improvement or a declining neurologic status.

Although once used as a treatment following head trauma, corticosteroids are no longer recommended in head trauma patients. Their use has been extensively evaluated in people and has shown no beneficial effect and may even result in worse morbidity and mortality rates. Detrimental effects of corticosteroids include immunosuppression, hyperglycemia, and gastrointestinal disturbances.

Fluid Therapy

The goal of fluid therapy of the head trauma patient is to restore a normovolemic state. It is deleterious to dehydrate an animal in an attempt to reduce cerebral edema. Aggressive fluid therapy and systemic monitoring are required to ensure normovolemia to maintain adequate cerebral perfusion pressure.

Crystalloid, hypertonic, and colloid fluids should be given concurrently to help restore and maintain blood volume following trauma. Crystalloids are usually given initially for the treatment of systemic shock. These balanced electrolyte solutions may be given at shock doses (90 mL/kg for dogs, 60 mL/kg for cats). Typically, it is recommended that the shock dose be given in fractions starting with one-third to one-fourth of the calculated volume, frequently reassessing the patient for normalization of mean arterial blood pressure, mentation and central venous pressure, if monitored, and giving additional fractions if needed. Unfortunately, crystalloid solutions will extravasate into the interstitium within one hour of administration, requiring additional fluid resuscitation.

Hypertonic and colloid fluid therapy can rapidly restore blood volume using low-volume fluid resuscitation; additionally, colloids remain in the vasculature longer than crystalloid fluids. These fluids should be used with caution as without concurrent administration of crystalloid solutions, hypertonic and colloid solutions can lead to dehydration. Other benefits of hypertonic fluids include the ability to improve cardiac output, restore normovolemia, and reduce inflammation after trauma. Hypertonic saline may be preferred in hypovolemic, hypotensive patients with increased ICP.

Hypertonic saline improves cerebral perfusion pressure and blood flow by rapidly restoring intravascular blood volume. Additionally, the high sodium content of hypertonic saline draws fluid from the interstitial and intracellular spaces, subsequently reducing intracranial pressure. Contraindications to administration of hypertonic saline include systemic dehydration and hypernatremia. Hypertonic saline only remains within the vasculature for about one hour so it should be followed by colloids to maximize its effects. A dose of 5–6 mL/kg (dogs) and 2–4 mL/kg (cats) of 7.5% NaCl should be given over 5–10 minutes.

Colloids (i.e., Hetastarch, Dextran-70) allow for low-volume fluid resuscitation, especially if total protein concentrations are below 50 g/L or 5 g/dL. These fluids also draw fluid from the interstitial and intracellular spaces, but have the added benefit of staying within the intravascular space longer than crystalloids. Hetastarch is typically given at 5–6 mL/kg boluses in dogs and 2–4 mL/kg in cats over 5–10 minutes, with frequent patient reevaluation. A total dose of 20 mL/kg/day may be given. In addition to volume resuscitation, oxygen-carrying capacity should be considered, especially if the packed cell volume <30%. The use of oxyglobin and other hemoglobin-based oxygen carriers has not been well evaluated in head trauma but initial studies suggest that they could play a valuable role.

Systemic blood pressure may require additional treatment to maintain adequate cerebral perfusion pressure. A mean arterial pressure of 80–100 mmHg should be the target. Hypotension should initially be treated with fluid resuscitation but persistent hypotension may require treatment with vasoactive agents (i.e., dopamine 2–10 μg/kg/min). Additionally, systemic hypertension may occur as a sequela to intracranial hypertension as a result of the Cushing reflex. Systemic hypertension secondary to ICP elevation should be treated by aggressively treating elevated ICP; the use of additional drugs to modulate the blood pressure should be avoided unless all attempts to lower ICP have been exhausted.

Head trauma patients should be positioned to maximize arterial circulation to the brain and improve venous drainage. This goal is best achieved by elevating the animal's head at a 30° angle. It is important to ensure the jugular veins are not occluded and that no restrictive collars are placed around the neck, which would elevate ICP.

Oxygen Therapy and Management of Ventilation

Oxygen supplementation is recommended in all patients following head trauma. Control of PaO_2 and $PaCO_2$ is mandatory and will affect both cerebral hemodynamics and ICP. Permissive hypercapnia should be avoided because of its cerebral vasodilatory effect that increases ICP. Hypocapnia can produce cerebral vasoconstriction through serum and CSF alkalosis. Reduction in CBF and ICP is almost immediate although peak ICP reduction may take up to 30 minutes after PCO_2 has been changed.

The amount of oxygen within the blood can be assessed by measuring oxyhemoglobin saturation with a pulse oximeter (SpO_2), measuring the PaO_2 with blood gas analysis in conjunction with measurement of circulating haemoglobin concentration. Calculation of oxygen delivery to the tissues requires measurement of both arterial oxygen content and cardiac output. Measurement of mixed venous oxygen can provide an indirect measure of adequacy of oxygen supply to the tissues. The amount of carbon dioxide within the blood can also be assessed by arterial blood gas analysis as well as via capnography. Capnography provides breath-by-breath assessment of adequacy of ventilation assuming normal cardiovascular function. This technique measures CO_2 in the expired patient gases (P'$ETCO_2$), which approximates the CO_2 tension in the alveoli. As alveolar gases should be in equilibrium with arterial blood, P'$ETCO_2$ can be used to approximate $PaCO_2$ unless severe pulmonary dysfunction is present.

The goal of oxygen therapy and management of ventilation is to maintain the partial pressure of oxygen in the arterial blood supply (PaO_2) greater than or equal to 90 mmHg and the $PaCO_2$ below 35–40 mmHg. If the patient is able to ventilate spontaneously and effectively, supplemental oxygen should be delivered via "flow-by"; confinement within an oxygen cage prevents frequent monitoring. Facemasks and nasal catheters should be avoided if possible as they can cause anxiety which may contribute to elevations of intracranial pressure.

Patients with severe head injury require mechanical ventilation to maintain these arterial blood gas concentrations at their optimal levels. The absolute indications for mechanical ventilation include loss of consciousness, rising $PaCO_2$ of >50 mmHg and falling SPO_2 despite appropriate treatment.

There are no contraindications to the use of positive end-expiratory pressure (PEEP) in hypoxemic patients. With adequate volume resuscitation, PEEP does not increase ICP nor does it lower CPP, and it may actually decrease ICP as a result of improved cerebral oxygenation. Assessment of adequacy of ventilation can be made by measurement of arterial CO_2 or alternatively using capnography.

Diuretics

Intracranial pressure can be aggressively addressed with the administration of osmotic diuretics. Osmotic diuretics such as mannitol should not be given to any patient without being certain that the patient has been volume resuscitated. If not, their use can precipitate acute renal failure. For this reason, they are reserved as tier 2 therapies.

Mannitol improves CBF and reduces ICP by decreasing edema. After administration, mannitol expands the plasma volume and reduces blood viscosity, which improves CBF and delivery of oxygen to the brain. Additionally, mannitol assists in scavenging free radicals, which contribute to secondary injury processes. Vasoconstriction occurs as a sequela to the increased partial pressure of oxygen, leading to an immediate decrease in ICP. Additionally, the osmotic effect of mannitol reduces extracellular fluid volume within the brain.

Mannitol (0.5–2.0 g/kg) should be given as a bolus over 15 minutes to optimize the plasma-expanding effect. Continuous infusions of mannitol increase the permeability of the blood–brain barrier, exacerbating edema. Lower doses of mannitol are as effective at decreasing ICP as higher doses, but may not last as long. Mannitol reduces brain edema over about 15–30 minutes after administration and has an effect for approximately 2–5 hours. Repeated dosing of mannitol can cause diuresis, leading to reduced plasma volume, increased osmolarity, intracellular dehydration, hypotension, and ischemia. Therefore, adequate isotonic crystalloid and colloid therapy is critical to maintain hydration. Additionally, administration of mannitol should be reserved for the critical patients (MGCS of <8), a deteriorating patient, or a patient failing to respond to other treatment. Administration of furosemide (0.7 mg/kg) prior to administration of mannitol has a synergistic effect at lowering ICP. Currently, there is no evidence to indicate that mannitol is contraindicated in the presence of intracranial hemorrhage, as has been suggested.

Seizure Therapy

Seizures should be aggressively treated to prevent worsening of the secondary effects in the brain parenchyma due to associated brain hypoxia and subsequent development of edema. Seizure activity may occur immediately following trauma or may be delayed in onset. The need for antiseizure prophylaxis after severe brain trauma remains controversial in human medicine. Human patients treated in the first seven days after head trauma with anticonvulsants have a significantly lower risk of posttraumatic seizures within this time period than if not treated. Beyond seven days from injury, there appears to be no benefit to prophylactic treatment.

Diazepam (0.5–2.0 mg/kg) can be given intravenously to treat seizures. Additionally, phenobarbital (2–3 mg/kg) may also be given intravenously or intramuscularly and continued parenterally following a loading dose (18–24 mg/kg over a 24–48-hour period) if necessary. Recently, the use of intravenous levetiracetam (20–60 mg/kg) has been described for emergency seizure treatment as it may be effective for up to eight hours without causing much sedation and without needing hepatic metabolism. Refractory seizures at the time of head trauma may require additional therapy such as a continuous infusion of diazepam (0.5–1.0 mg/kg/h) or propofol (4–8 mg/kg bolus to effect followed by 1–5 mg/kg/h CRI).

Some patients may require long-term management of seizure activity with antiepileptic medications. However, if maintenance therapy is continued beyond seven days and seizure activity is not noted over a 3–6-month period, antiepileptic treatment may be slowly withdrawn. Therapy should be reinstituted if seizures return with an unacceptable frequency.

Refractory Head Trauma

Failure of fluid therapy, oxygenation and ventilation strategies, and osmotic diuretics to stabilize the patient and/or improve the neurologic status significantly warrants radical therapy and such cases should be considered for advanced imaging such as MRI. The treatments discussed here have not been evaluated in veterinary medicine in terms of their efficacy and remain controversial or unproven in human head trauma.

Hyperventilation

Hyperventilation has been suggested as a method of quickly lowering ICP. Hypercapnia causes vasodilation and subsequent increases in ICP so hypoventilation should be avoided. Mechanical or manual ventilation may be used to lower partial pressure of carbon dioxide in the arterial blood ($PaCO_2$ <35 mmHg) to reduce ICP in deteriorating patients responsive to no other treatment and with no surgical lesions. The prolonged use of hyperventilation should be avoided as reduction in cerebral $PaCO_2$ less than 30–35 mmHg causes vasoconstriction which ultimately leads to decreased cerebral blood flow and ischemia.

Hypothermia

At this time, hypothermia is an experimental treatment which has not been validated in veterinary medicine and remains controversial in human medicine. Following trauma, the cerebral metabolic rate may be increased, leading to exacerbating secondary effects. Controlled hypothermia and induction of coma reduce cerebral metabolic rate and have been reported in human head trauma patients and recently in a veterinary patient. Hypothermia can be achieved by cooling a patient to a rectal temperature of 32–35 °C, which reduces cerebral metabolic rate and oxygen consumption, leading to decreased CBF and ICP. However, reduction of core body temperature carries risks and may lead to the development of cardiac arrhythmias, coagulopathies, electrolyte disturbances, hypovolemia, and insulin resistance. Coma may also be induced using barbiturates, but this prevents neurologic evaluation and requires induction of mechanical ventilation.

Surgery

Surgical intervention is reserved for patients that do not improve or deteriorate despite aggressive medical therapy. Advanced imaging (CT or MRI) is necessary for surgical planning and is also reserved for similar patients. Surgery may be indicated to remove hematomas, relieve intracranial pressure, or address skull fractures. Ventricular obliteration and mass effect identified on advanced imaging should be considered strong indicators for surgical treatment in any animal which does not improve with medical therapy.

Extraaxial hematomas can be removed through a generous craniectomy. Surgery in these patients may lead to significant hemorrhage requiring blood transfusions. Removal of hematomas may exacerbate bleeding as compression of bleeding vessels is removed, leading to reaccumulation of blood even after surgery. Intraaxial hematomas are typically managed conservatively. Surgery may be indicated in a deteriorating patient with subacute enlargement of a previously small hematoma.

Hemorrhagic parenchymal contusions can cause severe neurologic signs, depending on their location. They are typically managed conservatively. Cerebellar contusions causing fourth ventricle and brainstem compression are an indication for surgery in humans in an effort to reduce continued compression and the risk of herniation. Surgery for cerebellar contusions may be indicated prior to neurologic deterioration because these signs are less reversible with conservative management.

Intracranial hypertension should be treated initially with the therapies discussed previously. However, in about 20% of human head trauma patients, additional decompressive surgery is also required. Surgery is beneficial in deteriorating patients before irreversible brain damage occurs indicated by bilateral pupillary dilation. Surgical intervention for intracranial hypertension involves creation of a large craniectomy over the most affected site followed by a durectomy or duraplasty to allow the brain to swell.

Typically, skull fractures do not require surgical intervention. However, significantly contaminated, comminuted fractures may require surgical debridement, especially if

open. In dogs, such fractures of the frontal sinus may be associated with traumatic pneumocephalus and this should be considered in any dog deteriorating despite aggressive medical therapy. If surgical intervention is pursued, aggressive debridement should include removal of all devitalized tissues and bone and should be guided by imaging. Large bone fragments may be spared and replaced after thorough debridement, cleaning, and soaking in an antibiotic solution.

Following surgery, seizure and antibiotic prophylaxis are recommended. Phenobarbital at 2–3 mg/kg IV every 6–8 hours for 48 hours followed by maintenance parenteral therapy is advised. An alternative approach is to use levetiracetam at 20–60 mg/kg IV every 8 hours followed by 20 mg/kg orally every 8 hours.

Prognosis for Animals with Head Trauma

Prognosis is dependent on severity of neurologic signs and response to treatment. Potential complications associated with brain trauma include coagulopathies, pneumonia, sepsis, transient or permanent central diabetes insipidus, and seizures. Treatment in brain trauma patients should be immediate and aggressive if the animal is to survive and recover to a level that is functional and acceptable to the owner. The ultimate goal in the management of brain trauma in veterinary medicine is for the pet to maintain a good quality of life. Many patients can recover if systemic and neurologic abnormalities are identified and treated early. Dogs and cats have a remarkable ability to compensate for the loss of cerebral tissue, making it important not to make rapid prognostic conclusions based on the initial appearance of a pet suffering from brain injury.

Predicting the outcome for an individual patient can be difficult. Multiple prognostic factors have been identified in human medicine. The most important factors identified include age, cause of injury, Glasgow Coma Scale motor score, pupil response to light, and CT scan characteristics, including the presence of subarachnoid hemorrhage. Secondary insults of hypotension and hypoxia have also been found to add important predictive information.

The association between a patient's score using the MGCS and prognosis has been evaluated. This evaluation showed an almost linear correlation between score and probability of survival within the first 72 hours. Therefore, patients with a high score had a high probability of survival while patients scoring low on the MGCS were unlikely to survive. A score of 8 on the MGCS was associated with about a 50% chance of survival. The MGCS was recently evaluated with long-term survival at one and six months following injury. Again, a linear trend between MGCS and survival at one and six months was demonstrated. An association between MGCS and long-term patient outcome could allow prediction of acceptable patient recovery and aid in decision making at the time of injury.

In humans with head trauma, hyperglycemia on admission is a frequent component of the stress response to the injury, a significant indicator of severity of injury, and a potent predictor of the patient's outcome. A recent study in dogs and cats suggests that head trauma in these species may be associated with hyperglycemia and that the degree of hyperglycemia can be associated with severity of head trauma. However, the degree of hyperglycemia does not seem to be associated with outcome for dogs and cats with head trauma. Because hyperglycemia can potentiate neurologic injury, iatrogenic hyperglycemia should be avoided in patients with head trauma.

Seizures and Movement Disorders

Michael Podell, DVM, DACVIM (Neurology)

MedVet, Worthington, OH, USA

Seizures

Pathophysiology

Epilepsy is a heterogeneous disease of diverse etiology, electrophysiologic and behavioral seizure patterns, and responses to treatment. As such, the pathogenesis of epilepsy is multifactorial. Genetically determined seizure susceptibility factors play a crucial role in the response of the brain to triggering or precipitating factors, also known as the seizure threshold.

A basic tenet in the mechanism of epilepsy is the presence of an imbalance in excitatory and inhibitory neurotransmission. A seizure develops when the balance shifts towards excessive excitation. Glutamate is the principal excitatory neurotransmitter and gamma-aminobutyric acid (GABA) is the main inhibitory neurotransmitter involved in this process in the brain. Conditions leading to excessive excitation or loss of inhibition result in depolarization of neurons without normal regulatory feedback mechanisms. The result is a paroxysmal depolarization shift of a neuronal aggregate. In response to this sudden change in brain activity, local surrounding inhibitory zones are established to try to prevent the spread of this epileptogenic activity. If inhibition is unsuccessful, other neuronal aggregates are excited through thalamocortical recruitment, intrahemispheric association pathways or interhemispheric commissural pathways. Successful recruitment of a critical number of areas with synchronized depolarization then leads to a seizure (Figure 70.1).

History and Clinical Signs

Classification of seizures and epilepsy into a universally accepted, coherent and relevant scheme for clinicians has been an ongoing dynamic process in human epilepsy since the early 1980s. The standardized classification scheme for seizures and epilepsy established by the International League Against Epilepsy (ILAE) in the 1980s provided the first basis for a taxonomic foundation for an analytic approach in the diagnosis and treatment of epilepsy. The proposed diagnostic scheme consists of five levels or axes as proposed by Engel and revised by Berg *et al*. for people and Podell for dogs (Box 70.1).

Axis 1: Seizure (Ictal) Phenomenology

A seizure can be defined as a nonspecific, paroxysmal, abnormal event of the body. An epileptic seizure is defined by the ILAE as a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain. Thus, an epileptic seizure has a specific neural origin. Absolute confirmation that a seizure is epileptic may be difficult as it requires simultaneous observation of behavioral and electroencephalographic changes. As a result, historical information is often used to diagnose an epileptic seizure. The clinical features of epileptic seizures can be separated into four components.

1) The prodrome is the period prior to the onset of seizure activity. Owners report that they can "predict" the onset of their pet's seizures based on behavior exhibited during this time, such as increased anxiety-related behavior (i.e., attention seeking, whining), reluctance to perform normal activity patterns, and increased hiding (especially in cats).
2) The aura is the initial manifestation of a seizure. During this period, which can last from minutes to hours, animals can exhibit stereotypical sensory or motor behavior (e.g., pacing, licking), autonomic patterns (e.g., salivating, urinating, vomiting) and even unusual psychiatric events (e.g., excessive barking, increased/decreased attention seeking).

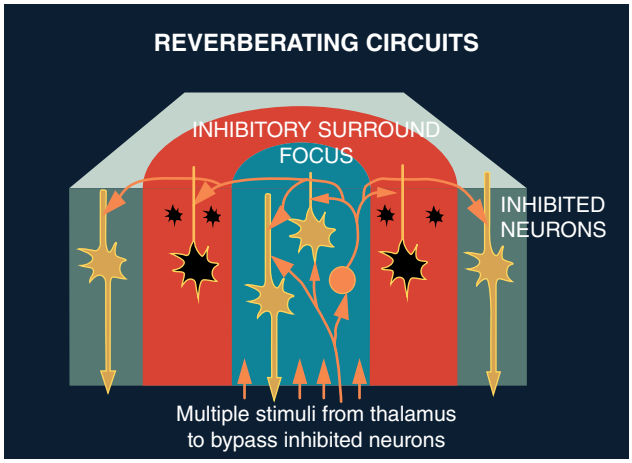

Figure 70.1 Pathophysiology of epileptic seizure generation. Reverberating circuitry between the cerebrocortical epileptic focus and the subcortical thalamic pathways provides a mechanism to overcome the natural inhibitory surround defense against seizure propagation that leads to expanding and propagating epileptic seizure foci in epileptic patients. This process can become a feed-forward, self-propagating mechanism of drug-resistant epilepsy when antiepileptic drug treatment is delayed.

3) The ictal period is the actual seizure event, manifested by involuntary muscle tone or movement and/or abnormal sensations or behavior, lasting usually from seconds to minutes.
4) The postictal period follows the actual seizure and can last from minutes to days. During this time, an animal can exhibit unusual behavior, disorientation, inappropriate bowel and/or bladder activity, excessive or depressed thirst and appetite, or actual neurologic deficits including weakness, blindness, and sensory/motor disturbances. Often, owners observe only the postictal period as evidence that their pet has had a seizure.

Regardless of the cause, a patient's epileptic seizures may be recurrent over time or may occur as a single event. If the patient has a chronic brain disorder characterized by recurrent epileptic seizures, then that patient has epilepsy. Status epilepticus can be defined as a state of continuous seizure activity lasting for five minutes or longer, or repeated seizures with failure to return to normality within 30 minutes.

Box 70.1 Diagnostic categorization for epilepsy

Axis 1: Seizure (ictal) phenomenology

- Seizure:
  - Epileptic seizure
  - Nonepileptic episodes
- Epilepsy
- Status epilepticus

Axis 2: Seizure type

- Focal:
  - Without impairment of consciousness or awareness
    - Sensory only (olfactory, hallucinatory)
    - Motor and/or autonomic components
      - Focal motor with or without automatisms
      - Autonomic only
  - With impairment of consciousness or awareness
    - Altered sensory and/or motor activity
    - Evolving to generalized seizure
- Generalized:
  - Tonic-clonic
  - Tonic only
  - Clonic only
  - Atonic only
  - Myoclonic (or any combination with tonic, clonic, and/or atonic)
- Absence
- Unknown cause

Axis 3: Epilepsy syndromes

- Electroclinical syndromes by age of onset
  - Neonatal
  - Infancy
  - Childhood
  - Adult
- Structural or metabolic syndromes
- Epileptic encephalopathies (progressive neurologic dysfunction)
- Unknown cause (idiopathic)

Axis 4: Etiology

- Genetic
- Structural (symptomatic)
  - Congenital
  - Acquired
- Metabolic
- Unknown
  - Cryptogenic
  - Idiopathic

Axis 5: Impairment from epilepsy

- Temporary (<1 week) vs prolonged (>1 week)
  - Motor: paresis, fatigue
  - Sensory: vision loss, somatosensory deficits
  - Behavioral: change in obedience, housebreaking, altered attention seeking, agitation, anxiety

Axis 2: Seizure Type

Epileptic seizures are divided into focal and generalized types. Focal seizures are the manifestation of a discrete, epileptogenic event in the cerebral cortex. The focal nature of this seizure type is associated with a higher incidence of focal intracranial pathology. Focal seizures can be associated with or without impaired consciousness or awareness and are typically characterized by motor or sensory disturbances.

Focal motor seizures are commonly seen as facial muscle twitching whereas sensory focal seizures are manifested by more abnormal behavioral disorders.

More complex behavior patterns with focal seizures include impaired consciousness, often with bizarre behavioral activity. Previously termed complex partial or psychomotor seizures, these events are now classified as automatisms or automotor seizures. Animals may show "fly-biting" behavior patterns, become aggressive without provocation, howl incessantly, become restless or exhibit a variety of motor disturbances. Cats may show a variety of abnormal behaviors or motor signs, including drooling, hippus, excessive vocalization or random, rapid running behaviors indoors. Whenever a focal seizure is suspected, the clinician should be suspicious of a focal cerebral disturbance and plan the diagnostic workup accordingly.

Generalized seizures are subdivided into tonic-clonic, tonic, clonic, myoclonic, atonic or absence types. The terms *convulsive* (grand mal) and *nonconvulsive* (petit mal) seizures are no longer in use. Generalized seizures originate from both cerebral hemispheres from the start, or more commonly progress secondarily from focal seizures. Unlike focal seizures, generalized seizures are not necessarily associated with focal cerebrocortical disease.

Epileptic spasms are currently classified as a discrete seizure type, as it has yet to be determined whether these events have a focal or generalized onset based on electroclinical data from humans.

Axis 3: Syndrome

By definition, a syndrome is a group of signs or characteristics that defines a particular combination of clinical abnormalities, often due to a specific genetic disorder. Epilepsy syndromes are not well defined in veterinary medicine, although familial epilepsies are now being identified with segregation analysis.

Axis 4: Etiology

Genetic (Idiopathic) Epilepsy

A diagnosis of genetic epilepsy is most common in purebred dogs with the first onset of seizures between 1 and 5 years old, a normal interictal neurologic examination, and if there is a lengthy initial interictal period (>4 weeks). A high percentage of these patients also exhibit cluster seizures. A genetic basis has been reported in numerous dog breeds, including Belgian shepherd dogs, border collies, poodles, beagles, springer spaniels, Shetland sheepdogs, vizslas, Irish wolfhounds, lagotto Romagnolos, and retrievers. True genetic epilepsy is much less common in cats due to their more diverse genetic background. As such, all cats should be evaluated for underlying structural or metabolic seizures before a diagnosis of genetic epilepsy is made.

Structural or Symptomatic Epilepsy

These types of epileptic seizures are the direct result of either structural brain pathology or metabolic disease. Younger animals are more prone to developmental and encephalitic diseases, while older dogs (>7 years of age) are more likely to develop intracranial neoplasia. As expected with underlying cerebral pathology, these animals are more likely to exhibit focal or multifocal neurologic deficits. However, focal lesions in "silent" cortical areas of the brain (e.g., olfactory, pyriform and occipital lobes) may have seizures as the only neurologic problem. This presentation has been seen in cats due to feline infectious peritonitis (FIP) and meningioma. Metabolic (formerly reactive) epileptic seizures are a reaction of the normal brain to transient systemic insult, toxic reaction or physiologic stresses. Animals of any age may be affected. Small-breed dogs are more predisposed to develop seizures secondary to portosystemic shunts at a younger age. Typically, a higher seizure frequency occurs initially until the underlying metabolic or toxic insult is corrected, but evidence of systemic illness is often present concurrently.

Unknown Cause of Epileptic Seizures

A variety of epileptic seizures arise without an apparent cause but are thought to have a more specific etiology. Previously termed or cryptogenic epileptic seizures, these events are believed to be due to an underlying unidentified brain disease. Many of these dogs are over the age of 7 without identifiable brain lesions but with a high prevalence of drug-resistant epilepsy, with close to 90% of the cases requiring more than one antiepileptic drug (AED) for treatment.

Axis 5: Impairment from Epilepsy

The majority of postictal signs in cats and dogs are transient, such as disorientation, visual impairment, salivation, incontinence, and altered behavior. More prolonged or recurrent seizure activity can lead to permanent sensory deficits (vision deficits), cognitive changes (altered obedience), and loss of normal personality. Chronic seizures have been shown to induce microglial activation and cerebral angiogenesis in Shetland sheepdogs with familial epilepsy.

Diagnosis

The most important component in approaching a seizure case is acquiring a thorough and accurate history. The purpose is to establish overall frequency, seizure type, patterns of occurrence, relationship to daily activity (e.g., exercise, sleep) and severity of postictal effects. Inquiries regarding the seizure event should address a description of the event, time of day, duration, and postictal effects. Video segments of events can be extremely helpful for clinicians to determine whether an epileptic event has occurred. Owners should be encouraged to video an event if possible and to try and distract the animal to determine whether the event can be terminated with external stimuli. Distractability often implies a nonepileptic event. A charting technique measuring seizure frequency and severity should be developed to aid objective evaluation of future therapeutic success. Owners should be provided with a calendar to record the frequency and description of all observed and suspected seizures.

The interictal status of cerebrocortical function (between seizures and after the postictal period) can be evaluated by asking questions concerning the animal's behavior, vision, gait, and sleep/wake patterns. For example, if the dog is more withdrawn or attention seeking, showing any unusual episodes of aggression or irritability, or fails to follow simple commands, then a structural cerebral problem should be suspected. Likewise, subtle gait disturbances (stumbling up or down the stairs), visual disturbances (occasionally bumping into objects on one side) and restless sleep patterns may indicate forebrain problems.

The sequence of diagnostic testing for any animal with seizures should proceed from the least to the most invasive (and expensive) modality. A complete blood count (CBC), biochemistry panel, urinalysis, and blood pressure measurement should be performed for all animals being evaluated for an epileptic seizure.

For dogs, additional testing is based upon the age, breed, seizure type, seizure frequency, and neurologic examination findings.

Advanced Metabolic and Infectious Disease Testing

Pre- and postprandial serum bile acid study with serum ammonia levels in dogs less than 1 year of age and those being started on hepatic metabolized antiepileptic drug (AED) therapy.

Other individual tests for toxin exposure (e.g., plasma lead, serum cholinesterase assay), parasitic or rickettsial infection, or systemic illness are based on the clinical picture at the time of presentation. For cats, basic screening should include a retroviral screen for feline leukemia and feline immunodeficiency virus and testing for serum antibodies to *Toxoplasma gondii*. Testing for the virus that causes feline infectious peritonitis is not recommended, as the correlation between a positive titer and active CNS infection is low.

Magnetic Resonance Imaging (MRI) Brain Scan

- All dogs 7 years of age or older and all cats with an initial onset of seizure(s), regardless of the seizure pattern or frequency or outcome of neurologic examination.
- Patients with an abnormal interictal exam or behavior.
- Drug-resistant epileptic patients.
- Cerebrospinal fluid (CSF) analysis is recommended in any animal with multifocal neurologic deficits or lesions observed on MRI scans or if the scan is normal.

Electroencephalogram (EEG)

Electroencephalogram analysis is beneficial for identifying underlying epileptic foci in the dog but the overall usefulness of this test for determining diagnosis and treatment has yet to be proven.

Therapy

Management of epilepsy in cats and dogs often requires a lifetime commitment by the owners. The owner must be willing to medicate their pet several times per day, travel to emergency clinics at unpredictable times, follow up with periodic reevaluations and diagnostic testing, and watch their pet carefully for adverse effects of therapy.

Despite all the time, financial, and emotional commitment, a significant number of dogs may still continue to have seizures. Thus, proper client education is critical in preparing owners for understanding their pet's condition and the potential associated lifestyle changes. In particular, owners need to know that a diagnosis of epilepsy implies an increased risk of premature death with the prognosis dependent on a combination of veterinary expertise, therapeutic success, and owner motivation.

Decision-Making Strategies for AED Therapy

The decision regarding when to start AED treatment is based on a number of factors, including etiology, risk of recurrence, seizure type and its effect on the patient, as well as the risk of treatment. Risk factors for seizure recurrence are not well established for cats and dogs. A number of relative risk factors have been identified in epileptic people, including current or previously defined cerebral lesions or trauma, the presence of interictal EEG epileptic discharges (up to 90% recurrence rate) and a history of marked postictal adverse effects (Todd paralysis). Evidence-based guidelines from several international groups are well established for humans based on the risk:benefit ratio and predictability factors of drug

effect. From these guidelines, several commonalities exist for guiding clinical practice, including confirmation of an epileptic seizure event and seizure type, obtaining a definitive diagnosis, knowledge that recurrent seizure activity is correlated with poorer long-term treatment success, and the influence of treatment on the patient's quality of life. Thus, the decision to treat is a reflection of the treatment goals to reduce or eliminate epileptic events, reduce seizure severity, avoid adverse effects, and reduce seizure-related mortality and morbidity.

Initiating Treatment

Overwhelming evidence exists in humans that there is no benefit in starting treatment after a single unprovoked event However, the earlier AED therapy is initiated, the better the potential outcome may be for seizure control.

Reasons to initiate AED therapy include the following.

- Structural epilepsy is diagnosed.
- Status epilepticus has occurred (ictal event of five minutes or longer).
- Two or more isolated seizures occur within a six-month period.
- Two or more cluster seizure events (two or more seizures within a 24-hour period) occur within a 2–3-month period.
- The first seizure is within one month of a traumatic event.
- Severe or unusual postictal effects are present (e.g., prolonged blindness, aggression).

Drug Selection

Selection of AED is based on a number of factors, including seizure type, efficacy, and tolerability. No evidence exists that any single AED provides a better outcome for adults with unprovoked epilepsy when early treatment is initiated. Monotherapy is still the recommendation for new-onset epilepsy. The use of a single AED has the advantages of no drug interactions, more predictable pharmacokinetic and pharmacodynamic properties, less potential for adverse effects, and less expense to the client.

Antiepileptic drugs are classified into three broad mechanistic categories which decrease either the seizure onset or spread of seizures:

- enhancement of inhibitory processes via facilitation of GABA action
- reduction of excitatory transmission
- modulation of membrane cation conductance.

Success Parameters

The treatment of epilepsy should be goal oriented and approached in an objective fashion. Eliminating or significantly reducing the number and severity of seizures and maintaining a normal lifestyle for both the patient and owner are all important considerations. Whilst many drugs may provide initial improvement in seizure control, long-term efficacy is dependent on many factors. With only approximately 60–80% of human and canine epileptic patients responding to treatment, evaluating the reasons for recurrent seizure activity (refractory epilepsy) is important.

These factors can be separated into three "Ds": Disease-related, Drug-related or Dynamic-related factors. Disease-related factors include the presence of an undiagnosed underlying brain disease, such as cortical dysplasia, prior trauma or an active disease process. Occult conditions can lead to localization-related epilepsy, where epileptic foci develop drug resistance due to architectural brain changes.

Drug-related factors include an ineffective mechanism of action, development of tolerance and alteration of the drug target or uptake over time. Seizure-specific therapy targets a drug for a specific seizure type, and inappropriate drug selection may result in poor control. The reasons for drug tolerance or loss of effectiveness can be categorized as either metabolic (pharmacokinetic) or functional (pharmacodynamic). Metabolic tolerance is due to altered drug metabolism, which occurs in an unpredictable fashion. As such, a change in drug dosage does not result in a parallel change in serum drug level. During this time, autoinduction of the cytochrome P450 enzyme system increases drug clearance and is not dose dependent. Serum drug levels decline over time with the same dose until steady-state clearance is achieved. Concomitant drug usage that either inhibits or stimulates the P450 system also alters hepatic metabolized AED levels. Functional drug tolerance, also known as pharmacoresistance, is due to reduced drug transport through the blood–brain barrier, long-term downregulation of the target receptor or genetic factors that alter cellular metabolism of the drug.

Dynamic-related factors are now being discovered in relation to gene polymorphisms that affect AED pharmacokinetic or pharmacodynamic properties. As a result, altered drug metabolism or action is no longer predictable when compared with the general patient population. In addition, a placebo effect has been demonstrated in epileptic dogs, indicating that nonpharmacologic therapeutic effects may play a role in canine epilepsy treatment.

First-Generation AEDs

Phenobarbital

Phenobarbital (PB) has the longest history of chronic use of all AEDs in veterinary medicine. It is a relatively inexpensive, well-tolerated drug and has documented success in preventing seizures. Phenobarbital has a high

bioavailability, being rapidly absorbed within two hours and with a maximal plasma concentration obtained within 4–8 hours following oral administration. Almost one-half of the drug is protein bound. The majority of phenobarbital is metabolized by the liver, with approximately one-third excreted unchanged in the urine. Phenobarbital is an autoinducer of hepatic microsomal enzymes (P450 system), which can progressively reduce the elimination half-life with chronic dosing.

Adverse Effects Overall, phenobarbital is well tolerated at therapeutic serum concentrations in the dog and cat. Idiosyncratic drug reactions to phenobarbital can be either behavioral or biochemically mediated. A more serious idiosyncratic reaction is development of an immune-mediated neutropenia or thrombocytopenia in dogs, as well as anemia. Rare acute, idiosyncratic hepatotoxic reactions may also be present, as evidenced by a rapid elevation of alanine aminotransferase (ALT) and abnormal dynamic bile acid levels. The drug should be stopped immediately if either neutropenia or dramatic elevations in ALT are noted and replaced with a nonhepatic metabolized AED.

The most serious and potentially life-threatening complications that can occur with long-term phenobarbital therapy are hepatotoxicity and development of superficial necrolytic dermatitis in dogs. Documentation of a serum phenobarbital concentration >35 µg/mL had the highest correlation with the development of hepatotoxicity. All animals on chronic phenobarbital therapy should have a routine biochemistry panel performed every 6–12 months to monitor for the development of chronic hepatotoxicity. A bile acid tolerance test should be performed to evaluate liver function if ALT levels suddenly increase or if the serum albumin level starts to decrease. Hepatotoxicity is uncommon to occur in cats.

Dosage and Monitoring The appropriate starting dose of phenobarbital is 2.5 mg/kg orally q12h in dogs and 2.5 mg/kg q24h in cats. An intravenous loading dose can be used to produce a rapid rise in serum blood concentration. This starting dose is the only time a weight-based dosage is used. All future adjustments should be based on serum drug concentrations in conjunction with clinical assessment.

The goal of drug level monitoring is to be proactive rather than reactive in seizure prophylaxis. Serial serum trough phenobarbital concentrations should be evaluated at 14, 60,180, and 360 days after the initiation of treatment, at six-month intervals thereafter, if the pet has more than two seizure events between these time points, and at two weeks after a dosage change. Although blood level fluctuations may not be dramatic throughout the day in dogs with steady-state concentrations, blood samples are best taken in the early morning, prior to dosing, in a fasted dog, to increase consistency in comparison with published information, maintain consistency in interpretation, and remove diurnal or dietary-induced fluctuations of absorption.

Adjustments in AED dosages are undertaken either to enhance the effect or to reduce the adverse effects. The most efficacious and safe trough therapeutic phenobarbital range is 15–30 µg/mL. An optimal starting level is between 20 and 25 µg/mL. Increments of 5 µg/mL are beneficial if seizures are occurring at an equal frequency or worsening after 30 days of therapy. Cats in general can tolerate higher serum levels in the 30–45 range without complications.

Adjustments of the trough phenobarbital levels can be calculated with the following formula:

$$\left(\text{Desired concentration} / \text{Actual concentration}\right) \times \text{total mg PB per day} = \text{Oral daily dose of PB}\left(\text{mg}\right)$$

Potassium Bromide

Potassium bromide can be used as either monotherapy or as an add-on AED of choice in the dog. Concomitant potassium bromide and phenobarbital administration decreased seizure number and severity in the majority of dogs in several studies, with seizure-free status ranging from 21% to 72% of all treated dogs. In general, many canine refractory idiopathic epileptic patients may benefit from potassium bromide. By allowing a reduction in the use of drugs metabolized by the liver, potassium bromide therapy may also reduce the incidence of hepatotoxicity. Bromide is not recommended for use in cats due to potential for life-threatening allergic asthmatic reaction.

Pharmacology A starting dose of 40 mg/kg/day potassium bromide is slowly metabolized in the dog, with a median elimination half-life of 15.2 days, Steady-state concentrations fluctuate between dogs, most likely due to individual differences in clearance and bioavailability. Dietary factors also alter serum drug concentrations, with high-chloride diets resulting in excessive renal secretion and lower serum concentrations.

Adverse Effects Potassium bromide is generally well tolerated in the dog. The most common adverse effects seen with potassium bromide and phenobarbital combination therapy are polydipsia, polyphagia, increased lethargy, and mild ataxia with increasing serum concentration. Pancreatitis and gastrointestinal intolerance have also been reported. Chronic use at higher serum concentations can result in pelvic limb ataxia and excess sedation.

Administration and Monitoring Potassium bromide can be administered at a starting dose of 40 mg/kg/day when used as sole therapy or 30 mg/kg/day when used as an add-on drug to phenobarbital. Potassium bromide serum concentration should be measured at one month and at the first steady-state concentration (approximately 8–12 weeks). The recommended goal is to achieve steady-state trough serum concentrations of 25 µg/mL for phenobarbital and 2000 mg/L for potassium bromide. The range is highly individualized according to the seizure pattern of each dog. Further reductions in phenobarbital can be attempted if a seizure-free period is maintained for six months. The dosage is adjusted according to the formulae given below.

Potassium bromide monotherapy is recommended for dogs with underlying liver disease, less frequent seizure activity (<3 per year) and for some dogs with idiopathic epilepsy. The use of potassium bromide monotherapy is not recommended for high initial frequency seizure activity, if secondary epilepsy is present, or if unwarranted adverse effects persist (e.g., weakness, extreme polydipsia).

Adjustment of bromide dose can be calculated with the following formula:

$$\begin{aligned}&(\text{Target Css} - \text{Actual Css}) \times (\text{Clearance/Bioavailability})\\ &= (2000\ \text{mg/L} - \text{Actual Css}) \times 0.02\\ &= \text{New mg/kg/day added to existing dose}\end{aligned}$$

where Css = steady-state concentration.

Second-Generation AEDs

Zonisamide

This is a substituted 1,2-benzisoxazole derivative that works by both blocking the propagation of epileptic discharges and suppressing focal epileptogenic activity. Broad-spectrum antiepileptic activity has been reported against a variety of seizure types, with particular improvement in the treatment of adult myoclonus epilepsy. Zonisamide can be an efficacious and well-tolerated drug in dogs with recurrent generalized seizures refractory to phenobarbital or potassium bromide therapy. Over 70% of dogs with refractory idiopathic epilepsy responded well to zonisamide add-on therapy in one study, with 58% responding favorably in another.

Pharmacology Zonisamide is well absorbed, has a relatively long half-life (18–28 hours) and high protein-binding affinity (70%) in dogs. In cats, zonisamide is more slowly metabolized, with a half-life of 33 hours. Zonisamide is hepatic metabolized and thus influenced by concurrent administration of other similarly metabolized drugs. Phenobarbital dosages should be reduced by 25% at the time of starting zonisamide due to the enhanced hepatic enzyme induction and clearance of zonisamide.

Adverse Effects The major adverse effects include sedation, dry eye, ataxia, inappetence, and vomiting, often related to metabolic and renal tubular acidosis. Cats are more likely to develop adverse effects of anorexia, vomiting, diarrhea, and ataxia at doses over 10 mg/kg/day. A decrease in circulating total serum T4 levels can occur and acute idiosyncratic hepatic necrosis has been reported in the dog. Patients with a history of sulfa drug hypersensitivity should not be prescribed zonisamide.

Dosage and Monitoring Zonisamide is available as a generic medication in dosages of 25 mg, 50 mg, and 100 mg. The starting dose in dogs is 10 mg/kg every 12 hours and 5 mg/kg once daily in cats. Trough serum drug levels should be obtained at 14 and 45 days, then every six months if no seizures are observed or in 10 days after a drug adjustment.

Levetiracetam

This is the *S*-enantiomer of the ethyl analogue of piracetam and has a unique mechanism of action mediated by binding to the presynaptic vesicular protein, SV2A, which decreases glutamate neurotransmitter. The drug has shown to be an effective add-on AED in the cat but not as conclusive in the dog.

Pharmacology In dogs, the drug is well absorbed, is rapidly metabolized with an estimated elimination half-life of 4–8 hours, and is predominantly renal excreted (>80%). However, wide fluctuations of drug metabolism occur in the dog. The oral dose should be increased when dogs are receiving phenobarbital concurrently as lower serum levels can potentially be related to the induction of serum hydrolases. A new extended-release formulation of levetiracetam has been shown to have a half-life in excess of seven hours in dogs following oral administration, giving rise to the potential for twice-daily administration

Adverse Effects Levetiracetam is the best tolerated of all the current AEDs used in veterinary medicine. Sedation is the most common initial adverse effect that typically dissipates over time.

Dosage and Monitoring The initial dose of 10–20 mg/kg orally q12h is gradually incremented to ≥20 mg/kg orally q8h. The therapeutic range is not well defined and drug monitoring is recommended only to establish the pharmacokinetic pattern of the individual patient.

Drug tolerance over time, known as the "honeymoon effect," can occur. However, wide individual patient drug metabolism may be associated with this phenomenon. As such, this author advocates incremental escalation by 10 mg/kg/dose per week when seizures persist to a maximal tolerated dose. No upper limit dosage exists due to a high therapeutic index (safety) for this drug. A parenteral formulation is available for intravenous loading at 40–60 mg/kg over 15–30 minutes in a 1:1 diluted saline solution.

Third-Generation AEDs

Lacosamide

This is a functionalized amino acid proven to decrease neuronal discharge frequency and synaptic excitability. The postulated mechanisms of action include selective slow inactivation of sodium channels and novel binding to collapsin response mediator protein-2. In humans, the drug is well absorbed, has minimal first-pass effect with predominant renal excretion, low protein binding, favorable drug–drug interactions with other AEDs, and is well tolerated. Clinical trials in humans have demonstrated a comparable decrease in seizure frequency with that of levetiracetam and zonisamide at a dose of 100–200 mg orally q12h. A parenteral formulation is available for intravenous loading. The author has used lacosamide to successfully treat refractory idiopathic epilepsy in dogs at a dose range of 5–10 mg/kg q12h.

Rufinamide

This novel drug is structurally unrelated to any other AED. Its main mechanism of action is related to prolongation of the inactive state of the sodium channel, thus preventing neuronal depolarization. In humans, the drug is absorbed slowly and has low bioavailability. Renal excretion is high and no induction of the hepatic P450 system has been found, although other hepatically metabolized drugs decrease the serum concentration. Of a total of nine double-blinded studies in humans, five revealed a positive effect of rufinamide to treat refractory partial seizures but not generalized seizures. In beagle dogs, the mean terminal half-life ranged between five and 14 hours. In people, dose-dependent adverse effects include sedation, fatigue, and dizziness. Initial dosing in the dog is 20 mg/kg q12h. Serum concentration can be monitored to achieve a therapeutic range of 10–25 μg/mL. A parenteral formulation is not currently available.

Imepitoin

This drug is the first AED that acts as a low-affinity partial agonist at the GABA-A benzodiazepine receptor site. The advantage is that imepitoin is associated with fewer adverse effects of sedation and ataxia, and is less likely to develop functional drug tolerance or physical dependence, compared to the full agonist AED drugs like phenobarbital and diazepam. Imepitoin was recently approved for use in canine epilepsy in Europe and is undergoing clinical investigation for FDA approval in the United States.

A summary of AED therapy is shown in Table 70.1.

Movement Disorders

Cats and dogs can develop a variety of unusual movement disorders that bewilder even the most seasoned clinicians due to the difficulty in determining their neuroanatomic origin and etiology. Movement disorders include a wide range of neurologic disturbances, characterized by either excess (hyperkinesia) or reduced (bradykinesia) movements. These abnormal involuntary movements (AIMs) refer to a number of muscle jerks, twitches, postures, and oscillations that have been classified in human neurology with official terms such as tic, chorea, tremor, dystonia, and myoclonus. Uncontrolled muscle contractions may be of muscle or neuronal origin.

History

The saying "A picture is worth a thousand words" is made for movement disorders. The ability to visualize the characteristics of AIMs should be supplemented with a detailed history to characterize the nature of the movement disorder. Information regarding anatomic distribution, rhythmicity, amplitude, frequency, speed of onset and offset of the movement, relationship to posture and activity, situations that alleviate or exacerbate the movement, presence or absence during sleep, and affected littermates are all essential to help determine the neuroanatomic localization and potential etiology. If the movement disorder is not present at the time of the examination, owners should be encouraged to video the events for future review. Many times, the initial few minutes of observation will solidify the clinical perspective, allowing an accurate diagnostic and therapeutic course of action to proceed.

Etiology and Pathophysiology

The process of initiation and completion of voluntary movement is a complex one that relies on coordination of serial communications between multiple components of the central and peripheral nervous system. Failure of any of these components to complete their assigned tasks can result in either loss of the desired movement or excessive, abnormal movements. A summary of movement disorders in dogs is provided in Box 70.2.

Table 70.1 Summary of antiepileptic drug therapy in the dog

	Clinical pharmacology								
Drug	**$T_{1/2}$ (h)**	**Tss (d)**	**Vd (L/kg)**	**Protein binding (%)**	**Therapeutic range**	**Dosage**	**IV load dose**	**Monitor**	**Guidance advice**
Bromide	20–46 days	100–200	0.45	0	Monotherapy: 1000–3000 mg/L; with phenobarbital at 1500–2500 mg/L	40–60 mg/kg orally q24h	3 % Sodium bromide 800 mg/kg/24h	At 1 and 3 months and then q6 months or q1 month post dose change	Synergistic effect with PB No hepatotoxicity Inexpensive
Clorazepate	5–6	1–2	1.6	85	20–75 µg/mL (nordiazepam)	2–4 mg/kg PO q12h	No	NR	Longer acting than diazepam Complex partial seizure therapy Inexpensive
Felbamate	5–6	1–2	1.0	25	25–100 mg/L	20 mg/kg PO q8h	No	NR	Complex partial seizure therapy Risk of blood dyscrasia Expensive
Gabapentin	2–4	1	0.2	0	4–16 mg/L	10–20 mg/kg PO q8–12h	No	NR	For use with liver compromised patients
Levetiracetam	4–8 and 2–4 with PB	2–3	0.5	<10	Variable	10–40 mg/kg orally q8–12h	30–60 mg/kg/15 min	Only to establish if elimination half-life is very short	Very well tolerated Minimal liver metabolism Use in older patients first
Phenobarbital	24–40	10–14	0.8	40	15–35 mg/dL Optimal level is 20 mg/dL	2.5 mg/kg orally q12h	16 mg/kg/5 min	At 14, 45 and 180 days, then q months or 14 day post dose change	Effective and predictable all seizure types Close monitoring first 3 months is essential
Zonisamide	15–20	3–4	1.5	50	10–40 µg/mL	5–10 mg/kg PO q12h	No	At 2 and 6 weeks then q6 months or 14 day post dose change	Effective and predictable all seizure types Well tolerated Generic available
Lacosamide	ND	ND	ND	ND	ND	5 mg/kg q12h	3 mg/kg/15 min	ND	Well tolerated Very expensive
Rufinamide	5–14	2–4	ND	ND	ND	20 mg/kg PO q12h	No	At 1 week and q6 months	Well tolerated Very expensive

IV, intravenous; ND, not determined; NR, not recommended; PB, phenobarbital; PO, by mouth (*per os*).

Box 70.2 Classification of hyperkinetic movement disorder types

Neuromuscular disorders
- Myotonia
- Tetany and tremor
  - Hypocalcemia
- Fasciculations
  - Benign
    - Exercise
    - Stress
  - Toxicity
  - Metabolic: hypercalcemia
  - Other causes of neuropathy
- Myokimia
- Environmental (hypothermia)

Central nervous system disorders
- Noncerebellar
  - Myoclonus
    - Spinal
    - Proprioceptive
    - Epileptic
    - Toxicity
  - Tetanus
  - Tremor
    - Essential
    - Toxicity
    - Idiosyncratic drug-induced
    - Metabolic
      - Hypoglycemia
      - Hepatic or uremic encephalopathy
    - Degenerative disease
- Cerebellar-related tremor disorders
  - Congenital
    - Neonatal syndromes
      - Hypoplasia
      - Malformation
      - Granuloprival degeneration
      - Hypo-dysmyelinogenesis
      - Axonopathy
    - Postnatal syndromes
      - Abiotrophy
      - Lysosomal storage diseases
  - Acquired
    - Inflammatory
      - Infectious
      - Immune-mediated
    - Neoplasm
    - Vascular/traumatic
    - Toxin
    - Idiopathic

Hyperkinetic Movement Disorders

Myotonia

Myotonia is a sustained muscle contraction with delayed relaxation. Myotonia congenita has been reported in the chow chow and miniature schnauzer dog breeds, and seen sporadically in a number of other breeds. The disease is due to a failure of normal myocyte chloride conductance resulting in delayed muscle hyperpolarization, and therefore delayed relaxation. As an inherited autosomnal recessive disease, puppies are affected from birth. Clinical signs are seen within the first few months of life and characterized by a stiff, "sawhorse" stance upon ambulation, with improvement in gait as exercise time increases. Some dogs may suffer from dysphagia and respiratory problems due to contraction of the tongue and oropharyngeal muscles. Affected dogs have hypertrophied glossal and proximal appendicular muscles that exhibit percussion dimpling upon being struck with a percussion hammer.

Electromyographic recordings demonstrate the classic myotonic discharge of a high-frequency waxing-waning spontaneous discharge that produces a "dive-bomber" or revving motorcycle sound. Muscle biopsy is typically normal. Treatment revolves around avoiding excessive exercise in the cold and maintaining a normal exercise routine, as drug therapy has not been shown to be effective.

Tetanus and Tetany

Tetanus is a continuous sustained extensor muscle contraction. The cause is the tetanus toxin released by *Clostridrium tetani* bacterial infection of domestic animals. The disease occurs when the tetanus spores localized to an anaerobic environment, such as a necrotic wound, transform into the toxin-producing form. The exotoxin, tetanospasm, travels from the infected site via peripheral nerves to the central nervous system. The toxin prevents the release of the inhibitory neurotransmitter glycine from interneurons in the spinal cord and brain, resulting in excessive excitation of brainstem and motor neurons.

Both cats and dogs are fairly resistant to tetanus. When infected, they can exhibit an extreme stiffness progressing to extensor rigidity of all limbs, spastic facial muscles and trismus within 5–10 days of infection. A "grimacing" expression with the ears pulled back is usually seen. Occasionally, localized tetanus may affect only a single limb or be confined to the facial muscles. Many

animals are hypersensitive to external stimuli. The diagnosis is based predominantly on a history of recent wounds and clinical signs. Initial treatment consists of aggressive wound debridement, parenteral penicillin or metronidazole treatment, muscle relaxant therapy (diazepam constant-rate infusion at 0.3 mg/kg/h or pentobarbital 3–10 mg/kg IV to effect) and nutritional support. Tetanus antitoxin (100–1000 IU/kg IV) has been reported to reduce the duration of clinical effects. A test dose of 0.2 mL SC should be given first to test for anaphylactic reaction. Careful attention should be given to hydration and nutritional support, as the trismus can prevent adequate fluid and food intake. Complete remission of clinical signs will usually occur within several weeks to months.

Tetany is a variable and intermittent extensor muscle contraction. It may accompany both central and peripheral nervous system diseases. In dogs, tetany is most commonly seen with hypocalcemia-associated parturition or hypoparathyroidism. Total calcium is typically below 7.0 mg/dL. Dogs will often suffer from an inability to rise, extensor muscle contractions, and hyperthermia (from muscle contractions). Secondary hypoglycemia may also be seen due to the excessive muscle movements. Treatment is focused on initial muscle relaxation with benzodiazepines, followed by calcium and vitamin D supplementation.

Myoclonus

Myoclonus is defined as a sudden, rapid, involuntary muscle movement of short duration caused by active muscle contractions (positive myoclonus) or pauses in muscle activity (negative myoclonus). Classification can be by clinical presentation, site of origin, or etiology. Reflex myoclonus to auditory stimuli has been reported in the retriever dog breeds. Spinal myoclonus arises from abnormal neuronal discharges originating in the spinal cord and is of two main types: segmental and propriospinal. Segmental myoclonus can occur in canine distemper-infected dogs, producing a repetitive, myoclonic jerk motion of one or more limbs, even during sleep. Epileptic and drug-induced myoclonus in dogs are examples of an etiologic classification.

Fasciculations and Myokimia

Muscle fasciculations are spontaneous contractions of muscle fibers within a motor unit and arise from ectopic electrical activity in the distal axons. Fasciculations typically are the manifestation of irritability of the neuronal cell body (motor neuron) or its accompanying axons. As such, they are most often associated with motor neuron disease and peripheral nerve disorders. Fasciculations can be more readily observed in the distal appendicular muscles and the tongue but can be difficult to detect in more obese animals. One can usually detect a fine "rippling" movement of the muscle as a sign of fasciculation.

The differential diagnoses of muscle fasciculations range from the benign to the more severe neuromuscular disease. Benign, or contraction, fasciculations can be seen after strenuous exercise and possibly in very tense animals. Other transient muscle fasciculations can be associated with hypercalemia, hypomagnesemia, and certain toxic drug reactions, to include theophylline, terbutaline, caffeine and methylxanthine (chocolate toxicity), and anticholinesterase agents (i.e., pyridostigmine and neostigmine used for the treatment of myasthenia gravis). Fasciculations associated with neuromuscular disease are most likely to be present after the onset of clinical signs of weakness. Degenerative feline and canine motor unit disease and more advanced cases of distal axonopathy in the dog are conditions that are more likely to be associated with muscle fasciculations.

Myokimia is a pattern of abnormal muscle contraction that produces a "rippling" or "writhing" appearance of the area involved. The change is the result of spontaneous discharges of large motor units. Myokimia is an indication of neuronal disease followed by sprouting of the motor unit territory in response to the denervation. Myokimia or myokimia-like syndrome has been described in Jack Russell terriers and is associated with hyperthermia and collapse.

Tremor Syndromes

A number of tremor syndromes have been described in affected humans that are also seen in small animals. Tremor is defined as a rhythmic oscillation of a body part and classified according to its anatomic distribution, frequency (tremors/s, or Hertz) amplitude (fine or coarse with increasing severity), presence at rest, standing (posture), or movement or performance of specific tasks (intention), The degree of tremor (amplitude) is often variable, and can be exacerbated with emotional (anxiety) and physical activity and stimulant drugs (e.g., caffeine). The two main types of tremor are known to occur either at rest or with action. Rest tremor describes an involuntary, rhythmic oscillation of a body part completely supported against gravity. This tremor could be seen in a leg with the animal lying down and not supporting weight. Action tremor occurs during voluntary contraction of skeletal muscle and is classified as postural, kinetic, isometric or task-specific. Kinetic tremor describes oscillation during guided voluntary movement, also known as an intentional tremor, and is the most common type seen with cerebellar disease in small animals.

Essential Tremors

Physiologic and essential tremor syndromes are the most common in people and can occur in older dogs, in

particular aging terrier breeds. In dogs, it is a pure clinical syndrome characterized by progressive action tremor of pelvic limbs, starting with posture that worsens with activity and excitement. Severity can range from barely perceptible tremor to altered gait and balance problems. Signs can progress as the dog ages.

Tremor Associated with Neuromuscular Disease

Tremor attributed to weakness is almost always associated with underlying nerve disease. Most likely, this type of tremor is an exaggeration of the normal physiologic tremor that results from the synchronized discharge of enlarged motor units in patients with a reduced number of surviving motor neurons. Dogs with advanced peripheral neuropathies can present with this type of tremor in the pelvic limbs. The tremor is exaggerated after exercise and while standing. Other conditions that directly affect nerve function with this type of tremor include compressive neuropathy from lumbosacral disk disease or stenosis, nerve sheath tumors, and other mass effects or entrapment syndromes involving the nerve.

Drug-Induced Tremors

Drug-induced tremor has been reported in the cat and dog. Predictable tremor can be seen with stimulant toxicity (e.g., caffeine, amphetamines, cocaine, etc.). Other potential drugs that have induced tremor in humans include valproic acid, amiodarone, procainamide, and lithium. Tardive dyskinesia represents a wide variety of involuntary movements in humans, including chorea, dystonia, akathisia, myoclonus, tremor, and stereotypies. Stereotypy, or rhythmic involuntary movements, is the most common manifestation resulting from exposure to dopamine receptor-blocking agents, such as phenothiazine (e.g., acepromazine) or antiemetic drugs (e.g., metoclopramide).

Cerebellar-Related Tremors

By far the most common cause of tremor in small animals is cerebellar syndromes and disease. Cerebellar diseases are often associated with a conglomeration of signs related to abnormal motor activity to include any or all of the following: tremors, bilaterally symmetric ataxia without paresis, dysmetria, vestibular signs (head tilt, nystagmus, falling), absent menace with preservation of vision, and pupillary changes. An altered resting posture is often present, with affected animals demonstrating truncal ataxia (swaying of the body back and forth or side to side) and compensatory broad-based stance for balance, known at titubation (cerebellar postural tremor). Cerebellar tremors are associated with diffuse cerebellar cortical diseases. These intention tremors are characterized by a fine head tremor that worsens with initiation of voluntary head movements. The more acute-onset diseases affecting the cerebellar cortex usually result in more pronounced tremor disturbances. Severe action-related tremors may affect the entire body, with complete loss of all muscular coordination, and failure to posture and prehend food. Ensuing hyperthermia, rhabdomyolysis, and related complications from continuous muscle activity require that these patients be aggressively treated on an emergency basis (see later). Fortunately, many "pure" cerebellar diseases can be treated and/or compensated for by the patient.

Cerebellar syndromes associated with tremor can be divided into congenital and acquired diseases (see Box 70.2). Congenital neonatal syndromes represent diseases of the newborn animal in which the clinical signs are present from birth and nonprogressive. In contrast, the clinical signs of congenital postnatal diseases begin in the pediatric animal after birth and are slowly progressive. Acquired cerebellar diseases can be either acute or chronic in onset, with rapid progression most commonly seen with inflammatory diseases and toxic exposures (e.g., mycotoxins, metaldehyde, macadamia nuts).

Diagnosis

The diagnostic approach to an animal with AIMs starts with an evaluation of whether the movement disorder is hyperknetic, hypokinetic or paroxysmal (Figure 70.2). The next step is to determine if the animal exhibits any signs of tremor of the head, neck or other areas of the body. Animals without tremor should then be evaluated for signs of excessive rigidity or stiffness. Constant extensor muscle rigidity is more likely to be a sign of tetanus, while variable extensor muscle rigidity is associated with tetany. An initial metabolic evaluation of a complete blood count, serum chemistry panel, ionized calcium, and creatine kinase should be performed. Tetanus is diagnosed predominantly on clinical signs and history, while tetany is diagnosed typically on the presence of hypocalcemia or other metabolic disorder.

If no extensor muscle rigidity is detected, then signs of abnormal muscle movement of myotonia, fasciculation, or myokimia should be suspected. These signs are all indicators of underlying neuromuscular disease, and as such merit further specific diagnostic testing for either peripheral neuropathy or myopathy. Again, an initial metabolic evaluation of a complete blood count, serum chemistry panel, ionized calcium, and creatine kinase should be performed. The next level of testing would be electrodiagnostic evaluation with electromyography and nerve conduction testing. Electromyography (EMG) tests the stability of the muscle membrane.

If tremor is present as part of the history or clinical examination, then the next step is to determine if any paresis is present. Care must be taken not to confuse

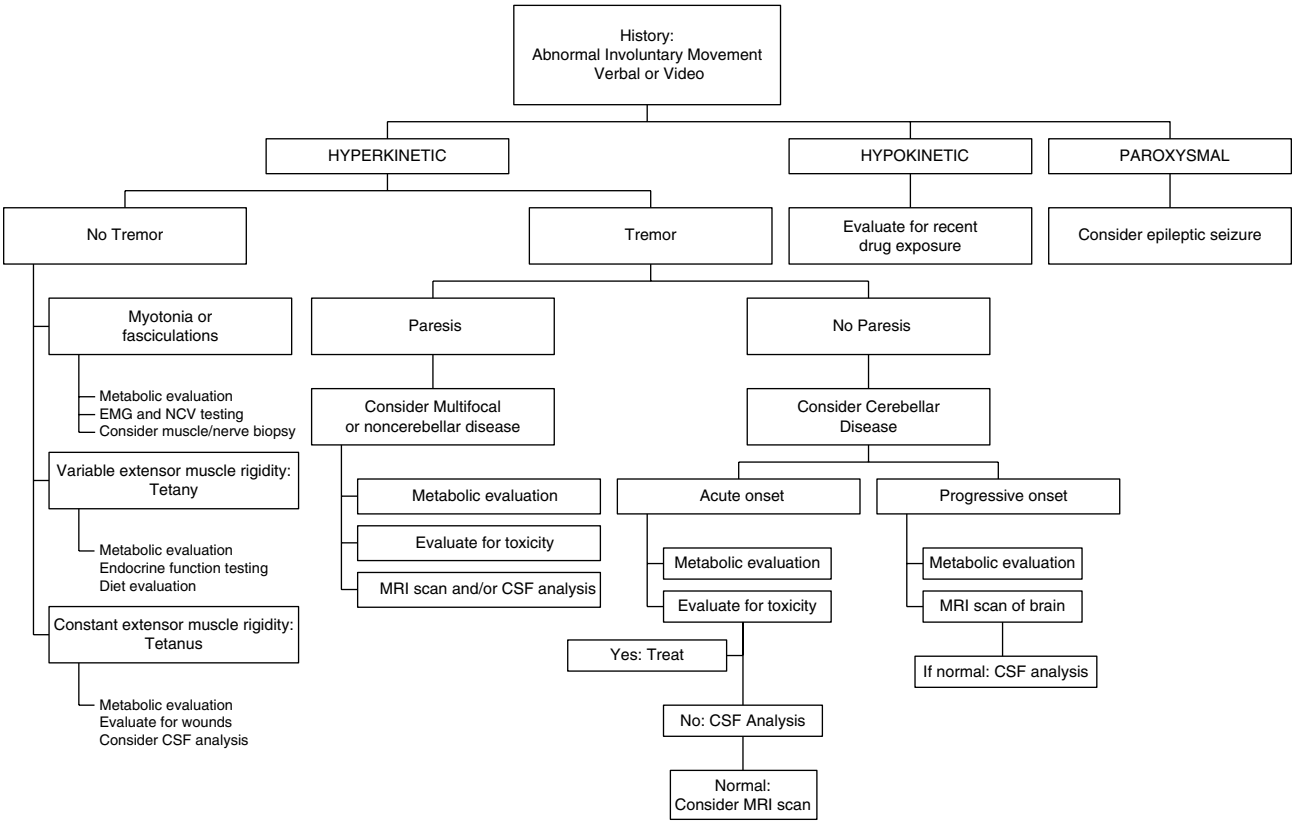

Figure 70.2 Diagnostic paradigm for hyperkinetic movement disorders.

weakness with falling from incoordination. A reliable test is to hop an animal on each leg individually to see if it will collapse on that leg during testing. A weak animal will not be able to support weight on that limb, while an uncoordinated one will. If paresis is present, then one should consider either a multifocal or noncerebellar central nervous system disease. A history of possible toxicity exposure should be ruled out prior to pursuing more advanced testing. If the metabolic evaluation is normal as stated above, then a MRI scan of the brain and/or spinal cord with possible cerebrospinal fluid (CSF) analysis is warranted to evaluate for the underlying etiology.

If paresis is not present with the tremor syndrome, then it is most likely that the animal is suffering from a pure cerebellar disease process. Acute onset of clinical signs is now more suggestive of either a toxic reaction or inflammatory disease process. If toxicity is documented, then no further diagnostic testing may be needed, and symptomatic therapy can be instituted. If toxicity cannot be documented, then a CSF analysis is recommended. If the CSF is normal, then MRI scanning of the brain may be necessary. If the disease process is more chronic and progressive in nature, then the patient should be evaluated for a possible mass lesion of the cerebellum with an MRI scan prior to collection of CSF for analysis.

Treatment

The goal for the control of tremors in small animals is to determine the etiology, remove any inciting cause (toxin or iatrogenic), and provide immediate and prolonged symptomatic relief for acquired diseases. A number of treatments for essential tremor have been proposed for people, with varying results. First-line treatments useful in the dog include phenobarbital at 2.5 mg/kg PO BID, or a beta-adrenergic antagonist (propranolol 2.5–10 mg PO BID to TID). Benzodiazepines appear not be effective in humans or dogs (personal experience). Topiramate, has recently been shown to be efficacious in refractory essential tremor cases in humans at a dose range of 100–200 mg/day.

Recommended emergency treatment for acute onset of suspected acquired tremor disease should be based on an IV loading dose of diazepam or midazolam at 0.5 mg/kg IV followed by constant-rate infusion (CRI) of either drug at 0.5 mg/kg/h in 0.9% saline at 1.5 times the maintenance fluid rate. This situation can be life-threatening and requires a rapid therapeutic approach. Adjuvant therapy to stabilize hyperthermia should be given.

Disorders of the Forebrain

Sam N. Long, BVSc, PhD, DipECVN

Centre for Animal Referral and Emergency, Melbourne, Australia

Anatomy/Function

The forebrain, also known as the prosencephalon, encompasses the two cerebral hemispheres, together with the diencephalon (the most rostral part of the brainstem, itself consisting of the thalamus, hypothalamus, and epithalamus). It is regarded as a region of the brain separate from the rest of the brainstem because it is separated in part by the tentorium cerebelli from the other main compartment within the cranial vault, the caudal fossa. In addition, the forebrain is responsible for those functions in both animals and humans which are commonly thought of as the "higher" functions: memory, behavior, personality, learning, and integration. It is the forebrain that receives information from the outside world, integrates it with memory and other functions, makes decisions based on this information and predicts the outcomes of those decisions in order to select the most appropriate one. Anatomically, this occurs within what are known as the association areas. Rather than being a distinct area of the brain, the association areas are a dense, interconnecting network of interneurons with short axons and widespread dendrites that essentially have no beginning and no end. In dogs and cats, the association areas represent approximately 20% of the cerebral cortex compared with approximately 85% in humans.

The other main areas within the cerebral cortex are the projection areas. These regions are the primary sensory and motor cortex (responsible for receiving sensation and generating motor program output), the primary visual and auditory centers (for receiving vision and hearing), and the rhinencephalon (responsible for receiving olfactory information – evolutionarily this is the most primitive part of the brain).

Sitting between and below the cerebral hemispheres, and connecting them to the rest of the brainstem, is the diencephalon. The most important functional components of the diencephalon are the thalamus, a major gateway for all information entering and leaving the cortex, and the hypothalamus, which houses higher control over the major endocrine systems such as the pituitary–adrenal axis and thyroid function, amongst others, as well as regulating temperature, appetite, and sodium homeostasis.

The clinical significance of these anatomic structures is that disorders affecting the forebrain result in the clinical signs detailed in Table 71.1.

Etiology/Pathophysiology

Lesions within the forebrain can arise as one of a number of pathologic processes, often categorized using the DAMNIT-V system (Degenerative, Anomalous, Metabolic, Neoplastic/Nutritional, Inflammatory, Traumatic/Toxic and Vascular). A complete list of differential diagnoses is provided in Box 71.1.

It is important to note that clinical signs are dependent not on the nature of the lesion/disease, but on where it arises (and how rapidly). A patient presenting with signs of right-sided forebrain disease (e.g., circling, unilateral blindness in the left eye with normal pupillary light reflexes, left-sided proprioceptive deficits) may be suffering from any one of the following diagnoses: an ischemic infarct, a primary brain tumor, granulomatous meningoencephalitis, or a bacterial abscess. For this reason, details of history and signalment are extremely important to collect since they provide the only way of narrowing this list of differentials.

Table 71.1 Clinical signs of forebrain disease

Clinical sign	Notes
Seizures	Can occur with lesions in the cerebral hemispheres, thalamus or hypothalamus
Propulsive walking	
Circling	Patients with forebrain disease circle towards the side of the lesion, but without signs of vestibular disease (no head tilt or nystagmus present)
Head pressing	
Obtundation	Obtundation describes decreased responsiveness to normal stimuli. This is often a sign of bilaterally symmetric, global cerebral hemisphere disturbance. Further disturbance of level of consciousness (i.e., stupor or coma) is more likely to signify the presence of a brainstem lesion
Contralateral cortical blindness	Absent menace response (as a result of absent vision) with normal consensual and indirect pupillary light reflex occurs as a result of lesions in the occipital cortex or affecting the internal capsule, caudal to the level of the lateral geniculate nucleus, on the side opposite the affected eye
Proprioceptive deficits	Patients with forebrain disease often have a relatively normal gait but significant proprioceptive deficits that are only evident on testing or on negotiating stairs or other difficult terrain
Decerebrate rigidity	Decerebrate rigidity (increased extensor tone in all four limbs with opisthotonus) indicates severe, bilateral forebrain disease and is a reflection of functional disconnection of the cerebral peduncles from the brainstem
Hemi-inattention syndrome	This occurs rarely as a result of lesions affecting the sensory cortex and is most commonly evident while eating. Patients with hemi-inattention syndrome will eat one half of a bowl of food, apparently ignoring the other half unless it is rotated 180°. The lesion is situated within the cerebral hemisphere contralateral to the "ignored" side of the body
Behavioral/memory changes	The most commonly noted behavioral and memory changes seen in patients with forebrain disease include loss of toilet training, loss of recognition of family members or toys, and changes in personality
Vestibular signs	Lesions in the thalamus will rarely produce vestibular signs. This is most commonly reported in patients with cerebrovascular accidents

Box 71.1 Differential diagnoses for forebrain disease according to underlying etiology

Degenerative	Lysosomal storage diseases
	L2-hydroxyglutaric aciduria in Staffordshire terriers
Anomalous	Hydrocephalus
	Lissencephaly
	Porencephaly
	Hydranencephaly
	Meningoencephalocele (Dandy-Walker syndrome)
Metabolic	Hepatic encephalopathy
	Renal (uremic) encephalopathy
	Hypoglycemia
	Electrolyte abnormalities: hypo/hypernatremia
	Hypothyroid myxedema coma
Neoplastic	Meningiomas
	Glial tumors:
	Oligodendrogliomas
	Astrocytomas
	Ependymomas
	Choroid plexus tumors
	Pituitary tumors
	Metastatic disease
	Lymphosarcoma
Nutritional	Thiamine deficiency
Infectious/inflammatory	Viral: distemper, feline infectious peritonitis, rabies, Borna disease virus
	Protozoal: *Toxoplasma*, *Neospora*
	Fungal: *Cryptococcus*, *Aspergillus*, blastomycosis, others (pheohyphomycotic encephalitis)
	Rickettsial: Rocky Mountain spotted fever, *Ehrlichia*
	Bacterial: abscess; meningitis
	Parasitic: *Cuterebra*, verminous encephalitis
Inflammatory (noninfectious)	Granulomatous meningomyeloencephalitis
	Necrotizing encephalitides
Idiopathic	Idiopathic epilepsy
Toxins	Lead
	Organophosphate
	Metronidazole
	Cyanide, sodium fluoroacetate, hydrocarbons, other heavy metals
Vascular	Hemorrhagic and ischemic infarcts
	Feline ischemic encephalopathy

Degenerative and Developmental Causes

Storage Diseases

There are a large number of diseases caused by congenital deficiencies in the enzymatic pathways that are involved in degrading lysosomal waste products within cells. The biochemical pathways involved are complex but the majority of described storage diseases involve a deficiency of a lysosomal acid hydrolase enzyme. A deficiency in any one enzyme leads to a build-up of undegraded products within lysosomes in the cell's cytoplasm which ultimately enlarge and cause the death of the cell. Although cells in all body organs are affected, neurons are especially vulnerable since they are postmitotic, permanent cells. Most of these conditions affect young animals at early ages, affect both males and females, and are autosomal recessively inherited. Most commonly, the initial clinical signs are referable to cerebellar dysfunction but two in particular, alpha-fucosidosis and ceroid lipofuscinosis, may show up with signs of forebrain disease initially, including behavioral changes, dullness and vision abnormalities (typically abnormal depth of vision or inability to focus rather than blindness), followed by generalized ataxia, dementia, tetraparesis, tremors, and seizures. Affected breeds include border collies, Tibetan terriers, English setters (ceroid lipofuscinosis), and springer spaniels (alpha-fucosidosis).

In alpha-fucosidosis, the diagnosis can occasionally be made on hematologic examination (40% of lymphocytes may have cytoplasmic vacuoles) or genetic testing. In ceroid lipofuscinosis, skin biopsy and demonstration of autofluorescent pigment may confirm the diagnosis. Imaging studies and cerebrospinal fluid (CSF) taps are typically normal and CSF may be normal or show vacuolated macrophages (alpha-fucosidosis). Generally, these diseases are progressive and nontreatable, with death occurring by the second or third year of life, although gene therapy has been shown to reverse clinical signs in a feline model of alpha-mannosidosis, suggesting gene therapy may one day become available.

L2-Hydroxyglutaric Aciduria

This is a poorly characterized condition reported over the past 10 years in young to middle-aged Staffordshire terriers. Initially reported in the UK, the disease has now been seen worldwide. Clinical indications include vague prosencephalic signs – abnormal behavior, anxiety, difficulty/slowness in learning (owners may describe these dogs as dull), and an abnormal, ataxic gait (difficult to localize). Signs may also include seizures in some cases. The onset of the condition is from 6 months onwards, with both males and females affected and with some dogs presenting in middle age.

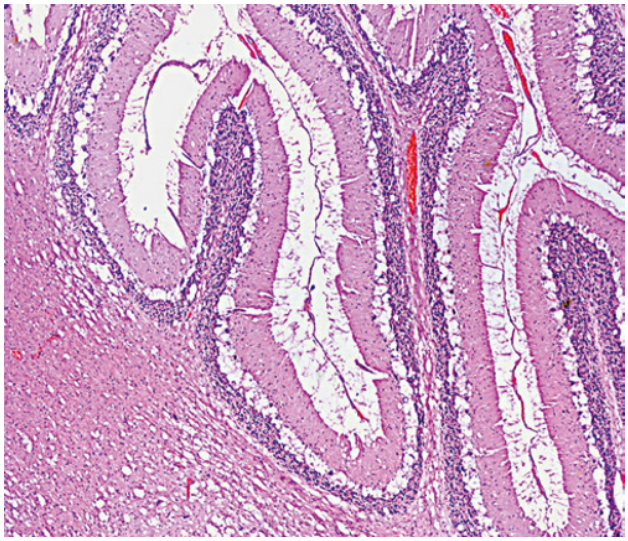

Figure 71.1 Histopathology of the cerebellum of a dog with L2-hydroxyglutaric aciduria. Note the vacuoles in the Purkinje cell layer and molecular layer as well as the deep cerebellar white matter.

The condition is caused by an inborn error of metabolism leading to widespread vacuolation within neurons in the brain with excess secretion of L2-hydroxyglutaric acid in the urine (organic acid). Diagnosis may be suggested by magnetic resonance imaging (MRI) finding (lack of distinction between gray and white matter on T2-weighted MRI scans with diffuse cerebral atrophy) and demonstration of excess organic acid in the urine, and genetic testing is now available (Figure 71.1). Overall, the long-term prognosis is guarded as the condition is untreatable but some dogs with mild signs may live a relatively normal life if seizures are controlled with anticonvulsant medication.

Anomalous Causes

Hydrocephalus

Hydrocephalus is a pathologic enlargement of the ventricles as distinct from ventriculomegaly which describes enlargement of the ventricles which may or may not be pathologic (there is considerable breed-related variation in ventricular size, with brachycephalic dogs such as boxers and bulldogs often having larger ventricles than other breeds). True hydrocephalus may occur due to obstruction in the ventricular system (obstructive or noncommunicating form; most common) or overproduction of CSF from tumors of the arachnoid granulations and choroid plexus (nonobstructive or communicating hydrocephalus; less common).

Causes of obstruction may be either congenital (stenosis of the mesencephalic aqueduct, failure of opening of the lateral apertures of the fourth ventricle) or acquired (secondary to inflammatory disease or neoplasia or other cysts obstructing part of the system). Dilation of the ventricular system upstream of the obstruction results in clinical signs. In mature animals with acquired hydrocephalus, the cause may not be determinable and is often presumed to be the result of clinically inapparent inflammation or hemorrhage within the ventricular system. Enlargement of the ventricular system can also occur with age – as the cerebral cortex tissue volume decreases, so ventricles get larger to take up the extra space available (this is also known as hydrocephalus *ex vacuo*).

Clinical signs predominantly refer to the area affected, most commonly the forebrain but potentially also hindbrain if the fourth ventricle is affected. Seizures, behavioral changes, cortical blindness, dullness, head pressing, and circling are all reported in association with this condition. Occasionally vestibular signs are also present. Diagnosis requires imaging – either MRI or CT, or ultrasound in dogs where an open fontanelle is present for placement of the ultrasound probe. This applies to congenital cases in particular, and often the skull is abnormally large and dome-shaped with divergent strabismus as a result of displacement of the orbits. On all imaging modalities, the lateral ventricles appear abnormally enlarged, and in congenital cases a very thin rim of cerebral cortex may surround these (Figure 71.2). Depending on the level of obstruction, the third and/or fourth ventricle and mesencephalic aqueduct may also be enlarged. MRI may reveal the presence of increased fluid signal (on T2-weighted or FLAIR scans) in the periventricular tissue if the development of the hydrocephalus is acute. The septum pellucidum which normally separates the lateral ventricles on midline may be absent.

Figure 71.2 Dorsal plane CT scan of the brain of a dog with obstructive hydrocephalus. Note the extreme paucity of cerebral cortex.

Treatment is either medical or surgical; reasonable long-term management is possible with corticosteroid therapy at antiinflammatory doses. Carbonic anhydrase inhibitors have also been used in acute stages of disease but cause significant electrolyte disturbances in the long term so are not recommended for chronic management. Recently, some authors have described omeprazole in some cases of acquired hydrocephalus based on experimental studies that suggest it may reduce CSF production by 26% but no evidence supports its use in dogs with hydrocephalus. Surgical treatment is also commonly performed which involves placement of a ventriculoperitoneal shunt via a small craniotomy which transfers fluid via a one-way, pressure-sensitive valve into the abdominal cavity for absorption by mesentery.

Long-term prognosis is generally good, with approximately 75% of cases improving or resolving following shunt placement. However, up to 22% may require subsequent revision to deal with blockage or infection which are common complications

Metabolic Causes

Hepatic and Uremic Encephalopathy

The pathogenesis of hepatic encephalopathy (HE) is poorly understood. Hepatic insufficiency from a number of causes, including acute liver failure, chronic liver failure (including cirrhosis), congenital portosystemic shunts and congenital urea cycle enzyme abnormalities, can all result in secondary prosencephalic disease. As a consequence, various substances pass from the portal circulation directly into the systemic circulation without undergoing detoxification. These include ammonia (probably integral to the pathogenesis of dysfunction), various amino acids (especially the aromatic amino acids phenylalanine, tyrosine, and tryptophan), short-chain fatty acids, mercaptan and various biogenic amines, indoles and skatoles, incriminated in causing HE. Increased intracellular osmolality from too-rapid glutamine accumulation (ammonia is metabolized by astrocytes to glutamine) may result in cerebral edema, which also may play a role in development of cerebral hyperemia and increased intracranial pressure. Glutamine, short-chain fatty acids, aromatic amino acids, and mercaptans are sodium/potassium ATPase inhibitors.

Other theories pertaining to the pathogenesis of HE include perturbed monoamine neurotransmission as a result of altered plasma amino acid metabolism; imbalance between excitatory amino acid neurotransmission (glutamate) and inhibitory amino acid neurotransmission (gamma-aminobutyric acid, GABA); and increased cerebral concentration of an endogenous benzodiazepine-like substance.

Clinical signs relate to prosencephalic disease: behavioral changes (vocalizing, aggression), dullness, ataxia, circling, aimless wandering, blindness, seizures, and head pressing. In severe cases this can progress to stupor or coma. Diagnosis is made on biochemistry panels together with pre- and postprandial bile acid tolerance tests. Ammonia levels can also be measured but are very labile and should only be relied on if quality control standards associated with performing the test are high. If imaging studies are performed, MRI may show (precontrast) T1-weighted hyperintensities in the caudate nucleus, amgydala and hippocampus and/or cingulate gyrus. Treatment is directed at the underlying hepatic disease. Ligation of portosystemic shunts (or coil embolism) is the treatment of choice for animals with congenital shunts.

It is also important to note that when treating animals with seizures secondary to hepatic insufficiency, anticonvulsants that are metabolized by the liver should be avoided (e.g., phenobarbitone, diazepam). Potassium bromide or levetiracetam are preferable as first-line therapy. In addition, animals that have portosystemic shunts ligated may develop seizures shortly postoperatively, for reasons that are poorly understood (and independent of whether the patient has HE prior to shunt ligation). Various causes have been postulated, including the existence of endogenous benzodiazepine-like ligands within the brain of these patients. These seizures are frequently very difficult to control if they occur; potassium bromide at 100 mg/kg PO QID for 24 hours followed by 30 mg/kg PO SID dosing has been recommended but is not always effective, and levetiracetam has also been proposed as a useful treatment. Propofol constant-rate infusions (CRIs) have also been reported to be effective.

In addition to HE, a rare encephalopathy associated with end-stage renal disease is also reported, with clinical signs including depression or stupor, seizures, muscle fasciculations, and myoclonic head-bobbing movements. The diagnosis is usually straightforward, with profound uremia evident on biochemistry panels, usually with accompanying hyperphosphatemia. The underlying cause is unknown, with suggested mechanisms including depressed cerebral oxygen consumption, cerebral hypoxia, increased brain calcium levels, and increased blood levels of parathyroid hormone (PTH). In experimental uremia, the electroencephalogram (EEG) changes associated with disease can be abolished if parathyroidectomy is performed before induction of uremia. Prognosis is poor as a result of the underlying renal disease but treatment with calcitriol (1.5–3.4 ng/kg/day PO) can reduce signs of neurologic depression in animals with chronic uremia, as long as phosphate levels are normal to prevent renal mineralization.

Electrolyte Disturbances

Hypoglycemia

There are two main causes for hypoglycemia: insulin-secreting tumors (insulinomas) of the pancreas, and overdosage of diabetic patients with insulin (especially when not eating). Young puppies (less than 3 months of age) are also prone to hypoglycemia in association with cold, starvation or gastrointestinal (GI) disease, and hypoglycemia may also be seen in animals with portosystemic shunts. Clinical signs associated with hypoglycemia include behavioral changes, weakness, ataxia, collapse, transient blindness, and seizures. Signs are often intermittent, becoming more frequent as the disease progresses, and may be associated with periods of fasting, exercise or excitement. Rarely, polyneuropathies may also occur with hypoglycemia; tetraparesis/plegia, facial nerve signs, hyporeflexia, and hypotonia are the most commonly seen signs associated with these. Central nervous system (CNS) signs occur because neurons are unable to synthesize or store glucose and rely almost entirely on glucose derived from the blood.

Diagnosis of hypoglycemia secondary to insulinoma requires demonstration of hypoglycemia in a fasting blood sample, together with elevated insulin levels (from paired samples). Treatment is directed at removing the underlying cause of hypoglycemia plus administration of dextrose solutions (5%). In animals with inoperable insulinomas, prednisolone and diazoxide can be used but the prognosis is guarded to poor, with survival of 90 days only (vs 12–14 months for resectable tumors).

Sodium Abnormalities

Neurologic signs may be seen in association with both hypernatremia and hyponatremia.

Hypernatremia

Hypernatremia occurs with sodium >156 mEq/L (dogs) or >161 mEq/L (cats). Causes include:

- *excess water loss*: diabetes insipidus (central or nephrogenic), burns, fever, osmotic diuresis (acute/chronic renal failure, diabetes mellitus, diuretics, or IV solute administration such as mannitol, glucose or urea), osmotic diarrhea (lactulose therapy, malabsorption syndromes, infectious enteritides), hot weather

- *excess salt intake*: salt poisoning, administration of IV hypertonic solutions (NaCl), sodium bicarbonate, or saline emetics
- *insufficient water intake*: lack of access, inability to drink, CNS disease resulting in primary adipsia (absence of thirst), mental depression, congenital adipsia.

Marked hypernatremia may induce cerebral signs, such as depression, weakness, irritability, uncharacteristic aggression, confusion, propulsive circling, dementia, seizures, coma, and death as the result of cellular dehydration of neurons. Neurologic signs may not occur until serum Na levels exceed 170–175 mEq/L (>350 mOsm/kg), although the severity of neurologic signs depends especially on the rate of increase, with signs being most severe in animals with rapidly developing hyperosmolality.

Treatment depends on the rate at which hypernatremia develops; overrapid correction can lead to worsening clinical signs (due to a relative hyponatremia and movement of water from the vascular spaces into the brain). Replacement of the water deficit should be undertaken using 5% dextrose with the aim of correction of the deficit over 24 hours (or longer). In animals with acute-onset hypernatremia, correction of Na levels at a rate of 1.0 mEq/h is acceptable. However, if the hypernatremia is more chronic, Na levels should not be allowed to change at more than 0.5 mEq/h. In animals with excess salt intake, diuretics should be given in conjunction with fluid therapy to avoid pulmonary edema.

Hyponatremia

Hyponatremia occurs when serum Na levels are less than 146 mEq/L in dogs (151 mEq/L in cats). Hyponatremia can be further divided into *true hyponatremia* (associated with total body water in excess of Na – serum osmolality is low, <290 mOsm/L) and *pseudohyponatremia* (low Na with normal or increased serum osmolality).

Clinical signs of hyponatremia relate primarily to the rate of onset of hyponatremia. In acute hyponatremia, sodium levels within the brain are relatively normal while sodium levels within the vascular spaces are low. Water flows down its concentration gradient into the brain, producing cerebral edema and raised intracranial pressure (ICP). Signs include generalized weakness, depression, stupor, coma, seizures, and dementia. Treatment is aimed at increasing sodium levels: use hypertonic saline (3–5%) when serum Na <115 mEq/L. The Na deficit is calculated using:

$$\text{Defect}\,(\text{mEq/l}) = (140 - \text{measured Na}) \times \text{bodyweight}\,(\text{kg}) \times 0.3$$

The replacement fluid should be given slowly over 12–24 hours. For animals with hypovolemic hyponatremia, normal isotonic saline can be used. For animals with normovolemic or hypervolemic hyponatremia associated with excessive water intake or renal retention, water restriction (i.e., limiting water intake to less than urine output) can be performed. In instances where severe neurologic signs are seen associated with normal or excessive intravascular fluid, frusemide (2–4 mg/kg IV) can be used to promote renal water excretion.

Chronic hyponatremia may be more difficult to treat since overrapid correction of the deficit can result in a worsening of clinical signs associated with central pontine myelinolysis. Lesions appear in white matter associated with death of oligodendrocytes and loss of myelin, resulting in bilaterally symmetric lesions in the pons and rarely (10% of cases) thalamus, subthalamic nuclei, striatum, internal capsule, amygdala, lateral geniculate body, white matter of the cerebellum and deep layers of the cerebral cortex. The postulated hypothesis is that with chronicity, cells within the brain extrude intracellular electrolytes followed by organic osmolytes ("idiogenic osmoles"), in order to reduce the risk of brain edema. When sodium is replaced intravascularly as part of fluid therapy, osmotic attraction of water out of cells in the brain results in dehydration of brain tissue. Clinical signs occur several days after fluid treatment: ataxia, weakness, hypermetria, visual deficits, depressed menace response (with normal pupillary light response [PLR]), reduced proprioception, exaggerated licking movements, episodic myoclonus, whole-body spasms, obtundation, and tetraparesis. Prognosis for recovery is reasonable; in one study of two dogs, one died but the other recovered over 4–7 weeks. As a result, it is important to stick to the guideline of replacing Na at a rate no greater than 0.5 mEq/L/h.

Neoplastic Causes

Brain Tumors

Tumors affecting the brain can arise as one of several forms.

- Primary tumors arise from cells and structures of the brain itself.
- Secondary tumors arise from cells and structures adjacent to the brain.
- Metastatic tumors arise from spread of a tumor at a distant site.

The most common tumors that affect dogs (and humans) are primary tumors. They occur with a slightly greater incidence than in people (14–15 per 100 000 dogs vs 8–9 per 100 000 people at risk). The most common types include:

- meningiomas
- astrocytomas

- oligodendrogliomas
- choroid plexus papillomas
- pituitary macroadenomas
- ependymomas
- primitive neuroectodermal tumors (PNETs).

Meningiomas are the most common brain tumors seen in both dogs and cats (approximately 45% of all primary brain tumors in dogs). They are thought to arise from arachnoid cap cells of the meninges and occur anywhere along a meningeal surface (e.g., cerebral convexity, falx cerebri, at the cerebellopontine angle, in the olfactory lobe), or within a ventricle. They can occur as a discrete focal mass, as an *en plaque* form or with large cystic components within them. On imaging, they have a broad-based dural attachment and are often associated with hyperostosis of the overlying bone (approximately 50% of the time in cats). Contrast enhancement is typically homogenous. Noncontrast-enhancing areas associated with necrosis are not uncommon in dogs. Histopathologically, they appear benign; in cats, they are often well encapsulated and removable surgically but in dogs tend to creep into the Virchow-Robin spaces surrounding meningeal vessels so microscopic disease usually remains after debulking.

Astrocytomas and oligodendrogliomas together are often referred to as gliomas. Astrocytomas are thought to arise from an astrocyte precursor cell while oligodendrogliomas are thought to arise from an oligodendrocyte precursor, although this is by no means certain. They occur with approximately equal frequency – approximately 17% and 14% of all primary brain tumors in dogs, respectively. Astrocytomas in humans are graded using a four-grade classification scheme created by the World Health Organization, WHO Grade I being a very small subset (pilocytic astrocytomas), grade II encompassing most astrocytomas, Grade III anaplastic astrocytoma, and Grade IV glioblastoma multiforme.

Oligodendrogliomas may occur more frequently in boxers and more commonly in periventricular white matter. They can also spread along CSF pathways. Imaging features of both types suggest an intraaxial tumor (arising from within the brain tissue). On MRI, oligodendrogliomas are frequently hypointense on T1-weighted scans and hyperintense on T2-weighted scans, as befitting their gross mucinous appearance. Astrocytomas tend to be more solid in appearance on imaging with greater and more heterogenous contrast uptake.

Choroid plexus papillomas arise from the choroid plexus of the lateral, third or fourth ventricles. Since they arise from essentially a collection of blood vessels, they tend to enhance very strongly and uniformly following contrast administration on imaging studies. Most are histologically benign but a few can be anaplastic (choroid plexus carcinoma). They can also seed along CSF pathways and implant in other parts of the neuraxis.

Pituitary macroadenomas arise from the hypophyseal stalk and expand dorsally into the thalamus/hypothalamus, and on imaging appearance commonly look like "mushroom clouds."

Ependymomas and PNETs occur relatively uncommonly; ependymomas arise from ependymal cells lining the ventricular system, whilst the PNET's origin is currently unknown.

Secondary tumors most commonly include adenocarcinomas arising from the nasal epithelium and invading the brain, and osteosarcomas, fibrosarcomas or multilobulated tumors of bone arising from the skull that compress the brain.

Metastatic tumors arise from tumors that spread hematogenously (since there is no lymphatic drainage within the brain). Common candidates include lymphoma, metastatic carcinoma (from mammary gland, lung, and GI tract, most commonly) and hemangiosarcoma. Histiocytic sarcoma can also occur in the brain (both as a metastatic tumor and as a primary brain tumor).

Clinical signs associated with tumors reflect their site of origin. In the case of meningiomas, it is common for tumors to have been present for several months before the onset of clinical signs as these tumors grow slowly, allowing the brain to accommodate. Tumors arising in the prosencephalon often cause seizures and cortical blindness. Seizures without interictal abnormalities may be seen with tumors arising on the ventral midline or in the rostral parts of the prosencephalon.

Diagnosis requires either MRI or computed tomography (CT) scanning. CSF taps may show albuminocytologic dissociation (increased protein with normal cell counts) in tumors with significant necrosis, and very occasionally may reveal neoplastic cells (with lymphoma most commonly, but also metastatic carcinomas and very occasionally with oligodendrogliomas or choroid plexus papillomas).

Treatment requires surgical debulking (where location allows) followed by irradiation with megavoltage sources. Typical hyperfractionated dose schedules include 2–3 Gy daily doses up to a maximum of approximately 50 Gy. Survival times in dogs are reported to approach a median of two years, with some patients living three or four years following diagnosis. At present, there is little evidence to support different treatment modalities for different tumor types, with the exception of meningiomas in cats, for whom surgical debulking alone often results in survival times of up to 4–5 years. However, in people some tumor types (particularly oligodendrogliomas) are chemosensitive, associated with particular patterns of genetic rearrangements in these tumors (loss of heterozygosity of the short arm of chromosome

1 and the long arm of chromosome 19) and it may be that in the future the same features may be identified in canine oligodendrogliomas.

Nutritional Causes

Thiamine Deficiency

Thiamine (vitamin B1) deficiency occurs sporadically in dogs and cats either if commercial rations are naturally low in thiamine or if food is treated with excessive heat or sulfites/sulfur dioxide preservatives. One recent report also describes a series of cats fed a commercial dry-food diet without any obvious problems in formulation. All-fish diets in particular are a risk factor since many species of fish contain thiaminases. Thiamine is essential for carbohydrate metabolism (especially glucose) via the Krebs cycle and deficiency leads to increased levels of pyruvate and lactate, together with reduced red blood cell transketolase activity. The brain is particularly susceptible since it is dependent on glucose or lactate-pyruvate for energy.

Clinical signs of thiamine deficiency include anorexia, vomiting, depression, wide-based hindlimb stance, ataxia, progressive paraparesis, crouching hindlimb gait, torticollis, head ventroflexion, circling, generalized tonic-clonic seizures, weakness, opisthotonus, coma, and death. Proprioceptive and menace deficits may be seen, along with tremors and occasionally nystagmus. Some dogs show signs of hysteria. In cats, vestibular signs, head tremors, dilated poorly responsive pupils and absent menace response are common. With severe lesions, semicoma, persistent crying, opisthotonus, limb spasticity, and death may occur. Lesions consist of polioencephalomalacia, bilaterally symmetric in periventricular gray matter, brainstem nuclei (the red nucleus and vestibular nuclei are commonly affected), cerebellar peduncles, and cerebral cortex.

Treatment requires prompt administration of thiamine hydrochloride 25–50 mg/day IM in dogs (10–20 mg IM cats) over several days. Complete remission of clinical signs usually occurs if treatment is initiated promptly, although some cats have been reported to have residual visual and proprioceptive deficits.

Inflammatory/Idiopathic Causes

Noninfectious Inflammatory Diseases

Meningoencephalomyelitis of Unknown Origin

Meningoencephalomyelitis of unknown origin (MUO) in the dog comprises a variety of conditions that are thought to be immune mediated in nature and which involve inflammation of the brain, meninges, and/or spinal cord. MUO is the umbrella term used to encompass granulomatous meningoencephalomyelitis (GME), necrotizing leukoencephalitis (NLE), and necrotizing meningoencephalitis (NME). GME is an angiocentric, mixed lymphoid, infiltrative process that predominantly affects the CNS white matter and leptomeninges. The clinical signs of all these conditions vary depending on those parts of the nervous system where the lesions are most severe. Commonly, however, the clinical picture is one of multifocal, asymmetric, intracranial disease seen in a young to middle-aged (or older) small-breed dog.

Granulomatous Meningoencephalitis

Three forms of GME have been described based on morphologic and clinical characteristics: disseminated, focal, and ocular. The disseminated form typically manifests with acute onset of rapidly progressive clinical signs suggestive of a multifocal CNS disorder whereas focal GME is associated with clinical signs suggestive of a single space-occupying mass with an insidious onset and slowly progressive course. The ocular form of GME manifests with acute onset of visual impairment and dilated nonresponsive pupils caused by optic neuritis. Dogs with the ocular form can subsequently develop CNS lesions.

The cause of GME is unknown, with immune-mediated, infectious, and neoplastic causes proposed as possible etiologies. Historically, GME was once classified within a group of conditions known as reticulosis, the neoplastic form of which has since been reclassified as B cell lymphoma occurring within the brain, suggesting that there are features of the disease which are common to cancer. Other investigations have focused on the nature of the immune system attack on the brain which appears to be similar to a delayed-type hypersensitivity and which involves antibodies directed at astrocytes. So far, efforts to identify an underlying infectious trigger for the immune response have been unsuccessful.

Necrotizing Leukoencephalitis and Necrotizing Meningoencephalitis

Necrotizing leukoencephalitis and NME both started out as conditions identified in certain breeds, with NLE being called Yorkshire terrier encephalitis and NME called pug encephalitis. Since these early reports in specific breeds, an increasing number of dogs of other (and mixed) breeds have been identified with these conditions, including Yorkshire terriers with pug encephalitis and vice versa. The necrotizing meningoencephalitides differ from those in GME in distribution and severity. Both are characterized by extensive necrosis and nonsuppurative inflammation. In NME, the lesions tend to involve more of the cerebral gray and subcortical white matter. The neurologic signs are acute and progressive

and reflect a forebrain disorder, with seizures observed in most dogs. NLE is characterized histologically by multifocal areas of extremely severe mononuclear inflammation surrounding a large malaciac gliotic center, predominantly affecting the brainstem and periventricular cerebral white matter. Brainstem signs with central vestibular dysfunction predominate, although a mixture of forebrain and brainstem signs also occurs.

The etiopathogenesis of GME, NME, and NLE likely is multifactorial: familial predisposition, infectious agents, and immunopathologic mechanisms all may play roles in disease pathogeneses. GME is responsible for up to 25% of canine CNS disease.

Diagnosis and Treatment

A female predisposition for GME has been reported and the disease is most common in young to middle-aged dogs. Most cases of the necrotizing meningoencephalitides described so far have occurred in young and adult animals (6 months to 7 years) with no gender predisposition.

Confirmation of a diagnosis of GME, NME, and NLE requires histopathologic confirmation, and as such is infrequently achieved antemortem. Extraneural signs such as hyperthermia are rare. Blood examination may be normal or reveal a stress leukogram. CSF findings include a pure mononuclear pleocytosis or a mixed cell population (particularly in acute cases), bearing in mind that cytology cannot discriminate between immune-mediated, infectious, and neoplastic considerations for canine meningoencephalitis. Similarly, the absence of CSF abnormality does not rule out the possibility of GME, particularly in dogs pretreated with corticosteroids or where the lesions are not in close proximity to the ventricular system and subarachnoid space. CSF findings in dogs with NME or NLE reveal a moderate pleocytosis with mononuclear cells or mixed cell pleocytosis and mild to marked elevation of protein concentration.

Imaging findings in MUO are nonspecific but can help to support the suspected clinical diagnosis. CT scan may reveal hyperdense lesions after injection of contrast medium intravenously. Most frequently, the diagnosis is made following MRI scans. The most consistent MRI finding in dogs with the multifocal form of GME is the presence of multiple hyperintense T2-weighted (T2W) and fluid-attenuated inversion recovery (FLAIR) lesions scattered throughout the cerebral white matter. Contrast enhancement may be present and may be strong (occasionally with ring enhancement) or mild. Central nervous system lymphosarcoma and, less commonly, glial neoplasms and metastatic neoplasia can present with similar clinical and imaging findings and should therefore be part of the differential diagnosis list. The focal form of GME presents on CT or MRI as a nonspecific single space-occupying mass. The more characteristic distribution of the lesions observed in breed-specific meningoencephalitis (NLE or NME) may aid in the imaging diagnosis of these conditions.

At present, immunosuppression is the mainstay of therapy for MUO. Most clinicians treat with corticosteroids together with adjunctive immunosuppression, although whole-brain radiation therapy has also shown promise in the treatment of GME in some cases (supporting the hypothesis that neoplasia might be part of the etiopathogenesis). Response to corticosteroids is variable and may be temporary, but dogs often have a favorable initial response to steroid monotherapy. Typically, secondary immunomodulatory agents are added once negative serology and PCR results have ruled out other disease.

In a clinical setting, steroid monotherapy may resolve signs associated with MUO in some dogs, but insufficiently or only transiently provides resolution in others. Most studies suggest that longer survival is achieved with additional therapy. The most commonly used additional immunomodulatory drugs include cytosine arabinoside (CA) at 50 mg/m^2 q12h SC for two days (using a regime that involves therapy initially at three-weekly intervals, then reducing to every four weeks, every five weeks, and continuing every six weeks thereafter), ciclosporin at 5–10 mg/kg q12h PO, procarbazine at 25–50 mg/m^2 q24h PO, azathioprine at 2 mg/kg q24h PO for 14 days before tapering to every other day, mycophenolate 10–20 mg/kg q12h PO, and leflunomide at 2–4 mg/kg q24h PO. A prednisone/vincristine/cyclophosphamide (COP) protocol has also been described, although this has not been shown to provide longer survival than a prednisone/CA protocol and is associated with more adverse effects. Treatment is monitored by clinical response and regression of neurologic deficits and occasionally repeated CSF analysis and MRI.

The prognosis for long-term remission in proven cases of GME and the breed-specific meningoencephalitides has been reported as being poor. However, such reports have been limited to histopathologically confirmed cases of GME that died or were euthanized as a result of the severity of their disease, so the poor prognosis in these studies may be biased. Most recent studies have reported several years survival in dogs with MUO with aggressive immunosuppression, and potentially cure, although ultimately other side-effects (predominantly hepatic failure) may be life-threatening.

Infectious Diseases

Encephalitis and meningitis often exist concurrently in dogs and cats with infection of the CNS. Numerous

infectious agents have been incriminated and include viruses (distemper, rabies, parvovirus, parainfluenza, herpes, feline leukemia, feline immunodeficiency virus), bacteria, rickettsia (*Ehrlichia*, Rocky Mountain spotted fever), protozoal (*Toxoplasma*, *Neospora*), fungi (blastomycosis, histoplasmosis, cryptococcosis, aspergillosis, coccidioidomycosis), and spirochetes (Lyme disease, leptospirosis). Adding to this list, a number of parasites have been reported to affect the brain during aberrant migration (*Toxocara*, heartworm, *Cuterebra* larvae) and the incidence of these depends mainly on geographic location. CSF and infectious titers or DNA testing performed on serum or CSF are the most reliable antemortem diagnostic tests for identifying infectious CNS diseases.

Canine Distemper Virus Encephalomyelitis

Canine distemper virus (CDV) is a paramyxovirus that commonly infects the CNS of dogs and other carnivores. Unvaccinated and vaccinated dogs are at risk for this disease, and although the prevalence of infection seems to be decreasing in some countries, sporadic outbreaks have been reported in several countries, particularly where vaccination coverage is incomplete. Systemic signs of disease such as respiratory and gastrointestinal involvement are reported to precede the neurologic signs by 2–3 weeks. However, many dogs have no previous history of disease prior to the onset of neurologic signs. Many dogs probably develop transient CNS infections without concurrent clinical signs. Lesions may be found in gray (polioencephalomyelopathy, PEM) and/or white matter (leukoencephalomyelopathy, LEM). Since the lesions are predominantly demyelinating in nature, it has been proposed as a model for the study of multiple sclerosis. PEM is more frequently seen in immature dogs while a combination of PEM and LEM is more common in mature animals.

Infected dogs can present with a variety of neurologic signs that tend to be progressive. Clinical signs in dogs with chronic CDV encephalomyelitis may have a chronic insidious or waxing and waning course, and are often not associated with systemic signs of CDV. The classic syndrome of distemper myoclonus (repetitive and continual myoclonic jerks that affect the whole body or just one body part with a characteristic 1 Hz frequency) can be pathognomonic.

The diagnosis of CDV can be difficult. CSF analysis is often the most helpful diagnostic test. However, an inflammatory response is often lacking in the acute stage of the disease, with mononuclear pleocytosis more often observed in the chronic stage. Immunofluorescent staining of conjunctival tissues, urine sediment, tracheal wash or CSF leukocytes for CDV antigen is variably successful, but positive results are occasionally obtained in dogs with chronic CDV encephalomyelitis. Identification of neutralizing CDV antibodies in serum is of questionable value in previously vaccinated dogs, and demonstration of CDV antibodies in CSF can be complicated if CSF is contaminated with peripheral blood. Several PCR techniques have been described for the detection of CDV in various tissues and body fluids, some of which are now commercially available, and these can be applied to CSF; this is probably the most specific and sensitive test for the antemortem diagnosis of CDV encephalomyelitis regardless of the clinical form of disease present.

The chronic form of the disease is typically slowly progressive, although clinical signs may be well tolerated for long durations. Therapy is mainly supportive and symptomatic. Overall, prognosis is poor although the disease is not fatal in all dogs and some may recover.

Feline Infectious Peritonitis (FIP)

Two biotypes of feline coronavirus (FCoV) exist: feline infectious peritonitis virus (FIPV) that causes FIP, and feline enteric coronavirus (FECV) that induces mild enteritis from which cats typically recover. FIPV has been shown to arise within individual patients from a spontaneous mutation of existing FECV infection. FIP is a clinical disease that arises due to infection of macrophages by FIPV, which subsequently results in the immune-mediated formation of pyogranulomatous lesions with an affinity for serosal, pleural, uveal, meningeal, and ependymal membranes (surface-related disease).

The neurologic clinical variant of FIP is the most common infectious cause of meningoencephalomyelitis in the cat, as well as being the most prevalent spinal cord disease of cats. Although the effusive form is about four times more common than the noneffusive form, neurologic involvement is more common with the noneffusive (or "dry") form of the disease and develops in cats with humoral immunity, but with partial cell-mediated immunity (immunity sufficient to induce granulomatous inflammatory reaction around virus present in macrophages, but not quite adequate to eliminate the infection). The pathogenesis involves FIP virus inducing a pyogranulomatous and immune complex-mediated vasculitis involving the meninges, ependymal lining, periventricular brain tissue, and choroid plexus of the CNS. As a result, clinical signs most commonly arise as a result of hydrocephalus secondary to obstruction of the ventricular pathways.

Cats with FIP are typically young (<3 years of age), pure-bred, from multiple cat households and the disease is more common in sexually intact males. The main route of infection with FCoV is oronasal from contact with infected feces. Asymptomatic carriers are not common.

Clinical signs most commonly relate to hydrocephalus and associated forebrain syndrome (seizures, cortical blindness, obtundation) although central vestibular signs are often also reported, as the meningitis caused by FIP may be more severe in the ventral brainstem and at the base of the cerebellum, and choroid plexitis and ependymitis are frequently severe in the caudal fossa.

The diagnosis of FIP is challenging, especially when signs are restricted to the CNS. Hematology findings may include anemia, leukocytosis, and hyperglobulinemia. Serum tests for anticoronavirus antibodies have a low specificity and a negative serum titer does not exclude the possibility of FIP-associated neurologic disease because soluble antibodies can form immune complexes and escape detection by standard tests. There is also considerable overlap in titers in cats with and without FIP (some cats with FIP have low titers, while many cats with high titers never develop FIP). The CT and MR abnormalities present in the brains of cats are well described and include meningeal contrast enhancement, choroid plexitis (contrast enhancement), ependymitis, granuloma formation, and obstructive hydrocephalus, most commonly due to blockage of the mesencephalic aqueduct. CSF analysis may reveal a predominantly neutrophilic or mixed cell pleocytosis, but can be normal. CSF total protein concentration is often markedly elevated (>200 mg/dL). Documentation of elevated coronaviral antibody concentrations, especially in cerebrospinal fluid, confirms exposure and is supportive of the diagnosis. However, this result must be interpreted with respect to the integrity of the blood–brain barrier. Positive coronavirus-specific PCR performed on CSF can be used as a relatively reliable antemortem diagnostic tool.

Treatment of FIP is immunosuppressive or immunomodulatory in nature, but the disease should be considered terminal in virtually all affected cats. Corticosteroids, chlorambucil, cyclophosphamide, and interferons have been used with variable efficacy in FIP cases.

Protozoal Encephalitis

Toxoplasmosis and neosporosis are polysystemic protozoal diseases capable of causing heterogeneous signs of peripheral and CNS dysfunction. Natural infection with *Toxoplasma gondii* is more common in cats, but also occurs in dogs. Ingestion of tissue from infected intermediate hosts (ingestion of encysted bradyzoites) is the most common cause of infection in both species. Other forms of infection include fecal contamination and *in utero* infection. With *Neospora caninum*, dogs are affected, most commonly via *in utero* transmission, although they may also be infected by ingestion of intermediate host tissue.

Following acute systemic infection in intermediate hosts in which the organism can be disseminated to many body organs (this phase may be subclinical), tissue cysts form most commonly in the CNS, skeletal muscle, and heart muscle. The parasites are mainly intracellular and subclinical infection may persist for the life of the host, although activation of toxoplasmosis may occur in association with severe immunosuppressive disorders. These protozoal organisms have the potential to cause an extremely variable number of clinical neurologic syndromes. Two main forms are observed:

- encephalomyelitis – neurologic signs associated with protozoal encephalomyelitis are variable and may reflect a focal or multifocal disease process
- *Neospora* myositis-polyradiculoneuritis – this is probably the most commonly reported infectious myositis in dogs and presents with severe pelvic limb paresis and skeletal muscle fibrosis in young dogs, especially those less than six months of age.

A tentative antemortem diagnosis of toxoplasmosis is established in dogs most commonly through elevated IgM titers, IgG seroconversion, or documentation of a positive clinical response to an antiprotozoal treatment regimen. In cats, an elevated serum or CSF IgM titer is considered diagnostic for toxoplasmosis. However, a positive titer can be found in animals previously subclinically infected with either organism and demonstration of a rising titer with serial (monthly) testing may be required to confirm a diagnosis of active disease. Neosporosis is diagnosed by serologic detection of indirect fluorescent antibody titers in dogs. Demonstration of tachyzoites of either organism in various tissues or body fluids is also diagnostic but rarely achieved. CSF analysis typically demonstrates pleocytosis with a mixed population of neutrophils and the presence of small and large mononuclear cells. Eosinophils may also be seen. Sensitive PCR assays have been reported for the detection of both *Neospora caninum* DNA and *Toxoplasma gondii* DNA in biological samples. Muscle biopsy is indicated in dogs with polyneuropathy/polymyositis and may reveal nonsuppurative inflammation and tachyzoites within myocytes.

Treatment for both diseases is identical. Clindamycin (10–15 mg/kg PO q812h for a minimum of 12 weeks) is the preferred therapy. However, TMS (15 mg/kg PO q12h) in combination with pyrimethamine (1 mg/kg/day PO) may also be effective. Folic acid or brewer's yeast supplementation should be considered (5 mg/dog/day) in animals receiving this latter therapy. The prognosis for survival is fair to good, but recovery of neurologic function may be incomplete in those animals with severe clinical signs. In the author's experience, some cases may require long-term (a year or possibly longer) therapy,

suggesting selective immunodeficiency in some animals contributing to the presence of infection.

Bacterial Meningoencephalitis

Bacterial infection of the CNS is a relatively rare cause of encephalitis and/or meningitis in dogs and cats compared with other species. Bacterial infection of the brain can be the consequence of hematogenous spread (metastasis from distant foci of infection), penetrating injury to the skull (bite wound, bullet, surgery) or direct extension of infection from the middle/inner ear, eyes or nasal sinuses. Infection of the CNS may result in an abscess and/or, much less frequently, collection of pus (empyema) in subdural or epidural locations. Brain abscesses are life threatening due to systemic and local toxicity (in the early stages of cerebritis) and increased intracranial pressure (during/after capsule formation). Clinical signs are largely the result of the inflammatory reaction that the bacteria provoke.

Affected animals can present with a wide variety of neurologic signs of intracranial disease that reflect a focal anatomic diagnosis suggesting a space-occupying lesion or a multifocal syndrome associated with many small microabscesses. These signs are usually rapidly progressive and frequently fatal if left untreated. Fever is present in approximately 50% of cases at presentation. Hematology usually reflects an inflammatory process (leukocytosis with or without left shift) or can be normal. Imaging of the brain (CT or MRI) may be suggestive of an inflammatory process and may reveal a defect in the skull suggestive of a penetrating injury or signs suggestive of otitis media/interna.

Cerebrospinal fluid analysis usually reveals an elevated nucleated cell count, with the majority of cells being degenerate neutrophils, and marked elevation in total protein concentration. Bacteria may be visible in the spinal fluid. In some cases, CSF can be normal or may show nonspecific inflammatory changes. CSF should be cultured if it contains degenerate neutrophils although it is uncommon for culture to be positive. Urine and blood culture should also be considered in animals in which there is no obvious source of infection.

Treatment of abscesses centers around antibiotic therapy, often for long periods, based on culture and drug sensitivity testing of organisms isolated from the abscess. When cultures cannot be obtained, a broad-spectrum antibiotic, such as third-generation cephalosporins and enrofloxacin or metronidazole, can be used. In the early stages antiinflammatory doses of corticosteroids to reduce surrounding edema are indicated, and seizure control with anticonvulsants may be required. Antibiotic therapy should be maintained for several weeks after clinical signs have resolved. Surgical decompression by craniectomy is indicated in cases of brain abscess that do not respond to medical management.

Mycotic Meningoencephalitis

Fungal CNS infections other than cryptococcosis are uncommon in dogs and cats. Small animals with mycotic CNS infections can have neurologic signs that range from peracute in onset to insidiously progressive, and lesion localization is often suggestive of multifocal disease.

Cryptococcus neoformans is the most commonly implicated systemic mycotic agent causing CNS signs in both dogs and cats. Extraneural organ involvement is often present, but may be clinically occult, or absent in some cases. Brainstem disease resulting in signs of vestibular dysfunction is frequently reported. Peripheral vestibular disease has also been reported to be a sequel of cryptococcosis in cats.

The diagnosis of cryptococosis is best established by cytologic or histologic demonstration of the organism, with its characteristic capsule, from tissue aspirates or biopsies, or in body fluids, such as urine or CSF; organisms can be identified in the CSF of more than 90% of dogs with CNS signs. In cases in which organisms cannot be demonstrated, serologic testing using the latex agglutination procedure that identifies cryptococcal capsular antigen is recommended. Serologic testing can be performed on blood or CSF, although CSF is preferred. Latex agglutination testing is generally considered to be both highly sensitive and specific. CT and MRI imaging of the brain in cats and dogs with cryptococcosis have demonstrated numerous and variable abnormalities including single or multifocal mass lesions, meningeal enhancement, intraparenchymal ring enhancement associated with "punch hole" lesions in the gray matter, and choroid plexus enhancement.

The recommended therapy for CNS cryptococcosis is fluconazole (5 mg/kg PO q12h), as this agent effectively penetrates CNS tissues. Intrathecal administration of amphotericin B has also been described. The length of therapy required is often protracted, and serial serologic monitoring has been recommended. Treatment should ideally be continued until clinical signs have resolved, CSF analysis has normalized, and two consecutive titers performed one month apart have been negative. However, relapses have occurred after consecutively negative serum titers, and it has been suggested that when possible, treatment should continue until the patient is seronegative and all previously documented intracranial MR abnormalities have resolved. Newer antifungal agents, such as voriconazole, offer advantages including excellent CNS penetration, a broader antifungal spectrum, and greater potency than either fluconazole or itraconazole, and thus may prove to be beneficial for the treatment of CNS cryptococcosis in dogs and cats.

Vascular Causes

Cerebrovascular Accidents

Cerebrovascular accident (CVA), also known as stroke, is defined as a sudden onset of nonconvulsive and nonprogressive focal brain signs secondary to cerebrovascular disease (any pathology affecting the blood supply of the brain). By convention, these signs must remain for more than 24 hours to qualify for the diagnosis of CVA; if the clinical signs resolve within 24 hours, the episode is called a transient ischemic attack or TIA.

Causes and Pathophysiology

Ischemic strokes result from occlusion of cerebral blood vessels by a thrombus or embolism while hemorrhagic strokes result from rupture of blood vessel walls within the brain parenchyma or subarachnoid space.

Ischemic Stroke

Ischemic strokes have been reported infrequently in the veterinary medical literature when compared with the human medical literature. Suspected underlying causes identified in histopathologically confirmed cases include:

- septic thromboemboli associated with bacterial endocarditis or other sources of infection
- atherosclerosis associated with primary hypothyroidism and miniature schnauzers with hypertriglyceridemia
- aberrant parasite migration (*Cuterebra*) or parasitic emboli (*Dirofilaria immitis*)
- embolic metastatic tumor cells
- intravascular lymphoma
- fibrocartilaginous embolism
- aortic or cardiac embolism.

However, in those cases which are not severe enough to warrant admission to the postmortem room, a concurrent medical condition can be found in just over 50% of dogs. The most commonly encountered conditions are:

- hyperadrenocorticism
- chronic kidney disease
- hypothyroidism
- hypertension.

Chronic kidney disease and hyperadrenocorticism were the most commonly suspected underlying causes for the hypertension in one study. No underlying cause could be identified antemortem in nearly half of the dogs; this type of infarct of unknown origin is referred to in humans as cryptogenic. No age, sex or breed predisposition has been identified in dogs but Cavalier King Charles spaniels (CKCS) and greyhounds appear to be overrepresented.

Reports of ischemic stroke in cats are scarce. The term *feline ischemic encephalopathy* (FIE) has been used to describe cases of peracute onset of clinical signs consistent with a unilateral cerebral or brainstem problem caused by ischemia. Although the cause remains unknown in most cases, some of them have been linked to *Cuterebra* migration. It is believed that the migrating parasite, or the host response to it, leads to vasospasm in the cerebral vasculature (typically middle cerebral artery).

Failure of blood supply (which results in decreased perfusion pressure within one area of the brain) leads to the development of ischemia, progressing to infarction if this is severe and persists. An infarct describes the area of compromised brain parenchyma that results from this process. The initial drop in perfusion pressure may occur either secondary to vascular obstruction that develops within the occluded vessels (thrombosis) or due to obstructive material that originates from another vascular bed and travels to the brain (thromboembolism). Two distinct regions of an infarct can be distinguished: the core, where ischemia is severe and infarction develops rapidly; and the penumbra surrounding the core, which shows a more moderate decrease of cerebral blood flow (CBF), allowing longer durations of ischemic stress to be tolerated. Tissue within the penumbra has the potential for recovery and therefore is the target for interventional therapy in acute ischemic stroke.

Hemorrhagic Stroke

In contrast to the high incidence in humans, intracerebral hemorrhage resulting from spontaneous rupture of vessels is considered rare in dogs and cats. Secondary hemorrhage has been reported in dogs in association with:

- rupture of congenital vascular abnormalities
- primary and secondary brain tumors
- inflammatory disease of the arteries and veins (vasculitis)
- intravascular lymphoma
- brain infarction (hemorrhagic infarction)
- impaired coagulation.

Nontraumatic subarachnoid hemorrhage has been reported in dogs but remains very rare when compared to its occurrence in humans, where aneurysmal rupture is the most common underlying cause.

In hemorrhagic stroke, blood leaks from the vessel directly into the brain, forming a hematoma within the brain parenchyma, or into the subarachnoid space. The mass of clotted blood causes physical disruption of the tissue and pressure on the surrounding brain. This alters CNS volume/pressure relationships with the possibility of increasing intracranial pressure and decreasing cerebral blood flow. In addition, the tissue downstream of the ruptured vessel(s) undergoes ischemia as a result of the loss of blood supply. As the volume of the hematoma

initially develops, ICP typically remains constant due to a system of compensation known as cerebrovascular autoregulation. However, with progressive expansion of the hematoma, these mechanisms become exhausted, after which further increases in the volume of the clot become associated with a dramatic increase in ICP. In severe cases, this increase in ICP causes a decrease in perfusion of the brain and ultimately fatal herniation of the brain at the level of the foramen magnum.

Clinical Presentation

Neurologic signs seen in stroke patients are characteristically peracute or acute in onset and nonprogressive or regressive in their evolution. Initially, deficits observed are usually focal, often asymmetric and ultimately related to the area of the brain involved. The combination of abrupt onset and focal, often asymmetric localization should raise the index of suspicion for vascular disease. The initial signs are then followed by an arrest and regression of the neurologic deficits in all except the fatal strokes, although worsening of edema (associated with the secondary injury phenomena) can result in progression of neurologic signs for a short period of 24–72 hours. In addition, intracranial hemorrhage can present with progression of signs for up to 24–72 hours before regression as a result of reorganization of the hemorrhage and edema resorption.

Neurologic deficits usually reflect a focal anatomic diagnosis and depend on the location of the vascular insult (telencephalon, thalamus, midbrain, pons, medulla, cerebellum). Infarction of an individual brain region is associated with specific clinical signs that reflect the loss of function of that specific region.

Diagnosis

Advanced imaging (CT, conventional and/or functional MRI) is a prerequisite for confirming a diagnosis of stroke, for defining both the vascular territory involved and the extent of the lesion, as well as distinguishing between ischemic and hemorrhagic disease. Imaging studies are also necessary to rule out other causes of neurologic deficit such as tumor, head trauma, and encephalitis.

Computed tomography images are frequently normal during the acute phase of ischemic stroke, making the diagnosis of ischemic stroke using CT an exercise in the exclusion of other differential diagnoses. In part, this is due to the relatively noisy CT images of the brain in animals with a large skull to brain ratio, compared with people. Early CT signs of ischemia can be subtle and difficult to detect even by very experienced readers and include parenchymal hypodensity, loss of gray–white matter differentiation, subtle effacement of the cortical sulci, and local mass effect. By way of contrast, CT is exquisitely sensitive for the detection of acute hemorrhage in hemorrhagic stroke. Acute hemorrhage is evident as a hyperdensity on CT due to hyperattenuation of X-rays by the globin portion of blood, particularly for the first eight days following onset. The attenuation decreases until the hematoma is isodense about one month after the event. The periphery of the hematoma contrast enhances from six days to six weeks after onset, due to revascularization.

Magnetic resonance imaging can be used to identify ischemic stroke within 12–24 hours of onset and to distinguish hemorrhagic lesions from infarction. T2-weighted and FLAIR images are particularly useful in imaging of ischemic stroke since they allow correlation of the lesion with anatomic structures and vascular territories. With these sequences, ischemic infarction appears as a hyperintense lesion. The conformity of an infarct to a vascular territory is an important element in the diagnosis that helps in distinguishing these lesions from other differentials. Ischemic infarcts are limited to the region of the brain vascularized by the affected vessel, and are often wedge-shaped in appearance with resultant sharply demarcated borders. There is minimal to no mass effect associated with these lesions. Changes are best appreciated in the gray matter and are well visualized in deep gray matter structures such as the thalamus and basal ganglia due to their selective vulnerability to ischemia. Contrast enhancement (associated with reperfusion) is not usually seen until at least 7–10 days but the inverse is a useful indicator – lack of contrast uptake in the ischemic region often results in a noticeably darker area on postcontrast T1-weighted scans.

In the case of hemorrhagic stroke, particular characteristics of hematoma evolution are useful in making the diagnosis with conventional sequences. As the hematoma ages, oxyhemoglobin sequentially breaks down into several paramagnetic products – first deoxyhemoglobin, followed by methemoglobin, and finally hemosiderin. The earliest possible detection of hemorrhage depends on the conversion of oxyhemoglobin to deoxyhemoglobin which occurs after 12–24 hours. Whilst oxyhemoglobin provides a signal similar to that of normal brain parenchyma, the iron exposed to surrounding water molecules in the form of deoxyhemoglobin creates a signal loss, making it easy to identify on T2-weighted and susceptibility-weighted sequences. Gradient echo (T2-weighted) sequences are exquisitely sensitive to the disruption of the local magnetic field that this creates and show hemorrhage as dense hypointense regions.

In addition to conventional MRI sequences, several functional MRI (fMRI) techniques have been developed for the early diagnosis of stroke. These include diffusion and perfusion imaging and magnetic resonance angiography (MRA). Diffusion-weighted imaging (DWI) is

used commonly in humans in the diagnosis of acute stroke. DWI sequences detect the random diffusion of water molecules through tissues. When brain parenchyma loses its blood supply, energy delivery to neurons fails and water becomes trapped within cells by cell membranes. This can be detected on DWI sequences as a hyperintense region within the brain representing brain parenchyma in which water diffusion is restricted as a result of this energy failure. In addition to DWI, perfusion-weighted imaging is employed to depict regions of hypoperfusion in the brain and can document the tissue "at risk" (i.e., penumbra) by comparing the results with the findings on DWI. In addition, MRA can noninvasively assess the intracranial vessels of stroke patients.

Cerebrospinal fluid analysis is unlikely to confirm a diagnosis of CVA but helps to rule out inflammatory CNS disease. CSF is variable in dogs and cats with CVA. In most cases, it is either normal or reflects a mild mononuclear or neutrophilic pleocytosis. CSF proteins are occasionally elevated.

Identification of Underlying Causes of Stroke

In the case of presumptive or confirmed ischemic stroke, ancillary diagnostic tests should focus on evaluating the animal for hypertension (and its potential underlying causes), endocrine disease (hyperadrenocorticism, hypothyroidism, hyperthyroidism, diabetes mellitus), kidney disease (especially protein-losing nephropathy), heart disease, and metastatic disease. Diagnostic tests in presumptive or confirmed cases of hemorrhagic stroke should focus on screening the animal for a coagulopathy, hypertension (and potential underlying causes), and metastatic disease (particularly hemangiosarcoma).

Treatment and Prognosis

Once the diagnosis of a stroke has been made, any potential underlying or associated disease should be identified and treated accordingly. Generally, treatment of these patients aims to provide supportive care, maintain adequate tissue oxygenation, and manage neurologic and nonneurologic complications. Nursing management of a recumbent dog will be vital to the success of more specific therapies. Such management includes attention to the prevention of decubital ulceration, aspiration pneumonia, and urine scald, in addition to physical therapy and enteral nutrition provision. More specific therapies are aimed at preventing further neurologic deterioration.

Most cases of ischemic stroke recover within several weeks with only supportive care. Potential underlying causes should be investigated and treated accordingly to limit the risk of recurrences. Definitive therapy in people involves thrombolytic therapy in an attempt to salvage the ischemic penumbra – tissue surrounding the ischemic core in which rapid restoration of the blood supply may reverse the initial damage. However, the window of opportunity for this to occur is approximately six hours, making it very rarely achievable in animals. Monitoring and correction of basic physiologic variables are important, as is maintaining normal blood pressure.

The most important consideration in hemorrhagic stroke is maintenance of cerebral perfusion by treatment of hypotension and elevated ICP, as well as treating the underlying cause if one has been identified. The medical management of dogs with intracranial hemorrhage commonly includes:

- stabilization of the patient (airway protection, monitoring and correction of vital signs)
- assessment and monitoring of the neurologic status
- determination and treatment of potential underlying causes of the hemorrhage
- assessment of the need for specific treatment measures, including management of increased ICP.

The risk of neurologic deterioration and cardiovascular instability is highest during the first 24 hours after the onset of an intracranial hemorrhage, as the space-occupying lesion slowly expands and cerebral vasogenic edema develops. During this phase, if the neurologic status deteriorates, aggressive therapy to control ICP with mannitol (0.25–1 g/kg administered IV over 20 min) or other agents may need to be considered, and in rare cases craniotomy to alleviate cerebral edema.

The prognosis for ischemic or hemorrhagic stroke depends overall on the initial severity of the neurologic deficit, the initial response to supportive care, and the severity of the underlying cause if one has been identified. Most cases of ischemic stroke recover within several weeks with only supportive care and there appears to be no association between the region of the brain involved, the type of infarction (territorial or lacunar), and outcome. However, dogs with a concurrent medical condition have a significantly shorter survival time than those with no identifiable medical condition. Dogs with a concurrent medical condition are also significantly more likely to suffer from recurrent neurologic signs due to subsequent infarcts.

Feline Ischemic Encephalopathy

Feline ischemic encephalopathy (FIE) represents a peculiar variant of cerebrovascular disease. FIE is an ischemic necrosis of cerebral tissue that has been reported sporadically in male and female cats of all ages, especially in summer months in the US. Clinical signs are usually acute in onset, nonprogressive, and variable, and typically suggest unilateral cerebral or brainstem involvement. Signs may include depression, head tilt, anisocoria, circling, seizures, and changes in attitude/

behavior. Clinical signs may be modified or disappear with time and, unlike other forms of cerebrovascular accident, multiple episodes may occur. Hematology, blood chemistries, and skull radiographs are usually normal while MRI reveals classic signs of a major ischemic infarct. CSF analysis may be normal or show mild to moderate elevations in cell numbers (usually monocytic) or protein levels. Lesions are usually unilateral and may involve up to 75% of one cerebral and/or cerebellar hemisphere. The major area of infarction is frequently in the distribution of the middle cerebral artery.

The cause of this enigmatic ischemic condition has been uncertain but clinical similarities between FIE and *Cuterebra* infection of the brain have historically been noted. Intriguingly, at postmortem some of these cats have been found to harbor *Cuterebra* larvae within the cranial vault (commonly within the olfactory bulbs and optic nerves following migration through the cribiform plate) – and some of the changes visualized are associated with the migration track of the parasite. However, much of the vascular compromise occurs in locations distant to the parasite, suggesting an elaborated toxic factor causing disseminated vasospasm and consequent ischemia. It should be noted that although this association has been noted in the US, some cats in other countries in which *Cuterebra* is not found can also be affected with similar ischemic lesions.

Treatment is largely supportive. Prognosis is often favorable since many of the signs seen initially will ameliorate; however, behavioral changes and uncontrollable seizures may persist.

72

Vestibular Disease

Tammy Stevenson, DVM, DACVIM (Neurology)

Veterinary Specialty Hospital, San Diego, CA, USA

The term *vestibular disease* is used to describe a neuroanatomic localization within the vestibular system of any cause, and therefore, is not a specific diagnosis.

The purpose of the vestibular system is to provide balance by adjusting limb extensor/flexor tone to accommodate for changing head and body positions. This results in controlled and coordinated eye-head-trunk-limb movement with proper postural support.

The structures of the vestibular portion of the inner ear include semicircular canals that are responsible for conveying information regarding acceleration in angular planes, and the utriculus and sacculus which convey information regarding linear acceleration and static head position (relative to gravity). Information from these receptor organs travels via the vestibular portion of the vestibulocochlear nerve (CN VIII) to the vestibular nuclei (four on each side of the brainstem – rostral, caudal, medial, and lateral), through the caudal cerebellar peduncle, to the flocculonodular lobes of the cerebellar hemisphere. The dorsal spinal nerves of C1–3 provide input to head position and balance and can also cause vestibular signs when dysfunctional.

Dysfunction of one or more parts of the vestibular system may result in the signs we classically recognize as "vestibular disease" – a head tilt, nystagmus, walking in circles, ataxia/falling or even rolling, abnormal limb extensor tone, and nausea/vomiting. These signs are due to the vestibular system's extensive connections with various parts of the central nervous system (CNS).

- Projections via the medial longitudinal fasciculus to the nuclei of CN III, IV, and VI which control the extraocular eye muscles. In homeostatic conditions, these connections result in normal physiologic nystagmus (oculocephalic reflex), and with dysfunction, pathological nystagmus.
- Projections via the vestibulospinal tract, to the neck, trunk, and limbs, resulting in appropriate head/neck position relative to gravity and with movement, and appropriate limb tone and position relative to gravity and head position. Dysfunction results in head tilt, and imbalance in extensor tone such that the animal leans or circles to the side with less tone.
- Projections to the vomiting center (in the reticular formation) leading to ptyalism, inappetence, and vomiting.
- Projections to the cerebral cortex to provide conscious awareness of the body's position in space via the thalamus (pathway not well identified), and awareness of dysfunction such that the patient may "feel bad."
- Projections to the cerebellum (via the caudal cerebellar peduncle, in the vestibulocerebellar tracts) which may result in decreased extensor tone on one side of the body and increased tone on the other (leaning).

As with all problems involving the CNS, the location of the lesion, not what caused the lesion(s), determines the signs you see. Therefore, a thorough neurological examination is critical to proper localization and an accurate differential list which, in turn, guides the diagnostic plan.

Peripheral versus Central Disease

For vestibular disease, the first step is differentiating peripheral from central disease. Peripheral vestibular disease is characterized by a head tilt and circling towards the side of the lesion, and pathological nystagmus with the fast phase away from the lesion. Unfortunately, central vestibular disease cannot be definitively ruled out on exam alone. However, any of the following abnormalities can lead to a confident central localization.

- Cranial nerve deficits other than VII or VIII. Deficits associated with VII or VIII alone can be seen with both peripheral and central disease, as can sympathetic dysfunction (Horner syndrome). Involvement of other

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

cranial nerves is typically due to brainstem involvement where the cranial nerve nuclei are situated and there may also be concurrent mentation changes due to the diffuse projections of the reticular activating system (RAS) in this location.
- Cerebrothalamic dysfunction – mentation changes, seizures, head turn +/– wide circles, visual deficits, proprioceptive deficits, etc. Signs are due to multifocal/diffuse disease or increased intracranial pressure.
- Cerebellar signs – intention tremors, hypermetria, truncal sway, absent menace with intact vision. Cerebellar lesions produce ipsilateral signs (or bilateral if diffuse/multifocal cerebellar involvement).
- Proprioceptive deficits +/– paresis – proprioceptive deficits may come from a lesion interrupting the flow of information anywhere along the pathway from the cortex through the thalamus and brainstem (which may result in varying degrees of paresis) or from the cerebellum (no paresis).

The presence of one or more of the above signs, by definition, localizes the problem to the CNS. Central disease may be due to a multifocal problem (i.e., infections, inflammatory disease, lymphoma, multiple metastatic lesions), from increased ICP leading to compression of adjacent vestibular structures, or from direct involvement of the central vestibular system.

Examination of the vestibular patient can be challenging, making localization difficult. For example, patients that are profoundly affected by nausea and imbalance often feel/act mentally dull and lethargic. Supporting patients to assess proprioception can be futile when they are rolling and flailing. Finally, it is important to consider any preexisting disease that may suggest two localizations or multifocal disease, such as a history of cervical pain or seizures.

Nystagmus has been classically used to localize vestibular disease as peripheral versus central, but this should be undertaken with caution. Vertical nystagmus is strongly suggestive of, but not definitive for, central disease. Constant, unchanging horizontal nystagmus is associated with peripheral disease.

Paradoxical vestibular disease is associated with lesions in the rostral and medial vestibular nuclei, the caudal cerebellar peduncle, or the flocculonodular lobe of the cerebellum, and therefore it is always central in origin. Lesions associated with any of these neuroanatomic localizations should produce lateralizing signs. Once the side is determined (i.e., side of proprioceptive deficits, hypermetria), if the head tilt/circling is away from the lesion, +/– the fast phase of the nystagmus towards the lesion, then it is considered paradoxical vestibular disease.

Etiology

To ensure a complete list of differential diagnoses, breaking down differentials into larger categories and then fitting specific differentials into those categories will help limit oversights.

- Degenerative
- Anomalous/congenital
- Metabolic
- Neoplasia, nutritional
- Infectious, inflammatory, idiopathic, iatrogenic
- Toxic, traumatic
- Vascular – hemorrhagic or ischemic

In general, acute versus chronic history should help with ranking differentials. Acute histories are more commonly associated with idiopathic disease, vascular events (ischemic vs hemorrhagic), toxin exposure (metronidazole, ronidazole) +/– otitis interna (usually with an associated chronic otitis externa/media). Thiamine deficiency is often acute and can progress rapidly in cats. Of course, there are always exceptions.

Peripheral Vestibular Disease

Anomalous/Congenital

Some animals are born with signs of peripheral vestibular disease, either unilateral or bilateral. Bilaterally affected animals are commonly deaf as well. The exact cause is unknown, although both degeneration of the vestibular nerve and inflammation of the labyrinth have been described. Recent research suggests a possible genetic mutation in a doberman puppy. The signs are often noted when the animal first becomes mobile. Head tilt and ataxia, +/– circling are seen. Bilaterally affected animals may look more "cerebellar," swinging the head back and forth, and have a more generalized appearance to the ataxia. Often pathological nystagmus is not appreciated and physiological nystagmus is frequently decreased/absent in these bilaterally affected patients. Most animals will remain static or improve with time, but deafness is typically permanent. Congenital vestibular disease and deafness are possible in any breed, but reported breeds include Siamese, Burmese, and Tonkinese cats, Dobermans, cocker spaniels, akitas, German shepherds, beagles, and smooth fox terriers.

Primary secretory otitis media is a disease most commonly seen in Cavalier King Charles Spaniels and less commonly in other brachycephalic breeds, such as french bulldogs. It results in a collection of mucoid effusion in the tympanic bulla presumably due to these breeds extreme nasopharyngeal confirmation compromising normal drainage. It is rarely associated with vestibular signs.

Idiopathic

Canine idiopathic vestibular disease is common in older dogs. The history is often an acute onset of head tilt, nystagmus (fast phase away from the head tilt), ataxia/falling/rolling, drooling/nausea, inappetence, and vomiting. The severity can be quite variable, from mild to extreme. There is no specific treatment, but symptomatic therapy with antinausea/antiemetic medications for apparent nausea, fluid support to maintain hydration until they are eating, +/– diazepam (GABA modulator acting centrally to suppress vestibular responses) can help the patient feel better during recovery. Appropriate recumbent care is necessary in nonambulatory patients, especially since they will often lie only on one side. Improvement can be quick (hours) but more commonly takes 1–3 weeks and often there is a residual head tilt. Signs are exacerbated in the dark since visual compensation is the primary means for improved function. It is uncommon, but possible, for idiopathic vestibular disease to recur. However, repeated events should encourage diagnostic testing to exclude other causes.

Feline idiopathic vestibular syndrome can occur in cats of any age and affects outdoor cats more frequently. It appears to be more common in the summer and fall months in the northeastern United States, although this timing is not appreciated in other parts of the country. Clinical signs are similar to canine idiopathic disease, but vomiting is less common. Diagnosis is based on exclusion of other causes of peripheral vestibular disease. Cats also spontaneously recover within a few weeks.

Infectious

Otitis Media/Interna

Ascending infection via the auditory tube can result in otitis media/interna in the absence of otitis externa. Otoscopic exam may not be conclusive in these cases unless there are obvious changes to the tympanic membrane (bulging, rupture). Otitis externa is often present without concurrent otitis media/interna. Therefore, definitive diagnosis of otitis media/interna typically requires advanced imaging. This may not be practical in all cases. Cats with otitis media may also have evidence of Horner's syndrome as the sympathetic fibers pass through the bullae in this species. Since the facial nerve travels near the horizontal external ear canal and by the bulla, severe and chronic ear disease may also result in signs of facial paresis/paralysis if the periauricular tissues are involved. Depending on the severity of the problem, treatment may involve medical or surgical management. Typically, the outcome is better for surgical management with antibiotic/antifungal therapy based on culture and sensitivity results. Clinical signs may still be present after resolution of infection due to permanent nerve damage, including deafness.

Inflammatory

Nasopharyngeal Polyps

A polyp is a fleshy mass composed of granulation tissue covered with respiratory epithelium, that originates from the lining of either the auditory tube or the middle ear. The primary etiology is unknown, but viral and/or chronic inflammatory processes are suspected to play a role. They are most common in cats 1–5 years of age but have been documented in much older cats as well, with an equal distribution in males and females. Polyps can also lead to secondary infection or inflammation of the middle and inner ear, and therefore, patients may present with vestibular signs. Since the mass can also grow into the pharyngeal area, signs of sneezing and gagging may be the presenting clinical complaint. Polyp removal is typically via traction or surgical approach (ventral bullae osteotomy) but recurrence is possible. Rarely dogs are affected.

Cholesteatoma

A cholesteatoma is a nonneoplastic concretion of keratin debris, keratinizing epithelium, and epidermoid cystic structure(s) that is thought to be a rare sequela of chronic inflammation and is reported infrequently in dogs with otitis media. The cholesteatoma results in bullae expansion and secondary osteolysis. Patients often present for pain on opening the mouth, pain on palpation of the ear, +/– peripheral vestibular signs. Surgical intervention is necessary, so it should not be mistaken for primary infectious otitis and managed medically. There are imaging characteristics that can help differentiate it from primary infectious otitis which should prompt surgical intervention. Risk of recurrence after surgery is high. Monitoring with advanced imaging every 6–12 months should be considered.

Neoplasia

Any neoplastic process adjacent to the vestibular anatomy (such as squamous cell carcinoma, adenocarcinoma, osteosarcoma, fibrosarcoma, chondrosarcoma) can potentially result in peripheral vestibular signs. The mass may track along the skull base where cranial nerves exit their respective foramina, resulting in one or more of the following in addition to vestibular signs: facial paralysis, change in voice, stridor, difficulty swallowing, and tongue deviation or dimpling/contracture. If there are no changes in mentation and no proprioceptive deficits or paresis, localization to the peripheral vestibular system would still be suspected (i.e., the process has not yet invaded the cranial vault to any appreciable degree on exam). Advanced imaging and cytology/biopsy would be needed to determine the extent of the disease, treatment options, and prognosis.

Toxicity

Drug toxicity (topical, intravenous, and inhaled drugs) can result in both deafness and vestibular signs by damaging the hair cells or the vestibulocochlear nerve itself. Antibiotics (aminoglycosides, erythromycin, minocycline, topical choramphenicol, etc.), antiseptics (chlorhexidine), diuretics (furosemide), and miscellaneous other agents (salicylates, propylene glycol, ceruminolytic agents, lead, mercury, etc.) are all recognized as causes of ototoxicity in veterinary patients, with aminoglycoside being the most commonly reported cause. NSAIDs are a well-recognized cause of reversible toxicity in people. Early recognition and withdrawal of the medication may limit damage, but by the time signs are recognized, the damage may be permanent. Even when animals do not recover fully from peripheral disease due to ototoxicity, they usually compensate adequately to maintain a good quality of life.

Metabolic

Hypothyroidism is often linked to peripheral vestibular disease, although the association is tenuous. If hypothyroidism is detected in a patient with peripheral vestibular disease, treatment should be considered.

Trauma

Since the vestibular apparatus is housed in the hardest bone in the body, the petrous temporal bone, trauma is not a common cause of vestibular disease. However, blunt trauma, typically hit by car, can result in skull/bulla fractures, hemorrhage in the soft tissues of the middle and inner ear and lead to vestibular disease. Horner's syndrome and facial paralysis may also result from direct trauma or soft tissue swelling/hemorrhage involving the adjacent tissue as they are in close proximity to CN VIII. Treatment for the vestibular signs would be supportive care and time. Resolution of vestibular signs may be incomplete.

Central Vestibular Disease

Brain tumors, stroke-like events, drug toxicities (such as metronidazole and ronidazole), nutritional deficiencies (thiamine), infections (such as distemper, feline infectious peritonitis, *Toxoplasma gondii*, *Neospora caninum*, and fungal infections) or diseases that cause inflammation of the brain (such as granulomatous or necrotizing meningoencephalitis) may all lead to central vestibular disease in both the dog and the cat.

Anomalous/Congenital

Malformations resulting in central vestibular signs may be present at birth but can progress over time due to obstruction of CSF flow either within cystic structures (i.e., arachnoid cysts/diverticuli) or leading to progressive dilation of the fourth ventricle. Arachnoid diverticuli within the quadrigeminal cistern are more commonly associated with seizures if clinical signs are present at all, but vestibulocerebellar signs may be noted. Caudal occipital malformation syndrome (also called a Chiari-like malformation) that leads to a degree of obstructive hydrocephalus and dilation of the fourth ventricle or bulbomyelia may result in central vestibular signs. Severe generalized hydrocephalus can occasionally be associated with vestibular signs because of fourth ventricle involvement, but this would be an uncommon clinical sign. Malformations leading to high cervical instability (i.e., atlantooccipital or atlantoaxial subluxation/luxations) can rarely lead to secondary edema and inflammation extending cranial to involve the vestibular nuclei but caudal nuclei involvement would also be present.

Infection

Otitis can extend through the internal acoustic meatus and result in intracranial disease with compression of the brainstem from abscess formation or even active meningitis/encephalitis, although this is less common. Infectious agents are usually bacterial, but fungal disease is also possible.

Systemic infections involving the CNS or infections apparently isolated to the CNS are uncommon in dogs, with the exception of certain signalments and geographic locations: *Cryptococcus* on the west coast, coccidiodiomycosis in desert locales, histoplasmosis and blastomycosis in the Midwest, to name a few. Infections typically cause multifocal signs that may include the vestibular system.

Young dogs and cats are at higher risk for viral diseases, with distemper and FIP being the most commonly diagnosed.

Neospora and distemper appear to have a predilection for cerebellar involvement which may result in vestibular signs.

Vascular

Vascular events (ischemic vs hemorrhagic) typically have an acute onset, but may appear progressive over a 24-hour period. Causes of vascular events often do not have an underlying identifiable cause, but screening for causes of thromboembolic disease, +/− bleeding disorders, is warranted.

Hypertension, primary or secondary, can lead to vestibular episodes. Many of these cases mimic idiopathic vestibular disease in history and examination findings, but the events will often recur, similar to TIAs in people, and only resolve or improve once hypertension is controlled. In cases where there is an acute onset of vestibular signs that clearly localize to the central vestibular system, the cerebellum is most commonly involved, in

the author's experience. MRI may be normal or show evidence of ischemia within the vestibular system. A normal MRI cannot exclude an ischemic event as the area of compromised tissue may be smaller than the resolution of the MRI (especially in small patients and low field magnets), or sequencing that best highlights tissue ischemia may not be available (software limitations). MRI done in close temporal relationship to the onset of signs could miss lesions that may be evident if done a few hours to days later. Very small hemorrhages or ischemic areas may be missed if gradient echo or diffusion-weighted sequences are not pursued.

Hypothyroidism can result in the formation of atherosclerosis, leading to vascular thrombosis and signs mentioned earlier.

Hemorrhagic vascular events are less common and underlying causes such as thrombocytopenia, clotting deficiencies (rodenticide toxicity, liver disease, etc.), metastatic hemangiosarcoma, and hypertension should be investigated.

Inflammatory

Inflammatory CNS disease (i.e., granulomatous meningoencephalitis, necrotizing meningoencephalomyelitis, and breed-specific encephalitides) is one of the more common diseases neurologists diagnose. Young to middle-aged toy-breed dogs are typically affected, but any age and breed are susceptible. It usually presents as multifocal disease and the patient may have one or more of the following clinical signs: vestibular signs, cervical pain, paresis, cranial nerve deficits, circling, obtundation, seizures. The cause is unknown but may be a combination of genetic predisposition and an antigenic trigger (recent illness, vaccination/medication, environmental antigenic stimulation) resulting in an inappropriate immune system attack on nervous tissue. MRI and spinal fluid analysis are needed at a minimum to determine a diagnosis. Often ruling out infectious disease (i.e., PCR on CSF, serology, cultures, etc.) is necessary as the inflammation may be secondary to another cause. Biopsy would be needed for a definitive diagnosis and, given the invasiveness, risk and cost associated, is not often pursued. Therefore, treatment is based on the signalment, history, and collection of diagnostic results supporting a sterile inflammatory disease process.

As with other immune/inflammatory diseases, treatment involves immunosuppression with one or more medications (i.e., prednisone, cytosar, azathioprine, cyclosporine, etc.) for a prolonged period of time, often months, sometimes years. Response to treatment can be quite variable, but in the author's experience many patients can be weaned off drugs with the less severe forms of disease. Inflammatory granulomas can cause mass lesions that may be mistaken for neoplasia. These granulomas seem to have a predilection for the cerebellar pontine angle, leading to vestibulocerebellar signs, but can occur in other locations as well.

Neoplasia

Neoplastic processes that affect the central vestibular system include those that are commonly found at the cerebellar pontine angle (CPA), such as malignant peripheral nerve sheath tumors of the trigeminal nerve that extend intracranially, meningiomas, chorioid plexus tumors, or ependymomas. Meningiomas, gliomas, round cell tumors, and metastatic disease involving the cerebellum (flocculonodular lobe) or brainstem vestibular nuclei can also result in vestibular signs. Changes in intracranial pressure due to neoplastic mass lesions elsewhere can result in vestibular signs due to brainstem or cerebellar compression (including cerebral herniation under the tentorium cerebelli or cerebellar herniation from the foramen magnum). MRI, +/−CSF, and surgical or CT-guided biopsy are necessary to confirm an antemortom definitive diagnosis of neoplasia. However, most diagnoses of intracranial neoplasia are made on imaging characteristics and treated as such with radiation therapy, +/− chemotherapy with definitive diagnosis only confirmed after necropsy.

Nonneoplastic Mass Lesions

Epidermoid cysts, dermoid cysts, and teratomas are thought to arise from trapped ectodermal embryonic tissue as the neural tube is closing and therefore could be included in the anomalous category. When found intracranially, they appear to have a predilection for the caudal fossa and thus can produce vestibular signs. Other nonneoplastic mass lesions that could produce vestibular signs include arachnoid cysts/diverticuli, inflammatory granulomas, cholesterol granulomas, infectious abscesses/granulomas, parasitic cysts, and hematomas.

Nutritional

Thiamine deficiency (vitamin B1) in carnivores often includes signs of central vestibular disease in addition to cerebrothalamic signs (mental dullness, seizures) and postural changes, cervical ventroflexion (in cats in particular), and paraparesis in dogs. Cat are more commonly affected than dogs and signs can progress rapidly. Unconventional diets (raw fish diets, diets cooked at very high temperatures, diets with sulfur dioxide preservatives) are typically the cause, but even commercial diets can lead to thiamine deficiency. Bilaterally symmetric changes on MRI (most apparent on FLAIR and gradient echo sequences) within the brainstem nuclei (caudal colliculi are most affected) are classic for thiamine deficiency. Histologic changes include petechial hemorrhages, edema, and neuronal necrosis.

Ideally, patient thiamine levels +/– diet thiamine levels would be pursued. Often, supplementation with thiamine and resolution of signs may be the only option. The signs are completely reversible if treated in a timely manner and fatal if untreated.

Metronidazole and Ronidazole Toxicity

Toxicity associated with metronidazole is most often found with high doses (15–30 mg/kg BID) or prolonged therapy even at more conservative doses. Signs vary in severity and often appear more cerebellar than vestibular, but may include vertical nystagmus or ocular tremors, intact vision with absent menace, mild to severe generalized ataxia, possibly progressing to a nonambulatory state with decerebellate posturing, hypermetria in ambulatory patients (sometimes more severe in the PL), kyphosis, and proprioceptive deficits without loss of strength.

Discontinuation of the medication will result in resolution of signs over days to weeks, but treating with IV or oral diazepam (0.5 mg/kg TID 3–5 days) can expedite recovery.

Ronidazole is most commonly used for the treatment of tritrichomonas foetus in cats and toxicity results in similar signs as above.

The mechanism of toxicity is not known. In people, changes on MRI show bilaterally symmetric alterations in the cerebellar dentate nuclei signal intensity and often the vestibular nuclei as well. There is speculation that it may be mediated by thiamine deficiency due to similar MRI changes in patients diagnosed with Wernicke encephalopathy.

Meningoencephalitis and Meningomyelitis

Christopher L. Mariani, DVM, PhD, DACVIM (Neurology)

College of Veterinary Medicine, NC State, Raleigh, NC, USA

Etiology/Pathophysiology

The meninges comprise three connective tissue layers that surround the brain and spinal cord: the pia mater, arachnoid mater (these collectively known as the leptomeninges), and the dura mater (or pachymeninx). Inflammation of the meninges, known as meningitis, may remain confined to these structures, or may also involve the underlying brain and/or spinal cord, termed *meningoencephalitis* and *meningomyelitis* respectively.

There are a whole host of infectious diseases that can cause inflammation of the meninges or underlying central nervous system (CNS) in small animals. These include viral, bacterial, fungal, rickettsial, protozoal, and parasitic organisms (Table 73.1). These organisms may infect the CNS as part of a systemic, multiorgan process (e.g, *Rickettsia rickettsia*, canine distemper, *Blastomyces dermatitidis*) although some agents display a notable neurotropism with CNS entry via the bloodstream or nasal passages (e.g., *Cryptococcus neoformans*, *Cladophialophora bantiana*). Within the CNS, these infectious agents may cause clinical signs through a variety of mechanisms. Their presence often results in an immune response with resulting inflammation. Such an inflammatory response can occasionally involve the vasculature supplying the CNS, leading to vascular injury and resulting ischemic or hemorrhagic disease. Inflammation of the ependymal surface and changes in the viscosity of the cerebrospinal fluid (CSF) can result in disruption of CSF flow and obstructive hydrocephalus (e.g., with feline infectious peritonitis [FIP]). Some organisms can infect neurons or glia, causing direct dysfunction or death of these cells (e.g., canine distemper virus).

Despite this large number of organisms that can cause CNS disease, documented infections comprise a very small proportion of small animal meningoencephalitis and meningomyelitis cases. Cats are generally considered more likely to develop infectious CNS disease than dogs, although documentation of infectious agents is still difficult in this species. In dogs, the vast majority of meningoencephalitis and meningomyelitis cases appear not to have a direct infectious cause, and are often termed "sterile" as a result. In these animals, invading immune cells lead to CNS inflammation and resulting clinical signs. Whether these represent a response to an as yet undetected infectious organism, an overactive immune-mediated response to an unknown environmental trigger or a true autoimmune process remains to be determined. However, broad screening studies aimed at detecting previously unknown infectious agents have thus far been relatively unrewarding, and an immune-mediated process appears more likely for the majority of canine cases.

There are several well-recognized syndromes that occur in dogs where infectious agents have not been identified (Table 73.2). Many of these conditions are highly breed associated and a genetic role in their pathophysiology has long been suspected. Such a role has been best investigated in pug dogs with necrotizing meningoencephalitis (NME). Several studies in this breed have shown a strong association of disease with a specific haplotype localized in the major histocompatibility complex (MHC) II region of chromosome 12. This finding resembles what is seen in many immune-mediated diseases in humans, including multiple sclerosis. However, this association probably does not identify a strictly causative mutation, but likely confers an increased risk of disease development, and it is suspected that other factors, such as the presence of a "trigger" to set the disease in motion, also play a role. Interestingly, other dog breeds with NME that develop a histologically identical lesion do not seem to share the same at-risk haplotypes as pugs and clearly more work to define these underlying susceptibilities needs to be done.

The pathophysiology of most canine and feline meningoencephalitides is relatively poorly understood,

Table 73.1 Infectious agents causing meningoencephalomyelitis in small animals

Category of agent	Examples of specific organisms
Viral	Canine distemper virus, feline infectious peritonitis, feline immunodeficiency virus, rabies, pseudorabies, West Nile virus
Fungal	*Cryptococcus neoformans*, *Coccidioides immitis*, *Blastomyces dermatidis*, *Aspergillus* spp., *Cladophialophora bantiana*
Rickettsial	*Ehrlichia canis*, *Rickettsia rickettsia*, *Anaplasma phagocytophilum*
Bacterial	*Streptococcus* spp., *Bartonella* spp., *Borrellia burgdorferi*, *Leptospira* spp.
Protozoal	*Neospora caninum*, *Toxoplasma gondii*, *Entamoeba histolytica*
Parasitic	*Cuterebra* spp., *Dirofiliaria immitis*, *Baylisascaris procyonis*, *Angiostrongylus* spp., *Prototheca* spp.

and has been sparsely investigated. One exception is steroid-responsive meningitis-arteritis (SRMA), which is a systemic inflammatory condition with a focus of inflammation in the leptomeninges and its associated arteries.

Epidemiology

Environmental conditions and exposures play an important role in the transmission of many of the infectious organisms that cause meningoencephalitis or meningomyelitis. These include housing density and animal-to-animal transmission (e.g., canine distemper virus, FIP), transmission via wildlife bites (e.g., rabies, feline immunodeficiency virus [FIV]), exposure to soil or stagnant water sources (e.g., *Blastomyces dermatidis*, *Cryptococcus neoformans*, *Entamoeba histolytica*), or transmission from insect or arthropod vectors (e.g., *Dirofilaria immitis*, *Ehrlichia canis*, *Rickettsia rickettsia*). As mentioned above, most of the CNS inflammatory diseases seen in

Table 73.2 Presumed noninfectious inflammatory central nervous system (CNS) conditions in dogs

Condition	Breeds predisposed	Neuroanatomic distribution	Typical cerebrospinal fluid results	CNS imaging
Steroid-responsive meningitis-arteritis (SRMA)	Boxer, Bernese mountain dog, beagle, petit basset griffon Vendéen, Nova Scotia duck tolling retriever, Weimaraner	Meninges of cervical region, rarely involves underlying CNS	Marked neutrophilic pleocytosis	Possible meningeal enhancement, may be normal
Granulomatous meningoencephalitis (GME)	Terriers, miniature poodle	Preferentially affects medulla, cerebellum, and cervical spinal cord	Moderate-marked mononuclear or mixed pleocytosis	Meningeal enhancement, contrast-enhancing CNS parenchymal lesions, focal mass lesion possible
Necrotizing meningoencephalitis (NME)	Pug, Maltese, Chihuahua, shih tzu, papillon, Pekingese	Forebrain	Mild-marked mononuclear pleocytosis; occasionally normal	Meningeal enhancement, brain parenchymal lesions with or without enhancement, loss of gray-white matter distinction, mass effect possible
Necrotizing leukoencephalitis (NLE)	Yorkshire terrier, French bulldog	White matter of forebrain and brainstem	Mild-marked mononuclear pleocytosis; occasionally normal	Brain white matter parenchymal lesions with or without enhancement
Idiopathic eosinophilic meningoencephalitis	Rottweiler, golden retriever	Brain usually involved, occasionally spinal cord	Eosinophilic pleocytosis (>20% eosinophils)	Possible meningeal enhancement and parenchymal CNS lesions; poorly described and variable in literature
Generalized tremor syndrome ("little white shaker/shaky dog disease")	Often small white dogs	Likely diffuse CNS	Mild mononuclear pleocytosis or normal	Possible meningeal enhancement, often normal; poorly described in literature
Greyhound meningoencephalitis	Greyhounds	Forebrain (olfactory bulbs, frontal and temporal lobe gray matter, caudate nuclei)	Mild-moderate mononuclear pleocytosis, can be normal	Brain parenchymal lesions with minimal or absent contrast enhancement

dogs have no known infectious etiologies, and are likely immune-mediated processes that occur in individuals with a genetic predisposition after some sort of antigenic "trigger." Such triggers remain unknown at this time but might be related to exposure to environmental antigens or to antigens from infectious agents not involving the CNS (e.g., respiratory or gastrointestinal infection).

Signalment

Although dogs and cats of any age or breed can be affected by inflammatory CNS disease, certain populations are predisposed to its development. Infectious diseases occur more frequently in younger animals, which may be related in part to maturation of the immune system or vaccination failures. As mentioned above and detailed in Table 73.2, many of the apparent noninfectious canine meningoencephalitides have strong breed predispositions, and these diseases also have fairly consistent ages of onset. As a general rule, meningoencephalitis occurs more frequently in young to middle-aged animals. Gender seems to play a minor role in most of these diseases, although some early reports of GME and a more recent study of NME have described a female predominance. In contrast, most of the dogs reported to develop eosinophilic meningoencephalitis have been male.

History and Clinical Signs

The history may reveal important predisposing factors for some of the infectious diseases, including vaccination history, exposure to ticks or mosquitoes, animal bites, ingestion of raw food or carrion, and exposure to soil or stagnant water. Obtaining a thorough travel history may elucidate additional potential differential diagnoses as some of the tick-borne and fungal diseases have clear geographic distributions.

Clinical signs of meningoencephalitis and meningomyelitis typically have an acute onset with progression over time; chronic infection or inflammation of the CNS is unusual. The signs seen are dependent on the region of the nervous system that is involved. Animals with meningitis (including SRMA) typically present for pain, particularly cervical pain, and neurologic deficits are frequently absent or subtle. Patients with forebrain involvement may present with seizures, altered mentation, depressed consciousness, visual deficits, and compulsive pacing or circling. Brainstem disease can result in cranial nerve deficits such as vestibular dysfunction, facial nerve paralysis, pupillary abnormalities, strabismus, dysphagia, megaesophagus or tongue atrophy together with ataxia and paresis of all four limbs. Myelitis also results in ataxia and paresis, together with spinal pain and possibly deficits in segmental spinal reflexes. Postural reaction deficits may be seen with lesions in any of these regions. One hallmark of inflammatory disease of the CNS is that it frequently results in a multifocal distribution of signs (i.e., multifocal lesion localization), which is uncommonly seen with other disease processes.

Occasionally, signs that are very characteristic for a specific disease may be noted, such as distemper "myoclonus" or rigid limb extension due to muscle contractures in dogs with *Neospora caninum* infection. In addition, some infectious diseases may involve multiple organ systems, producing signs referable to the respiratory system (e.g., canine distemper, blastomycosis), bone (*Coccidioides immitis*), integument (canine distemper, blastomycosis), gastrointestinal tract (canine distemper, *Prototheca*) or other systems. Involvement of other systems is not typical for the "sterile" meningoencephalitides, although occasionally polyarthritis is seen in dogs with SRMA.

Diagnosis

A complete blood count may show abnormalities with certain infectious agents, such as thrombocytopenia with rickettsial infections or eosinophilia with some parasite or protozoal diseases. If CNS inflammation is part of a multisystemic infectious or inflammatory process, then a neutrophilic or monocytic leukocytosis may be evident. Serum chemistry may similarly show abnormalities in certain conditions such as hyperglobulinemia with FIP or *Ehrlichia canis* infections or changes indicative of renal or hepatic dysfunction in multisystemic infections. However, in most animals with inflammatory CNS disease, the complete blood count (CBC), serum chemistry, and urinalysis are relatively unremarkable. Although infrequently analyzed, acute phase proteins may show changes in some animals, such as elevations in serum C-reactive protein, fibrinogen or serum amyloid A protein.

A diagnosis of meningoencephalitis or meningomyelitis is most commonly made with advanced diagnostic imaging and analysis of CSF. Conventional imaging tests such as radiography or ultrasound have little role in the diagnostic process outside of screening other organs within the thoracic and abdominal cavities for disease. Myelography is a technique that involves the injection of contrast material into the subarachnoid space, followed by radiography of the vertebral column. Interruptions in the flow of contrast material can result in several imaging patterns indicating mass lesions in

extradural, intradural-extramedullary or intramedullary locations. Although myelography may be abnormal with meningomyelitis if a mass effect or spinal cord swelling is a component of the disease process, these abnormalities are nonspecific and rarely facilitate a definitive diagnosis. In addition, myelography itself results in inflammation of the meninges and spinal cord, which can worsen clinical signs, and so this intervention must be pursued with caution. Therefore, more advanced imaging modalities are preferred for patients with potential inflammatory CNS disease, if available.

Computed tomography (CT) is a technique that utilizes X-rays to produce cross-sectional images of desired anatomic structures. Software packages allow manipulation of images to highlight tissues of varying densities ("windowing") and images can be obtained both before and after the administration of intravenous contrast material, which can highlight areas within the CNS where normal vascular barriers are compromised (e.g., neoplastic tissue, areas of inflammation). Computed tomography can also be combined with myelography to improve visualization of contrast within the subarachnoid space, which increases the diagnostic utility of this latter technique. In animals with meningoencephalitis or meningomyelitis, CT may show areas of hypodensity within the brain or spinal cord parenchyma respectively, corresponding to inflammation and associated edema; these areas often show enhancement after contrast administration. Meningeal enhancement, either occurring alone or in conjunction with parenchymal enhancement, may also be noted. There are some limitations associated with CT imaging, including a relative lack of sensitivity for inflammatory lesions when compared with magnetic resonance imaging (MRI) and the occurrence of a phenomenon known as beam hardening artifact, which compromises imaging of the medulla oblongata due to the thick nature of the adjacent petrous temporal bone.

Magnetic resonance imaging is currently the gold standard for visual evaluation of CNS anatomy and associated disease states. Compared with CT, it has improved sensitivity for the detection of most CNS pathology, including inflammatory diseases. It utilizes a completely novel technology that does not rely on ionizing radiation but rather on placing the patient in a high magnetic field and delivering radiofrequency pulses, which change the movements and behavior of hydrogen atoms (protons) within the patient. As these protons move, they create a magnetic signal that is captured to generate images. As protons are primarily concentrated within water in biologic tissues, the differences in water content between different tissues and different pathologic processes are what determine the contrast within the images generated. The parameters controlling delivery of the radiofrequency pulse and capture of the resulting signal can be adjusted to create many different sequences, which can highlight or remove signals associated with certain tissues or pathologies. Inflammatory lesions generally appear as hypointense on T1-weighted images and hyperintense on T2-weighted images, with some degree of enhancement after contrast administration. Enhancement of both parenchymal lesions and meninges can be seen after intravenous contrast administration. This enhancement varies in intensity and uniformity, and may be influenced by a variety of factors including the degree of inflammatory cell infiltrate, associated tissue edema and the presence of necrotic tissue within the lesion.

The analysis of CSF is an integral part of the diagnostic process for patients with inflammatory CNS disease. Cerebrospinal fluid can be collected from the cerebellomedullary cistern or the lumbar subarachnoid space. Normal CSF has very few leukocytes (0–5/μL), an absence of erythrocytes, and a low protein concentration (0–20 mg/dL). Meningeal, brain or spinal cord inflammation usually leads to increases in leukocytes (pleocytosis) and protein concentration within the CSF. Occasionally, an infectious (e.g., canine distemper) or noninfectious meningoencephalitis or meningomyelitis will lead to an increased protein without a corresponding increase in white blood cell numbers, which is known as albuminocytologic dissociation. Cytologic evaluation of the CSF can also provide valuable information to the clinician. The composition of leukocytes within the CSF can provide clues to an infectious etiology in some cases (e.g., eosinophilic pleocytosis with parasitic and some fungal infections, lymphocytic pleocytosis with viral infections) or can be associated with presumed immune-mediated conditions in others (e.g., neutrophilic pleocytosis with SRMA, mononuclear pleocytosis with NME). In rare cases, infectious organisms can be visualized on CSF cytology (e.g., *Cryptococcus neoformans*).

It must be noted that CSF pleocytosis is not exclusive to inflammatory disease, as such a pattern can also be seen with other conditions, including neoplasia or acute trauma. In addition, albuminocytologic dissociation is a common and relatively nonspecific change seen with compressive, vascular, neoplastic, and degenerative CNS diseases. As a result, CSF evaluation is ideally performed in conjunction with advanced diagnostic imaging (preferably MRI) in order to rule out these other conditions.

Despite utilizing both CNS imaging and CSF analysis, the diagnosis can remain elusive in some cases. The most common scenario is difficulty in distinguishing inflammatory from neoplastic disease. In these situations, obtaining meningeal and/or brain tissue for histologic evaluation may be the best way to arrive at a definitive diagnosis. Brain biopsy is rarely performed for suspected

meningoencephalitis, although advances in stereotactic biopsy systems and minimally invasive methods may help in making such an option more acceptable to both clinicians and the owners of affected animals. As GME, NME, and NLE are diagnoses that can only be made with histopathology, many clinicians will refer to cases of inflammatory CNS disease diagnosed with imaging and CSF analysis as meningoencephalitis of unknown etiology (MUE) or unknown origin (MUO). This designation typically does not include dogs with SRMA, eosinophilic meningoencephalitis, or greyhound meningoencephalitis as these patients have distinctive signalments, clinical syndromes, imaging findings, and/or CSF abnormalities (see Table 73.2).

A variety of assays are available to identify infectious agents within the blood, CSF or other body fluids. These include assays for organism antigens (e.g., *Cryptococcus neoformans*), antibodies generated against the organism (e.g., IgG and IgM for canine distemper or *Toxoplasma gondii*), and polymerase chain reaction (PCR) for organism DNA or RNA. Cytologic findings associated with other body systems (e.g., inclusion bodies in cells from a conjunctival swab in animals with canine distemper) may also aid in the diagnosis of certain infectious diseases and prompt additional testing for suspected organisms.

Therapy

Therapy for meningoencephalitis and meningomyelitis depends on the underlying etiology causing the inflammation, but typically involves antimicrobial, antiinflammatory or immunosuppressive medications. There are no antiviral medications known to be effective or currently recommended for use in small animals with CNS viral infections, and treatment for these patients remains largely supportive. Animals with a documented or suspected bacterial meningoencephalitis are ideally treated with an antibiotic that shows good penetration of the blood–brain and blood–CSF barriers (Table 73.3). Antifungal medications are indicated in some patients, and these also vary in their ability to penetrate the CNS. Doxycycline not only has antibacterial activity with good CNS penetration, but also is the drug of choice for animals with rickettsial infections. Animals with *T. gondii* or *N. caninum* infections may respond to sulfa antibiotics, clindamycin and/or pyrimethamine. Animals with infectious meningoencephalitis often benefit from short-term, antiinflammatory doses of glucocorticoids, although immunosuppressive doses and prolonged administration of these medications should be avoided as they can impair clearance of the infecting organisms and substantially worsen clinical signs.

Table 73.3 Antimicrobial medications for meningoencephalitis and meningomyelitis

Medication	Dosing	Indications	Additional considerations
Potentiated sulfonamides (e.g., trimethoprim/sulfa)	15 mg/kg q12h	Bacterial meningitis, protozoal disease of central nervous system (CNS)	Consider concurrent folate supplementation
Clindamycin	5–25 mg/kg q12h	Bacterial meningitis, protozoal disease of CNS	Penetration of CNS controversial
Doxycycline	5–10 mg/kg q12–24h	Bacterial or rickettsial disease of CNS	
Third-generation cephalosporins	Variable	Bacterial meningitis	
Chloramphenicol	25–50 mg/kg q8h (dog) or 12–25 mg/kg q12h (cat)	Bacterial meningitis	Concurrent use with phenobarbital not recommended
Fluoroquinolones (enrofloxacin, ciprofloxacin)	5–15 mg/kg q12h (ciprofloxacin) 2.5–10 mg/kg q12h (enrofloxacin)	Bacterial meningitis	Penetration of CNS controversial Avoid higher doses in cats due to retinal toxicity
Metronidazole	10–15 mg/kg q12h	Bacterial meningitis (anaerobic)	CNS toxicity possible at higher doses
Meropenem	25 mg/kg IV q8h	Bacterial meningitis	Doses up to 40 mg/kg q8h have been suggested but not tested in veterinary patients
Fluconazole	2.5–10 mg/kg q12–24h	Fungal infections	
Pyrimethamine	0.5–1 mg/kg q24h	Protozoal infections	

Treatment of the "sterile" meningoencephalitides focuses on the control of inflammation and suppression of the immune system with glucocorticoids and in some cases additional immunosuppressive medications. Prednisone or dexamethasone is often started at antiinflammatory doses after imaging studies and CSF collection, pending the results of infectious disease testing. Antimicrobial drugs are usually indicated while awaiting these results. When the clinician has ruled out infectious causes, the patient is reassessed and their response to therapy is evaluated. Some animals will respond fully to antiinflammatory glucocorticoids. However, those with an absent or partial response will often benefit from escalation to an immunosuppressive dose (Table 73.4). If remission is achieved, this dose is continued for an extended period and then the dose is slowly reduced over a period of weeks to months. Some animals are eventually able to have their glucocorticoid therapy discontinued, although they must be monitored closely for relapse of clinical signs. Conversely, many patients require long-term and often life-long therapy.

Some conditions, such as SRMA, generalized tremor syndrome and idiopathic eosinophilic meningoencephalitis, can typically be managed with glucocorticoids alone. This strategy can also work for patients with GME, NME or NLE although anecdotal evidence suggests that these dogs do not respond as well, and may benefit from additional immunosuppressive therapy. This benefit may occur due to additional mechanisms of immunosuppression (typically interference with lymphocyte proliferation) or by allowing a decreased glucocorticoid dose, which reduces adverse effects and improves overall management. Several different immunosuppressive drugs have been utilized in this scenario (see Table 73.4), and choice is based primarily on clinician preference, as rigorous studies demonstrating a

Table 73.4 Antiinflammatory and immunosuppressive medications for meningoencephalitis and meningomyelitis

Medication	Dosing	Mechanism of action	Adverse effects	Additional considerations
Prednisone or prednisolone	0.5–1.0 mg/kg q12–24h (antiinflammatory); 2.2–6.6 mg/kg/day (immunosuppressive)	Regulation of inflammatory gene expression, impaired leukocyte migration, interference with arachidonic acid cascade and cytokine production	Polyuria, polydipsia, polyphagia, gastrointestinal ulceration, hypercoagulability, hepatopathy	Prednisolone preferred in cats
Dexamethasone	0.07–0.15 mg/kg q12–24h (antiinflammatory); 0.3–1.0 mg/kg/day (immunosuppressive)	As for prednisone	As for prednisone	
Cytosine arabinoside	200 mg/m^2 IV over 8–24 hours or 50 mg/m^2 SC twice daily for 2 days	Interferes with pyrimidine (DNA) synthesis	Nausea, vomiting, bone marrow suppression, hepatic toxicosis	
Leflunomide	3–4 mg/kg/day	Interferes with pyrimidine (DNA) synthesis	Nausea, diarrhea, lethargy, bone marrow suppression (rare)	
Azathioprine	2 mg/kg q24h initially (5–14 days) then 0.5–1.0 mg/kg q48h	Interferes with purine (DNA) synthesis	Vomiting, diarrhea, bone marrow suppression, hepatic toxicosis	Clinical effect may be delayed up to 4–6 weeks
Mycophenolate mofetil	10 mg/kg q8h or 20 mg/kg q12h (dogs)	Interferes with purine (DNA) synthesis	Vomiting, diarrhea	
Ciclosporin A	5 mg/kg q12–24h	Calcineurin inhibitor (inhibits T cell proliferation)	Inappetence, vomiting, diarrhea, gingival hyperplasia, papillomatosis, hepatic or renal toxicosis (rare)	May adjust according to response or blood concentrations; concurrent ketoconazole administration may allow lower dose
Lomustine (CCNU)	60–90 mg/m^2 q4 weeks	Alkylating agent	Bone marrow suppression, hepatic toxicosis	
Procarbazine	25–50 mg/m^2 q24h	Alkylating agent (suspected)	Nausea, vomiting, bone marrow suppression, hepatic toxicosis	

clear benefit of these medications have not yet been published. The use of other immunomodulatory interventions, such as intravenous immunoglobulin and plasmapheresis, is an intriguing possibility that has yet to be investigated in small animal patients. Anticonvulsant therapy is utilized in animals with seizures. Dogs with generalized tremor syndrome may also benefit from concurrent diazepam therapy. Although the pain associated with meningoencephalitis or meningomyelitis usually improves dramatically with glucocorticoid therapy, additional analgesics such as gabapentin or opioid medications may prove beneficial until the inflammation subsides.

The primary means of monitoring response to therapy in animals with inflammatory CNS disease is assessment of clinical signs based on examination and questioning of the owners. Although complete normalization is ideal and achievable in many patients, some animals are left with residual deficits. A significant challenge for the clinician is to determine if such deficits are the result of active inflammation or permanent damage (i.e., loss of cells or tissue) to the CNS. Periodic monitoring with a CBC and serum biochemistry is indicated in patients receiving glucocorticoids or other immunosuppressive drugs to detect adverse effects associated with therapy (e.g., myelosuppression, hepatic failure) as well as infections occurring secondary to immunosuppression. Monitoring of serum drug concentrations is not routinely performed, although some clinicians will utilize this for ciclosporin A. Similarly, repeat CNS imaging and/or CSF evaluation can be helpful in some patients to assess the degree of ongoing inflammation and other pathology, although this is not routinely performed by all clinicians and is obviously dependent on the owner's financial means. Serial monitoring of antibody or antigen titers can be useful in the monitoring of some infectious diseases.

Prognosis

The prognosis for animals with inflammatory CNS disease is highly variable, and depends on both the underlying etiology as well as an individual's response to therapy. Some animals with viral disease may clear the virus, and the prognosis depends on the amount of damage that occurred to the CNS while infected (e.g., canine distemper). These animals may survive, although often with residual deficits (e.g., distemper "myoclonus"). Conversely, some viral diseases such as rabies, pseudorabies, and FIP are invariably fatal. Fungal disease typically requires long-term and often life-long therapy. Animals with bacterial or protozoal diseases can be treated successfully although they may be left with residual deficits and the prognosis is typically guarded.

Dogs with SRMA, generalized tremor syndrome, and idiopathic eosinophilic meningoencephalitis, usually have a good prognosis, with full resolution of clinical signs and long-term remission after therapy, although relapses are possible. The prognosis for dogs with GME, NME, and NLE is much more variable. Although some of these patients may respond fully to treatment, life-long therapy is typical, and many dogs will have an incomplete response. In addition, some dogs progress and die in spite of aggressive treatment. However, the prognosis for cases cited in the literature is likely to be overly pessimistic, as there is a bias towards dogs that have had disease confirmation via histopathology. Finally, the prognosis for animals with greyhound meningoencephalitis has been suggested to be poor, although aggressive therapeutic intervention has not yet been described in the literature.

Diseases of the Neuromuscular Junction

David Lipsitz, DVM, DACVIM (Neurology)

Veterinary Specialty Hospital, San Diego, CA, USA

The neuromuscular junction (NMJ) consists of the efferent nerve terminals, the neuromuscular cleft, and the postsynaptic membrane. As an action potential reaches the presynaptic nerve terminal, voltage-gated calcium channels open, allowing Ca^{2+} ion efflux into the presynaptic nerve terminal. This Ca^{2+} influx allows synaptic vesicles containing neurotransmitter to dock and fuse with the sarcolemma in the process of exocytosis, thereby releasing the neurotransmitter acetylcholine (ACh) into the synaptic cleft. Fusion of the vesicular and plasma membranes is mediated by SNARE (soluble N-ethylmaleimide-sensitive fusion) proteins. Some of the SNARE proteins that are used for synaptic vesicle exocytosis include synaptobrevin (VAMP1), syntaxin 1a, and synaptosome-associated protein 25 (SNAP-25). These SNARE proteins may be the target of many disease processes and toxins.

The ACh released from these vesicles then diffuses through the synaptic cleft and binds to the nicotinic acetylcholine receptors (nAChRs) located on the specially folded postsynaptic muscle fiber sarcolemma. The adult nACHR has been shown to have four different protein subunits (α, β, δ, ε). The receptor is arranged in the fashion of five subunits: 2 α1, β1, δ, ε. These subunits span the lipid bilayer, creating a water-filled pore which forms a "hydrophobic girdle" that acts as a barrier to ion permeation. When ACh binds to the receptor, it undergoes conformational change that allows a preferential influx of Na+ > Ca++ and an efflux of potassium. This region is also closely associated with a high density of sodium channels in order to promote and amplify the signal to assure the propagation of an action potential to generate muscle contraction. As the sodium ions move into the muscle membrane, local depolarization occurs in what is termed an endplate potential (EPP) which spreads across the surface of the sarcolemma, with the ensuing excitation-contraction coupling allowing the muscle fiber to contract. The magnitude of the EPP is dependent on the amount of ACh released and the amount of nAChRs but there is normally an abundance of both, resulting in a large safety factor for neuromuscular transmission. Acetylcholinesterase then breaks down the ACh (producing choline and esterase) and the ACh diffuses away from the synapse, allowing the sodium channels to close. New ACh molecules are synthesized when the choline is transported, through reuptake into the presynaptic terminal.

The clinical presentation in animals with neuromuscular transmission disease is very similar regardless of whether the disorder is presynaptic (i.e., botulism) or postsynaptic (i.e., myasthenia gravis). There is usually a symmetric progressive generalized weakness in all limbs. Exercise intolerance is often seen as well. Tendon reflexes may or may not be intact. There is often facial muscle, laryngeal, pharyngeal or esophageal weakness associated with these disorders. Sensory function is unaffected, as would be expected.

Myasthenia Gravis

Myasthenia gravis (MG) is a neuromuscular transmission disorder caused by a reduction in the number of functional nAChRs on the postsynaptic membrane. It is usually the result of an acquired autoimmune disease and much less commonly a congenital disorder.

Clinical Presentation

Myasthenia gravis should be a consideration in any animal being examined for focal or generalized neuromuscular weakness. The clinical signs may be focal in nature and limited to esophageal dilation leading to regurgitation, pharyngeal dysfunction causing dysphagia and laryngeal paresis/paralysis causing dysphonia (voice change). Multiple cranial nerve abnormalities may also occur in

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

the absence of generalized muscle weakness. One study demonstrated that 43% of dogs with a confirmed diagnosis of MG (positive AChR antibody titer) did not have clinically detectable limb muscle weakness. The remaining 57% of dogs had generalized weakness, with 13% of these having no esophageal or pharyngeal dysfunction.

The classic presentation of a dog with MG is generalized muscle weakness that worsens with activity but not all animals display this exercise intolerance. Dogs are more likely than humans or cats to develop megaesophagus because the canine esophagus contains more skeletal muscle than smooth muscle. If megaesophagus is present there is a higher risk of aspiration pneumonia. An acute fulminating form of MG (<5% of cases) has been described. These dogs present with acute onset of rapidly developing signs. They are usually tetraparetic/plegic with marked respiratory distress due to a combination of aspiration pneumonia and respiratory muscle weakness. These animals require intensive care and may need ventilatory support. For this reason, acute fulminating MG has a higher mortality rate. This form has also been associated with a higher rate of thymoma. Thirty to 50% of dogs with thymoma may develop MG. In order for these cases to resolve, thymectomy is recommended.

The clinical signs of MG in cats are also variable, with the two most common clinical signs being generalized weakness without megaesophagus and generalized weakness associated with a cranial mediastinal mass. The incidence of megaesophagus and dysphagia was lower compared to dogs. Myasthenia gravis was also documented in five hyperthyroid cats. These cats developed weakness 2–4 months after treatment with methimazole and were seropositive (AChR antibodies). It was postulated that the drug caused a reversible lack of tolerance to self-AChRs

Acquired Myasthenia Gravis

Acquired MG is an immune-mediated disorder in which autoantibodies (typically IgG) against postsynaptic nicotinic AChRs of skeletal muscle are produced, resulting in impaired neuromuscular transmission.

In acquired MG, there is a T lymphocyte-dependent production of specific autoantibodies directed against the main immunogenic region (MIR) of the nicotinic ACHR, which is located at the extracellular tip of the α1-subunits, allowing antibodies to cross-link AChRs and induce antigenic modulation. These antibody complexes result in immune-mediated destruction of the postsynaptic receptor via three main mechanisms:

- there is complement-dependent lysis of the postsynaptic membrane caused by antibodies bound to AChRs
- antibody cross-linked AChRs result in increased internalization of AChRs, a decreased receptor lifespan and a decrease in the total number of AChRs
- direct inhibition of AChR function.

A familial acquired MG has been reported in the Newfoundland and Great Dane.

Diagnosis of Acquired Myasthenia Gravis

The diagnosis of MG cannot be made on clinical signs alone and should be considered in any animal with signs of neuromuscular disease. Other diseases that may have similar clinical presenting signs include inflammatory and noninflammatory myopathies, polyneuropathy, especially acute ones such as polyradiculoneuritis, endocrine disorders such as hypoadrenocorticism or other diseases of neuromuscular transmission such as tick paralysis, botulism, and organophosphate toxicity. A minimum database including a complete blood count (CBC), chemistry profile with creatine kinase (CK), urinalysis and potentially a thyroid panel should be done to rule out other conditions resulting in or contributing to weakness. Thoracic radiographs may identify megaesophagus, aspiration pneumonia, or a cranial mediastinal mass.

The use of the short-acting anticholinesterase drug edrophonium chloride (Tensilon®) (dogs 0.1–0.2 mg/kg IV and cats 0.25–0.5 mg total dose) may provide a presumptive diagnosis of MG but there are both false-positive and false-negative results. An overdose of edrophonium or its use in a nonmyasthenic patient may cause parasympathetic overstimulation and necessitate the use of atropine sulfate. Cats should be pretreated with atropine as they appear to be more sensitive to edrophonium. Dramatic improvement in muscle strength after edrophonium administration provides a presumptive diagnosis of MG but other myopathic or neuropathic disorders may also show an improvement. Dogs with fulminant MG may not have enough AChRs available to elicit a noticeable response. In dogs with focal MG, there may not be a positive response to the edrophonium chloride test or it may be hard to judge the improvement, for instance in a dog with megaesophagus alone. Unfortunately edrophonium chloride is no longer clinically available therefore this type of testing would be limited to clinicians who have any remaining supply of edrophonium. It is the authors clinical experience that injectable neostigmine can be used as a diagnostic challenge as well. Standard dosing (dogs 0.04 mg/kg IM) is used and the time to respond skin may be up to 30 minutes.

Electrodiagnostic testing may also be useful to add supportive evidence to the diagnosis and exclude other neuromuscular disorders. Electromyography (EMG) and

nerve conduction studies are normal in MG. Repetitive nerve stimulation may show a decremental response of the compound muscle action potential but does lack sensitivity and specificity. More than one muscle group should be tested, especially in patients with focal MG. Single-fiber EMG (SFEMG) is a sensitive test of neuromuscular transmission and techniques for recording SFEMG have been described in both the cat and the dog. SFEMG records the variability of consecutive discharges of the interpotential interval between two muscle fiber action potentials belonging to the same motor unit (jitter). In MG, the jitter values are increased. SFEMG is technically difficult to perform and not widely available. All these electrodiagnostic tests need to be performed under general anesthesia so may not be suitable for all cases of neuromuscular weakness based on their anesthetic risk assessment.

The gold standard for the diagnosis of MG is the demonstration of serum autoantibodies directed against muscle AChRs. The test is extremely sensitive and specific but cannot predict the degree of weakness or severity of the disease. Immunosuppressive drugs may lower the antibody titers and serum should ideally be submitted before the use of corticosteroids or other immunosuppressive drugs. An AChR antibody titer of greater than 0.6 nmol/L in the dog and 0.3 nmol/L in the cat is diagnostic for MG, with rare false-positive results. Seronegative MG occurs in approximately 2% of dogs with generalized MG but the incidence of seronegative focal MG is unknown. The AChR assay is species specific and while there is cross-reactivity, canine or feline assay systems should be used. Low-positive titers may be missed if a human AChR is used as an antigen.

Congenital Myasthenia Gravis

Congenital MG is characterized as a postsynaptic deficiency of ACh receptors with no evidence of autoimmune destruction, with a congenital familial form (autosomal recessive trait) having been described in Jack Russell terriers, springer spaniels, and smooth fox terriers. A congenital MG was described in three 8-week-old miniature smooth-haired dachshunds. These dogs had decreased density of ACh receptors in intercostal muscle biopsy samples with no demonstrable AChR antibodies or antibody complexes demonstrated against the AChR in muscle biopsies. Interestingly, their clinical signs resolved spontaneously at six months of age which is not typical but is similar to a familial infantile myasthenia described in humans. There are a few cats reported with congenital MG.

Diagnosis of Congenital MG

The diagnosis of congenital MG should be considered in any young animal with the typical clinical presentation of acquired MG (see later). Regurgitation associated with megaesophagus has been reported in congenital MG but not as commonly as in acquired MG. As expected based on the pathology, serologic tests for AChR antibodies would be negative. A positive edrophonium (Tensilon) response test (0.1–0.2 mg/kg IV) can be consistent with the diagnosis of congenital MG but does not allow for differentiation of the acquired form of the disease and a negative test does not exclude the diagnosis of congenital MG. Other neuromuscular disorders may be excluded by routine serologic and electrophysiologic testing and muscle and nerve biopsy. Fresh-frozen muscle biopsy samples may also be evaluated for localization of AChE, AChR, AChR subunits, IgG, and complement components at the neuromuscular junction. Quantification of muscle AChR may be done but requires a fresh muscle specimen intact from origin to insertion, such as external intercostal or anconeus muscle.

Anticholinesterase drugs should be of benefit in animals with AChR deficiency. Congenital cases of MG do not seem to respond as completely as the acquired disease with full return of strength being unusual. The weakness can often progress to death within the first year but with proper care and anticholinesterase therapy, some affected Jack Russell terriers have survived several years. Both cats reported with congenital MG survived several years.

Seronegative Myasthenia Gravis

Seronegative MG does occur and the patients may have the same clinical presentation as a seropositive case. Seronegative MG in dogs is defined as a patient with clinical signs suggestive of MG, a positive edrophonium response, supportive electrodiagnostic testing (decremental response on repetitive nerve stimulation, increased jitter on SFEMG), improvement of muscle weakness after anticholinesterase therapy, and at least two negative serum AChR antibody titers. The antibody titers should be repeated 1–2 months apart as seroconversion may occur.

Seronegative MG may occur because there are antibodies directed against non-ACHR end plate proteins, the antibodies are all bound to the endplates with little to no circulating antibodies, or the antibodies may be lost during the AChR extraction procedure.

In humans, autoantibodies have been detected against a receptor tyrosine kinase, MuSK, in about 70% of AChR seronegative patients. The MuSK enzyme is located on the postsynaptic membrane and induces acetylcholine accumulation. A dog with a negative AChR antibody titer and positive MuSK autoantibodies has been identified. The ryanodine receptor (RyR) may also play a role in MG. This channel receptor is responsible for the release of calcium necessary for muscle contraction. Autoantibodies

against RyR have been detected in both humans and dogs and in conjunction with AChR antibodies can cause a severe form of thymoma-associated MG.

In people with MG, autoantibodies directed at striational muscle proteins (myosin, actin, alpha-actinin, titin, sarcoplasmic reticulum) have been described. They have also been described in the dog. Since these proteins are normally not exposed to circulating antibodies they are thought to be nonpathogenic but may reflect muscle damage in cases where the AChR antibody titer is negative, thereby supporting a diagnosis of MG. Eighty percent of human patients with thymoma and MG, 24% of thymoma patients without MG, and 30% of MG patients without thymoma have antistriational antibodies. The incidence in dogs is not known.

Treatment

There are many reported treatments of MG but well-controlled prospective studies are not available. Many canine patients will undergo spontaneous remission. In one study, 47/53 (88.7%) AChR antibody-positive patients treated with anticholinesterase drugs alone went into remission over an average of 6.4 months. This included focal, generalized, and fulminating forms. The presence of spontaneous remission needs to be considered when evaluating any treatment modality. Good clinical judgment should be used when determining the therapeutic options in a case of MG. The presence or absence of dysphagia, esophageal weakness or megaesophagus may necessitate alternate feeding procedures such as elevated feedings, a "Bailey Chair" (www.baileychairs4dogs.com) or a gastrotomy tube.

Anticholinesterase inhibitor (AChEI) drugs are the key therapy for MG and work by prolonging the action of acetylcholine at the neuromuscular junction. The dose may need to be titrated to effect as these drugs have both muscarinic and nicotinic effects. A return to full muscle strength is the goal. Animals can develop a cholinergic crisis (weakness, abdominal pain, salivation, and diarrhea) and need treatment with atropine and a decrease in dosage or discontinuation of the AChEI. The most commonly used drugs are pyridostigmine bromide (Mestinon® 1–3 mg/kg PO BID-TID) and neostigmine bromide (Prostigmin® 2 mg/kg/day divided to effect). Pyridostigmine is most commonly used because it has a longer duration and fewer muscarinc effects. It is available as a tablet, syrup, and timed-release formulation. In critically ill patients or those with regurgitation that cannot take oral medication, a constant rate infusion (CRI) of pyridostigmine bromide (0.01–0.03 mg/kg/h) may be used. The author has used neostigmine as a CRI at the same dosage but found that it had many more adverse GI signs.

Corticosteroids may be used to treat MG if the patient is not adequately responding to anticholinesterase therapy alone. The optimal dosing regimen has not been determined prospectively in the dog, but large immunosuppressive doses are not recommended, especially in the face of aspiration pneumonia. In mild to moderately affected myasthenic dogs, a dose of 0.5 mg/kg daily to every other day has been recommended. There are reports of high-dose methylprednisolone therapy benefiting people but this must be used with caution in dogs. Other immunosuppressants and immunomodulators that have been described in case studies/series in the veterinary literature are azathioprine, ciclosporin A, and mycophenelate mofetil. These are uncontrolled retrospective case series and although success was noted in many of these cases, the use of these drugs should be tailored to each individual case at this time. As an example, a retrospective study of 27 dogs with AChR-positive antibody titers reported that there was no beneficial effect in dogs treated with pyridostigmine in combination with mycophenelate mofetil compared to pyridostigmine alone. Plasmapheresis has been described as a successful treatment in a single case report and more recently has been described in several dogs that had therapeutic plasma exhange. These were serologically confirmed patients with marked generalized weakness, megaesophagus, and aspiration pneumonia that were not adequately responding to traditional treatment. These dogs responded well to the therapy. Although promising, this may have limited value due to cost and the need for specialized equipment.

The management of severely compromised respiratory patients due to aspiration pneumonia and intercostal or diaphragm weakness usually needs to be done at facilities with intensive care facilities and the ability to ventilate patients if needed. Respiratory failure is the most common cause of death in these patients. Antibiotics with the potential for neuromuscular blockade such as aminoglycosides and ampicillin should be avoided.

Serial monitoring of the AChR antibody titer should be done in all patients and treatment should continue until the antibody titer is negative. This would need to be interpreted in light of any concurrent immunosuppression.

Treating acquired feline MG is very similar to the dog but since there is a higher incidence of thymoma in cats, all patients should have thoracic radiographs whether or not signs of megaesophagus or respiratory distress are present. The natural course of the disease in cats is also not known so we do not know if they also have spontaneous remission. Cats can be treated with anticholinesterase drugs but may also handle the adverse effects of corticosteroids better than dogs and therefore these may be more beneficial.

Other Disorders of Neuromuscular Transmission

Presynaptic Disorders

Tick Paralysis

A salivary neurotoxin secreted by certain tick species can interfere with ACh release, resulting in impaired neuromuscular transmission and clinical weakness. The signs are usually that of an acute progressive lower motor neuron (LMN) disease. The North American common wood ticks, *Dermacentor variabilis* and *Dermacentor andersoni* (Rocky Mountain wood tick), are most often responsible for the disease. In Australia, *Ixodes holocyclus* is the most important species. Less commonly associated ticks are *Ixodes cornuatus*, *I. hirsti*, *I. pacificus*, and *I. scapularis*.

The clinical signs are commonly seen as pelvic limb ataxia that then progresses to involve the thoracic limbs, leading to recumbency in 24–72 hours. Dysphonia and dysphagia can be early signs, and masticatory muscle weakness and facial paresis may also be present. Death may occur within several days from respiratory paralysis. The diagnosis is made by clinical signs and resolution of signs following tick removal. Prognosis is usually good, with recovery occurring in 1–3 days following complete tick removal.

In Australia, the clinical signs with *Ixodes* spp tend to be more severe and include autonomic disturbances that include peripheral vasoconstriction, arterial hypertension, increased pulmonary capillary hydrostatic pressure, pulmonary congestion and edema, tachyarrhythmias, and pupillary dilation. In addition to the previously described clinical presentation, other signs may include voice change, depressed gag reflex, megaesophagus, salivation, regurgitation and/or vomiting, dyspnea, and cyanosis. Death may occur within 1–2 days in untreated patients. In addition to tick removal and supportive care, neutralization of circulating toxins can be attempted with tick antitoxin serum. The antitoxin serum adverse effects are anaphylaxis and autonomic disturbance. The antiserum treatment needs to be given in the early stages of the disease and is expensive. Alpha-adrenergic blocking agents such as phenoxybenzamine hydrochloride and prazosin may help with the hypertension. Severely affected animals with respiratory compromise may require ventilator support.

The prognosis can be guarded even with appropriate treatment. The prognosis seems to be inversely related to the severity of clinical signs, as dogs with mild disease recovered more quickly than those with severe paresis/paralysis and respiratory compromise.

Botulism

Botulism occurs by ingesting the preformed neurotoxin (exotoxin) of *Clostridium botulinum* which is contained in carrion or spoiled food. In rare cases, botulism may occur as a result of colonization of the gastrointestinal (GI) tract (toxico-infectious) or wound infection. There are eight botulinum toxins but type C1 is the most common in dogs although there have been infrequent reports of type C2 and D. Botulism has not been reported in the cat.

Botulinum neurotoxins inhibit neurotransmitter release from the presynaptic nerve terminals by cleaving proteins required for synaptic vesicle fusion with the plasma membrane. They may affect either the synaptic vesicles (synaptobrevin) or the plasma membrane (SNAP-25 and syntaxin), depending on the neurotoxin serotype. The neurotoxins enter the nerve terminal by specifically interacting with the luminal domain of synaptic vesicle proteins (synaptotagmin or SV2, depending on serotype) which are briefly exposed during exocytotic membrane fusion. This leads to a presynaptic blockade of ACH release and resulting muscle weakness. There may be some disturbance in autonomic function as well.

The clinical signs may occur within hours to days and are typically an acute onset of symmetric diffuse LMN dysfunction starting in the pelvic limbs and progressing forward. The severity of dysfunction may range from mild weakness to complete tetraplegia with respiratory paralysis. The spinal reflexes are not intact and there is often paresis associated with cranial nerve functions such as the facial musculature, laryngeal, pharyngeal and esophageal musculature.

The diagnosis can be made by detection of the toxin in ingested material, serum, vomit, and feces and by a neutralization test in small mice. Samples should be collected as early as possible in the course of the disease. ELISA tests have been used in the detection of botulinum toxin in people but not for type C (reportedly used in cattle) so obtaining a diagnosis by this method would be difficult. Electrodiagnostic studies may be useful to differentiate botulism from other acute disorders such as polyradiculoneuritis. There may be a slight decrease in motor nerve conduction velocity and decreased amplitude of the compound muscle action potential (CMAP). Repetitive nerve stimulation may reveal a decremental response at low (>5 Hz) rate or incremental response at high (>50 Hz) rate. EMG may show some spontaneous activity such as fibrillation potentials and positive sharp waves but it is often normal.

Treatment of botulism consists of supportive care, with mildly or moderately affected dogs recovering over a period of several days. Intensive management may be required for dogs needing ventilatory support or having megaesophagus and dysphagia as they are at high risk for

aspiration pneumonia. Recumbent nursing care, which includes frequent turning, good padding to prevent decubital ulcers and bladder care, is essential for a good recovery and to avoid secondary complications. Oral antibiotics are of no benefit, unless toxico-infectious botulism is suspected and in that case penicillins or metronidazole would be indicated. Administration of *C. botulinum* antitoxin needs to be type specific and would not be beneficial unless a specific type C-antitoxin were available. The antitoxin administration only helps to inactivate circulating unbound toxin and not toxin already fixed at the site of neuromuscular junction damage so, depending on the timing of administration, it could be too late in the course of the disease to use. Complete recovery is possible with proper care and should occur within 1–3 weeks. Dogs with aspiration pneumonia and respiratory paralysis may have a more guarded prognosis depending on severity and the ability to obtain respiratory support.

Postsynaptic Disorders

Organophosphate and Carbamate Toxicity

Organophosphates (OP) and carbamates are commonly used compounds found in many pesticides and insecticides. They are long-acting anticholinesterases that irreversibly bind acetylcholinesterase (AChE) in nervous tissue and muscle, allowing accumulation of ACh to cause continuous cholinergic stimulation. This occurs in central, muscarinic, and nicotinic cholinergic synapses, resulting in clinical signs that include autonomic overstimulation (salivation, lacrimation, urination, defecation) and neuromuscular dysfunction. A delayed OP-induced polyneuropathy has also been described. Clinical toxicity in veterinary medicine is usually associated with inappropriate or accidental dosing, with cats being more susceptible to these compounds than dogs. Historical information is imperative to reaching the diagnosis.

Although serum cholinesterase concentrations can be measured, the results are usually not available in a timely fashion so a presumptive diagnosis based on history and clinical signs is enough to begin treatment.

Clinical signs of OP intoxication are usually dominated by the autonomic effects, but neuromuscular signs include a stiff rigid gait, muscle tremors, and fasciculation (except for fenthion).

Treatment for these toxicities consists of reducing further exposure or absorption by bathing or gastric lavage as appropriate. Atropine sulfate can be titrated to effect to counteract the parasympathetic signs. Pralidoxime chloride (2-PAM or protopam chloride) and pralidoxime mesylate (P2S) can be used in OP toxicity but not in carbamate toxicity (except for aldicarb). These oxime reactivators cause release the bound AChE from the OP compound.

Drug-Induced Neuromuscular Blockade

Certain drugs have been shown to induce NMJ blockade in veterinary medicine although most reports are experimental, with very few documented clinical cases. The most commonly associated antibiotics are aminoglycosides, lincomycin, penicillamine, polymyxins, and tetracyclines. The mechanism of action in aminoglycoside NMJ blockage is presynaptic inhibition of ACh release as a result of blocked calcium influx. There is also blockage of calcium influx on the postsynaptic membrane. The degree of transmission impairment with aminoglycosides depends on the specific drug and the balance between the pre- and postsynaptic effects. The most potent effects, in descending order, are from neomycin, kanamycin, amikacin, gentamicin, and tobramycin. Penicillamine has been documented to cause an immune-mediated MG in people. Polymyxins have their most profound effect on the postsynaptic membrane by acting as a noncompetitive nondepolarizing agent. Tetracyclines have the proposed effect of chelating calcium ions and thereby depressing the effect of ACh on the postsynaptic muscle fiber.

It is important to remember that these drugs can potentiate neuromuscular blocking agents used during surgical procedures or may worsen or unmask preexisting disorders of neuromuscular transmission. The use of these agents should be avoided in the treatment of other neuromuscular disorders such as MG patients. Other drugs that have a reported effect on neuromuscular transmission are antiarrhythmic agents, phenothiazines, methoxyflurane, magnesium, and the antiprotozoals chloroquine and quinine. Methimazole has been documented to cause a reversible drug-induced autoimmune MG in hyperthyroid cats.

Black Widow Spider Envenomation

The black widow spider (*Lactrodectus* spp.) has a worldwide distribution. The most potent component of its venom is the purified fraction B known as alpha-latrotoxin. The toxin causes a massive release of neurotransmitter and loss of synaptic vesicles. The synaptic vesicle loss is caused by increased fusion and docking of the synaptic vesicles with the plasma membrane and inhibition of new vesicle formation.

The cat appears to be more susceptible to envenomation and the clinical signs usually occur within the first eight hours. There are fine muscle tremors, muscle spasticity, abdominal rigidity, pain, and profound flaccid muscle weakness. Hypertension and electrolyte abnormalities may also occur.

Treatment consists of administering the appropriate antivenin and supportive care. A rapid response to the antivenin is reported in people.

Snake Envenomation

There are four families of snakes that produce venom which causes neuromuscular blockade: Atractaspididae (African mole viper), Colubridae (bloomsang, twig snake), Elapidae, and Viperidae. The Elapidae have three major subfamilies: Elapidae (cobras, mambas, coral snakes), Hydrophiinae (sea snakes), and Laticaudinae (sea kraits). The Viperidae have two major subfamilies: Crotalinae (pit vipers, copperheads, cotton mouths, and rattle snakes) and Viperinae, the "Old World" vipers (carpet vipers, adders, desert vipers).

The pit viper toxin that causes neuromuscular weakness is the Mojave toxin. It causes a presynaptic block of ACh release which can then lead to complete neuromuscular blockade when there is a facilitatory release of neurotransmitter leading to complete cessation of neurotransmitter release. The Elapidae family, such as the coral snake, produce at least three neurotoxins (taipoxin, beta-bungarotoxin, and notexin). These toxins have phospholipase A_2 activity and damage synaptic vesicles. There is also a change in the morphologic structure of the motor axon terminal, including a decreased number of synaptic vesicles. The clinical signs of snake envenomation are of a progressive neuromuscular weakness with cranial nerve involvement, with death usually resulting from respiratory paralysis. If the snake can be identified then the use of antivenin has a positive effect on outcome, especially the coral snake.

Myopathies

Marguerite F. Knipe, DVM, DACVIM (Neurology)

School of Veterinary Medicine, University of California Davis, Davis, CA, USA

Etiology/Pathophysiology

Myocytes are specialized cells, with contractile elements (actin and myosin) comprising the majority of the intracellular space, along with the other organelles (mitochondria, lysosomes, etc.) Disruption of myocytes (myofibers) will result in decreased ability to contract the muscle with appropriate strength. Myopathies occur secondary to either intrinsic pathology within the myofiber itself (noninflammatory myopathy) or infiltration and damage by inflammatory cells (myositis) from infectious or immune-mediated disease. Any disruption of the muscle membrane or intracellular structures results in myofiber dysfunction, whether through accumulation of storage products, through cellular infiltration, or dysfunction of the sarcolemma, other cytoskeletal proteins, or membrane ion channels.

Epidemiology

The wide range of etiologies for myopathies makes delineating epidemiology difficult for each specific disease. About one-third of canine generalized inflammatory myopathies (myositides) are associated with infectious agents, although a causal relationship will be difficult to determine unless histopathologically confirmed. There is also an association with canine polymyositis and skeletal muscle lymphoma, whether through malignant transformation of infiltrating lymphocytes, a paraneoplastic syndrome, or as primary skeletal muscle lymphoma.

Signalment

Inherited myopathic processes (Box 75.1) typically exhibit clinical signs in young animals (<6 months old) and may be static or progressive. Acquired myopathies (Box 75.2) may develop at any age, and are often progressive unless the underlying cause is addressed.

Some myopathies have (to date) only been described in certain breeds (Box 75.3), and presentation by one of these breeds with appropriate clinical signs should raise suspicion for one of these breed-associated myopathies.

History and Clinical Signs

Functional manifestations of myopathies may include gait abnormalities (lameness, stiff or stilted gait), exercise intolerance, focal or generalized weakness, dysphonia, dysphagia, regurgitation, possibly megaesophagus, muscle tremors and/or fasciculations, and postural alterations (e.g., cervical ventroflexion, especially in cats). The history and clinical signs of patients with myopathies are often the same as with other neuromuscular diseases (neuropathies and junctionopathies), so noting these signs in the patient's history often just localizes a problem to the neuromuscular system, and not necessarily specifically to a nerve, muscle, or junction problem.

Specific physical manifestations of myopathies may include decreased muscle mass (atrophy or hypotrophy) or even hypertrophied muscles in some diseases (myotonia congenita, some muscular dystrophies). Very young patients with muscle diseases may have limb deformities

Box 75.1 Inherited myopathies (all non-inflammatory)

Muscular dystrophies
- Myotonias and other channelopathies (myotonia congenita, hyperkalemic periodic paralysis)
- Congenital myopathies (nemaline rod myopathy, centronuclear myopathy, others)
- Metabolic myopathies (glycogen or lipid storage diseases)
- Mitochondrial myopathies

Box 75.2 Acquired myopathies

Inflammatory myopathies
- Infectious – bacterial, protozoal, etc.
- Immune mediated
  - Masticatory muscle myositis (MMM)
  - Polymyositis
  - Dermatomyositis
  - Inclusion body myositis
  - Lymphoma-associated polymyositis

Endocrine myopathies
- Hypothyroidism
- Hyperadrenocorticism

Electrolyte imbalance, especially potassium, calcium, magnesium

Cachexia

Box 75.3 Breed-associated myopathies

Familial polymyositis
Hungarian Vizsla dogs, Newfoundland, boxer

Dermatomyositis
- Collie, Shetland sheepdog

X-linked myotubular myopathy
- Labrador retriever

Centronuclear myopathy
- Labrador retriever, border collie

Muscular dystrophies
- Golden retriever, Japanese spitz, Labrador retriever, cats, German short-haired pointer, Cavalier King Charles spaniel, miniature schnauzer, among others

Inherited myopathy of Great Danes

Glycogen storage diseases
- Curly-coated retrievers (type IIIa)
- Lapland dog (type II)
- English springer spaniel (phosphofructokinase deficiency – type VII glycogen storage disease)

or orthopedic abnormalities secondary to the effects of abnormal muscle forces on the bones.

Patients with myositis (inflammatory myopathies) may exhibit apparent myalgia or pain on muscle palpation. Dogs with masticatory muscle myositis often present with apparent pain on opening the mouth or chewing.

Diagnosis

History, physical, and neurologic examinations permit the clinician to localize a problem to the neuromuscular system. Further isolating the problem to a myopathic process typically requires a combination of serologic, functional, and histologic evaluation of the muscle.

Hematology/Serology

In certain myopathic diseases with prominent myonecrosis or rhabdomyolysis, serum creatine kinase (CK) level may be elevated (normal 55–260 IU/L), and in some myopathies (e.g., muscular dystrophy), serum CK can be markedly elevated (>50 000 IU/L). CK is specifically released secondary to damage to the myofiber sarcolemma. Not all myopathies have elevations in CK, so a normal CK does not rule out a myopathic process; however, with appropriate clinical signs, elevated serum CK will raise the suspicion of a myopathy.

Canine masticatory muscle myositis (MMM) is an immune-mediated disease against the 2M myofibers, exclusively located in the muscles of mastication (temporalis, masseter, pterygoids, rostral digastricus). A serologic assay for 2M antibodies is available through the Comparative Neuromuscular Laboratory (http://vetneuromuscular.ucsd.edu/), and is highly sensitive and specific.

Functional

Electromyography (EMG) performed on the anesthetized patient assesses the stability of the muscle membrane. Normal muscle maintains electrical silence on EMG, while myofibers with membrane instability will depolarize spontaneously, resulting in abnormal spontaneous activity (fibrillation potentials, positive sharp waves, complex repetitive discharges). One EMG abnormality specific for myotonia is the presence of myotonic discharges which spontaneously wax and wane, but more often than not, EMG alone is not sufficient to diagnose a myopathy. Abnormal spontaneous activity on EMG indicates either a myopathic process or denervation of that muscle, so motor nerve conduction velocities should be done to assess nerve function, as well as muscle and nerve biopsies to assess muscle histology.

Electromyography is useful to confirm that the motor unit is affected and helps the clinician determine the extent of the disease process (focal, generalized). EMG may be especially helpful to screen for subclinical disease; a common recommendation for EMG examination is to assess a minimum of two limbs, usually the thoracic and pelvic limbs on one side of the patient. Often, only one side is examined with EMG to maintain the opposite limbs free of iatrogenic mechanical injury from the exploring needle so biopsies can be obtained. Sometimes an additional limb is examined (e.g., both pelvic limbs and a thoracic limb), especially if the clinician wants to assess the contralateral limb for comparison.

Histology

A definitive diagnosis of a myopathy is based on histologic abnormalities of the muscle. For the clinician, biopsy selection, handling, and processing are extremely important. Prior to biopsy, clinicians must decide whether they will submit fresh muscle to a specialized laboratory for processing, or will take samples to submit in formalin for routine histopathologic evaluation. Fresh muscle must be packed appropriately and shipped overnight to the lab, so the clinician must schedule sampling and shipping so that the muscle arrives in good condition.

For generalized disease processes, biopsies of the triceps, biceps femoris/quadriceps, and cranial tibial muscles permit evaluation of both proximal and distal muscles, as well as the thoracic and pelvic limbs. Temporalis muscle, if affected, is another muscle frequently sampled, particularly if there is a clinical suspicion of MMM (although measuring serum 2M antibody titer is less invasive – see Hematology/Serology earlier). If a different, specific muscle is the only one affected, then the clinician should consider sampling that as well. By sampling multiple muscles, the clinician increases the likelihood of obtaining a biopsy with pathologic changes, since only a small portion (about 1 cm^3) of any muscle is taken, and focal or multifocal processes may be missed. Two laboratories process international veterinary fresh muscle samples, and information on shipping is available on their websites (see Resources below).

Muscle histopathology is broadly categorized into inflammatory (true myositides) or noninflammatory (dystrophic) myopathies (see Boxes 75.1 and 75.2). Macrophages are present for myofiber phagocytosis from any cause, but true myositis is characterized by excessive cellular infiltration in the endo- and perimysium, with lymphocytes, neutrophils, and eosinophils, as well as macrophages. If the myositis is secondary to an infection, the causative agent may be apparent in the biopsy, but again, the small sample makes it highly likely that microorganisms may be missed.

Noninflammatory myopathies may have vacuoles, abnormal accumulations within the myofibers, loss of normal cytoskeletal architecture (cores), necrosis and phagocytosis with macrophages only, may have nonspecific abnormalities, or may be completely normal on histopathology.

Therapy

For inflammatory myopathies, specific treatment for the infectious process or immunosuppression is indicated, but for most noninflammatory myopathies, unless an underlying or concurrent treatable disease is identified that could cause the myopathy (e.g., electrolyte imbalance, endocrine disease, etc.), there are no definitive treatments.

Nonspecific Therapy

Nutritional supplementation with L-carnitine (50 mg/kg PO q12h), co-enzyme Q10 (100 mg PO q24h), and vitamin B complex for "muscle support" has been recommended for many noninflammatory myopathies, and there are only anecdotal reports of clinical improvement with these medications.

Inflammatory Myopathies

If an infectious etiology (parasitic, bacterial, protozoal, etc.) is identified on biopsy or suspected clinically, appropriate antimicrobial therapy should be instituted. In small animal medicine, immune-mediated myositides are likely more common than infectious, and immunosuppressive therapy is required. In some cases, immune-mediated myositis may be secondary to a chronic infection. Clinicians may choose from several different immunomodulatory drugs, including glucocorticoids, azathioprine, and cyclosporine.

Prognosis

Prognosis will depend on the specific underlying myopathy, and can range from grave to excellent. Some inherited myopathies may have tolerable clinical signs and function throughout the life of the patient (e.g., some myotonias), while others progress relentlessly to markedly impair quality of life (e.g., muscular dystrophies).

For most acquired myopathies, if the underlying cause is identified and appropriately treated, patients may have an excellent outcome.

Myelopathy

Joan R. Coates, DVM, MS, DACVIM (Neurology)

Department of Veterinary Medicine and Surgery, College of Veterinary Medicine, University of Missouri, Columbia, MO, USA

Myelopathy is a nonspecific term representing pathologies that result in signs of spinal cord dysfunction. It is important for the clinician to recognize the neurologic signs of myelopathy and to differentiate from or avoid misdiagnosis of other mimicking orthopedic and neuromuscular (nerve, muscle, neuromuscular junction) disorders. Signalment, history, and physical and neurologic examination findings will establish presence of a myelopathy, provide neuroanatomic localization and consideration of differentials. Ultimately, with neurodiagnostics to narrow the differential diagnosis, appropriate therapies can be selected for treatment or management of patients with spinal cord disease.

History

An accurate clinical history is important in defining the cause of the myelopathy. Time of onset (sudden or insidious), rate of progression (static, gradual or rapid), and temporal relation (intermittent/episodic, stable or chronic) can be established. Acute disorders such as fibrocartilaginous embolism (FCE), aortic thromboemboli, trauma, discospondylitis, and Hansen type I intervertebral disc herniation and meningomyelitis often present with sudden onset and can be rapidly progressive (Table 76.1).

Chronic disorders such as spinal canal/spinal cord neoplasia, degenerative lumbosacral syndrome, cervical spondylomyelopathy, degenerative myelopathy, and Hansen type II intervertebral disc herniation cause insidious signs of myelopathy (Table 76.2).

Pathophysiology

The spinal cord serves as a conduit for the upper motor neuronal fibers, sensory pathways and the origin of the motor units of the cervical, thoracic, lumbar, sacral, and caudal segments. The severity of motor and sensory deficits from spinal cord disease is dependent upon the rapidity of disease onset, extent of lesion involvement, and the area within the vertebral column.

Spinal cord injury occurs through primary mechanical and secondary injury mechanisms. Primary injury results from extrinsic or intrinsic injury processes causing laceration, compression, contusion, ischemia, and inflammation of the tissue. The acute stage consists of primary tissue effects after injury such as central hemorrhage after a severe compression/concussive injury. Typically, myelopathic changes initially involve the gray matter with centrifugal spread to the white matter. Sequential hemorrhage, edema, and neuronal necrosis depend on severity and type of injury. The primary injury initiates a cascade of vascular, ionic, and biochemical events, associated with ischemia that contributes to secondary spinal cord injury processes and irreversible neuronal damage. Physical attributes of the chronic stage subsequent to secondary injury mechanisms include cavitation, presence of apoptosis, and Wallerian degeneration. Neurodegenerative diseases related to underlying inherited, metabolic or toxic causes result in intrinsic neuronal degeneration involving the cell body, axon, and/or myelin.

Clinical Signs

The primary objective of the neurologic examination in spinal cord disease is to determine an accurate neuroanatomic localization (C1–5, C6–T2, T3–L3, L4–S3, and caudal segments) (Table 76.3) and lesion distribution (focal, multifocal, diffuse). Careful interpretation of the neurologic examination is essential to avoid diagnostic procedures that are inappropriate for lesion determination and potentially harmful to the patient.

Table 76.1 Differential diagnosis for acute-onset myelopathy

Differential category	Differentials	Comments
Degenerative	*Hansen type I intervertebral disc herniation*	Asymmetric or symmetric
Anomalous	*Atlantoaxial instability*	Usually symmetric
Neoplastic	*Metastatic, vertebral body tumors, pathologic fracture, histiocytosis, lymphoma, other hematopoietic neoplasia*	Often asymmetric
Inflammatory (infectious)	*Bacterial, protozoal, and fungal meningomyelitis, canine distemper virus, feline infectious peritonitis, discospondylitis, spinal cord epidural empyema*	Asymmetric or symmetric
Inflammatory (noninfectious)	*Steroid-responsive meningitis-arteritis, granulomatous meningoencephalomyelitis*	Usually symmetric
Trauma	*Fracture/subluxation*, acute noncompressive intervertebral disc herniation	Asymmetric or symmetric; nonprogressive
Vascular	Fibrocartilaginous embolism, *aortic thromboembolism*	Usually asymmetric; nonprogressive

Italicized differentials indicate diseases associated with hyperesthesia on spinal palpation.

Table 76.2 Differential diagnosis for chronic myelopathy

Differential category	Differentials	Comments
Degenerative (spinal cord)	Degenerative myelopathy, myelinopathy, neuronopathy, axonopathy, subarachnoid diverticulum, storage disorders	Symmetric
Degenerative (vertebral column)	Hansen type II intervertebral disc herniation, *cervical spondylomyelopathy (wobbler syndrome)*, *degenerative lumbosacral syndrome*, spinal synovial cyst, diffuse idiopathic skeletal hyperostosis, spondylosis deformans, mucopolysaccharidosis, osteochondromatosis	Symmetric or asymmetric
Anomalous	Chiari-like malformation (*syringohydromyelia*), *atlantoaxial instability*, vertebral malformation, myelodysplasia, spinal stenosis, dermoid sinus	Usually symmetric
Neoplastic	*Meningioma, primary spinal cord (oligodendroglioma, astrocytoma, ependymoma), nephroblastoma*	Often asymmetric
Inflammatory (infectious)	Bacterial meningomyelitis, canine distemper virus, feline infectious peritonitis, protozoal, fungal	Asymmetric or symmetric

Italicized differentials indicate diseases associated with hyperesthesia on spinal palpation.

General Proprioceptive Ataxia

General proprioceptive (GP) ataxia reflects the lack of information reaching the central nervous system (CNS) responsible for the awareness of movement and position of neck, trunk, and limbs in space. Due to anatomic proximity within the spinal cord of the proprioceptive pathways and motor tracts, proprioceptive abnormalities often overlap with those caused by upper motor neuron (UMN) weakness. A deficit of GP appears as misplacement or knuckling of the foot, which may not occur with every step, and poorly controlled swaying of the body. The feet may be crossed or placed too far apart. Overall movement of the limbs lacks coordination.

Paresis/Plegia

Paresis/plegia is a deficit/loss of ability to carry out voluntary motor function. The terms lower motor neuron (LMN) and UMN are applied to differentiate two basic types of neurologic weakness. Clinical signs of UMN weakness are characterized by spasticity with normal to increased spinal reflexes and muscular hypertonia. LMN weakness manifests as flaccidity, hyporeflexia to areflexia and muscle atrophy that is severe and rapid in onset. Neuroanatomic localization to a specific spinal cord region is upon UMN or LMN signs (see Table 76.3). In addition, the affected limbs have inadequate or absent voluntary motion, which may be described as monoparesis/plegia (involvement of one limb), paraparesis/

Table 76.3 Neurologic signs associated with spinal cord regions

	Clinical signs			
Evaluations	**C1 to C5**	**C6 to T2**	**T3 to L3**	**L4 to S3 and caudal segments**
Mental status	Normal	Normal	Normal	Normal
Posture	Normal; wide-based stance all limbs; +/- recumbency; horizontal neck carriage	Normal; wide-based stance all limbs, recumbent; +/– horizontal neck carriage	Normal; falling; acute – Schiff–Sherrington posture,	Normal; falling; tail tone decreased or flaccid
Gait	Normal, GP/UMN ataxia (PL > TL), spasticity all limbs, tetraparesis/ plegia, hemiparesis/ plegia	Normal, spastic PL, GP/ UMN ataxia (PL > TL), shorten stride TL, tetraparesis/plegia, hemiparesis/ plegia	GP/UMN PL ataxia, symmetric or asymmetric spastic paraparesis/plegia	GP PL ataxia, weakness may vary; symmetric or asymmetric (more often with cauda equina) paraparesis/ plegia
Cranial nerves	Normal; bilateral or ipsilateral Horner syndrome	Normal; bilateral or ipsilateral Horner syndrome	Normal	Normal
Postural reactions	Normal, mild-severe deficits (PL > TL); absent	Normal, mild-severe deficits (PL > TL); absent	Mild-severe deficits; absent	No deficits; mild-severe deficits; absent
Spinal reflexes	Normal, hyperreflexia all limbs	Normal, hyporeflexia or absent reflexes TL; normal to hyperreflexia PL	Normal to hyperreflexia PL	Hypo- to areflexia; pseudohyperreflexic patellar reflex with sciatic nerve dysfunction
Spinal hyperesthesia	None; mild-severe on palpation; resists neck movements	None; usually mild; may resist neck movement	None; mild-severe on palpation	None; mild-severe on palpation; accentuate on tail extension
Sensation (nociception)	Usually normal; severe lesions may show mild-severe sensory loss	Usually normal; severe lesions may show mild-severe sensory loss	Mild-severe sensory loss; absent	None; mild-severe (more common with intumescence lesion) sensory loss
Micturition	Usually intact; may have detrusor areflexia; sphincter hypertonia	Usually intact; may have detrusor areflexia; sphincter hypertonia	Usually affected with loss of motor function, detrusor areflexia-sphincter hypertonia	None; mild-severe detrusor areflexia; sphincter hypotonia

C, cervical; GP, general proprioceptive; L, lumbar; LMN, lower motor neuron; PL, pelvic limb; S, sacral; T, thoracic; TL, thoracic limb; UMN, upper motor neuron.

plegia (involvement of pelvic limbs), tetraparesis (involvement of all limbs) or hemiparesis (involvement of the ipsilateral thoracic and pelvic limbs).

Gait is assessed with regard to coordination, voluntary motor functions, and direction. The action of gait is characterized by swing (flexion) and stance (extension) phases. The voluntary motor system involves recruitment of the flexor muscles to initiate the swing phase and the postural system recruits extensor muscles for the stance and propulsive phases. Animals with UMN weakness will often have a gait of long stride length, whereas with LMN weakness the stride length is shortened. The gait in animals with spinal pain may have a shortened stride length. Animals with joint, muscle, or meningeal pain often appear to be "walking on eggshells." Thoracic or pelvic limb lameness may represent radicular pain (nerve root signature).

Postural Abnormalities

Abnormal postures can be specific for vertebral column abnormalities and spinal cord dysfunction. Ventroflexion of the neck is a common phenomenon in animals with disorders of neuromuscular weakness (especially cats) or pain. Animals with spinal malformations can show kyphosis (dorsal deviation), scoliosis (lateral deviation), and lordosis (ventral deviation). A stiff neck or an arched back is often reflective of cervical or generalized spinal pain. Neck pain may manifest with horizontal neck carriage, increased muscle tone, and intermittent spasms/ jerks. The animal tends to move by turning the entire body when changing directions. When the arched back is centered to the thoracolumbar region, this may indicate pain localized to the caudal thoracic and lumbar regions. Arching of the back with low head carriage also

can be observed in animals with neck pain. An animal with pain localized to the lumbosacral area will have its pelvic limbs tucked under the caudal abdomen.

Postural Reaction Deficits

Various postural reactions (paw replacement, hopping, hemiwalking, wheelbarrow, extensor postural thrust) can further define the location and symmetry of the weakness. Asymmetric weakness is common with vascular, inflammatory, and compressive myelopathies.

Spinal Reflex Abnormalities

Spinal, myotatic, and withdrawal reflexes can assist with neuroanatomic localization to specific spinal regions (see Table 76.1). Presence of hypo- to areflexia of limb reflexes can localize the lesion to within an intumescence. The cutaneous trunci reflex can further assist with localization of a thoracolumbar spinal cord lesion.

Hyperesthesia

Hyperesthesia denotes an unpleasant behavioral response to a nonnoxious stimulus. As part of a routine neurologic examination, spinal hyperesthesia is evaluated by deep palpation of the spinal epaxial musculature and by detecting resistance with flexion-extension and lateral movements. Testing for spinal hyperesthesia should be performed near the end of the neurologic examination. Spinal palpation should begin distal to the suspected lesion localization. Cervical spinal hyperesthesia can be elicited by deep palpation of the cervical spinal musculature near the vertebral transverse processes. Clinical signs include caudal flinching of the ears, twitching spinal musculature, and behavioral signs of discomfort. The neck is manipulated by flexion, extension, and lateral movements. Normal animals have full range of movement with no resistance. Resistance or behavioral reluctance to move is evidence of spinal pain. Meningeal pain often is diffuse but will commonly localize to the cervical spine. Joint and muscle pain are assessed during palpation and evaluating range of motion of the limbs.

Differentials associated with spinal hyperesthesia include those associated with inflammation or compression (e.g., intervertebral disc herniation, neoplasia). Anatomic structures with nociceptors include the meninges, nerve roots, outer one-third of the disc, joints, periosteum, and muscle. Tissue damage or inflammation produces pain through stimulation of nociceptors that are sensitive to mechanical, thermal, and chemical stimuli. Neuropathic pain occurs with injury to neural tissue and represents abnormalities in transmission and somatosensory processing in the peripheral and central nervous systems. Some disease processes encompass both nociceptive/inflammatory and neuropathic pain mechanisms.

Loss of Nociception

Nociception (pain sensation) is considered the most important prognostic indicator for functional recovery of myelopathy. In dogs with thoracolumbar Hansen type I intervertebral disc herniation, the majority of those with intact nociception have an excellent prognosis. Dogs with loss of nociception longer than 24–48 hours prior to surgery have a poorer prognosis for return of ambulatory function. If surgery is performed within 12–36 hours, the prognosis is better for more rapid and complete recovery. In spinal fractures, however, animals with loss of nociception are assumed to have complete injury of neural tissues and have a poor prognosis for recovery.

Acute Spinal Cord Dysfunction

It is important to recognize specific physical and neurologic examination findings associated with acute spinal cord injury. Neurogenic shock is a systemic complication associated with severe cervical or cranial thoracic injury to the spinal cord. This syndrome results from sympathetic loss (decreased blood pressure and heart rate resulting from unopposed vagal tone) and continual vagal tone. This phenomenon results in loss of spinal cord blood flow regulation and subsequent ischemia. Neurogenic shock resolves with fluid therapy and pressor agents.

Spinal shock usually manifests as flaccidity of the limbs distal to the lesion. The spinal reflexes are depressed to absent. The bladder may be flaccid with urine retention and the sphincter hypotonic. This phenomenon may mislead a neuroanatomic localization if neurologic examination is not reassessed. The duration of spinal shock is proportional to the degree of species encephalization and thus may last only a few hours in quadrupeds. Cause may be cessation of tonic input of spinal neurons by excitatory impulses in descending pathways.

The Schiff–Sherrington posture is characterized by increased extensor tone of the thoracic limbs and flaccid paralysis of the pelvic limbs after acute T3–L3 spinal cord lesions. "Border cells," which exert inhibitory influences on extensor motor neurons of the thoracic limbs via the fasciculus proprius, are predominantly located in the L2–4 spinal cord segments. Damage to these cells or interruption of the fasciculus proprius as it ascends through the thoracolumbar spinal cord causes release of thoracic limb extensor motor neurons and hypertonia. Despite the increase in extensor tone, the thoracic limbs are neurologically normal. Schiff–Sherrington posture does not indicate that the spinal cord lesion is irreversible.

A *traction injury* of the spinal cord involving tethering of nerves often is traumatic in origin. This injury commonly involves the nerves associated with the sacrococcygeal and cervicothoracic spinal cord segments. Traction of nerves/nerve roots causes injury of associated spinal cord segments such as tail-pull and brachial plexus avulsion. For example, in cats with tail-pull injury, injury to the sacral segments affects the pelvic nerve and its innervation of the bladder, resulting in loss of bladder contraction.

Ascending and descending hemorrhagic myelomalacia should be suspected in dogs with thoracolumbar intervertebral disc disease (IVDD) that have an ascending loss of the cutaneous trunci reflex. Other neurologic signs of myelomalacia include loss of nociception caudal to the lesion, ascending and descending flaccidity, weakness and areflexia, which can lead to tetraplegia, hyperthermia, and respiratory distress. Death results from asphyxia from intercostal and diaphragmatic muscle paralysis. Clinical signs of ascending and descending myelomalacia may manifest in hours to several days from onset of paraplegia.

Diagnostic Approach

Diagnostic evaluation of an animal with spinal cord disease begins with bloodwork (complete blood count, serum biochemistry), urinalysis, and survey spinal radiographs. Thoracic radiography is recommended in animals older than 5 years or when neoplasia is considered a disease differential. If a diagnosis cannot be determined through these routine procedures, referral to a specialty practice is recommended.

Conventional radiography of the vertebral column can assist with recognition of obvious abnormalities such as congenital malformation, discospondylitis, fracture/luxation, and bone neoplasia. Meticulous technique, collimation, and proper patient positioning, usually under anesthesia or heavy sedation, are essential to detection of subtle changes that are often the key to a diagnosis. Although many lesions are obvious with cursory inspection, subtle changes may be difficult to appreciate.

However, in the majority of instances, the diagnostic capability of plain radiography of the vertebral column is limited. The diagnostic capabilities are improved with myelography, injection of iodinated contrast media into the subarachnoid space. Myelography is accurate and sensitive for identifying compressive lesions. Dynamic studies (traction, extension, flexion) also can be performed. Masses that occupy space in the vertebral canal (e.g., tumors, abscesses, disc herniations) cause alterations in the myelographic contrast column. The extradural, intradural/extramedullary, or intramedullary location can be determined by the type of distortion occurring in the contrast column.

Cross-sectional imaging includes computed tomography (CT) and magnetic resonance imaging (MRI) and is more likely to provide a definitive diagnosis. These imaging modalities are now available at many specialty practices. Lesion descriptions affecting the spinal cord are similar to those described for myelography. Administration of contrast media can improve visualization of pathology on MRI and CT. Intravenous administration of contrast media can increase the conspicuity of a lesion due to breakdown in the blood–brain barrier and better define its borders by creating greater contrast between the lesions and surrounding tissue.

Computed tomography is a cross-sectional imaging modality in which images are constructed based on the attenuation of X-rays through tissue. The main benefit of CT over conventional radiography is that with CT, there is greater soft tissue differentiation and lack of superimposition of overlying structures which greatly improves the evaluation of the vertebral column. CT also can assist with determining lesion extent after myelography. CT images should be evaluated for alterations in attenuation of tissues. Dark or relatively black areas are hypodense or hypoattenuating while light or relatively white areas are hyperdense or hyperattenuating. CT may provide more useful information than MRI in cases of vertebral fractures or subluxation where bony detail is important. Taking advantage of the density of dystrophic mineralized intervertebral disc material, CT can be used in the evaluation of chondrodystrophic dogs with suspected IVDD. Due to the inferior soft tissue contrast, assessment of soft tissues within spinal cord tissue is limited.

Magnetic resonance imaging is the preferred imaging modality for assessment of the spinal cord. The primary reason for this is the superior soft tissue contrast that MRI provides, allowing differentiation of anatomic structures. No other imaging procedure provides conspicuity of soft tissue discrimination along with exceptional resolution. Imaging can be performed in different planes (transverse, sagittal, dorsal) without loss of resolution, enabling examination of complex anatomic regions. MRI is based on the magnetic properties of hydrogen atoms, which are extremely abundant in tissues containing water, protein, and fat. Lesions are characterized based on number (single or multiple), intensity (hypo-, hyper-, isointense in relationship to an adjacent normal area), distribution of the intensity (homogeneous or heterogeneous), lesion borders (well or poorly defined), anatomic location of the lesion as well as lesion location in reference to the spinal cord and meninges. Similarly, lesions are characterized based on pattern of contrast enhancement.

Cerebrospinal fluid (CSF) is contained within the subarachnoid space, which lies between the arachnoid and pia mater. Cerebrospinal fluid analysis will assist with determining the presence of inflammatory disease. Abnormalities in CSF cytology and protein are sensitive indicators of CNS disease but rarely specific for a disease process. On occasion, infectious organisms or neoplastic cells may be identified. The CSF profile, including protein content, cell counts and cytology, will assist the clinician to narrow the differential diagnosis.

Additional diagnostic procedures include electrodiagnostic evaluation (electromyography and nerve conduction studies), CSF protein electrophoresis, serology, and exploratory surgery.

Differential Diagnosis

Myelopathies can be classified according to the DAMNIT V scheme (degenerative, anomalous, metabolic, neoplastic, nutritional, inflammatory-infectious/noninfectious, traumatic, toxic, vascular) (see Tables 76.1 and 76.2).

Degenerative

Degenerative conditions of the spinal cord can occur in both young and adult animals. Myelinopathies, axonopathies, and neuronopathies present initially with progressive signs of paraparesis and eventual tetraparesis. Many of these conditions are breed specific and inherited. Recent identification of gene mutations has enhanced our understanding of the underlying pathogenesis for many degenerative conditions associated with ion channel defects, abnormalities in protein aggregation, loss of enzyme function (storage disease), and dysfunction in protein metabolism and growth factors.

Canine degenerative myelopathy (DM) is an adult-onset neurodegenerative disease. Most dogs are at least 8 years old before onset of clinical signs. The initial signs of degenerative myelopathy typically include asymmetric GP ataxia and spastic paresis in the pelvic limbs. At this stage, segmental spinal reflexes are indicative of UMN loss. Dogs become nonambulatory paraparetic within one year after onset. When euthanasia is delayed, weakness can ascend to the thoracic limbs with emergence of LMN signs, dysphagia, and widespread muscle atrophy. Recently, a missense mutation in the gene superoxide dismutase 1 (*SOD1*) was established as a genetic "risk factor" for dogs developing DM. Dogs that are homozygous (two copies of the mutant allele) for the *SOD1* mutation are considered at risk for developing degenerative myelopathy. Because a variety of common acquired compressive spinal cord diseases can mimic early DM, a presumptive diagnosis is made by ruling out other spinal cord disorders by cross-sectional imaging and CSF analysis combined with results for the *SOD1* mutation analysis. A dog with progressive T3–L3 myelopathy that has normal neurodiagnostics and is homozygous for the *SOD1* mutation is likely to have degenerative myelopathy.

Degenerative conditions of the vertebral column such as intervertebral disc herniation, cervical spondylomyelopathy, and degenerative lumbosacral stenosis secondarily cause myelopathy by spinal cord compression. Other less common degenerative conditions of the vertebral column include synovial cysts, canal stenosis, and diffuse idiopathic skeletal hyperostosis (DISH).

Anomalies

Dogs and cats with congenital spinal malformations often have abnormalities involving multiple segments of the vertebral column and spinal cord. Malformations associated with the spinal cord are often referred to as spinal dysraphism that involve defects in closure of the neural tube. Such defects may also involve the vertebral column. Spinal dysraphism is a result of abnormal midline fusion and disrupts the normal pattern of spinal cord circuits. Other defects include syringomyelia, dermoid sinus, spina bifida, and caudal vertebral hypoplasia. Genetic mutations and exposure to toxic and infectious agents at certain stages of development can lead to these malformations. Abnormal formation of vertebral bodies by itself does not cause spinal cord dysfunction but some conditions can cause myelopathy from spinal cord compression or spinal canal stenosis.

Congenital anomalies affecting the craniocervical junction include atlantoaxial instability and atlantooccipital overlapping, which also can occur simultaneously. The subsequent spinal cord compression results in signs of C1–5 myelopathy or manifests as cervical spinal pain.

Metabolic

Endocrocrine-related peripheral neuropathies such as diabetes mellitus, hypothyroidism, and insulinoma paraneoplastic neuropathy reflect as sciatic nerve disease. Clinical signs appear in the pelvic limbs first and may mimic myelopathy.

Neoplastic

Tumors affecting the spinal cord are described as extradural, intradural-extramedullary, and intramedullary based on location with respect to the spinal cord. Intramedullary tumors include gliomas (astrocytoma, oligodendroglioma, and ependymoma) and neuronal-derived tumors. Common intradural-extramedullary

tumors include meningiomas, neuroepitheliomas, and nerve sheath tumors. Extradural tumors include primary bone tumors, metastatic tumors, and hematopoietic tumors (e.g., histiocytic disease, lymphoma, plasma cell tumors). Tumors that involve the vertebral body cause secondary spinal cord compression. Metastatic disease of the spinal cord can occur from spread within the CNS (drop metastasis) or from extraneural tissues via direct extension or hematogenously. Hemangiosarcoma, melanomas, and carcinomas are the most common tumors to metastasize to the spinal cord and vertebral column.

Inflammatory (Infectious, Noninfectious)

Meningitis (inflammation of the meninges) and meningomyelitis (inflammation of the meninges and spinal cord) cause focal or diffuse signs of myelopathy and severe spinal pain. Onset is acute, peracute or insidious. Signs typically progress but can wax and wane. Neurologic signs are variable and related to the area of spinal cord affected. Common clinical signs include GP ataxia, limb paresis, and paraspinal hyperesthesia. Lesion distribution can be focal or multifocal, causing asymmetric neurologic deficits. Animals with meningomyelitis could also have signs of encephalitis. Spinal cord MRI combined with CSF analysis is the most reliable diagnostic approach for identifying the presence and extent of CNS inflammation. Some infectious agents affect other organ systems in addition to the CNS. Serology and molecular techniques screen for infectious etiologies. Disease confirmation often requires biopsy or necropsy examination.

Common infectious diseases causing myelopathy include viral (e.g., feline coronavirus, feline infectious peritonitis, canine distemper virus, feline immunodeficiency virus, feline leukemia virus), protozoal, rickettsial, algal, and fungal diseases. In the dog, canine distemper virus and protozoa are the most frequently identified agents. Infectious meningomyelitis seems to be the most common cause underlying myelopathy in the cat. Granulomatous meningoencephalomyelitis (GME) and steroid-responsive meningitis-arteritis are noninfectious inflammatory diseases that predominate in the dog.

Inflammation/infections of the vertebral column can involve the vertebra (osteomyelitis, physitis) or intervertebral disc space (discospondylitis). Spinal cord epidural empyema is defined as an extensive accumulation of purulent material in the epidural space of the vertebral column related to direct extension of osteomyelitis or discospondylitis. Discospondylitis is associated with bacterial or fungal infection of the intervertebral disc and contiguous vertebrae. Hyperesthesia of the vertebral column is the primary clinical sign. Radiographic features of discospondylitis include lysis and sclerosis of the vertebral endplates. Pathologic changes and lesion extent can be more conspicuous with CT and MRI. Due to its zoonotic potential, *Brucella canis* screening is indicated. Antimicrobial selection should be based on susceptibility testing of bacteria isolated from urine or blood or from infected tissue.

Trauma

Animals with spinal fractures and luxations are assessed with minimal manipulation to prevent further injury and displacement of the spine. Nociception is assessed in plegic animals to assist with determining prognosis. Spinal fracture/luxation in dogs and cats is most commonly associated with severe external trauma and results in spinal cord dysfunction. Diagnosis is based on radiography or cross-sectional imaging of the entire spine. Nonsurgical or surgical management depends upon presence of instability. The prognosis for recovery from a spinal fracture/luxation with loss of nociception is considered poor.

Vascular Occlusive Disorders

Fibrocartilaginous embolic myelopathy is the most common cause of vascular occlusion of the spinal cord in dogs and infrequently can occur in cats. FCE most commonly affects the younger, larger dog breeds but also occurs in small dog breeds, with the miniature schnauzer overrepresented. Onset of signs is often peracute or acute with little progression. Key neurologic signs include asymmetric paresis with lack of paraspinal hyperesthesia. Localization frequently reflects the segments of the cervicothoracic and lumbosacral intumescences; however, segments within L4–S3 and T3–L3 are most commonly reported. The pathogenesis still remains enigmatic. Spinal cord arteries become occluded with fibrocartilage that originates from the nucleus pulposus of the intervertebral disc. The clinical presentation is sometimes difficult to distinguish from the concussive, noncompressive extrusions of the intervertebral disc. Prognosis is dependent on the severity of neurologic deficits, lesion location and extent, and owner's commitment to nursing care. The prognosis is favorable in patients that show improvement within two weeks of onset.

In cats with acute onset of asymmetric paresis/paralysis, aortic thrombosis is a primary differential. The pelvic limbs are commonly affected, with signs of loss of femoral pulse, pain and firmness in the muscles, and loss of nociception distally. Hypertrophic cardiomyopathy is the most frequent underlying disease. Diagnosis is suspected based upon clinical signs, elevated creatine kinase concentration, and evidence of cardiac disease. Initial therapy involves management of the cardiac disease, preventing further clot

formation and supportive care. Long-term prognosis is guarded during the early recovery phase.

Treatment

Treatment of myelopathy is determined based on the underlying disease diagnosis. Specific treatment approaches focus on surgical decompression of compressive lesions, excision/debulking of compressive masses (neoplasia, cyst), stabilization procedures and appropriate therapy of infectious and inflammatory diseases. Principles of appropriate supportive care and physical rehabilitation assist with expediting recovery and prevention of secondary complications of a recumbent patient.

Neuroophthalmology

Bradford J. Holmberg, DVM, MS, PhD, DACVO

Animal Eye Center, Little Falls, NJ, USA

Neuroophthalmology is a complex discipline involving the intricate relationship between the eye and the central nervous system (CNS). A thorough understanding of afferent and efferent pathways is crucial in the localization and diagnosis of neuroophthalmic disorders. A review of normal anatomy and physiology is beyond the scope of this chapter and can be found elsewhere. Abnormalities in the afferent or efferent arm may present as changes in vision, eye position, tear production, eyelid carriage, function, sensation, and pupil shape, size or response. This chapter will focus on common neuroophthalmic diseases.

Amaurosis

Amaurosis is defined as partial or complete vision loss without observable ophthalmic pathology. Clinical signs of vision loss include a reduced or absent menace response, inability to track a cotton ball, failure to navigate around stationary objects, and possibly an absent dazzle reflex or pupillary light reflex (PLR). Amaurosis may be caused by primary retinal disease, such as sudden acquired retinal degeneration syndrome (SARDS), retrobulbar optic nerve disease, or any lesion along the optic chiasm, optic tract, lateral geniculate nucleus, optic radiation, or visual cortex. Electroretinography (ERG) is essential in differentiating retinal disease from CNS disease as ERG will identify a retina that appears normal on examination but fails to function properly. Frequently, magnetic resonance imaging (MRI) and cerebrospinal fluid (CSF) analysis are instrumental in diagnosing a primary CNS cause of vision loss. Neoplasia is the most common CNS cause of vision loss in dogs and cats. Prognosis for return of vision is grave with SARDS and poor with CNS disease, depending on the underlying etiology.

Optic Neuritis

Inflammation of the optic nerve is usually bilateral and results in complete vision loss with the absence of pupillary light reflexes. On ophthalmic exam, the optic disc is enlarged and hyperemic with focal hemorrhages and peripapillary retinal detachment (Figure 77.1). If only the retrobulbar optic nerve is affected, the ophthalmic exam will be normal and diagnosis is confirmed through a normal ERG and abnormal MRI. T2-weighted MRI may reveal an enlarged, moderately hyperintense optic nerve. CSF analysis in dogs with optic neuritis is variable and may reveal a marginal to marked increase in protein or cellularity.

Optic neuritis can be secondary to infectious, inflammatory, and neoplastic disease. In dogs, infectious causes include viral (distemper and tick-borne encephalitis virus), fungal (cryptococcosis, blastomycosis, histoplasmosis), protozoal (toxoplasmosis), and bacterial (ehrlichiosis). Granulomatous meningoencephalitis is the most common inflammatory disorder, although idiopathic and necrotizing meningoencephalitides have also been reported. Primary optic nerve tumors and space-occupying retrobulbar masses may trigger secondary nerve inflammation. In cats, optic neuritis is often secondary to feline infectious peritonitis, but may be due to other infectious diseases, including cryptococcosis and toxoplasmosis. Most cases of optic neuritis are considered idiopathic due to lack of an apparent cause even with a thorough systemic medical work-up.

Treatment of optic neuritis is directed at the underlying cause when feasible. If no underlying cause is identified, immunosuppressive doses of corticosteroids are used to reduce inflammation. Even with appropriate therapy, prognosis for return of vision is poor and optic nerve atrophy is an unfortunate common end-result.

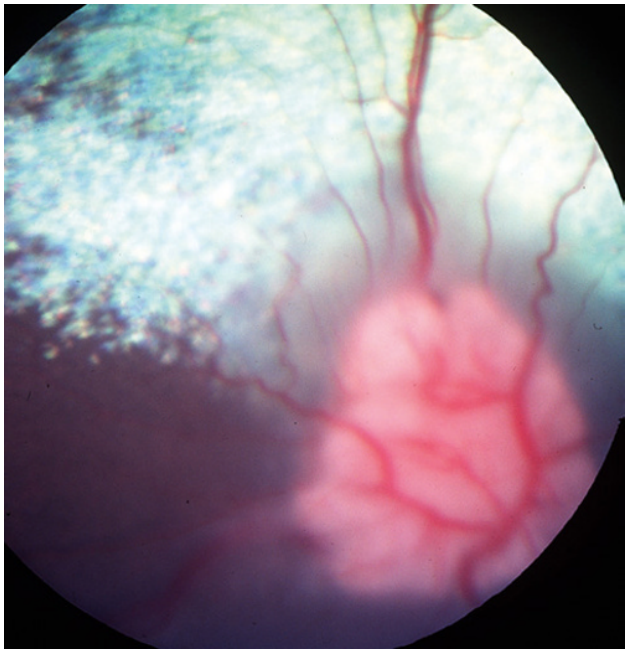

Figure 77.1 Idiopathic optic neuritis in a dog. Note the optic disc is edematous and hyperemic with peripapillary retinal detachment.

Anisocoria

Pupil diameter is regulated by autonomic control of the iris sphincter and iris dilator muscles. Anisocoria is defined as unequal pupils. Physiologic anisocoria may occur with heterochromia iridis or age-related iris atrophy with the affected pupil dilated. When not physiologic, determination of which pupil is abnormal can be challenging. Examination of the patient in bright, ambient, and dim light conditions facilitates diagnosis. An abnormal mydriatic pupil will not constrict completely in bright light compared to the normal pupil. In contrast, an abnormal miotic pupil will not dilate completely in dim light compared to the normal pupil.

Unilateral mydriasis in dogs and cats can have primary ocular or neurogenic causes. Ocular causes include iris atrophy, glaucoma, end-stage retinal degeneration, optic nerve atrophy, and pharmacologic dilation with agents such as tropicamide or atropine. Neurogenic causes include a lesion in the parasympathetic nerve, oculomotor nerve, or brainstem. Due to the unique innervation of the cat sphincter muscle by two short ciliary nerves controlling either side of the iris, parasympathetic denervation may result in hemiplegia and a "D" shaped or reverse "D" shaped pupil. Iris sphincter hemiplegia has been associated with trauma and iris stromal infiltration by lymphoma. Mydriasis alternating between eyes is secondary to feline spastic pupil syndrome. Cats affected with feline spastic pupil syndrome tend to be feline leukemia positive with C-type virus particles present within the ciliary nerves or ganglia.

Unilateral miosis in dogs and cats can be secondary to anterior uveitis, Horner's syndrome (discussed later), or pharmacologic agents such as pilocarpine or topical prostaglandin analogs. Anterior uveitis is differentiated from Horner's syndrome based on concurrent ophthalmic clinical signs including conjunctival hyperemia, episcleral congestion, corneal edema, blepharospasm, aqueous flare, keratic precipitates, and ocular hypotony.

Internal and External Ophthalmoplegia

Unilateral mydriasis may be secondary to an afferent or efferent defect. Afferent defects involve the retina, optic nerve, or optic tract. Efferent defects involve the oculomotor nucleus, oculomotor nerve, or iris sphincter muscle. Vision and PLR testing are vital in distinguishing afferent from efferent defects. Animals with afferent lesions are nonvisual, have an absent direct PLR, and an absent consensual (affected to nonaffected eye) PLR. Animals with efferent lesions are visual, have an absent direct PLR, and a normal consensual (affected to nonaffected eye) PLR. The presence of a normal consensual PLR from the nonaffected eye to the affected eye rules out an efferent arm lesion.

Efferent lesions may involve the oculomotor nucleus, oculomotor nerve, or iris sphincter muscle. Peripheral parasympathetic fibers along the medial aspect of the oculomotor nerve are responsible for pupillary constriction. The oculomotor nerve also innervates extraocular muscles (superior, medial, and inferior rectus, inferior oblique) and the levator palpebrae superioris muscle. Lesions affecting just the peripheral aspect of the nerve will result in mydriasis only, termed *internal ophthalmoplegia* (Figure 77.2). Lesions affecting the entire nerve will result in lateral strabismus and ptosis, adding the diagnosis of external ophthalmoplegia. External ophthalmoplegia is defined as paralysis of one or more of the extraocular muscles and may only involve the oculomotor nerve or may also involve the trochlear and abducens nerves.

When evaluating mydriasis, it is important to distinguish ophthalmoplegia from a pupillomotor defect. Pupillomotor defects are usually secondary to iris atrophy or previous topical anticholinergic medication administration. Animals with iris atrophy may have a slight direct PLR or may have a characteristic scalloped appearance to the pupillary margin. When these signs are absent, pharmacologic testing is useful in differentiating a pupillomotor defect from ophthalmoplegia.

Figure 77.2 Internal ophthalmoplegia in a dog. The right pupil is normal. The left pupil is mydriatic with an absent direct and consensual (right to left) PLR. Topical application of 2% pilocarpine resulted in pupil constriction within five minutes, confirming an efferent pathway deficit.

Pharmacologic testing has classically involved the use of both indirect- and direct-acting parasympathomimetics. Indirect acting agents, such as topical 0.5% physostigmine, will cause rapid pupillary constriction in cases of a preganglionic (proximal to the cilary ganglion) lesion due to release of acetylcholine stores at the postganglionic axon terminals. Direct-acting agents, specifically 1% to 2% pilocarpine, are more commonly used. One drop of pilocarpine acts directly on the iris sphincter muscle by binding to and activating acetylcholine receptors, inducing pupil constriction within 30 minutes. Use of a direct-acting agent will allow pupil constriction with both pre- and postganglionic lesions and therefore is useful in differentiating ophthalmoplegia from a pupillomotor defect but does not differentiate a preganglionic from a postganglionic site. Lack of pupillary constriction following administration of a topical parasympathomimetic confirms a pupillomotor defect. In a young dog or one without clinical evidence of iris atrophy, pharmacologic mydriasis is commonly the cause. A thorough history will aid in diagnosis.

Internal and external ophthalmoplegia occur as a result of oculomotor nerve, ganglion, or nucleus compression. They are a result of neoplasia, trauma, or inflammation at the level of the midbrain, brainstem, or cavernous sinus. Other CNS signs may be evident depending on the specific localization of the lesion.

The presence of concurrent internal and external ophthalmoplegia should prompt the clinician to evaluate for intracranial disease to explain involvement of multiple cranial nerves. Imaging (MRI) is the diagnostic tool of choice. Treatment is limited unless the underlying cause is found. Prognosis is poor as most cases progress to involve adjacent CNS sites.

Trigeminal Nerve Deficit

Two of the three branches of the trigeminal nerve provide sensory innervation to the eye, adnexa, and periocular skin. Lateral sensation is primarily via the maxillary branch and medial sensation via the ophthalmic branch. Corneal sensation is derived through afferent fibers within the long ciliary nerves that originate in the ophthalmic branch. Decreased or absent function is diagnosed through an absent palpebral reflex (i.e., blink response) and an absent corneal reflex. Lack of sensation must be distinguished from lack of motor function (facial nerve deficit) where the patient is unable to blink. Differentiation is accomplished by attempting to elicit a menace response or dazzle reflex while avoiding contact with the skin. A patient with trigeminal nerve dysfunction will blink in response whereas animals with a facial nerve defect will not have a palpebral reflex or normal menace response.

The long ciliary nerves derive from the nasociliary nerve, a branch of the ophthalmic branch of the trigeminal nerve. Inadequate function of the long ciliary nerves results in corneal anesthesia or hypoesthesia. With loss of these neurons, there is a loss of normal regulatory neuromediators such as acetylcholine, substance P, calcitonin gene-related peptide, and neuropeptide Y which are instrumental in maintaining normal corneal integrity. Neurotrophic keratitis describes pathology resulting from a trigeminal nerve defect. The decrease in corneal sensation leads to reduced corneal epithelial cell proliferation and delayed healing with corneal ulceration. Neurotrophic keratitis is likely secondary to trigeminal nerve trauma, but as in humans, diabetes mellitus and herpes virus may be predisposing factors.

The mandibular branch of the trigeminal nerve has both motor and sensory components. It is responsible for motor innervation to the masticatory muscles and sensation to the mouth, lower face, and ear. Bilateral disruption of the mandibular branch results in the inability to close the mouth. Ninety percent of cases are idiopathic and clinical signs typically resolve over three weeks. Prolonged cases may develop atrophy of the muscles of mastication. When the pterygoid muscles are affected,

Figure 77.3 Neurotrophic and neuroparalytic keratitis in a dog. Note the left eye is enophthalmic, the third eyelid is elevated, the ocular surface is dry, and a deep, infected stromal corneal ulcer is present. Also note the severe masseter and temporalis muscle atrophy. Neuroophthalmic localization of the lesion is at the petrosal temporal bone.

secondary enophthalmos and passive third eyelid elevation may occur (Figure 77.3).

Treatment for trigeminal nerve defects is supportive. Topical lubricating agents are recommended to support surface ocular health and symptomatic treatment for secondary corneal ulceration is indicated when necessary. As most cases are secondary to trauma or are idiopathic, prognosis for return of function is fair. Other reported causes of trigeminal dysfunction include neoplasia and polyneuritis of unknown origin.

Facial Nerve Paralysis

The efferent arm of the palpebral, menace, corneal, and dazzle reflex are all mediated by the facial nerve. The facial nerve arises at the facial nucleus in the brainstem and courses with the vestibulocochlear nerve through the petrosal bone before branching. Ultimately, the zygomatic branch innervates the orbicularis oculi and retractor anguli oculi muscles and controls the blinking response. Clinical signs associated with facial nerve paralysis may be restricted to the eye or may also involve other structures, depending on the site affected. Nonocular clinical signs associated with facial nerve paralysis may include deviation of the nasal septum toward the unaffected side, drooping of the ipsilateral lip or pinna, and lack of sensation to the inner pinna. Ocular signs of facial nerve paralysis include an absent palpebral reflex, neuroparalytic keratitis, and, potentially, neurogenic dry eye.

Differentiation of facial nerve paralysis from trigeminal nerve dysfunction can be difficult. Animals with facial nerve paralysis still have normal sensation and may retract their eye and elevate the third eyelid in response to a menacing gesture or painful stimulus applied to the adnexa. Animals with a trigeminal nerve defect have a normal menace response.

Without the ability to close the eyelids completely, neuroparalytic keratitis may arise due to chronic corneal exposure and tear film evaporation. With progression, corneal vascularization, scarring, and ulceration ensue (see Figure 77.3). Corneal protection is the treatment of choice and involves the use of topical lubricants, topical antibiotics, and possibly placement of a temporary tarsorrhaphy. If the parasympathetic fibers that run with the facial nerve to the lacrimal gland are affected, neurogenic dry eye will occur. Approximately 20% of dogs with facial nerve paralysis develop neurogenic dry eye that can be diagnosed by a routine Schirmer tear test. Concurrent neurogenic dry eye hastens corneal deterioration. Treatment with oral or topical parasympathomimetics will aid in return of tear production due to denervation hypersensitivity and upregulation of acetylcholine receptors at the lacrimal gland.

Facial nerve paralysis is reported to be idiopathic in 75% of dogs and 25% of cats. Other causes include surgery, trauma, neoplasia, hypothyroidism, and otitis media. Total ear canal ablation and bulla osteotomy surgery results in facial nerve paralysis or paresis in 49% of dogs and cats. Median time to restoration of function is 2–4 weeks. Neoplasia is an uncommon cause in dogs, but the most common in cats. Inflammation of the middle or inner ear is often present with facial nerve paralysis. With primary or secondary petrosal bone inflammation, other neuropathies may become apparent. The trigeminal, vestibulocochlear, glossopharyngeal, and oculosympathetic and parasympathetic nerves course through the petrosal bone. Therefore, additional clinical signs may include ocular and facial anesthesia or hypoesthesia, neurotrophic keratitis, masticatory muscle atrophy, vestibular disease, loss of taste sensation, and Horner's syndrome. Fifty to sixty percent of dogs and cats with facial nerve paralysis will have additional signs, with vestibular disease most common in cats and hypothyroidism or vestibular disease most common in dogs.

Treatment of facial nerve paralysis involves addressing the underlying cause when present. All patients with facial nerve paralysis should have a thorough otic exam and a thyroid level completed. If an underlying cause is not found, and true idiopathic facial nerve paralysis exists, supportive care to involve ocular lubrication and protection is indicated. Prognosis for return to function is guarded, with some cases improving in several weeks and others never.

Horner's Syndrome

Sympathetic fibers to the eye originate in the paraventricular nucleus of the hypothalamus, course within the spinal cord and exit between T1 and T3 into the thoracic cavity, forming the sympathetic trunk. These fibers travel through the mediastinum and join the vagosympathetic trunk in the neck before synapsing at the cranial cervical ganglion located adjacent to the tympanic bulla. All fibers prior to this synapse are considered preganglionic and those that course from the cranial cervical ganglion to the eye are considered postganglionic. Any disruption of nerve conduction along this circuitous route will lead to the classic clinical signs of Horner's syndrome.

Clinical signs include ptosis secondary to loss of tone in Müller's muscle of the upper and lower eyelid, miosis due to loss of sympathetic tone in the iris dilator muscle, and enophthalmos with secondary third eyelid elevation due to loss of smooth muscle tone of the periorbita (Figure 77.4). These four clinical signs are diagnostic for Horner's syndrome. Depending on where nerve conduction is disrupted, these may be the only clinical signs, or additional clinical signs may be present, including altered behavior/mentation, altered gait or paresis, spinal or neck pain, dysphagia, coughing, regurgitation, otitis media, vestibular disease, keratoconjunctivitis sicca, or facial nerve paralysis. Localization of the lesion is important for both prognosis and potential treatment.

Pharmacologic testing along with identifying clinical signs are useful in differentiating preganglionic from postganglionic Horner's syndrome. Topical application of indirect-acting sympathomimetic drugs such as 1% hydroxyamphetamine will induce norepinephrine release from postganglionic neurons, allowing immediate pupil dilation. This positive test confirms preganglionic Horner's syndrome. There is no effect of an indirect-acting sympathomimetic with cases of postganglionic Horner's syndrome. With the difficulty in obtaining these agents and abuse potential, this testing is rarely completed. Direct-acting sympathomimetic agents such as 0.001% epinephrine or dilute (1%) phenylephrine can be used to confirm a postganglionic lesion due to denervation hypersensitivity of smooth muscle. With a postganglionic defect, application of these agents will allow improvement of the clinical signs within 5–20 minutes. Lack of a response is suggestive, but not diagnostic, of a preganglionic lesion.

Figure 77.4 Horner's syndrome in a cat, demonstrating ptosis of the left upper eyelid, enophthalmos, third eyelid elevation, and miosis.

Preganglionic lesions carry a worse prognosis than postganglionic. The majority of preganglionic cases are secondary to neoplasia, vascular events, or significant head, neck, brachial plexus, or chest trauma. A diagnosis of preganglionic Horner's requires further diagnostics to localize the lesion and should include a complete blood count, serum biochemistry, thyroid level, thoracic radiography, MRI of brain and spinal cord, and CSF analysis. Treatment is directed toward the underlying cause. Prognosis for return of function is guarded.

Postganglionic lesions tend to be idiopathic or secondary to otitis media, but can be secondary to retrobulbar disease or trauma. If there is no evidence of ear disease, an idiopathic cause is assumed. Golden retrievers and Labrador retrievers between the ages of 10 and 12 years are overrepresented. Most cases of idiopathic, postganglionic Horner's syndrome resolve without treatment within two months.

Cavernous Sinus Syndrome

The cavernous sinus incorporates two venous sinuses located at the base of the cranial vault extending from the orbital fissure to the petrooccipital canal. The sinuses are joined by several anastomoses across the midline. Structures of clinical significance that pass through or are in close proximity to the cavernous sinus include the oculomotor nerve, trochlear nerve, ophthalmic and maxillary branches of the trigeminal nerve, abducens nerve, and postganglionic sympathetic axons.

Dogs and cats with cavernous sinus syndrome present with a multitude of clinical signs related to the affected cranial nerves, including internal and external ophthalmoplegia (mydriasis, ptosis, lateral or ventrolateral strabismus), corneal anesthesia, periorbital and facial anesthesia, and enophthalmos. Most cases are unilateral, with rare bilateral cases reported. Mean age of affected dogs and cats is 9 and 10 years of age, respectively.

Diagnosis is obtained through observation of the clinical signs. Advanced imaging, preferably MRI, is necessary to confirm the diagnosis. Most reported cases in dogs occur secondary to primary or metastatic neoplasia. In cats, intracranial neoplasia and infectious disease

have been reported. Long-term prognosis is poor even with treatment aimed at the underlying cause.

Dysautonomia (Key–Gaskell or Dilated Pupil Syndrome)

Dysautonomia is a rare, idiopathic condition in which there is generalized loss of autonomic nervous system function secondary to degeneration of parasympathetic and sympathetic neuronal ganglia. Ophthalmic clinical signs may be the first observed and include bilateral mydriasis with absent PLR, elevated third eyelids, ptosis, and decreased tear production. Dysautonomia can be readily differentiated from Horner's syndrome by the presence of mydriasis rather than miosis. Nonocular clinical signs may include xeromycteria, xerostomia, dysphagia, vomiting, regurgitation, gastric distension, anorexia, diarrhea, bradycardia, constipation, and urinary bladder distension.

Both cats and dogs can be affected, although the disease is much more prevalent in cats. A geographic distribution has been suggested, with most affected cats living in the United Kingdom and most affected dogs living in the American Midwest. Animals tend to be young and have a rapid onset (two days to two weeks). Although there is no known cause, 50% of cats in one study did test positive for *Clostridium botulinum* type C.

Diagnosis of dysautonomia is generally accomplished through the overt clinical signs. Pharmacologic testing as described previously for internal ophthalmoplegia and Horner's syndrome can be completed. In cases of dysautonomia, application of dilute pilocarpine will induce pupillary constriction and application of dilute epinephrine or phenylephrine will allow third eyelid retraction.

Treatment for dysautonomia is supportive. Prognosis for survival is poor, with 75–85% of animals succumbing to the disease or being euthanized due to the difficulty in maintenance of supportive care. Some cats have spontaneously recovered, although this is rare and should not be expected.

Dedication

To CB Chastain, Dick Nelson and Ed Feldman for trying their best to make me a better clinician. For someone interested in internal medicine and endocrinology I could not have had better mentors.

To all of my former students, interns and residents, thanks so much for always keeping me honest and forcing me to try to stay ahead of those I was supposed to be teaching.

To all the wonderful folks at Wiley (Erica Judisch, Gillian Whitley, Purvi Patel, Holly Regan-Jones, and Katrina Maceda) that made this book possible and tried their best to keep me on track. You turned the idea into reality and improved the book at every step in the process.

To my amazing children McKenna, Taylor, Ivy and Cole, thanks for letting me be a part of your lives. Being your Dad is the best job in the world.

To my amazing wife and best friend Maya. You make my life complete and I look forward to sharing every day with you.

Preface

Internal medicine is hard. Progress in science and technology makes it almost impossible to keep abreast of recent advances and on top of that, all of us want to balance our life both at work and home. Is there enough time in the day for everything?

There are a variety of ways in which we learn and the path is not the same for everyone. For those of us with an interest in internal medicine, and I'm assuming that includes the reader of this book, we rely on a number of resources. Our colleagues, continuing education seminars, the literature, professional educational networks, and reference textbooks. A concern of mine over the past few years has been the increasing reliance on technology to arrive at a clinical diagnosis rather than emphasizing the need to understand physiology and the value of a complete history and a thorough physical examination. We feel increasing pressure to arrive at a specific and definitive diagnosis and, more importantly, to arrive at that diagnosis almost immediately.

Your goal in internal medicine is not to arrive at a diagnosis. I would much prefer to see a pet respond to my treatment and recover without a definitive diagnosis than to arrive at a definitive diagnosis at necropsy. If you are successful in achieving a diagnosis, that can be very rewarding. However, your goal should be to accurately identify problems and address those problems in a logical, timely, and cost-effective manner, always weighing the risk/benefit of running myriad diagnostics versus improving the quality of life of your patient and the pet owner. While not every pet owner will be able to afford or desire to follow each and every one of our recommendations, it is our job to make sure that whatever decision the owner makes is based on being fully informed.

Illness is really physiology gone awry. If you have an understanding of what is normal, it makes your job of identifying the abnormal much easier. The body has a limited repertoire of responses to an insult so often many diseases will have very similar clinical presentations. While we all like to make lists of the 20 differential diagnoses for a given patient's abnormalities, it's important to recognize that in clinical practice, common things occur commonly and those differentials should be at the top of your rule-out list.

There are numerous excellent textbooks on the market and I use many of them on a daily/weekly basis. Some serve as definitive reference works for the topic under discussion. Some are brief, bullet point, clinically oriented texts that one can use to find something quickly. What I thought was currently lacking was a text that would be continually updated, provide enough background physiology to help the reader understand normal versus abnormal, and provide useful and, more importantly, clinically relevant material to help you with your patients.

The goal of this text was to first identify section editors who were recognized experts in their field both academically and clinically. The section editors then identified topics they felt were of greatest clinical importance and selected authors who could translate this information into a text that would be used every day. I hope we have achieved that goal. We will be updating the text online with new information and updated references on a quarterly basis, adding additional sections and chapters with future editions, and uploading podcasts consisting of interviews with the authors to highlight and emphasize the material in the text and any recent advances in the field.

We hope that you will find the text helpful and all credit for that success goes to the authors. Any omissions or errors lie with me so please let me know both the good and the bad so we can improve things going forward.

As my favorite philosopher once said "It's a magical world, Hobbes, ol' buddy, let's go exploring."

All the best and enjoy exploring the mysteries of medicine.

Dave

[2] *College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA*

Infectious diseases pose many challenges for veterinarians. How was my patient exposed to the pathogen? When did exposure occur? Where did the disease originate? Are there others infected? Does my patient pose a risk to other pets or people? How can I determine if things are getting better or getting worse? Understanding the epidemiology of infectious disease can help veterinarians answer these and other questions which can lead to better informed decisions which then improve patient outcomes and mitigate further spread of disease. Two essential areas of infectious disease epidemiology for the practicing veterinarian to understand are performing disease monitoring and surveillance activities and outbreak investigations.

Disease Monitoring and Surveillance

Disease monitoring and surveillance are important activities designed to assess the health and disease status of a population of animals. Monitoring and surveillance, while sounding similar to the lay person, are considered epidemiologically distinct terms. Specific diseases, described syndromes, or general health status are monitored by veterinarians through the systematic collection and recording of data. Disease monitoring activities provide information which can inform treatment and prognosis of affected animals, but does not typically elicit an intervention at the population level.

Disease surveillance activities may include collection of the same data used for disease monitoring, but activities are more intensive and purposeful. Surveillance is an ongoing, somewhat cyclic event which to be effective occurs over a considerable period of time. Surveillance methods can include testing programs for new additions to populations, such as FeLV testing of new cats entering an animal shelter or cattery, or annual testing for infectious disease, such as annual heartworm testing for dogs. In surveillance, when a specified threshold disease level is reached, prevention, control, or eradication measures are triggered and applied at the population level.

Although most small animal clinical practices deal with individual animals rather than owned populations, disease monitoring and surveillance activities are no less important to the clinic population. For example, veterinarians may erroneously assume low disease prevalence in their area because of historic patterns of disease, thereby preventing early detection of disease in that area. As people, animals, and vectors move more freely and establish new areas of residence, previously rare diseases may incrementally increase in incidence.

Small animal veterinarians also have a responsibility to participate in population surveillance programs established for public health. Public health agencies at both the state and federal level maintain a list of reportable diseases which include zoonotic diseases that affect companion animals. While maintaining a focus on human cases of disease, an increasing number of agencies now include reporting of zoonotic disease cases in companion animals. For example, the California Code of Regulations requires veterinarians to report cases of category A bioterrorism agents, such as anthrax, plague, and tularemia, as well as zoonotic diseases such as brucellosis (other than *B. canis*) and rabies to local health officials. Veterinarians should check routinely with their state veterinarian and local health departments to keep current on reporting regulations related to zoonotic disease and potential bioterrorism agents.

Small animal veterinarians may serve on the front line for preventing incursions of foreign animal diseases. In 2007, an astute small animal veterinarian in Mississippi found fly larvae on a 16-year-old dog imported from Trinidad and reported the findings to the Mississippi state veterinarian. Further diagnostics identified the fly

larva as *Cochliomyia hominivorax*, the New World screwworm, which had been successfully eradicated from the US in the 1960s.

Disease monitoring and surveillance activities can be formal or informal and help to identify increases in incidence of specific diseases or disease syndromes. Taking the time to formalize a hunch, collect and analyze data, and report findings to veterinary or public health officials may be the key to early identification of disease outbreaks within a practice population.

Outbreak Investigations

Outbreak investigations are parallel to a diagnostic workup of an individual patient. A series of steps, performed in a specific order, provide information which helps describe and diagnose the problem at hand, plus allows insight into measures to mitigate disease and prevent future spread. Sources will vary slightly on the number of steps involved in an outbreak investigation but this chapter will focus on a six-step process for outbreak investigation.

The outbreak investigation process mimics the clinical investigation process for individual animals with disease: recognize there is a problem, define the problem, gather subjective and objective information to better describe the problem, formulate a list of likely differentials, perform diagnostics to rule in or rule out differentials, design a treatment plan, and communicate findings with the client. Goals of an outbreak investigation are to verify the pathogen responsible for the disease, identify the source of disease in the population, determine methods of transmission, and define means to prevent further spread and future occurrences.

Pre-step (or Step Zero): Establish an Investigation Team

With outbreaks of food-borne or infectious disease affecting people, a team of physicians and epidemiologists is established prior to beginning an investigation. In small animal medicine, resources to assist in an investigation may be available through local departments of public health, especially if the outbreak has zoonotic potential or may significantly impact the mental well-being of owners or the community. Assistance may also be available from county or state veterinarians or local colleges of veterinary medicine.

Step 1: Confirm Presence of Disease Outbreak

Before moving forward with an investigation, confirmation of the presence of disease above normal levels must occur. Ideally, this would involve comparing current disease levels with historic endemic levels of disease in the area. Published prevalence studies from the literature may provide insight into endemic disease levels in specific geographic areas or populations. If endemic disease levels are unavailable, levels could be estimated by extracting diagnosis information from electronic medical records in previous years.

Step 2: Establish a Case Definition

Commonly seen diseases with available accurate diagnostic tests allow for easy establishment of a working case definition. For example, outbreaks of canine parvovirus are not uncommon and are reliably diagnosed by a combination of clinical signs and diagnostic test results. The disease under investigation may only present as a collection of clinical signs rather than through isolation and identification of a specific pathogen. In this situation, the case definition would include significant or unique clinical signs, signalment information, animal location (area of residence), and time of onset of disease.

Additional data from animals who meet the case definition should be collected to further inform the investigation. Data should include pertinent information from the patient history, physical exam, and diagnostic procedures. Patient outcomes or response to treatments should also be collected and recorded. As the investigation moves forward, the case definition will be continually refined in response to new information.

Step 3: Descriptive Epidemiology

Once the working case definition has been established, investigators should review available historical medical records to identify previous animals meeting the case definition. This allows for identification of the time point for the start of the outbreak. Data from previous cases, including species, breed, age, and sex, should be used to calculate prevalence of disease in various populations and further describe the disease epidemiology. Generating hypotheses for risk factors for disease will depend on this information.

Key descriptors for the outbreak investigation include temporal and geographic spread of disease. One of the easiest ways to describe these data is through epidemic curves (Figure 78.1). Epidemic curves inform hypotheses for disease introduction and transmission, estimate incubation periods, recognize possible pathogens, and identify possible interventions.

Point source epidemic curves are indicative of a common pathogen exposure in a group of animals in a single or relatively brief time point. They are characterized by a sharp slope at the beginning of the outbreak and a more gradual slope at the end. For infectious diseases, spread of the disease is limited to a single incubation period and further spread into naive populations does not occur.

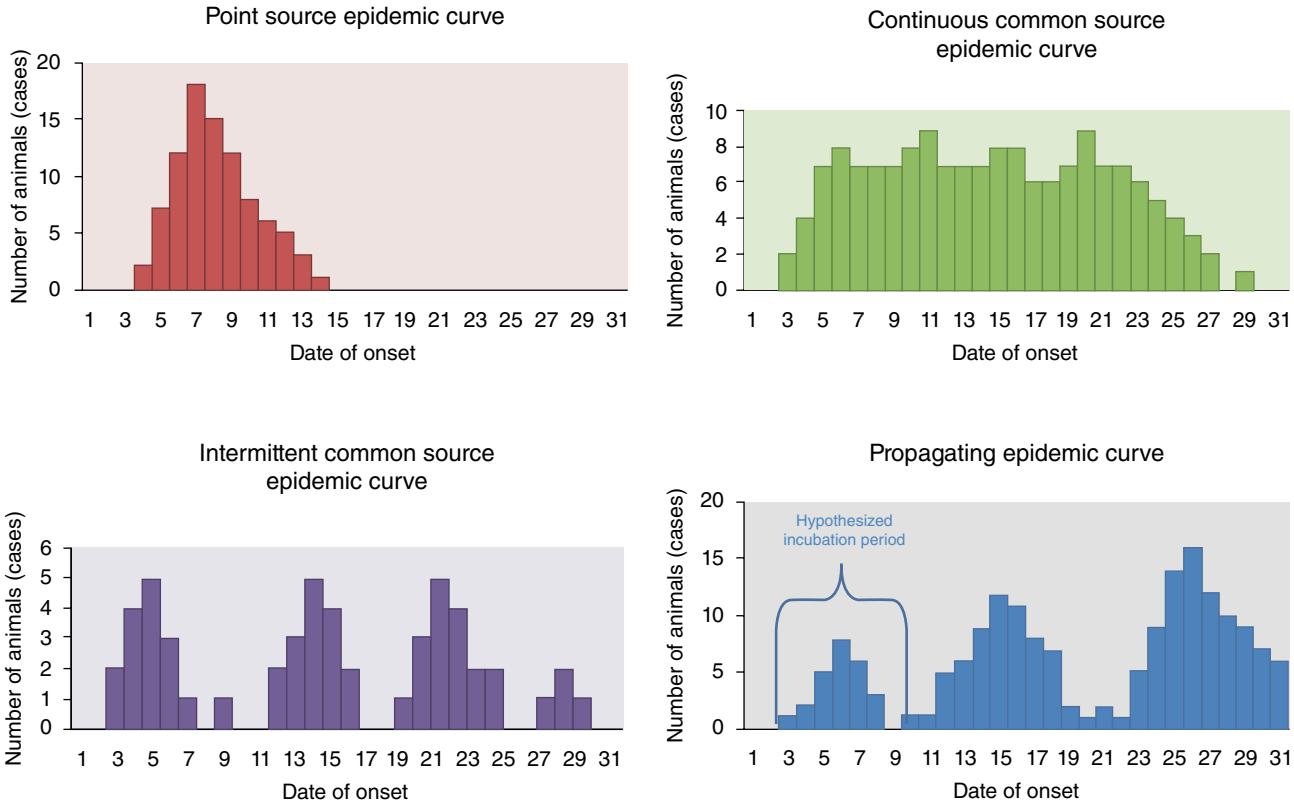

Figure 78.1 Epidemic curves.

Continuous common source epidemic curves also indicate a common pathogen exposure in a group of animals. Sharp onset and more gradual ending to the outbreak are similar to point source epidemics with the overall duration of the outbreak extending across a longer period of time which overlaps into multiple incubation periods.

Intermittent common source epidemic curves look like a series of point source epidemics across the measured time period. These epidemics may be misclassified as point source in nature when the studied time period is too brief to detect the sequential pathogen exposures. Periods between onset of case clusters can be used to estimate the incubation period of a suspected infectious pathogen.

Propagating epidemic curves resemble intermittent common source epidemics, but subsequent waves of infection peak at progressively higher levels of infection. These waves of infection represent secondary and tertiary cases of disease as a result of animal-to-animal spread of the pathogen. As with intermittent common source epidemic curves, periods of time between the onset of waves of infection can be used to estimate incubation period of a suspected infectious pathogen. If the pathogen responsible for the outbreak is yet undetermined, incubation period information can be used to narrow the list of potential pathogens.

Separate epidemic curves can be created for subpopulations of animals based on breed, age, or sex. Differences in the shapes of the curves may indicate potential risk factors for disease, helping to identify potential pathogens or intervention measures with a greater likelihood of success. Combining the temporal spread of a disease with the geographic spread can also provide further insight into potential pathogens and mechanisms for spread of disease between susceptible populations. For example, the CDC has published annual maps of the incidence of West Nile virus in people and animals from 2003 to 2019. These maps provide a visual reference for the spread of the disease from New York to California (wwwn.cdc.gov/arbonet/maps/ADB_Diseases_Map/index.html). Patterns of spread mapped against topographic information may support theories of vector-borne or water-borne disease and again may help with designing successful intervention strategies.

Step 4: Formulate and Test Hypotheses

Hypotheses related to disease introduction, spread, cause, and intervention will be formulated based on data gathered from animals meeting the case definition. If considered in isolation, the data can be informative but potentially deceptive. Without a nonaffected comparison population, false assumptions about prevalence

and risk factors can prevent implementation of successful interventions. This may lead to treatment failure and continued spread of the disease.

Observational studies facilitate comparisons between affected and nonaffected populations (cases and controls) with measures of association. Retrospective case–control studies are relatively quick and easy to perform, but may be hampered by incomplete or imperfect data collection or availability in medical records. Odds ratios can be calculated to identify risk factors for disease and support hypothesized control or prevention interventions.

Prospective cohort studies are more expensive and time consuming compared to case–control studies, but provide incidence data which lead to more accurate estimates of risk through relative risk calculations. Their prospective nature provides an opportunity for more complete data collection in both affected and nonaffected populations which would not be available in historical medical records. As with case–control studies, cohort studies also identify potential risk factors for disease and support interventions to reduce or prevent further disease spread.

Step 5: Implement Control and Prevention Measures

Descriptive epidemiologic data from epidemic curves and risk factors determined from observational studies must be carefully analyzed to determine what interventions will provide the greatest benefit and likelihood of success. Measures must be directed at controlling the current outbreak through treatment, if possible, and preventing continued spread of the disease into naive animals in the population.

In small animal clinical practice, these actions can provide significant challenges not encountered in populations under ownership or control of relatively few parties. When a population of animals has a single owner, the potential loss of a few animals is mitigated by the benefits of disease prevention in the larger population. Sacrificing a few animals for diagnostic procedures or to prevent further disease spread often makes economic sense. With companion animals, the value of individual animals does not lie just in dollars and cents, but also in an unquantifiable emotional value as a member of the family. The good of the population does not necessarily override the value of the individual, creating difficult choices for mitigating disease at a population level.

Recommendations for treating individual animals are likely to be accepted and, depending on the cause of the outbreak, individuals may have a good chance to recover from infection. Treatment options may be cost-prohibitive for some owners or treatment may be refused for various reasons. This may have little effect on spread of disease if owners follow strict isolation and quarantine protocols. Unfortunately, some owners may refuse quarantine and isolation procedures designed to stop the spread to naive animals and veterinarians have few options to mandate such procedures without a risk to public health or safety. In these situations, effective and compassionate communication of risk may help increase compliance and mitigate risk of further spread of disease.

Step 6: Communicate Findings

For public health outbreak investigations, communication of findings includes informing the healthcare community of the "who, what, where, when, why, and how" of the outbreak. This can increase awareness of the potential for continued spread of the disease and allow implementation of preventive measures and early detection of the disease in new populations.

If the disease outbreak under investigation has a public health implication, and local public health officials were not part of the investigation process, it is important to communicate relevant findings to the local public health department. Findings should include date of onset and conclusion (if outbreak has ended), case definition/diagnosis, populations affected, epidemic curves, and outcomes of control and prevention measures. This information should also be shared with other veterinarians in the practice area so results of the investigation can be used to control and prevent disease in the larger population of animals in the community.

Findings from new or novel disease outbreaks should also be communicated to the larger veterinary audience through publication in journals or presentations at continuing education functions. Increased awareness may prevent further outbreaks or mitigate the effects of outbreaks if they spread to new companion animal populations.

Conclusion

Epidemiology is an integral part of the daily practice of veterinary medicine whether veterinarians realize it or not. Tools and techniques for disease monitoring and surveillance and outbreak investigations are readily available and can add to a veterinarian's epidemiology

toolbox. Just as epidemiology is a science focused on populations, veterinarians should not work in isolation when investigating the incidence of disease in their practice populations. Local, regional, state, and federal veterinarians and health professionals should be part of the companion animal healthcare team responsible for rapid identification and resolution of diseases in the clinic and community populations.

Laboratory Diagnosis of Infectious Diseases

Laia Solano-Gallego, DVM, PhD, DACVP[1] *and Gad Baneth, DVM, PhD, DACVP*[2]

[1] *Dep. Medicina i Cirurgia Animals, Facultat de Veterinària, Universitat Autònoma de Barcelona, Barcelona, Spain*
[2] *School of Veterinary Medicine, Hebrew University, Rehovot, Israel*

Veterinarians use diagnostic testing for infectious diseases for two main reasons:

- to confirm acute or chronic infection in a dog or cat with clinical signs or clinicopathologic abnormalities compatible with infectious diseases
- to detect subclinical infection or certify that animals are free of infection.

Detection of infection may be pursued to screen clinically healthy animals living in endemic regions, to prevent transmission by blood transfusion, to avoid importation of infected dogs and cats to nonendemic countries, to avoid transmission of disease to people in contact with the animal, including immune-suppressed owners, to monitor response to treatment, and for research. Different diagnostic procedures can be used depending on the purpose of the diagnostic investigation and the pathogen most likely affecting the dog or cat based on the differential diagnosis list. Test results might also be interpreted according to the aim of the diagnosis, type of pathogen, and clinical status of animals.

Accurate diagnosis of infectious diseases requires an integrated routine approach consisting of thorough clinical history, physical examination, pertinent routine laboratory tests such as complete blood count (CBC), complete biochemical profile and urinalysis, diagnostic imaging and additional diagnostic testing, depending on the differential diagnoses list for each individual patient. In addition, specific pathogen diagnostic assays should be carried out when infectious diseases are at the top of the differential diagnoses list.

This chapter describes general concepts of diagnosis of viral, bacterial, protozoal, and fungal infectious diseases with an overview of the most common diagnostic methods employed for these infections. Specific diagnostic features of common infectious diseases in dogs and cats, geographic distribution, main transmission modes, chief clinical signs, clinicopathologic abnormalities, treatment, prognosis, and prevention will be described in detail in other chapters in this section.

The most commonly employed techniques for the diagnosis of infectious diseases in small animals include microscopic examination of microorganisms in cytologic preparations or histopathologic specimens, serology, polymerase chain reaction (PCR), and culture of the organism in appropriate medium, as described in the following subsections of this chapter. The advantages and disadvantages of these diagnostic techniques are listed in Table 79.1. Sample collection, transport, and preservation of specimens for the different diagnostic tests and pathogens are described in Table 79.2.

Protozoal and Arthropod-Borne Infections

Microscopic Examination

Diagnosis can be based on cytologic or histologic detection of pathogens, either contained inside cells or free in routinely stained smears. Detection by light microscopy of pathogens in cytologic preparations or histopathologic specimens might be difficult, depending on the type of microorganisms causing infection. However, cytology is a more rapid and simple technique for the detection of some microorganisms compared with histopathology. Histopathology commonly requires special staining to detect bacterial, mycobacterial, fungal or protozoal infections. Standard Romanowsky stains such as Giemsa are used for cytologic detection of the majority of organisms (Figure 79.1). Special stains can also be used in cytology for enhancing the visualization of microorganisms but are less frequently needed.

Although the specificity of these methods is high, it is important to highlight that identification of species

Table 79.1 Advantages and disadvantages of common diagnostic methods for the detection of infectious diseases in dogs and cats

Diagnostic techniques	Advantages	Disadvantages
Microscopic examination (cytology /histopathology)	• Permits direct detection of the pathogen and nature of the host response. • Findings could be suspicious of infection or allow exclusion of other differential diagnoses • Cytology is rapid and less invasive than obtaining tissues for histopathology by biopsy • Cytology usually permits easier visualization of pathogens when compared with histopathology	• Relatively low sensitivity for the detection of pathogens in tissues or body fluids • Requires the performance of other diagnostic tests such as immunohistochemistry and/or PCR when pathogens are not visualized • Does not distinguish between morphologically similar organisms • Requires expertise
Serologic testing (antibody detection)	• Detection of specific antibodies against the pathogen causing infection • Permits evaluation of seroconversion to confirm recent infection	• Does not detect the pathogen itself • Typically does not discriminate between vaccinated and naturally infected dogs or cats • Serologic cross-reactivity between related organisms is possible
– Qualitative	• Rapid in-clinic test	• Provides only positive or negative results • Variable sensitivities and performance with risk of false-negative results due to conservative cut-off level and use of recombinant proteins • A positive result will benefit from additional validation by quantitative serology
– Quantitative (IFA, ELISA)	• Determines the antibody level which is of major importance in some diseases such as leishmaniasis where high antibody levels in the presence of compatible clinical signs and/or clinicopathologic abnormalities are conclusive of clinical leishmaniasis	• Performance and accuracy of cut-off vary between laboratories • Frequent lack of sufficient standardization of techniques between laboratories • Low antibody levels frequently require further testing
Serologic testing (antigen detection)	• Allows the detection of pathogen	• May not be sensitive when low numbers of pathogens are present
Molecular testing	• Allows the detection of pathogen DNA and RNA • High sensitivity and specificity for target loci • Allows determination of pathogen load (by real-time PCR)	• False-positive results possible due to DNA contamination or to amplification of erroneous targets including host DNA • Different techniques used by diagnostic laboratories and lack of standardization
Culture	• Permits the isolation of pathogens and their maintenance for further comparisons and analysis • Facilitates in-depth identification of pathogens	• Time-consuming and laborious • Requires special equipment and biohazard conditions and therefore restricted to specialized laboratories • May require up to one month to provide a result

Source: Modified from Solano-Gallego and Baneth (2016). Reproduced with permission of John Wiley & Sons.
ELISA, enzyme-linked immunosorbent assay; IFA, immunofluorescence assay; PCR, polymerase chain reaction.

based solely on morphology is often not possible and molecular analysis is required for speciation. Sensitivity will depend on the time spent searching for microorganisms, type of pathogen, tissue sampled, amount of organism in the tissue (parasite load), and clinical status of the patient. Generally speaking, higher diagnostic sensitivity is found in sick animals compared with subclinically infected dogs or cats. The diagnosis of chronically infected and carrier animals remains a diagnostic challenge due to low and often intermittent parasitemia, or low tissue pathogen load, which frequently make pathogen observation by microscopic evaluation difficult. Therefore, the use of molecular diagnostic assays is strongly recommended in those cases. In addition, identification of protozoa in formalin-fixed, paraffin-embedded sections of different tissues may be facilitated by immunohistochemical methods such as immunoperoxidase staining or *in situ* hybridization techniques.

The optimal tissue or body fluid for sampling will depend on types of pathogen involved and lesions found

Table 79.2 Collection, processing, and transport recommendations for different diagnostic tests in small animal infectious diseases. Follow all governmental guidelines relevant to a given infectious disease agent and clinical specimen

Diagnostic test	Specimen type	Collection and processing	Shipment
Histology	Any tissue specimen	Samples collected for histology should never be >1 cm thick (preferably 5–7 mm thick). Fix in 10% buffered formalin (10× volume)	Double bag and leak-proof container with adequate fixative
Cytology	Any tissue specimen or fluid analysis	Air-dried smear should be prepared immediately after the sample has been collected to minimize cell deterioration. Alcohol fixation is not needed. Analysis of various effusions and fluids usually includes determination of protein content, total cell concentration, and cytologic examination. A sample of effusion/fluid should be collected into an EDTA tube for routine analysis. A second sample should be collected into a serum tube if any biochemical analyses are to be performed or if a bacterial culture is desired	Blood or cytologic smears should never be mailed to the laboratory in the same package with formalin-fixed tissues because formalin vapors will produce artifacts in the specimen. Cytologic preparation should be transported at room temperature in a plastic container. Fluid samples should be shipped chilled but not frozen
Antibody or antigen testing	Blood, plasma, serum, cerebrospinal fluid, urine samples or feces	Serology generally requires serum, but plasma is often satisfactory. For serum samples, the blood should be drawn into a plain tube or a separator tube. The sample should be held at room temperature for 20–30 min to allow complete clot formation and retraction. The sample should then be centrifuged at high speed (~1000 g) for 10 min. In some instances, paired samples may be required for an adequate diagnosis	Specimens can be refrigerated for up to a week prior to shipment to the laboratory. Specimens should be frozen at −20 °C or −80 °C if stored for a longer period. Specimens can be stored frozen for years without loss of antibody levels. For specimens collected for assays for antigen detection, results may be more susceptible to variation with long specimen storage. The laboratory should be contacted in order to determine specimen storage and handling requirements
Molecular testing	Any specimen	Collect aseptically to prevent contamination. For blood or bone marrow and DNA analysis, use preferably EDTA or acid citrate dextrose (ACD) anticoagulant	For DNA analysis: submit specimens held at room temperature within 24 h of collection. Specimens can be stored at 2–8 °C for 72 h, or at −20 °C or ≤−70 °C for prolonged storage. For RNA analysis: use stabilization solution or send immediately to the laboratory on wet ice. For storage, freeze specimens at or below −70 °C
Isolation-culture	Any specimen	Collect aseptically to prevent contamination. Some agents might have special requirements such as anaerobic culture or special media. Culture from blood should be collected in special media bottles designed to prevent coagulation and neutralize antibiotic residues if animal was treated	Normally, specimens should be refrigerated and not frozen and delivered directly to the laboratory within 24 h

on physical examination. Blood-borne organisms such as *Babesia* (Figure 79.2) can be found in blood smears, concentrated and stained buffy coat or splenic specimens. Other important tissue samples used for the detection of these pathogens are lymph node aspirates, skin touch impressions, bone marrow, joint fluid, cerebrospinal fluid (CSF) or other body fluids and tissues.

Serologic Testing (Antibody and Antigen Detection)

Antibody Detection

Several serologic methods can be used to detect specific serum antibodies directed against protozoal and arthropod-borne pathogens. Methods include the indirect fluorescent antibody (IFA) test, the enzyme-linked immunosorbent assay (ELISA), immunochromatographic rapid in-house devices, direct agglutination assays, and western blotting. The most common serologic tests employed in clinical practice are quantitative assays (IFA and ELISA) and qualitative tests (rapid in-house devices). In general, most of these methods have good sensitivities and specificities but sensitivity and specificity greatly depend on the antigens employed. Whole-parasite extracts are sensitive for the detection of subclinical or clinical canine and feline infections but provide lower specificity. On the other hand, assays that employ recombinant protein antigens are very specific but may lack

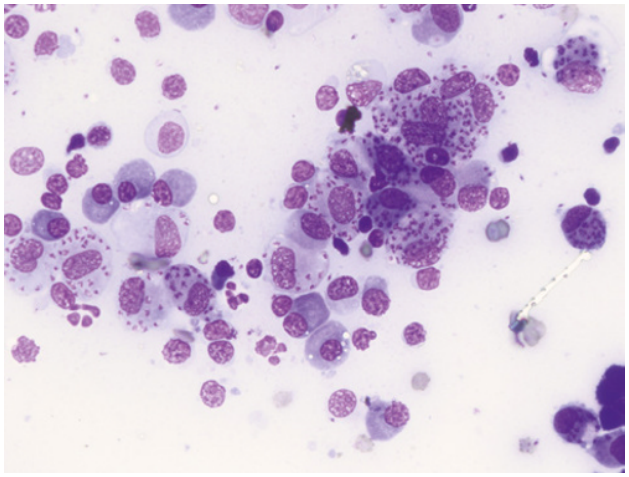

Figure 79.1 Lymph node aspirate from a dog. Note the increased numbers of plasma cells and macrophages with abundant intracellular *Leishmania* amastigotes (modified Wright stain, original magnification ×400).

sensitivity for the detection of infection, depending on the antigen employed and the level of serum antibodies.

Serologic cross-reactivity is common between pathogens of the same genus or otherwise closely related organisms. Therefore, cross-reactivity between antibodies directed at different pathogens is possible with some serologic tests, especially those based on whole-parasite antigen, and is less likely to occur when using recombinant protein antigens. It is important to note that the use of antigens of similar species will frequently result in cross-reaction at a high level. For example, antibodies against *Babesia canis* will cross-react with *Babesia vogeli* antigen. Pathogens of closely related different genera are more likely to cross-react at low levels, such as the cross-reactivity between antibodies to *Trypanosoma cruzi* and *Leishmania infantum*.

Antibody detection can indicate past exposure or present acute or persistent infection. Acute diseases may be difficult to diagnose due to the lack of detectable antibody production and low pathogen load in blood or other tissues. Therefore, false-negative results are possible in peracute or acute diseases. Evidence of seroconversion is fundamental in the diagnosis of some acute diseases. In these cases, the measurement of acute and convalescent antibody levels (paired samples) is confirmatory for acute infection. Antibody level determination may vary between different laboratories, and therefore, it is recommended to use the same laboratory and assay for comparison of antibody levels. Furthermore, variations are also likely between assays carried out on different days. Therefore, ideally, paired samples should be tested at the same time.

Seroconversion is considered when a fourfold or greater increase in antibody level is demonstrated in paired samples over a 2–4-week period, and in some particular infections longer than that, for instance in *L. infantum* infection where a serologic response develops months after initial infection. In addition, antibodies induced by vaccination may be detected by serologic assays, making it impossible to discriminate between vaccinated and naturally infected animals. Examples of this include vaccination against *B. canis* and *L. infantum*.

High antibody levels are associated with high tissue parasite loads and disease in some protozoal and arthropod-borne chronic diseases. In contrast, cases of animals with suspected clinical signs and compatible clinicopathologic abnormalities and low antibody levels require the use of additional detection methods to exclude or confirm the disease, because low antibody levels may also be detected in subclinical carriers suffering from a different clinical disease. Canine leishmaniasis is a good example of a disease in which moderate to severe clinical disease is usually manifested by medium to high antibody levels, whereas subclinical infection is more often associated with lower antibody levels or seronegativity.

Antigen Detection

The detection of circulating plasma or blood antigen specific for a pathogen is an additional and usually very specific serologic technique. This type of assay detects the presence of a circulating plasma or blood antigen. For example, the most common detection technique of canine heartworm infection caused by *Dirofilaria*

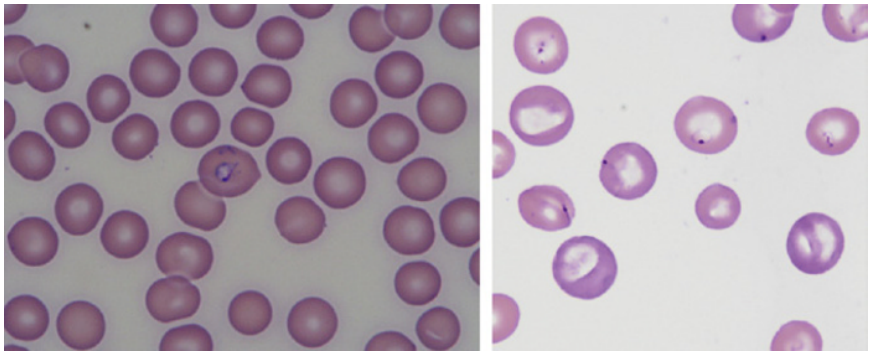

Figure 79.2 Blood smears from two different dogs. (*Right*) A large form of *Babesia*. (*Left*) Small forms of *Babesia* (modified Wright stain, original magnification ×1000).

immitis is based on detection of a circulating secretory antigen of the adult female worm.

Molecular Diagnostics

Polymerase chain reaction is a sensitive and specific diagnostic technique frequently employed for the diagnosis of protozoal and arthropod-borne diseases. It is used for diagnostic purposes, monitoring during and after treatment, research studies, and for screening of blood donors. Moreover, it is particularly useful for detection of infection in animals with low parasitemia levels and for speciation of pathogens. PCR can be carried out on DNA extracted from tissues, blood, body fluids, conjunctival and oral swabs, or even cytologic preparations or histopathologic specimens.

A large number of PCR assays and protocols using a variety of gene targets have been described for the detection of protozoal and arthropod-borne infections of dogs and cats. It is important to highlight that for diagnostic purposes, the best DNA target will often be the locus or gene with the largest number of copies per organism. For instance, the kinetoplast DNA (kDNA) of *L. infantum* is an excellent target as it has about 10 000 copies in each *Leishmania* amastigote. Other targets are more useful for distinguishing between species such as the leishmanial ribosomal internal transcribed spacer 1 (ITS1). Due to the fact that in some endemic areas, more than one species co-exist and infect animals, molecular techniques have been developed to discriminate DNA from different species of the same genus or related genera. These techniques include semi-nested PCR, reverse line blotting, PCR restriction fragment length polymorphism (RFLP), and high-resolution melting curve quantitative fluorescence resonance energy transfer PCR. Sequencing may also reveal infections with novel organisms that have not been described before.

It is important to highlight that negative results by molecular techniques only indicate that specific DNA was not detected under the assay conditions and should not be interpreted as absolute evidence for the absence of infection. In addition, false-positive results are possible due to DNA contamination or the amplification of DNA from other sources which may not be noticed if sequencing is not performed. Controls should be included in each step of the assay to ensure that DNA contamination has not occurred.

Isolation

Diagnosis may also be established by culture of the infectious agent. However, this technique is usually tedious and time-consuming. It sometimes requires special conditions and a long duration for obtaining results and therefore is less commonly used in clinical practice for parasites and arthropod-borne pathogens. This technique is employed in research studies because it permits the identification and maintenance of pathogens. It is important to highlight that some organisms, such as *Babesia* species, are difficult to culture. The culture method is pathogen specific and usually requires special media and temperature conditions. Special culture medium is used for the isolation of some protozoal pathogens, such as *L. infantum*.

Viral Infections

Microscopic Examination

Most viral infections are not diagnosed by microscopy. Viruses are too small to be detectable by light microscopy, but typical cytoplasmatic or intranuclear inclusion bodies caused by viruses may be detected in blood or tissue cells. Electron microscopy may be used for the detection of certain viruses such as canine parvovirus in feces of dogs shedding the virus, although this is a cumbersome, time-consuming technique which is often unable to specify the exact species involved in infection, as it relies on morphology.

Serologic Testing (Antibody and Antigen Detection)

Serologic tests are frequently used for the detection of viral infections in cats and dogs. There are a number of basic serologic techniques such as ELISA, IFAT, virus neutralization, complement fixation, agglutination, agar gel immunodiffusion, and western blotting. Serology can be aimed at detecting specific antibodies produced against a certain virus in the infected animal, as in the most common tests for feline immunodeficiency virus (FIV) which detect antibodies to the p24 core protein. It can also be aimed at the actual detection of a certain viral antigen in a body fluid such as the blood, as in the common feline leukemia virus (FeLV) antigen test based on the detection of the viral p27 capsid protein.

Rapid commercial tests are available for many of the common viral infections, and they are also frequently based on the detection of either antibodies against the virus or virus antigen. Rapid commercial tests are often based on immunochromatographic devices which produce a color response when antibodies against a virus are detected, or when the actual viral antigens are detected, if the assay is geared to the detection of antigen. These types of assays are often used for in-house rapid diagnosis in veterinary clinics and hospitals. Several manufacturers have produced such rapid assays for the detection of antibodies against FIV, antigenemia with FeLV, or the

presence of parvoviral antigen in the feces of dogs shedding this virus. The rapid assays that detect antibodies against a virus are often not quantitative and only produce a positive or negative result, in contrast to tests done in a specialized laboratory which frequently provide an antibody titer or quantitative measure related to the level of antibodies, such as the optical density in the ELISA.

Molecular Diagnostics

Molecular diagnosis of viruses includes the detection of specific nucleic acid sequences present in the targeted virus. Viruses may contain DNA or RNA, depending on the viral family to which they belong. PCR assays are commonly associated with the amplification of the nucleic acid sequence selected as the target for the assay and visualization of the product on a gel in conventional PCR, or its amplification and release of measurable fluorescence by real-time PCR which can also be quantitative. Amplification of nucleic acids from RNA viruses may require an additional reverse transcription step in which RNA is translated into cDNA and then amplified. RNA is less stable than DNA and is susceptible to rapid degradation unless stored in an RNA stabilization solution and frozen at –70 °C or below. A multiplex reverse transcription-nested PCR assay has been developed to differentiate between wild-type and vaccine strains of canine distemper virus.

An additional molecular diagnostic technique is the use of nucleic acid probes which attach specially to nucleic acid sequences in viruses and do not involve amplification of the virus's DNA or RNA.

Isolation

Isolation of virus from blood, secretions, or organ tissues is a common method of diagnosis for viral infections of dogs and cats. Isolation requires the use of appropriate media to transport the tested sample, a specialized laboratory, and rapid transportation to the laboratory in refrigeration. Viruses are usually taken from the transport media or the original fluid in which they were submitted (e.g., blood or CSF) and grown in various cell culture lines. Often virus isolation is attempted in multiple cell lines simultaneously as the host cell preference of the particular virus strain is unknown. Virus isolation from animals is usually performed with the addition of antibiotics and antifungal drugs to cell lines to prevent contamination with bacteria and fungi. While feline retroviruses such as FIV and FeLV are usually isolated from blood, isolation of canine distemper virus is usually attempted from the CSF, bronchoalvelor lavage, and transtracheal lavage specimens.

Bacterial Infections

Microscopic Examination

Most bacteria are detectable by high-power light microscopy of cytology specimens (Figure 79.3) but this is usually not sufficient for species identification and may serve as a relatively insensitive measure for the presence of bacteria in the sample. Furthermore, some anatomic sites such as the skin, oral cavity, gastrointestinal tract, and upper airway normally contain bacteria and it is usually difficult to distinguish between the normal flora and infection with pathogenic bacteria just by microscopic examination of the organisms. Gram stain, acid-fast staining, and other staining methods are ancillary techniques that can assist in the initial assessment of bacterial infection. Dark-field microscopy is helpful in the detection of spirochetes such as leptospires in urine samples.

Serologic Testing

Serology can be useful in the detection of some bacterial infections of dogs and cats. Detection of specific antibodies is helpful in the diagnosis of leptospirosis and a battery of serogroup antigens is used to find which serovar demonstrates the highest antibody titer and is either responsible for infection or closest to the *Leptospira* serovar present in the animal. Serology is also useful for the detection of exposure to intracellular bacteria such as *Ehrlichia canis* or *Anaplasma phagocytophilum*.

Isolation and Identification (Including Molecular Testing)

Culture has been the major technique for detection and characterization of bacterial pathogens for the past century. There are a number of different media for growth of bacteria from various groups with specific metabolic requirements. Often, one type of medium is used for the transport or initial growth of bacteria and other media are subsequently used for subculture with enrichment and selection of the bacteria suspected as cause of infection. The MacConkey agar medium selects for gram-negative bacteria. Cultures from an infection site are often placed initially into more than one medium when a broad spectrum of infective agents is suspected, for instance in aerobic and anaerobic specific media which also require specific growth conditions such as an anaerobic environment enriched with carbon dioxide for anaerobes.

Identification and characterization of isolated bacteria are usually done based on biochemical qualities and tests such as the catalase test and coagulase production.

Commercial biochemistry test strips enable the identification of cultured bacteria and automated commercial identification systems are often used in large bacteriology laboratories for rapid bacteria identification.

Some bacteria such as *Anaplasma platys* and hemotrophic mycoplasms (e.g., *Mycoplasma hemofelis*, *Candidatus Mycoplasma hemominutum*) are unculturable. The detection of these bacteria relies mainly on molecular biology techniques such as PCR amplifying DNA sequences which are specific for the suspected bacteria. Other bacteria such as *Rickettsia* spp., *E. canis*, and *A. phagocytophilum* are strictly intracellular and can only be grown in appropriate cell culture lines, restricting their isolation to research laboratories with expertise. Molecular techniques can also be useful for the identification of bacteria that have been propagated in culture and require classification to the species and strain levels. These can be sometimes be achieved by multigenic sequencing and characterization, with phylogenetic analysis.

Providing the bacteriology laboratory with a good clinical history, physical examination and initial blood test work-up and cytology findings can be very helpful in the selection of different isolation techniques. Sampling the correct organ sites is imperative and should be based on clinical judgment. Common body fluids and anatomic sites sampled for bacteriology from dogs and cats include urine, blood, feces, bronchoalveolar lavage, skin and ear, abdominal and pleural fluids, CSF, and cornea.

Interpretation of Culture Results

The results of culture should be interpreted cautiously, considering that the bacterium isolated, when culture is successful, may not actually be the cause of infection, or that in some other cases, culture is negative despite bacterial infection. This can be due to several reasons including technical difficulties in transporting the culture with infectious agent, use of incorrect isolation technique or culture site, intermittent shedding of bacteria to the blood or other body fluid, and previous antibiotic treatments.

Antimicrobial Susceptibility Tests

Determination of minimum inhibitory concentrations (MIC) for isolated bacteria can be helpful in deciding which antibiotic should be used for treatment of susceptible infections. This is also important in the detection of antimicrobial resistance, if present. The standard techniques for antibiotic susceptibility testing involve either gel diffusion or dilution methods. Although they can provide an idea of the antibiotics to which the isolated bacteria is susceptible *in vitro*, this does not always conform with the actual susceptibility due to *in vivo* factors such as accessibility to the infected tissue (e.g., decreased accessibility to abscesses), concentration of antibiotic in the affected tissue, and inhibition of antibiotics by body proteins.

Fungal Infections

Fungal agents have a remarkably varied spectrum of clinical picture: primary skin disease, single to multiple subcutaneous masses, mass lesions within body cavities, disseminated disease with multiple organ dysfunction, and disseminated disease that presents as single-organ dysfunction or as a cause of sudden death. Clinicopathologic findings are not specific but mild anemia of chronic disease, leukocytosis, hypergammaglobulinemia, hypoalbuminemia, and hypercalcemia can be present in some of these diseases. Primary (i.e., *Blastomyces*, *Coccidioides*, *Cryptococcus*, *Histoplasma*) and opportunistic pathogens, mainly saprophytic soil fungi (i.e., *Aspergillus*, *Basidiobolus*, *Cladosporium*, *Conidiobolus*), can be responsible for these diseases. Opportunistic fungi can cause disease by trauma and often present as a single subcutaneous mass. When dissemination occurs, it is often associated with decreased immunocompetence.

Microscopic Examination

Suspicion of fungal diseases should be made when macrophagic or macrophagic-neutrophilic inflammation is noted in any tissue by cytologic or histopathologic specimens. Bacterial inflammatory lesions (Figure 79.3) that are unresponsive to appropriate medical therapy should be investigated further to rule out underlying mycotic disease due to the fact that bacterial and fungal co-infections do occur.

Cytological evaluation of any tissue or body cavity fluid specimen is very useful for identification of fungal disease in dogs and cats. Cytology is a more rapid and simple technique for the detection of some fungal microorganisms than histopathology. Histopathology commonly requires special staining such as periodic acid–Shiff (PAS) or Gomori methenamine silver (GMS) to detect fungal infections. In addition, some laboratories offer immunohistochemistry for fungal organisms within tissues submitted for routine histopathology. Yeasts, different types of spores, and hyphae can be observed in cytologic specimens (Figure 79.4).

Cytologic features of most fungal pathogens are described elsewhere. Routine Romanowsky staining adequately stains most fungal organisms within cytologic preparations. Organisms that do not stain well appear as negatively stained elements (Figure 79.5).

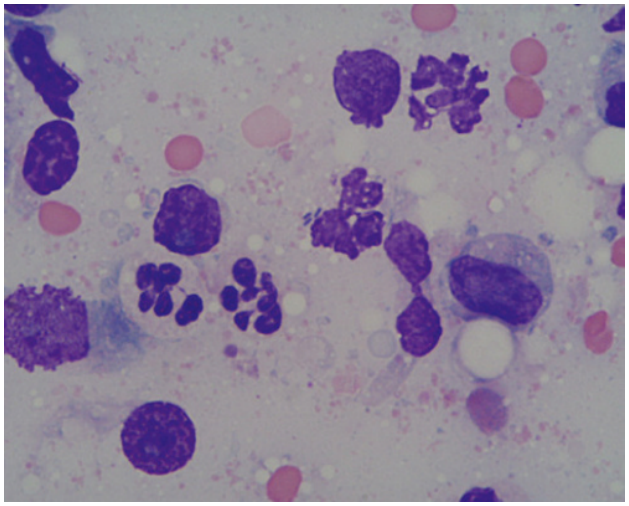

Figure 79.3 Kidney aspirate from a cat. Note neutrophilic-macrophagic inflammation with infection of rod-shaped bacteria (modified Wright stain, original magnification ×1000).

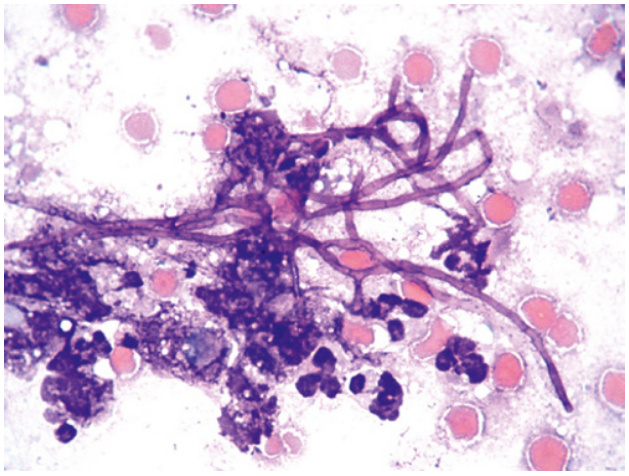

Figure 79.4 Thoracic mass from a German Shepherd dog. Note the necrotic background, increased numbers of neutrophils and *Aspergillus terreus* hyphae (modified Wright stain, original magnification ×1000).

India ink staining is commonly used for the identification of *Cryptococcus* species. The expertise of the individual evaluating the slide is the main variable in using cytology in the clinical setting. The sensitivity of cytologic and histologic evaluation varies considerably although specificity is high. Cytologic and histopathologic features cannot definitively identify the species and therefore culture and biochemical characterization or molecular analysis are mandatory for identification. It is important to highlight that morphologic features of fungi in tissue differ when grown on fungal media.

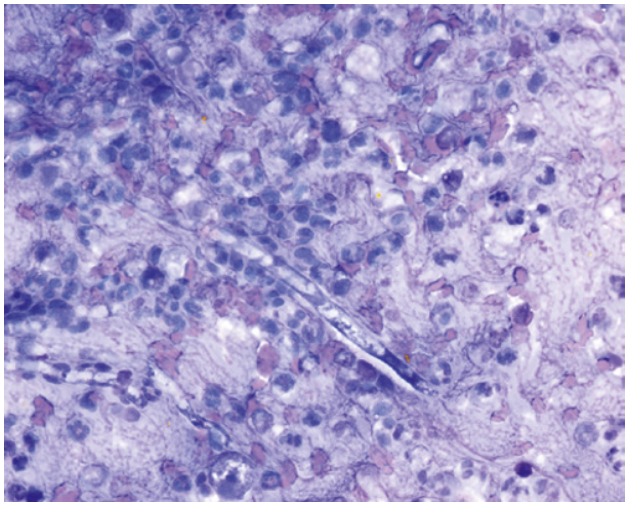

Figure 79.5 Inguinal subcutaneous mass in a dog. Note the marked neutrophilic inflammation and the evidence of unstained and partially pale basophilic hyphae (modified Wright stain, original magnification ×400).

Serologic Testing (Antibody and Antigen Detection)

Serology is used in the clinical setting to diagnose fungal disease in dogs and cats. However, interpretation of serologic results in some fungal diseases might be difficult and will benefit from additional cytologic or molecular evidence or culture. Limited studies are available regarding sensitivity and specificity of serologic testing of some fungal diseases. The majority of fungal serologic tests currently in use in veterinary medicine detect the antibody response to infection. A few tests detect fungal antigens, providing a definitive diagnosis if the antigen is sufficiently specific (such as the antigen-based latex agglutination test available for *Cryptococcus neoformans*). As with any serological test, cross-reactivity can exist between fungal agents. Positive serology provides evidence of exposure and supports the clinical findings. Paired serum samples (2–4 weeks apart) should be run at the same time. A fourfold increase or decrease in the antibody level is strong evidence of active disease. More details on current serologic tests available for fungal disease are described elsewhere in this section and in the literature.

Isolation and Identification (Including Molecular Testing)

Culture

The specific identification of fungal organism is based on culture of fluids or tissue. However, successful culture of fungal agents depends on several variables, including the

fungal organism itself, concentration of fungal elements in the sample, sample integrity, culture requirements of the fungal agent, and expertise of the laboratory performing the culture.

Obtaining and submitting the appropriate sample for culture and providing the laboratory with detailed history and clinical diagnosis are essential for a successful culture. Samples of urine, exudates, and body cavity fluids can be submitted in sterile serum collection tubes. Up to 10 mL of fluid is recommended. Samples of fresh tissue from a lesion can be submitted in a sterile container for culture.

Identification of fungal agents in cultures is time-consuming. The culture has to grow and form characteristic fruiting bodies, conidia, or arthrospores to allow morphologic identification of the fungus. Microscopic morphology of fungal reproductive structures is the most useful criterion for identification. It is strongly advised that fungal culture (other than for dermatophytosis) is performed in a reference diagnostic laboratory.

Molecular Testing

Molecular testing is less commonly employed for the diagnosis of fungal diseases in tissues or body fluids in veterinary medicine as it is for bacterial, viral, and protozoal diseases. Molecular techniques are the same as reported for other infectious diseases and include conventional, nested, and real-time PCR and sequencing. Common target genes are the 18S or 5.8S ribosomal gene or internal transcribed spacer (ITS) regions of ribosomal DNA. Fungal identification based on DNA sequencing is not always definitive because results depend on whether or not the DNA of the fungus in question has been previously sequenced and submitted to the genomic databases. Therefore, fungal identification based on DNA sequencing should include at least two DNA regions for comparison.

In contrast, PCR-based methods are commonly used to confirm identification of fungi culture in diagnostic laboratories. Commercial chemiluminescent-labeled DNA probes are available for some fungal agents such as *Blastomyces*, *Coccidioides*, and *Histoplasma*.

Canine Distemper

David S. Bruyette, DVM, DACVIM

Anivive Lifesciences, Long Beach, CA, USA

Etiology/Pathophysiology

Canine distemper virus (CDV) is a large (100–250 nm) ssRNA virus belonging to the genus *Morbillivirus* of the family Paramyxoviridae. Mutations affecting the CDV H protein required for virus attachment to host cell receptors are associated with virulence and disease emergence in novel host species. CDV has a lipoprotein envelope and a nonsegmented negative-stranded RNA genome consisting of six genes that code for a single envelope-associated protein (matrix [M]), two glycoproteins (hemagglutinin [H] and fusion [F] proteins), two transcriptase-associated proteins (phosphoprotein [P] and large protein [L]) and the nucleocapsid (N) protein, which encapsulates the viral RNA. Only one serotype of CDV is recognized with several co-circulating genotypes based on variation in the H protein.

Canine distemper has affected dogs worldwide for centuries, with descriptions of disease outbreaks in the European literature dating back to the 17th century. It was first formally described in dogs in 1905. Despite the introduction of modified live vaccines in the 1950s and their extensive uptake, the disease remains prevalent.

Systemic CDV infection, resembling distemper in domestic dogs, can also be found in wild canids (e.g., wolves, foxes), procyonids (e.g., raccoons, kinkajous), ailurids (e.g., red pandas), ursids (e.g., black bears, giant pandas), mustelids (e.g., ferrets, minks), viverrids (e.g., civets, genets), hyaenids (e.g., spotted hyenas), and large felids (e.g., lions, tigers). In addition, besides infection with the closely related phocine distemper virus, seals can become infected by CDV. In some CDV outbreaks, including the mass mortalities among Baikal and Caspian seals and large felids in the Serengeti Park, terrestrial carnivores including dogs and wolves have been suspected as vectors for the infectious agent. Lethal infections have been described in noncarnivore species such as peccaries and nonhuman primates demonstrating the remarkable ability of the pathogen to cross species barriers.

Canine distemper virus infection of dogs is characterized by a systemic and/or nervous clinical course and viral persistence in selected organs, including the central nervous system and lymphoid tissue. Main manifestations include respiratory and gastrointestinal signs, immunosuppression and demyelinating leukoencephalomyelitis (DL). The primary mode of infection is via inhalation. After initial exposure, dogs may mount a robust immune response and recover. It is estimated that as many as 75% of infections may actually be subclinical. Initially, CDV replicates in lymphoid tissue of the upper respiratory tract. Monocytes and macrophages are the first target cells which propagate the virus. Impaired immune function, associated with depletion of lymphoid organs, consists of a viremia-associated loss of lymphocytes, especially of CD4+ T cells, due to lymphoid cell apoptosis in the early phase. After clearance of the virus from the peripheral blood, an assumed diminished antigen presentation and altered lymphocyte maturation cause an ongoing immunosuppression despite repopulation of lymphoid organs.

Following a variable incubation period (1–4 weeks), animals develop a characteristic biphasic fever. During the first viremic phase, generalized infection of lymphoid tissues with lymphoid depletion, lymphopenia, and transient fever are observed. Profound immunosuppression is a consequence of leukocyte necrosis, apoptosis, and dysfunction.

The second viremia is associated with high fever and infection of parenchymal tissues such as the respiratory tract, digestive tract, skin, and CNS. The early phase of DL is the result of direct virus-mediated damage and infiltrating CD8+ cytotoxic T cells associated with an upregulation of proinflammatory cytokines such as interleukin (IL)-6, IL-8, tumor necrosis factor (TNF)-alpha, and IL-12 and a lack of response of immunomodulatory cytokines such as IL-10 and transforming growth

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

factor (TGF)-beta. A CD4+-mediated delayed-type hypersensitivity and cytotoxic CD8+ T cells contribute to myelin loss in the chronic phase. Additionally, upregulation of interferon-gamma and IL-1 may occur in advanced lesions. Moreover, an altered balance between matrix metalloproteinases and their inhibitors seems to play a pivotal role for the pathogenesis of DL.

Histologic manifestations include polioencephalitis and DL. The observations of $p75^{NTR}$-expressing bipolar Schwann cell-like glia in CDV-DL highlight the potential of Schwann cell-mediated remyelination and raise the hope for a beneficial regenerative process in CDV-DL. Though the central role of axonal damage as a triggering event is established in CDV-DL, the role of macrophage polarization in CDV-DL is currently unknown. In light of the fact that distinct macrophage responses have been linked to axonal regeneration, degeneration, demyelination, and remyelination, the elucidation of a potential macrophage polarization during CDV-DL appears to represent a promising field for future investigations and the development of new treatment strategies.

Recovery from CDV depends on the host immune response. A strong and effective cellular immune response can eliminate the virus prior to infection of parenchymal tissues, while weak and delayed cellular and humoral immune responses lead to virus spread and persistence, respectively.

Epidemiology

Canine distemper is a fatal disease of dogs with a worldwide distribution. With a mortality rate of around 50%, it is second only to rabies when it comes to virus-induced fatality in dogs.

Signalment

There is no breed or sex predilection. Animals <6 months are particularly vulnerable.

Clinical Signs

Signs most often involve the respiratory tract. Gastrointestinal (GI) signs may also occur. Affected dogs are listless and have a decreased appetite. In milder cases, signs may be similar to other agents of canine infectious respiratory disease complex. Subclinical infection with shedding may also occur, depending on the level of host immunity. Systemic signs are most common in unvaccinated dogs (e.g., puppies) as maternal immunity wanes. Conjunctivitis, nasal discharge, cough, and fever are classic signs. Respiratory infection may involve the lower respiratory tract with possible primary viral pneumonia. Secondary bacterial infection may occur. Vomiting and diarrhea may be present. Neurologic signs may be concurrent with epithelial signs (i.e., respiratory disease, conjunctivitis, vomiting, diarrhea) with encephalitis caused by direct viral replication. Alternately, neurologic disease may occur several weeks after resolution of epithelial invasion.

A significant amount of pathology results from the host's immune response to the virus, as well as the virus itself. Seizures and myoclonus are two of the more common signs. The latter may affect limbs or manifest as chewing motion of the jaw. Ocular disease may also occur. Lesions include anterior uveitis, optic neuritis, and retinal detachment. Infection during pregnancy may lead to abortion or stillbirth. Puppies infected before permanent dentition may have enamel hypoplasia. Digital hyperkeratosis ("hard pad disease") may be noted.

Diagnosis

Diagnosis is established via virus identification in a clinical sample through use of reverse-transcriptase polymerase chain reaction (PCR) of whole blood, a swab of conjunctiva or tissue, cerebrospinal fluid (CSF), or urine. When obtaining conjunctival scrapings, remove mucus and tears and using a sterilized, blunt metal spatula or dulled scalpel blade, repeatedly scrape the conjunctiva until a small amount of tissue can be lifted. Apply the tissue to a slide and submit the slide to an outside lab for immunofluorescence assay (IFA) testing. Urine is a good source for PCR testing in patients with CDV encephalitis after resolution of epithelial signs. CDV may be detected in urine for a longer period than other sample types. CDV detection in urine and CSF was equivalent in one study of neurologic cases. Postmortem evaluation and microscopic findings confirm infection. The specific lesion of CDV is eosinophilic intranuclear/intracytoplasmic inclusion bodies in glial cells, neurons, epithelial respiratory cells, and cells of the GI and urogenital tracts.

Virus isolation is the gold standard for diagnosis and is useful in low levels of viral infection through observation of typical syncytial cell formation. Immunocytology can be used to enhance the visibility of inclusion bodies by fluorescein-conjugated CDV antibodies.

Treatment

Treatment is supportive only (see Chapter 82). Antiviral medications are not routinely used or recommended. No single treatment is specific or uniformly successful.

Secondary bacterial infection frequently results in bronchopneumonia, which requires broad-spectrum antibiotic therapy +/− expectorants or nebulization. Parenteral therapy is required when GI signs or dehydration are present. Water, food, and oral drugs should be discontinued if vomiting and diarrhea are present, Parenteral antiemetics may be required. In dogs with status epilepticus, diazepam should be administered intravenously or per rectum, followed by phenobarbital for maintenance prevention.

Prevention

Control is accomplished through vaccination. Current vaccines include strains of the American lineage (Onderstepoort or Lederle strains). After recovery from natural infection or following booster vaccination, immunity can persist for years. Vaccination for CDV can begin as early as 6–8 weeks of age, with boosters every 2–4 weeks until at least 16 weeks of age. For naive puppies or adults vaccinated after maternal immunity has waned (approximately 16 weeks of age), a single attenuated live or recombinant vaccine may be sufficient to induce protection. In older vaccinated dogs, an annual or triennial distemper booster is recommended, depending on the risk for infection. Current AAHA guidelines should be consulted for specific vaccination recommendations in standard and high-risk situations. The AAHA 2017 canine vaccination guidelines state that measuring antibody levels provides a reasonable assessment of protective immunity. Information on antibody testing can be found at www.aaha.org/CanineVaccineTiters. No vaccine is 100% effective, but regular vaccination can help protect animals. CDV is susceptible to ultraviolet light, heat, drying, and all routinely used disinfectants.

Client education about purchasing puppies from crowded pet markets is important.

Prognosis

Prognosis is guarded, especially with CNS involvement.

Public Health Implications

Currently, CDV is not considered to be a public health concern. However, following the outbreaks of CDV infections in animal facilities in China, a CDV outbreak occurred in cynomolgus monkeys (*Macaca fascicularis*) in Japan in 2008. A corresponding CDV strain was isolated (CYN07-dV) and characterized, which efficiently utilized macaca CD150 as an entry receptor. Despite the similarity of the amino acid sequence of *Macaca mulatta* CD150 to the human sequence, the isolated virus did not efficiently infect human Vero-hSLAM cells. As long as a high percentage of the human population is immune to measles via vaccination, there is likely little concern for CDV making the transition to humans. However, that may change if measles should happen to be eradicated.

Canine Herpesvirus

Yvonne Drechsler, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Canine herpesvirus (CHV), a member of the Herpesviridae family, is a DNA virus that infects and replicates in mucosal epithelial cells and lymphoid tissue. Clinical signs vary depending on the age and immune status at time of infection. The virus replicates most efficiently at temperatures lower than 98.6 °F. Therefore, the ability to mount a febrile response aids in fighting infection. In addition, replication is favored in cooler body locations such as mucous membranes. As is common for herpesviruses, CHV will exist as a latent form in ganglia or lymphoid tissue after initial infection. The virus can be reactivated by stressors at any time, leading to shedding and transmission.

In naive pregnant females, infection will lead to systemic viremia, resulting in fetal death, abortion, and mummification. Puppies typically acquire the infection *in utero*, during passage through the birth canal, via contact with oronasal secretions of the dam, or from contact with other infected dogs shedding the virus. Acute neonatal viremia is associated with very high mortality in puppies younger than 3 weeks. Pregnant females, previously exposed to the virus, will confer passive immunity through nursing, while remaining asymptomatic. Older, naive puppies and adult dogs will usually show disease of the genitals, respiratory tract or eyes.

Epidemiology

Canine herpesvirus is common in several canine species, including dogs, coyotes, and wolves, and has a worldwide distribution. Studies in Europe have shown a seroprevalence of 39–88% in dogs. Infection is more common in multidog environments, such as shelters and kennels. Studies in shelter dogs have also shown that CHV may be implicated as an etiologic agent in canine infectious respiratory disease complex.

Signalment

Neonatal puppies up to 3 weeks are at greatest risk for severe disease and death. Male and female dogs older than 3 weeks generally develop mild clinical signs and recurring infections.

History and Clinical Signs

Infection and associated clinical signs occur by exposure to other dogs, and may be particularly common in kennels and other multidog environments. Clinical signs may also occur due to reactivation of previous infection provoked by various stressors. Immunocompromised animals are at higher risk of reoccurring infections, particularly dogs with diabetes mellitus, immune-mediated diseases, and lymphoma.

In young puppies 1–3 weeks of age, signs include depression, respiratory signs, anorexia, soft yellow or green stools and diarrhea, persistent crying, abdominal pain, petechial hemorrhages on mucous membranes and occasional presence of vesicles on genitals. Death usually occurs within 24–48 hours of showing clinical signs. Surviving puppies will most likely develop neurologic signs.

Older puppies and adults may present with upper respiratory signs, but in rare cases, more severe lower respiratory disease can occur. Signs of primary genital infection are characterized by vesicular lesions on the genital mucosa. Ocular signs may include conjunctivitis, corneal ulceration or keratitis, blepharospasm, photophobia, and ocular discharge.

Diagnosis

History, clinical signs, physical examination, a history of stress or evidence of immunosuppression should

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

increase the index of suspicion for infection. Sepsis is the primary differential for neonates. CHV can be isolated and grown from various tissues including liver, spleen, kidneys, and lymph nodes taken from puppies that died of systemic infection. Older animals showing signs of reproductive, respiratory or ocular disease will typically shed the virus in oral or genital mucosa, which can be sampled. In cases of active viremia, whole blood in EDTA can be used for virus isolation. Virus can also be detected using polymerase chain reaction (PCR), immunofluorescence assays, or electron microscopy. Serology will confirm presence of CHV antibodies, which indicates exposure but not necessarily active infection.

Therapy

Treatment options for young puppies with signs of systemic infection are limited. The progression of the disease is rapid and usually fatal. Supportive care is important. Intraperitoneal injection of 1–2 mL of pooled immune sera from female dogs that have given birth to CHV-infected litters has been suggested as a treatment for neonatal puppies. External warming may restrict viral growth, and it has been suggested that it may help prevent clinical signs in unaffected puppies. However, it is not effective in puppies that already show signs of infection. The efficacy and safety of antiviral drugs requires further research. Currently, there are no licensed medications for treatment of CHV in dogs. The antiviral drugs vidarabine and acyclovir have been described for treatment of neonatal puppies with CHV infection, but whether they are safe or effective has not been well studied, toxicity is a significant concern. There is no vaccination for CHV in the United States, but a vaccine is available in Europe.

Prognosis

The disease is usually fatal in neonates whereas milder or subclinical disease occurs in older animals with a competent immune system and the ability to thermoregulate. Immunosuppression may cause recrudescence of latent infection.

Public Health Implications

Like other herpesviruses, CHV is highly species specific and does not infect humans.

Canine Viral Enteritis

Margaret C. Barr, DVM, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Dogs are susceptible to several viral diseases that present with gastrointestinal signs either as the primary complaint or as a component of multisystemic disease. Canine parvovirus type 2 (CPV-2) is the most common cause of viral enteritis in dogs, but enteric canine coronavirus (CCoV) and canine distemper virus must also be considered as possible viral etiologies. Canine rotavirus causes diarrhea in neonatal puppies, similar to type A rotaviruses in other animal species. A multitude of other viruses, including two newly discovered viruses of dogs, canine kobuvirus and dog circovirus, have been identified in some cases of canine enteritis.

Because CPV-2 is the most clinically relevant of the canine enteric viruses, this section will focus on its characteristics, pathogenesis, and management. Table 82.1 provides a comparison of CPV-2 with some of the other canine enteric viruses.

Etiology/Pathophysiology

Canine parvovirus is a small single-stranded, nonenveloped DNA virus that infects and replicates in a variety of rapidly dividing cells. Entry into the host cells depends on interaction between the major capsid protein of the virus, VP2, and the transferrin receptor on the cell surface. Initial replication usually occurs in the oropharyngeal lymphoid tissues, followed by viremia and systemic replication in other lymphoid tissues, leukocyte precursors in the bone marrow, and intestinal crypt epithelial cells. Clinical signs may appear as early as four days after exposure but more typically occur about a week after infection.

Pathologic findings include gastrointestinal inflammation and hemorrhage predominantly in the small intestine, with characteristic crypt cell destruction and severe villous atrophy. The virus also causes lymphoid depletion, thymic lymphocytolysis, and mitotic arrest of bone marrow hematopoietic cells. Perinatal infection with CPV-2 can result in cardiac myofiber lysis and multifocal necrosis.

Epidemiology

Canine parvovirus is closely related to feline parvovirus and similar viruses of wild carnivores, such as mink enteritis virus and raccoon parvovirus. Since its emergence and worldwide spread in domestic and wild canids in the mid-late 1970s, CPV-2 has mutated to form antigenic variants CPV-2a, CPV-2b, and CPV-2c, which are all defined by amino acid changes in the major capsid protein, VP2. Although CPV-2 is unable to infect cats, subsequent variants have expanded host ranges and can replicate in feline cells.

The main route of infection for CPV-2 (as with most other enteric viruses) is through oral or nasal contact with feces or feces-contaminated material. *In utero* transmission of CPV-2 can also occur. The small compact size and nonenveloped structure of the virus make it highly resistant to inactivation by environmental conditions and easily transmitted on fomites. Infected animals shed the virus in high concentrations beginning around day 4 of infection and can continue to shed for several days after the resolution of clinical signs. Parvovirus is rarely detected in the feces of healthy dogs with no history of enteritis.

At least in some regions, there is a distinct seasonality to the occurrence of parvovirus enteritis, usually peaking in late summer to early fall.

Signalment

While male and female dogs of all ages are susceptible to infection, CPV-2 is most significant as a cause of gastroenteritis in puppies 6 weeks to 6 months of age. Puppies become susceptible to infection as maternally

Table 82.1 Comparison of CPV-2 and other canine enteric viruses

Virus	Molecular characteristics	Host specificity	Age most affected	Primary target cells and typical pathobiology	Clinical presentation	Additional information
Canine parvovirus 2 (*Parvovirus*, Parvoviridae)	ssDNA, nonenveloped, icosohedral capsid; variants CPV-2, 2a, 2b, 2c	Domestic and wild canids; CPV-2a, 2b, 2c – can also infect cats	6 weeks–6 months	Lymphoid cells, intestinal crypt epithelial cells, hematopoietic cells Intestinal crypt destruction/ severe villous atrophy; lymphoid, bone marrow and thymic depletion	Fever, depression, inappetence, vomiting, diarrhea (scant mucoid to profuse hemorrhagic); dehydration, electrolyte disturbances; endotoxemia	High level of genetic variation can lead to emergence of new antigenic variants
Canine enteric coronavirus (*Alpha- coronavirus*, Coronaviridae)	ssRNA, enveloped with large spike proteins, helical nucleocapsid; genotypes CCoV-I, CCoV-II (a & b)	Domestic and wild canids	>4 months Healthy dogs often shed CCoV	Enterocytes Moderate villous atrophy, deepening of crypts Pantropic variant has increased virulence and causes systemic disease	Usually mild, self-limiting diarrhea and vomiting Pantropic variant – fever, lethargy, hemorrhagic diarrhea, lymphopenia, neurologic signs	A distantly related *Beta-coronavirus* causes respiratory disease in dogs similar to SARS-CoV in humans
Canine distemper virus (CDV) (*Morbillivirus*, Paramyxoviridae)	ssRNA, enveloped; intracytoplasmic & intranuclear inclusions Closely related to human measles & rinderpest viruses	Domestic and wild canids; wild felids; variants infect raccoons, skunks, ferrets, marine mammals	3–6 months	Macrophages, lymphocytes, epithelial cells, neurons, glial cells (pancytotropic) Mild-moderate villous atrophy, hyperkeratosis, lymphoid and thymic depletion, encephalomyelitis	Multisystemic disease: lethargy, fever, vomiting, diarrhea, coughing, dyspnea, nasal and ocular discharge, conjunctivitis, keratitis, photophobia, seizures, dementia, ataxia, hyperesthesia, hyperkeratosis	"Old dog" encephalitis – rare form of CDV disease in older dogs years after primary infection
Canine rotavirus (*Rotavirus*, Reoviridae)	Segmented (11) dsRNA, non-enveloped; reassortment with A rotaviruses	Domestic and wild canids See Additional information column	Neonates	Mature enterocytes Mild villous atrophy	Usually mild, self-limiting diarrhea	Interspecies transmission and zoonotic potential with reassorted viruses
Canine kobuvirus (*Kobuvirus*, Picornaviridae)	ssRNA non-enveloped, icosohedral capsid	Domestic dogs and foxes, likely other canids – very few epidemiologic studies reported	Unknown	Not yet characterized	Has been isolated from stool samples of diarrheic dogs, but pathogenicity is currently unknown	Genetically similar to human Aichi virus A, a gastroenteritis transmitted through consumption of oysters
Dog circovirus (*Circovirus*, Circoviridae)	ssDNA, non-enveloped, icosohedral capsid Closely related to porcine circovirus	Domestic dogs; wild canids unknown	6 weeks–6 months	Not yet characterized	Unclear – has been associated with hemorrhagic gastroenteritis, vasculitis and vascular necrosis Granulomatous lymphadenitis, thrombocytopenia	Similar prevalence in healthy and sick dogs; probably most important as a co-pathogen with CPV-2 – increased mortality

derived immunity wanes and remain susceptible until they acquire active immunity, either through natural infection or through vaccination. The outcome of infection, ranging from subclinical infection to severe disease, seems to depend on individual host factors, with some breeds (notably American pit bull terriers, Rottweilers, Doberman pinschers, and German shepherds) having increased risk for severe enteritis.

History and Clinical Signs

Most puppies infected with CPV-2 present with a history of lethargy and inappetence. These signs are often accompanied by fever, abdominal pain, vomiting and diarrhea, which may lead to substantial dehydration. Although profuse, hemorrhagic diarrhea is a typical finding, many dogs with CPV enteritis will produce scant mucoid feces instead. Extensive damage to the small intestinal mucosa may result in coliform bacterial septicemia and endotoxic shock.

Lymphopenia is a consistent clinicopathologic finding; other changes may include neutropenia, anemia, thrombocytopenia, electrolyte imbalances (especially hypokalemia), hypoglycemia, and hypoalbuminemia. Serum C-reactive protein levels are often elevated in critically ill dogs and correlate loosely with increased risk of mortality.

Myocarditis occurs with perinatal infection of puppies born to naive bitches; puppies may present with dyspnea, weakness, and crying or experience sudden death. This syndrome is not commonly seen in vaccinated and/or CPV-endemic populations.

Diagnosis

Although parvovirus infection is the likely diagnosis in an unvaccinated puppy presenting with enteritis, fever, and lymphopenia, other enteric viruses may have a similar presentation. Diagnosis of parvoviral enteritis is best accomplished by observation of clinical signs along with detection of CPV-2 antigen (point-of-care enzyme-linked immunosorbent assay [ELISA] or hemagglutination) or DNA (polymerase chain reaction [PCR]) in feces or rectal swab specimens. PCR-based tests are more sensitive than antigen tests and can be used to identify the variant of the infecting CPV.

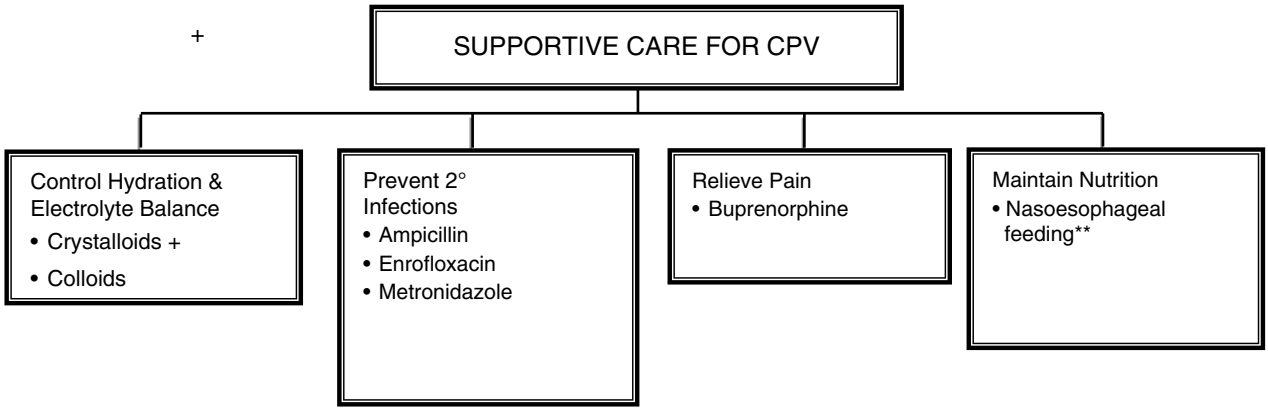
Therapy

Ideally, puppies infected with CPV-2 should be hospitalized and kept in isolation. Therapy for CPV-2 enteritis consists of aggressive supportive care to correct hydration, hypoglycemia, and electrolyte abnormalities such as hypokalemia, control pain and maintain nutrition. Antimicrobials should be administered to prevent and treat secondary bacterial infections (gram-negative and anaerobic) that arise from bacterial translocation across the compromised gastrointestinal tract or from neutropenia. Frequent (q8h) monitoring of blood glucose is necessary and supplementation of intravenous (IV) fluids with dextrose is often needed. Colloid therapy with hetastarch or plasma may be necessary in some patients, particularly those with severe hypoalbuminemia (Figure 82.1).

Red cell transfusion may be necessary in patients with significant blood loss. While treatment with recombinant human granulocyte stimulating factor and hyperimmune serum has not been shown to be of benefit, feline interferon-omega has shown promising results.

Prognosis

Puppies with severe enteritis have a very poor survival rate without treatment due to hypovolemic and septic shock and electrolyte/acid–base disturbances, while hospitalization with fluid therapy greatly improves their prognosis for recovery. A protocol for outpatient treatment of puppies whose owners cannot afford hospital care has been developed and is showing promise for improving the prognosis in these patients.



Prevention

Prevention of CPV-2 infection is accomplished by limiting contact of susceptible animals with potentially infected animals and premises while stimulating immunity with vaccination. Shelters, kennels, clinics, and other high-density units need to practice good sanitation, disinfection, and appropriate use of quarantine protocols and isolation facilities.

Because maternally derived antibody can interfere with immunization, vaccination with modified live virus vaccine is recommended every 3–4 weeks beginning at 6 weeks of age until the puppy is 16 weeks old (or 20 weeks old for high-risk breeds). Although current vaccines, which are composed of CPV-2 or CPV-2b, have been effective in protecting dogs against CPV-2c infection under experimental conditions, it is still unclear how protective these vaccines are under some field conditions.

Public Health Implications

Canine parvovirus-2 variants do not infect people, but feces should be treated as if other infectious agents that cause intestinal disease in people are present.

+ Potassium supplementation is important and should be adjusted based on frequent measurement of serum potassium.
# Ampicillin or cefazolin may be sufficient however improved gram-negative coverage may be needed. There is a risk of cartilage deformity in puppies treated with fluoroquinolones, however short-term(<7 d)therapy at 5 mg/kg q 24 hours may be warranted Once the patient is hydrated, aminoglycosides may also be considered for improved gram-negative coverage.
Metronidazole may be used to improve anaerobic coverage if needed.
** Use of the GI tract and trickle feeding is associated with improved survival compared to fasting, and is preferred over intravenous feeding due to the ability to provide nutrition to enterocytes and due to the risk of sepsis associated with parenteral nutrition.

Figure 82.1 Supportive care for CPV.

Viral Papillomatosis

Margaret C. Barr, DVM, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Dogs and cats, like many other species, are susceptible to development of papillomatous growths (warts) on the skin and mucous membranes. Most of the time, viral papillomas are benign and transient lesions but they can significantly affect the health of an animal if they progress to premalignant or malignant neoplastic lesions. Canine and feline papillomas and the viruses that cause them share many features and will be discussed together in this chapter.

Etiology/Pathophysiology

Papillomaviruses (PV) are small nonenveloped viruses with a circular double-stranded DNA genome enclosed in an icosohedral capsid. They belong to the large and diverse viral family Papillomaviridae, which currently includes over 280 types of papillomaviruses infecting most (if not all) mammalian species and many nonmammalian species. Each PV type demonstrates a strong host and tissue/site preference, with only a few examples of interspecies transmission.

Papillomaviruses replicate in epithelial cells of skin and mucous membranes, beginning their life cycle in the basal layer and progressing as the cells mature. Viral assembly and particle release are restricted to the stratum granulosum and stratum corneum. This pattern of replication is orchestrated by the complex expression of a series of early and late genes.

Infections are often subclinical, with frequent detection of papillomavirus DNA in normal skin of healthy dogs and cats. The typical presentation of papillomatosis (cutaneous or oral warts) occurs when high levels of PV early gene expression induce rapid expansion of the basal epithelial cell population followed by cell differentiation, epithelial thickening, hyperkeratosis, and exophytosis. Progression to malignant lesions occurs rarely in both dogs and cats, with some species differences in histologic features and clinical presentation. Disregulation and overexpression of two early genes, E6 and E7, have been linked to the development of PV-associated squamous cell carcinomas (SCCs).

In most animals, mild inflammation and a cell-mediated immune response lead to spontaneous regression of papillomas within 6–8 weeks. A humoral immune response produces antibodies that protect against reinfection with closely related types of PV. Immunocompromised animals may develop persistent and generalized papillomatosis with an increased risk of progression to malignant neoplastic transformation.

Epidemiology

Papillomaviruses infect domestic and wild canids and felids throughout the world. Although only a few canine and feline PV have been sequenced to date, almost 150 human PV types have been reported. In general, PVs are highly host specific; however, bovine papillomavirus type 1 infection causes equine sarcoid tumors in horses, and ruminant-like PVs have been linked to the development of feline sarcoids.

Papillomaviruses are transmitted through epidermal microabrasions or transepidermal inoculation of virus with contaminated fomites. Because the virus lacks an envelope, it is relatively resistant to adverse environmental conditions and difficult to kill with disinfectants. These facts, along with the ubiquity and diversity of PVs, make it likely that most animals will be infected at some point in their lives, but there is little information on the prevalence of PV infection in canine and feline populations.

Signalment

Dogs and cats of all ages and breeds can be infected with PVs. Young dogs are most likely to be affected by canine oral papillomatosis, while older animals with chronic persistent infections are more likely to develop bowenoid *in situ* carcinoma (BISC) and invasive SCC. Young pugs and miniature schnauzers seem to be disproportionately affected by canine pigmented plaques, suggesting that host genetic factors play a role in the development of this disease. Oral papillomas in dogs rarely progress to SCC but there is some indication that malignant transformation of canine oral papillomas may be increasing.

Oral and cutaneous papillomatoses are not observed as often in cats as in dogs; viral plaques are also uncommon but have been more clearly associated with PV infections in cats. Feline BISCs develop in middle-aged to older cats, occur disproportionately in cats with feline retrovirus infections, and are most severe in hairless breeds. Cutaneous and oral SCCs are common malignancies of older cats, with ultraviolet (UV) exposure being an important risk factor for some of these lesions. While feline PV DNA has been identified frequently in cutaneous SCCs found in UV-protected areas of the body, a strong association of oral SCC with PV infection in domestic cats has not been established.

Clinical Signs

Papillomatosis and viral plaque lesions are typically limited to the cutaneous or mucosal epidermis, sometimes occurring singly but more often in multiples. Lesions can range from papular or nodular lesions to pedunculated or cauliflower-like, hyperkeratotic masses. Infection rarely generates more than a mild inflammatory response, so systemic signs are not seen. Bowenoid *in situ* carcinomas develop as multicentric irregular regions of epidermal and follicular hyperplasia primarily on the face, shoulders, and limbs. These premalignant lesions are hyperkeratotic, pigmented plaques that may ulcerate. If progression to SCC occurs, it is usually as a single nonmetastatic but potentially highly invasive tumor. A summary of diseases associated with canine and feline PV infections is provided in Table 83.1.

Diagnosis

Diagnosis of oral papillomatosis is based on clinical presentation for most typical cases in young dogs. Other types of lesions require full-thickness excisional biopsy with histologic examination for a morphologic diagnosis. The etiologic diagnosis of papillomatosis can be

Table 83.1 Papillomavirus-associated disease in domestic dogs and cats

Disease	Species affected	Clinical presentation
Oral papillomatosis	Canine Feline – rare	Multiple, raised, smooth nodular to pedunculated, hyperkeratotic masses on oral mucosa and lips (dogs), or ventral tongue (cats); spontaneous regression is common
Exophytic cutaneous papillomatosis	Canine Feline – rare	Single to multiple pedunculated, hyperkeratotic masses often on head or feet; spontaneous regression is common
Endophytic cutaneous papillomatosis	Canine	Unpigmented, raised firm masses with central pores found on ventral abdomen or feet; do not usually regress
Pigmented plaques	Canine	Small to medium-sized flat to slightly raised, darkly pigmented, hyperkeratotic masses found in clusters on the limbs, axilla, ventral trunk or abdomen; do not usually regress; may progress to *in situ* carcinoma
Viral plaques	Feline	Multiple variably sized, slightly raised, hyperkeratotic masses that may or may not be pigmented; some may spontaneously regress while others progress to *in situ* carcinoma
Bowenoid *in situ* carcinoma (BISC)	Feline Canine – rare	Multiple scaly, crusting to ulcerating plaques frequently on face, neck and limbs; some may be slowly progressive and others become highly invasive or progress to squamous cell carcinoma
Squamous cell carcinoma (SCC)	Feline Canine – rare	Usually a solitary flattened ulcerated mass found in UV-protected areas of the body (as opposed to SCCs caused by UV exposure); rarely metastasize but can be highly invasive and damaging to surrounding tissue
Feline sarcoid	Feline	Slow-growing, solitary to multiple, smooth dense fibroblastic nodules that may ulcerate, located on head, neck and extremities; do not metastasize and are not highly invasive

UV, ultraviolet.

confirmed by immunohistochemical staining for PV group-specific antigens, *in situ* hybridization for PV nucleic acid detection, or electron microscopy to visualize viral particles. Polymerase chain reaction is a highly sensitive and rapid method for detection of PV DNA in biopsy specimens, but interpretation is difficult because PV DNA is frequently amplified out of normal canine and feline skin.

Therapy and Prognosis

Spontaneous regression of many nonmalignant PV-associated lesions makes treatment unnecessary in most cases. Immunosuppressive drugs like glucocorticoids and ciclosporin should be avoided, if possible, in infected animals. Provision of a high-quality diet and management of stress may help support an animal's immune response to the virus. Interferons and other immunomodulators have been tried in severe cases of papillomatosis, but solid evidence of their efficacy is not yet available. Azithromycin (10 mg/kg once daily for 10 days) was used in one small trial to treat canine oral and cutaneous warts with some apparent efficacy. The mechanism of action is unclear but it may be associated with immunomodulatory properties of the drug.

Surgical removal or cryotherapy may be effective if few lesions are present although new lesions may develop. Removal of premalignant and malignant lesions like BISCs and SCCs should include histologically confirmed normal tissue margins on all borders.

Prevention

Currently, there are no commercial vaccines available for canine and feline papillomatosis. Because most PV infections are subclinical or produce benign self-limiting lesions, immunization has not been a priority. The diversity of PVs makes it difficult to stimulate protective immunity against this family of viruses. If specific types of canine and feline PVs are demonstrated to be associated with the development of SCC, then targeting those viruses with vaccines would make sense. The use of vaccines against some types of human PVs associated with genital cancer suggests that vaccination could be effective against PVs in other species also.

Public Health Implications

Canine and feline papillomaviruses have not been demonstrated to be infectious to humans. However, human PV-9 was amplified from a cutaneous papilloma in a cat, and bovine PV causes equine (and possibly feline) sarcoids, proving that cross-species infection can occur under some circumstances.

Canine Influenza Virus

Ellen Collisson, MS, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

While influenza A viruses had for many years not been considered pathogens of concern in dogs, they are today a serious differential for canine respiratory problems. In 2004, a previously known equine strain of H3N8 influenza A virus emerged as a canine respiratory concern during an outbreak in greyhound racing dogs in Florida. Twenty-two dogs suffered from fever, followed by coughing and either recovery or, in the case of eight dogs, peracute death occurred associated with extensive hemorrhaging of the lungs, mediastinum, and pleural cavity.

Severe respiratory illness with mortality was reported in dogs in 2008 in Korea and later in China and Thailand due to an H3N2 strain of influenza that has been shown to originate from the avian virus and to also transmit from dog to dog. In March 2015, canine influenza virus (CIV) H3N2 was identified in the United States in the Chicago area and during the same year identified in dogs in at least 30 states throughout southern, eastern and midwestern United States. In 2015, shelter cats in Indiana were also diagnosed with an H3N2 strain.

Typical of other influenza A viruses, CIV viral particles capable of cell-to-cell or host-to-host transmission carry H (hemagglutinin) and N (neuraminidase) proteins that are anchored in the bilipid envelope coating the viral particle. These glycosylated proteins, used to define subtypes, are prone to mutations that result in the evolution of new influenza strains. A hallmark of influenza viruses is the eight-segmented RNA genome which provides a mechanism of rapid genetic change through segment reassortment. Thus, infection with more than one type of influenza virus can result in progeny that are a combination of RNA segments from more than one parent strain. In addition, the RNA polymerase which generates the viral RNA segments for progeny virus is error prone, creating mutations that may contribute to altered viral tropism, pathogenesis, and antigenicity.

Epidemiology

Influenza viruses are highly contagious and easily transmitted from dog to dog by aerosol or contact exposure, but the H3N2 also was found to infect cats, resulting in respiratory illness. The H3N8 virus has been shown experimentally to also infect cats. Animals in high-density environments, such as shelters, competition events, and breeding facilities, are at greatest risk of infection.

The original canine H3N8 outbreak in greyhounds, first recognized in January of 2004, had spread in a few months to tracks in six states, and as of April 2013 had been reported in 40 states (dogflu.com). Similar to influenza in other animals, a dog may be infected and shed contagious CIV for up to four days before clinical signs occur. Currently, infection of dogs is estimated to result in 80% morbidity and 1–5% mortality although higher rates of mortality have been reported. Humans have been reported to also carry the virus from an infected animal to a naive animal although the Centers for Disease Control (CDC) states that human infections with the CIV strains are not a health concern. This may be a matter of adaptation and infection with or without clinical illness.

The virus isolated from the lungs of dogs in Florida during the first cases of CIV was found to be a canine-adapted H3N8 virus originating from an equine H3N8 subtype, recognized as respiratory pathogens of horses since 1963. Unlike previous reports of influenza infections in dogs, which were self-limiting and not transmitted from dog to dog, the greyhound H3N8 virus of 2004 originating from an equine H3N8 virus and the H3N2 originating from an avian influenza virus were easily transmitted from dog to dog and, at least the latter, also from cat to cat. The sequencing of genomes of CIV isolates identified signature mutations that indicate stable changes in the canine-adapted viruses.

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

Cross-species infections frequently occur with influenza A viruses but adaptation to a new species is not common. Dogs are susceptible to infection with human strains, normally without clinical illness or transmission to other dogs. It is not known why the H3 strains seem to have adapted to the dog as a stable host, but it is possible that other strains could, with the appropriate mutations, evolve into true canine pathogens. In 2012, a novel H3N1 human H1N1 and H3N2 reassortant virus was reported to infect dogs subclinically in Korea but was not reported to transmit from dog to dog.

Signalment

Any dog that has not developed immunity specific for the H3N8 virus can be infected regardless of age, sex or breed. Being a highly contagious respiratory virus, the length of time that a dog may remain in a shelter has been associated with increased risk of infection with CIV. With available vaccines and greater likelihood of natural exposure, more animals will develop immunity and morbidity will likely decrease in all ages and breeds, and both sexes.

History and Clinical Signs

Clinical history is indistinguishable from other respiratory diseases of dogs and resembles influenza infections in other animals. Morbidity may be expected to be at least 60%, but it has been reported that as many as 80% of infected animals may develop clinical signs of infection. Between two and four days following infection, dogs may present with clinical illness, such as fever, sneezing, dyspnea, anorexia, depression and coughing, and ocular and nasal discharge that can become mucopurulent. Illness, especially coughing, may continue for 10–30 days post infection. The mortality is generally low. A minority of infected dogs will develop pneumonia with tracheitis and bronchitis. Complications of secondary infections from bacteria or mycoplasma may exacerbate lung involvement, such as hemorrhage in the lungs, mediastinum and pleural cavity, and greater mortality.

Diagnosis

Because clinical illness is similar to that of other respiratory illnesses in dogs, CIV involvement must be diagnosed by detection of viral antigen, viral RNA or the presence of specific antibody. Because of the short duration of virus infection, serology may be a more reliable means of diagnosing infection. Serologic evaluations usually require comparisons of paired sera to document seroconversion to confirm infection. CIV-specific antibodies can be detected as early as seven days after infection. Hemagglutination inhibition assays are used to determine antibodies specific for the H serotypes. However, convalescent sera, in the absence of widespread exposure, can often be used to identify specific infection. Enzyme-linked immunosorbent assay (ELISA) can be used to detect group-specific antibodies for influenza A viruses. The group-specific (not type-specific) ELISA is based on detecting specific antibody that binds to the nucleocapsid protein, which coats the viral genome segments and is highly conserved among all influenza A viruses.

Virus may be detected in samples collected with cotton or Dacron nasal swabs within four days after clinical signs are observed; that is, within seven days after infection. Necropsy-collected tissue from lungs or associated lymph nodes may be used to detect virus. Diagnosis of viral infection is often first determined using real-time reverse transcriptase polymerase chain reaction (PCR) of the gene that encodes the highly conserved matrix protein in influenza virion. A positive PCR result may be followed by viral isolation (after up to three passages) using Madin–Darby canine kidney cells or embryonated chicken eggs in order to determine the H and N subtypes of the isolated virus.

Subtyping the H and N of the viral isolates can also be determined by laboratories that have the tools for sequencing the viral genome. The hemagglutination inhibition assay is often used to determine the serotype of CIV strains in the US. Antibodies that react with virus inhibiting red blood cell agglutination of CIV serotype standards can be used to inhibit agglutination and thus identify the H subtype of the CIV isolate.

Therapy

Supportive therapy may be necessary to provide optimum conditions for the immune system to respond, eliminating infection and reducing the severity of clinical signs. Oxygen, intravenous fluids, and nebulization with coupage may be needed for dogs with pneumonia. Good nutrition and basic biosecurity measures that include disposable or dedicated protective clothing and the use of kennel-approved disinfectants can help to prevent viral spread. Soap and water hand washing which destroys the bilipid envelope membrane of influenza viruses is highly effective in inactivating the virus. Isolation of infected or suspected infected animals may protect dogs not exposed to the virus or vaccine although exposure is difficult to assess since infection occurs prior to the appearance of clinical illness.

Canine influenza virus survives in the environment for more than 24 hours. Because secondary bacterial and mycoplasma infections can cause complications, antimicrobials may be considered if clinical signs are severe or suggest co-infection. Antiviral drugs exist for influenza, but such treatments have not been approved for use in dogs. Information is lacking regarding their efficacy, doses or negative side-effects in dogs.

The Nobivac® Canine Influenza H3N8 and H3N2 inactivated bivalent vaccine from Intervet/Merck is labelled as effective at reducing disease severity. However, the capacity for influenza A viruses to mutate provides the risk of eventual adaptation and evasion of immunity from administered vaccines.

Prognosis

From 60% to 80% of CIV-infected dogs will present with clinical illness, but subclinically infected dogs will also shed contagious virus. Dogs will completely recover clinically within 2–3 weeks, sometimes, however, with a lingering cough. Animals that are generally in good health and well nourished are expected to recover without complications. While most infections will be self-limiting, mortality is considered to be between 1% and 5%.

Public Health Implications

With the reported transmissions of influenza from birds and other mammals to humans, we should consider CIV strains a potential public health concern. Influenza viruses are commonly transmitted across species although usually with subclinical infection and without further transmission within the second species. However, the CIV strains have not been reported to infect humans, even owners with known infected dogs, and the Centers for Disease Control does not consider the canine influenza viruses to be a human threat.

Feline Parvovirus

Margaret C. Barr, DVM, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Feline parvovirus (FPV) is the causative agent of feline panleukopenia, a disease that has also been called feline infectious enteritis, feline plague or feline distemper.

Etiology/Pathophysiology

Feline parvovirus is so closely related to canine parvovirus type 2 (CPV-2), mink enteritis virus, and raccoon parvovirus that all these viruses are now classified as a single species, *feline panleukopenia virus*. The genome of this small single-stranded DNA virus is packaged tightly in an icosohedral, nonenveloped capsid that is very resistant to environmental conditions. The feline transferrin receptor allows FPV access to a broad range of host cells, where it replicates in actively dividing cells including lymphocytes, enteric crypt epithelial cells, and bone marrow myeloid progenitor cells. Similar to the pathology seen with CPV-2 infection in dogs, intestinal villi are severely blunted, absorptive capacity is impaired, and gastrointestinal integrity is compromised in FPV-infected cats. The interruption of myeloid cell proliferation along with lymphocytolysis and redistribution of circulating white blood cells to inflamed tissues results in the characteristic and severe panleukopenia seen with this disease.

Perinatal infection (approximately three weeks before birth to three weeks after birth) of kittens results in infection of the central nervous system and impacts development of the cerebellum. The virus replicates in the dividing neuroblasts of the external granule cell layer, causing cerebellar hypoplasia in kittens that survive the infection. There is also evidence of FPV replication in Purkinje cells of the cerebellum but it is unclear how the virus replicates in these presumably postmitotic cells.

Epidemiology

Domestic and wild felids are susceptible to FPV infection, along with some nonfelid species like mink, raccoons, and foxes. Although canids are resistant to FPV infection, only a few mutations in the VP2 capsid protein gene led to the emergence of CPV-2. Feline parvovirus-associated disease is most often seen in multicat housing situations like animal shelters and breeding catteries, especially if rigorous sanitation, isolation, and vaccination protocols are not followed. Parvoviruses are shed at high titer in the feces of infected animals for several days after infection. Transmission is through the fecal–oral route, either directly or indirectly on fomites such as shoes, clothing, or feeding dishes.

Extensive prevalence data are lacking. The prevalence of anti-FPV antibodies in cats entering a Florida animal shelter, indicating either past exposure or vaccination, was just under 40%. If other cat populations in the US are similar, about 60% of cats are at risk for FPV infection. Anecdotal reports also suggest a recent resurgence of feline panleukopenia outbreaks, possibly associated with antigenic variation in FPV variants and the associated decreased efficacy of commercial vaccines.

Signalment

Susceptible cats of all ages can be infected, but young kittens experience a higher mortality rate (up to 90%) than older animals if not treated. There are no breed or sex predispositions reported for FPV.

History and Clinical Signs

The typical FPV patient will have a history of exposure to other cats in a high-density multicat environment and

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

little or no evidence of vaccination for FPV after 12 weeks of age. About two-thirds of FPV-infected cats will present with vomiting or diarrhea (occasionally bloody), but these signs may be absent or only transiently observed and reported as part of the animal's history. Anorexia, lethargy, and dehydration are also common clinical signs; fever is a less consistent finding. Sudden death with no apparent clinical signs may result from peracute FPV infection, especially in young kittens.

Leukopenia, due to neutropenia and/or lymphopenia, is present in most affected cats, but some cats are able to maintain normal leukocyte counts or may even have leukocytosis in response to secondary bacterial infections. Anemia, hypoalbuminemia, and electrolyte imbalances often occur in these cats. Sepsis can lead to the development of disseminated intravascular coagulation.

Diagnosis

Diagnosis of FPV infection is based on history (potential exposure, poor vaccination history) and clinical signs, including characteristic hematology changes. Confirmation of the diagnosis can be made through detection of fecal parvovirus antigens using point-of-care assays that are marketed for detection of CPV-2. Fecal samples or rectal swab specimens may also be submitted for PCR analysis of viral DNA.

Treatment

The same general principles of supportive care used for managing CPV-2-infected dogs can be applied to FPV patients (see Chapter 82). Rehydration and maintenance of electrolyte and acid–base balances, and blood glucose are of primary importance. Parenteral administration of broad-spectrum antimicrobial agents is also indicated to combat sepsis due to loss of integrity of the gastrointestinal tract lining and neutropenia. Extrapolation from canine research suggests that early reintroduction of enteral nutrition as soon as vomiting is controlled may be beneficial. Cats with severe anemia or hypoproteinemia may require blood or plasma transfusions, and intravenous nutrition should be considered for these cats if enteral feeding is not possible. Ancillary treatments may include immunomodulatory therapies such as passive immunoglobulin transfer using feline serum containing anti-FPV antibodies and active immune stimulation with feline recombinant interferon-omega, although one study showed no difference in survival for cats treated with the latter agent compared to controls.

Prognosis

Without treatment, a cat with severe enteric disease and leukopenia due to FPV infection has a poor prognosis. It is not clear just how effective good nursing care is at improving the prognosis for recovery. One study noted a 51% recovery rate of ill cats with a median hospitalization time of seven days, with a poor prognosis associated with leukopenia (specifically due to neutropenia), thrombocytopenia, hypoalbuminemia, and hypokalemia. Age was not associated with outcome in this group of treated cats. However, a recent retrospective evaluation of outcome predictors and survival time for FPV-infected shelter cats determined that only about 20% of hospitalized cats survived to discharge, with a median survival time of three days. In this population of cats, animals with signs of lethargy, low body weight, rectal temperature lower than 100.2 °F, and leukopenia during hospitalization had the poorest prognosis. Predictors of survival included history of antiparasitic therapy, and treatment with amoxicillin-clavulanic acid and maropitant.

Prevention

As with any virus infection, prevention of exposure to FPV would be the ideal method for preventing infection; however, the sturdy nature of the viral particles and high potential for environmental contamination decrease the feasibility of this approach. Good sanitation practices, strict isolation procedures, and prevention of overcrowding are all important methods for preventing outbreaks of FPV in multicat situations.

Vaccination of cats with commercial modified-live or inactivated FPV vaccines is considered to be a safe and effective method of FPV prevention, but recent studies showing a high degree of interference with vaccination by maternally derived antibodies have led to a change in vaccination protocols. Kittens should be vaccinated beginning at 6–8 weeks of age, continuing every 3–4 weeks until 16–20 weeks of age. Cats older than 16 weeks should be vaccinated twice, four weeks apart. Revaccination is at one year after the primary series and then every three years. If preexisting FPV antibody titers are relatively high, revaccination may have little or no benefit.

Public Health Implications

Feline parvovirus is not infectious to humans and does not pose a public health risk.

Feline Coronavirus

Yvonne Drechsler, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Feline coronavirus (FCoV) is a highly contagious virus that exists as two bioforms. Feline enteric coronavirus (FECV) is ubiquitous in multicat environments. This virus commonly causes an asymptomatic infection, which can persist in certain individuals. Sporadically and unpredictably, the infection turns pathogenic, in which case the virus is referred to as feline infectious peritonitis virus (FIPV), causing the highly fatal, systemic immune-mediated disease feline infectious peritonitis (FIP). The current hypothesis is that FIPV arises from the FECV by mutation, replicates in monocytes and disseminates, resulting in vasculitis and pyogranulomatous inflammation. However, our understanding of the pathophysiology of FIPV is very limited due to difficulties in replicating the virus in laboratory settings.

Epidemiology

Feline coronavirus is distributed worldwide and is ubiquitous in virtually all cat populations. There is great variability in prevalence among different cat populations. Two serotypes exist, I and II, with most epidemiologic studies indicating that serotype I is more common. However, most studies have been conducted in countries outside the United States so further study on serotype prevalence in the United States is needed.

The enteric virus, FECV, is readily transmitted via the fecal–oral route herefore, the prevalence of FCoV infection is generally associated with the number and density of cats housed together. The length of time spent in multicat environments also increases the risk of exposure. For example, the risk of exposure was estimated to be five times higher for cats living in shelters for longer than 60 days than for cats staying for shorter periods of time. Housing and husbandry practices that reduce exposure to feces and contaminated environments have a tremendous influence on the number of cats exposed to the virus. Although transmission of the pathogenic FIP virus occurs is controversial outbreaks in shelters have been reported. Therefore, quarantine of suspected FIP-infected cats is advisable.

Signalment

Although typically a disease of young cats and kittens, the age distribution of affected cats appears to be bimodal. Cats younger than 2 years of age or geriatric cats are most commonly diagnosed with FIP. In addition, certain pure breeds, most notably Persians and Burmese, appear to be more susceptible. Male and female cats are affected equally in some studies while others show a male predisposition. Immune-compromised animals, such as cats infected with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV), are also at increased risk.

History and Clinical Signs

Typically, cats from shelters, catteries, and multicat households are at higher risk of exposure and development of FIP due to the ubiquitous nature of the enteric virus in these settings. Stress due to overcrowding may also contribute to immune compromise and increased susceptibility to infection. Genetic predisposition has also been hypothesized to play a role in increased susceptibility in certain breeds.

Clinical signs associated with the benign enteric virus are typically gastrointestinal, manifesting as mild vomiting and/or persistent or intermittent diarrhea. In cases of FIP, cats may be asymptomatic or present with different levels of lethargy and anorexia. Other common findings include

Companion website: www.wiley.com/go/bruyette/clinical

weight loss, pale mucous membranes, fever of unknown origin, and uveitis. Commonly, a distinction is made between the wet (effusive) and dry (noneffusive) forms of FIP, but they are not mutually exclusive. In the wet form, abdominal distension due to the accumulation of exudative fluid is the most common presentation. A fluid wave on physical examination may be evident, but some cases will have less fluid accumulation, only detectable by abdominal ultrasound. Pleural effusion with secondary dyspnea, tachypnea, and muffled heart sounds may be present, whereas pericardial effusion is uncommon.

Common signs of the dry form are mild and intermittent fever, decreased appetite, weight loss, stunted growth, depression, pale or yellow mucous membranes, and palpable abdominal organ enlargement. Clinical signs may also reflect dysfunction of affected organs. Pyogranulomatous lesions may develop in one or more abdominal organs. If granuloma formation involves the intestine, constipation, diarrhea, or vomiting may be the major clinical signs observed. Enlarged mesenteric lymph nodes and palpable nodular irregularities on the surface of kidneys and liver may also be present on physical examination. Uveitis is the most common ocular abnormality documented in FIP cases, but other ocular lesions such as conjunctivitis, corneal precipitates, iritis, cuffing of the retinal vasculature and retinal detachment may be present. Neurologic signs can also be seen with FIP, the most common being behavioral changes, ataxia, central vestibular signs, hyperesthesia, nystagmus, and seizures. Any part of the CNS can become affected in this disease.

Diagnosis

With the exception of histopathology and immunostaining, no single laboratory test can definitely diagnose FIP. Therefore, the diagnosis of FIP continues to be based primarily on the combination of history of risk factors, signalment, clinical abnormalities, and laboratory findings. The diagnostic process starts with a good history and comprehensive physical examination.

Complete Blood Test and Biochemical Profile

Abnormalities may include anemia, which is usually nonregenerative. Evidence of hemolysis, with or without evidence of immune-mediated destruction, may be present. Lymphopenia, neutrophilia, sometimes with a left shift and toxic change, and thrombocytopenia also occur. Hyperbilirubinemia and elevated aspartate aminotransferase (AST) and alanine aminotransferase (ALT) may also occur. Hyperproteinemia (>8.0 mg/dL) due to hyperglobulinemia is a consistent finding, present in approximately 60% of cats with FIP. The hyperglobulinemia is usually polyclonal, although monoclonal gammopathy may occur. Hypoalbuminemia can be present, possibly due to hepatic insufficiency, vasculitis, protein-losing nephropathy or enteropathy, or due to decreased production associated with the acute phase reaction. A normal or elevated serum albumin:globulin ratio can help rule out FIP as it is often decreased in affected cats.

Acute Phase Proteins

Acute phase proteins are a class of proteins whose plasma concentrations increase or decrease in response to inflammatory disorders. Levels of alpha-1-acid glycoprotein, an acute phase protein, of >1.5 g/L in plasma or effusions are suggestive of FIP in cats with compatible clinical signs.

Effusion Fluid

Effusions from the abdomen or pleural space are typically clear, straw-colored, or viscous due to the high protein content. Rivalta's test can differentiate transudate from exudate (www.abcdcatsvets.org/). A test tube is filled with 7–8 mL of distilled water and one drop of acetic acid (98%) and mixed thoroughly. One drop of the effusion fluid is layered onto the surface of this solution. Diffusion of the drop indicates a negative result, and therefore most likely indicates a FIP-negative animal. If the drop floats slowly down in a drop or jellyfish-like shape or stays at the surface, the Rivalta's test is positive and the fluid may be considered an exudate. Fluid analysis is usually high protein (>3.5 g/dL) with a low nucleated cell count consisting primarily of neutrophils and macrophages, although findings may be variable. An effusion albumin:globulin ratio below 0.4 is suggestive of FIP.

Serology

Although different assays that detect antibodies directed against FCoV are commercially available, it is not possible to distinguish between exposure to FECV and FIPV infection. High antibody titer in serum does not always correlate with occurrence of FIP, and titers may be negative in cats with FIP. It has been suggested that many cats without FIP and who would never develop FIP have been needlessly euthanized due to a positive FCoV titer.

Reverse Transcriptase Polymerase Chain Reaction

Reverse transcriptase polymerase chain reaction (RT-PCR) assays can detect FCoV in a variety of samples

(feces, blood, effusion, cerebrospinal fluid [CSF], tissue, and saliva) with high sensitivity. However, as with antibody tests, distinction of FECV from FIPV is not possible at this time. The finding of virus in blood or tissue also does not confirm FIP because FECV may be amplified from these tissues in cats without FIP. A quantitative PCR test for blood, effusion, and tissue is available. The test is based on the hypothesis that replicating virus in peripheral blood and tissues suggests FIPV rather than FECV. However, because viremia also occurs with FECV infection, healthy cats may also test positive using this assay.

Histopathology and Immunostaining

Relatively distinctive inflammatory infiltrates associated with FIP are characterized by variable degrees of severity and contain a combination of macrophages, lymphocytes, and plasma cells, mixed with lesser numbers of neutrophils. The hallmark of the histopathologic lesions is a granulomatous to pyogranulomatous reaction with vascular orientation and vasculitis. Detection of intracellular FCoV antigen in macrophages in effusions by immunofluorescence, or in tissue by immunohistochemistry, can confirm the diagnosis, and is considered the gold standard if properly performed. Immunostaining may be falsely negative if virus is not present in a given sample or if antibodies do not cross-react with a particular strain.

Therapy

Supportive care and reducing stress are important. Specific treatment has been primarily focused on reducing the inflammatory and hyperimmune response to the virus. Unfortunately, increased survival has not been proven with any of these interventions. Of the immunosuppressants, prednisolone at immunosuppressive doses is currently the most consistently recommended. Although prednisolone may induce remission in some cats, treatment is not curative and may only slow the progression of the disease. Other immunosuppressive drugs such as chlorambucil have been used in combination with prednisolone but the risk:benefit ratio and efficacy are unknown. Feline interferon-omega treatment is an immunomodulatory therapy that may be considered to treat FIPV-infected cats, though studies show differences in efficacy. Similarly, a recent study showed that the immunostimulant polyprenyl extended the life of three cats with mild dry FIP, with two cats still alive after two years of the diagnosis. However, follow-up studies suggested no benefit in cats with more severe forms of the disease and its use is not recommended by some authors.

Recent studies by Pedersen *et al*. have focused on antiviral therapy. Initially, the investigators performed a study using a 3C protease inhibitor (GC376) which showed some success in treating cats with FIP. Although 19 of 20 cats recovered, disease relapse occurred and 18 months after infection only six cats remained disease free. In another study, a small molecule nucleoside analog, GS441524, was used in 10 infected cats who were successfully treated and healthy eight months after treatment, with two cats requiring a second treatment after initial relapse. This nucleoside analog works by acting as an alternative substrate for the viral RNA polymerase terminating replication. These studies are promising developments for future clinical trials and treatments.

Prognosis

With the development of FIP, prognosis is poor to grave, with a reported median survival time of 49 days. Euthanasia should be considered especially when quality of life is poor and there is no response to therapy within a short period of time. However, newer research indicates that antiviral therapy might be successful in cats with complete reversal of clinical signs (see earlier).

Prevention

The formation of antibody enhances disease, so development of an effective vaccine is difficult. At the time of writing, the available vaccine is not recommended by the American Association of Feline Practitioners. Reducing stress and overcrowding, cleaning litterboxes daily, avoiding fecal–oral contact by keeping litterboxes away from food and water dishes, and separating newly acquired cats and cats suspected of being infected are recommended husbandry practices.

Public Health Implications

Feline coronaviruses are not thought to infect humans.

Feline Leukemia Virus

David S. Bruyette, DVM, DACVIM (SAIM)

Anivive Lifesciences, Long Beach, CA, USA

Etiology/Pathophysiology

Like all retroviruses, feline leukemia virus (FeLV) is an enveloped RNA virus. It carries an enzyme (reverse transcriptase) that transcribes the viral RNA genome into DNA (the FeLV provirus), which is then integrated into the host's cell genome. Exogenous FeLV isolates are grouped into four major subcategories: FeLV-A, -B, -C, and -T. The dominant FeLV-A subgroup is horizontally transmitted and is found in all FeLV-infected cats; it is the most infectious but low in pathogenicity. FeLV-B and particularly FeLV-C are less prevalent. They arise within the individual cat after FeLV-A infection: FeLV-B develops via recombination of FeLV-A with endogenous FeLV-related sequences and FeLV-C and FeLV-T evolve from FeLV-A via mutations or insertions in the surface glycoprotein gene.

Feline leukemia virus is shed in large quantities via saliva, but it can also be found in feces, urine, and milk. FeLV is unstable in the environment and transmission is thought to require intimate friendly (or aggressive) contact between infected and uninfected cats. Contact with infectious saliva or, less probable, infectious feces may also be sufficient to transmit the infection (sharing of food bowls or litterboxes). In addition, FeLV can be transmitted vertically from the queen to her kittens.

Feline leukemia virus infection usually starts at the mucosa of the oropharynx. Subsequently, viral replication takes place in the adjacent tonsils and local lymph nodes. The virus is spread in the lymphoid tissues throughout the body via lymphocytes and monocytes. Replication in the bone marrow and infection of neutrophil and platelet precursors favor the initiation of secondary viremia and systemic infection. Cats that undergo bone marrow infection usually develop progressive infection. In cats that do not undergo bone marrow infection, only lymphocytes are provirus positive and usually no viral RNA is detectable in peripheral blood cells. In addition, some cats seem to abort infection prior to provirus integration and an antibody response may be the only sign of previous FeLV exposure.

After FeLV exposure, some, mostly young, cats develop progressive FeLV infection, characterized by persistent antigenemia/viremia. Cats with progressive infection shed high copy numbers of FeLV and pose an infection risk to other cats. Progressive infection is usually confirmed by repeated testing for antigenemia of the cat several weeks or a few months apart; only repeated positive antigen testing verifies the presence of a progressive infection, which is linked to a poorer prognosis than regressive FeLV infection. Cats with progressive FeLV infection are at high risk to die within a few months to years with FeLV-associated diseases (see Prognosis).

If a cat tests positive for FeLV p27 antigen, but upon later retesting becomes FeLV antigen negative, it has developed a regressive FeLV infection. Cats with regressive infection have mounted an effective immune response and recovered from FeLV viremia. Fortunately, most adult cats are found to develop regressive infections. Cats with regressive infection usually do not develop FeLV-associated disease. Clearance of antigenemia is observed mostly within a few (2–8) weeks, but in rare cases it can also occur after many months although the chance for recovery decreases with increasing time. Following recovery from antigenemia (regressive infection), latent infection can be identified for a few months to years by culturing bone marrow cells in the presence of corticosteroids. Provirus polymerase chain reaction (PCR) from peripheral blood or bone marrow is positive in these cats and viral plasma RNA detected by reverse transcriptase (RT)-PCR may be positive. Infection may be reactivated in latently FeLV-infected cats. The potential for reactivation seems to be associated with the FeLV isolate and generally decreases with increasing timespan.

Companion website: www.wiley.com/go/bruyette/clinical

Epidemiology

The prevalence of FeLV infection documented in cross-sectional surveys in North America has been declining throughout the past three decades and is attributed to testing and vaccination efforts. In the United States, 3.1% of cats in a large, nationwide dataset tested positive for FeLV in 2010, with increased risk among outdoor cats, unneutered males, and cats with other disease conditions (particularly respiratory disease, oral disease, and abscessation). Prevalence was highest in the midwestern and western regions of the United States and lowest in the northeast. Seroprevalence surveys of varying statistical power have found rates of positive test results to range from 3.6% in Germany and Canada to 4.6% in Egypt and 24.5% in Thailand.

In a national (United States) study, FeLV infection was diagnosed in 9% of cats undergoing treatment for bite wounds, approximately three times the rate for cats in general. FeLV is considered to be an age-dependent disease; young kittens are at higher risk of progressive infection and more rapid disease progression, whereas adults display some degree of age resistance. However, transmission can occur at any age, and factors affecting clinical course of disease are complex and incompletely understood.

Signalment

The susceptibility of domestic cats for FeLV infection varies and is mainly age dependent. Kittens are more prone to develop progressive FeLV infection than adult cats.

History and Clinical Signs

Feline leukemia virus-related disorders are numerous and include anemia, neoplasia, immunosuppression, immune-mediated diseases, reproductive problems, enteritis, neurologic dysfunction, and stomatitis. Some FeLV-B-infected cats develop lymphoid malignancies, while FeLV-C infection is associated with the development of aplastic anemia. FeLV-T is a T cell tropic cytopathic virus that causes lymphoid depletion and immunodeficiency in infected cats.

The anemia caused by FeLV is typically nonregenerative and normochromic. Less commonly, macrocytosis or regenerative hemolytic anemia is seen in 10% of FeLV-induced anemia cases. The cause of nonregenerative anemia is usually bone marrow suppression due to viral infection of the hematopoietic stem cells and the supporting stromal cells. Platelet dysfunction, thrombocytopenia, and neutropenia are all possible sequelae.

Lymphoma is the most frequently diagnosed malignancy of cats. Tumors such as lymphoma and lymphoid leukemia develop in as many as 30% of cats with progressive FeLV infections. Regressive infections are also implicated in the occurrence of these tumors in the absence of viremia, but cats with progressive infections may face an increased risk of lymphoma development as high as 60-fold. Most American cats with mediastinal, multicentric, or spinal forms of lymphoma are FeLV positive. However, these forms of lymphoma are becoming less common as the prevalence of FeLV decreases. Diffuse gastrointestinal (GI) lymphoma (small cell; T cell origin) is now more likely to be found in FeLV-negative cats of middle or older age and can be difficult to differentiate from inflammatory bowel disease. Fibrosarcomas and quasi-neoplastic disorders such as multiple cartilaginous exostoses (osteochondromatosis) can be associated with FeLV.

Leukemia is characterized by the neoplastic proliferation of hematopoietic cells originating in the bone marrow, including neutrophils, basophils, eosinophils, monocytes, lymphocytes, megakaryocytes, and erythrocytes. Feline leukemias are strongly associated with FeLV infection and typically involve neoplastic cells circulating in the blood. Lymphoid leukemias are further classified as acute and chronic. Acute lymphocytic leukemia is characterized by lymphoblasts circulating in the blood, whereas chronic lymphocytic leukemias have an increased number of circulating lymphocytes with mature morphology.

The immunosuppression caused by FeLV creates increased susceptibility to bacterial, fungal, protozoal, and viral infections. Numbers of neutrophils and lymphocytes in the peripheral blood of affected cats may be reduced, and those cells that are present may be dysfunctional. Many FeLV-positive cats have low concentrations of complement which may contribute to FeLV-associated immunodeficiency and oncogenicity, as complement is vital for antibody-mediated tumor cell lysis.

Immune complexes formed in the presence of moderate antigen excess can cause systemic vasculitis, glomerulonephritis, polyarthritis, and a variety of other immune disorders. In FeLV-infected cats, immune complexes form under conditions in which FeLV antigens are abundant and anti-FeLV IgG antibodies are sparse, a situation ideal for the development of immune-mediated disease.

Reproductive problems are commonly associated with FeLV infection. Fetal death, resorption, and placental involution may occur in the middle trimester of pregnancy, presumably as a result of *in utero* infection of fetuses by virus transported across the placenta in maternal leukocytes. Abortion typically occurs in late gestation.

Transmission during birth and nursing constitutes the greatest risk of producing live, viremic kittens. There is some evidence that regressively infected queens may pass virus on to their kittens either *in utero* or in milk. Neonatal kittens are at risk of rapidly progressive infection with clinical manifestations of hypothermia, dehydration, failure to nurse, and early mortality, collectively termed "fading kitten syndrome." It is likely that transmission from infected queens to their kittens is the single greatest source of FeLV infections.

Although neurologic disorders associated with FeLV are most often caused by compression of the brain and spinal cord by lymphoma tumor tissue, a mechanism for neuropathology is also suspected to result in peripheral neuropathies, urinary incontinence, and ocular pathology, including anisocoria, mydriasis, Horner syndrome, and central blindness even in the absence of visible compressive lesions on diagnostic imaging. If antineoplastic therapy is planned, it is important to distinguish neoplasia from neuropathy.

Stomatitis is more classically associated with feline immunodeficiency virus (FIV) infection, but FeLV infection can also predispose cats to chronic ulcerative proliferative gingivostomatitis. Clinical sequelae include pain, anorexia, and tooth loss. An immune-mediated mechanism is likely, particularly in combination with co-infections such as feline calicivirus.

Diagnosis

The outcome of a FeLV infection can be characterized using the results from virus isolation, immunofluorescence assays, detection of FeLV p27 capsid antigen in serum or plasma, and detection of FeLV provirus or viral RNA in the blood or some tissues by molecular assays. Serologic assays for the detection of FeLV-specific antibodies are currently not routinely used. Antigenemia (presence of p27 capsid antigen) is a marker of infection and in most, but not all cats, a parameter for viremia (presence of replication-competent virus). Detection of viremia by virus isolation is not widely available, laborious, and time consuming. In contrast, antigenemia can be easily detected using enzyme-linked immunosorbent assay (ELISA) in a specialized laboratory or by rapid point-of-care tests. Most cats will test antigen positive within 3–6 weeks after FeLV exposure. The detection of FeLV provirus in the peripheral blood or certain tissues like bone marrow using RT-PCR is more sensitive than the detection of antigenemia or viremia to demonstrate previous FeLV exposure. Thus, a certain proportion of pet cats can be found to be PCR positive but antigen negative. In an early study in Switzerland, 10% of pet cats were found to be FeLV provirus positive and FeLV antigen negative. Provirus PCR testing is positive sooner (1–2 weeks) after FeLV exposure than antigen detection in blood.

Some specialized laboratories offer RT-PCR for the detection of viral RNA. The detection of viral RNA in the saliva correlates well with the detection of antigen in the blood of infected cats. However, FeLV viral RNA in saliva and blood of experimentally infected cats was found as early as one week after FeLV exposure, at least two weeks before antigen detection in the blood.

Testing Cats for FeLV Infection

- Test sick cats for the presence of FeLV antigenemia/viremia (using antigen tests, virus isolation, RT-PCR from saliva).
  - Any cat that tests FeLV positive: retest the cat after 1–2 months to determine whether progressive or regressive infection prevails. Quarantine the cat during this period since the cat is a FeLV infection source for other cats. This procedure may be repeated if circumstances permit and/or the testing interval may be discussed with the cat owner.
- Test healthy cats for the presence of FeLV antigenemia/viremia (using antigen tests, virus isolation, RT-PCR from saliva).
  - Prior to the first FeLV vaccination, testing is recommended for every cat; prior to the second vaccination (booster of basic immunization), testing is recommended if the cat may have been exposed to FeLV in the last 4–8 weeks.
  - If the cat is at high risk for FeLV (outdoor access, multicat environment, any husbandry with changing cats, etc.).
  - If the cat has moved to a new environment (new home, shelter, cattery, etc.): if the cat tests negative, quarantine (keep from other cats and any potential FeLV exposure) and retest after 4–6 weeks for absence of FeLV antigen prior to introduction into the new environment.
  - Any cat that tests FeLV positive: retest the cat after 1–2 months to determine whether progressive or regressive infection prevails. Quarantine the cat during this period since the cat is a FeLV infection source for other cats. This procedure may be repeated if circumstances permit and/or the testing interval may be discussed with the cat owner.
- Test healthy cats for the presence of FeLV provirus in the blood (PCR). Confirmatory of positive or questionable antigen tests; true antigen-positive samples are highly provirus positive.
  - Early infection: provirus PCR from blood tests earlier positive than antigen tests.

  - If prior exposure to FeLV needs to be known: analysis of the FeLV situation in a cat colony with FeLV problems.
  - If the cat is used as blood or organ donor: FeLV can be transmitted by transfusion of FeLV provirus-positive blood. Antigen testing is not sufficient.
- Test sick cats for the presence of FeLV provirus in the blood (PCR). Confirmatory of positive or questionable antigen tests; true antigen-positive samples are highly provirus positive.
  - Early infection: provirus PCR from blood tests earlier positive than antigen tests.
  - If prior exposure to FeLV needs to be known: analysis of obscure clinical cases, analysis of the FeLV situation in a cat colony with FeLV problems, etc.
- Test any cat for the presence of FeLV viral RNA in the blood (RT-PCR). Early infection: RT-PCR tests earlier positive than provirus PCR and antigen tests. Not frequently used.

Kittens can be tested any time for antigenemia – maternal antibodies do not interfere with the p27 testing. A confirmed positive result is conclusive, while a negative result is not always; in some cases the kittens became positive only after weeks to months. Each kitten should be tested individually.

Treatment

Unfortunately, no curative treatment currently exists to cure retroviral infection. *In vitro* studies have yielded promising results suggesting virus-suppressing activity of human FDA-approved drugs used to treat HIV and other myelodysplastic syndromes against FeLV virus (e.g., raltegravir, tenofovir, gemcitabine, decitabine). Further research is needed to demonstrate efficacy and safety *in vivo* and in field trials, as well as to address affordability of these drugs for most cat owners. Feline interferon-omega and human interferon-alpha have been associated with improved survival, but concerns surrounding availability, cost, and absence of strong evidence in controlled field studies have limited their widespread integration into standard treatment protocols for FeLV.

Anecdotal reports of various antiviral and immunotherapeutic agents to reverse viremia, improve clinical signs, and prolong survival are abundant. Controlled studies using naturally infected cats have either not been performed or have not confirmed anecdotal observations. Treatment efficacy must be demonstrated in controlled clinical trials, because spontaneous reversion to seronegative status or prolonged survival is not uncommon, even in the absence of medical treatment. Some FeLV-positive cats can live without major disease complications for years with routine prophylactic care, good husbandry, minimal stress, and avoidance of secondary infections. Infected cats should be kept strictly indoors to reduce the risk of exposure to infectious agents and prevent transmission of the virus to other cats. Physical examinations focusing on external parasites, skin infections, dental disease, lymph node size, and body weight should be performed semiannually, along with a routine program for parasite control and annual fecal, complete blood count, chemistry panel, and urinalysis testing. All infected cats should be neutered. Owners should be advised to watch for signs of FeLV-related disease, particularly secondary infections.

Although FeLV-positive cats often respond well to treatment for secondary infections, therapy for such infections or other illnesses should be early and aggressive because of immunocompromise. Because FeLV is historically associated with rapid and grave disease, the modern prognosis varies considerably depending on husbandry, veterinary care, and individual immune system variation.

Prognosis

Large-scale studies have demonstrated an average survival of 2.4 years after diagnosis among positive cats (versus six years after testing for negative control cats), with 50% mortality in two years and 80% mortality by three years after diagnosis. Progression of disease is much more rapid in kittens, whereas some adult cats remain healthy for many years and may succumb to conditions unrelated to their retroviral status.

Prevention and Control

Feline leukemia virus is unstable in the environment and is susceptible to all common detergents and disinfectants. In a hospital or boarding setting, infected cats may be kept in the general population as long as they are housed in separate cages. Medical and surgical equipment contaminated with body fluids, even when dried, can be fomites for infection. Thorough cleaning and sterilization of equipment, strict attention to washing contaminated hands, and avoiding reuse and sharing of single-use and consumable supplies between patients are critical practices to prevent iatrogenic transmission.

Feline leukemia virus vaccines are noncore and are intended to protect cats against FeLV infection or reduce the likelihood of persistent viremia. Types of vaccines include killed whole virus, subunit, and genetically

engineered. Vaccines are indicated only for uninfected cats, because there is no benefit in vaccinating an FeLV-positive cat. Vaccination is the most effective way to prevent FeLV-associated disease. Currently, FeLV vaccines are very safe and have up to 98% efficacy. The American Association of Feline Practitioners (AAFP) Feline Retrovirus Management Guidelines include the recommendation that all kittens should receive the two-dose FeLV vaccination as a component of the routine initial vaccination series and should also receive a booster vaccination one year later. This is prudent, because rehoming and lifestyle changes such as outdoor access frequently occur as cats mature. Annual revaccination after maturity would depend on the cat's risk of FeLV exposure. The adult cat's risk of exposure to FeLV-positive cats should be assessed, and vaccines used only for those cats at risk. FeLV vaccines have been associated with development of sarcomas at the vaccination site, although the risk of tumor development is very low. Uninfected cats in a household with infected cats should be vaccinated; however, vaccination is not universally protective, and other means of reducing transmission to uninfected cats, such as physical separation, should also be used.

While testing of cats in an animal shelter environment is considered optional for individual housing, FeLV status should be determined before placement in group housing and is recommended at the time of adoption or foster home placement. Because tests are not 100% accurate, shelter cats placed in group housing should be vaccinated against FeLV, especially in long-term conditions such as sanctuaries. Because of the equivalent prevalence of FeLV among feral and free-roaming pet cats and the role of neutering in decreasing the spread of infection, expending resources on FeLV testing is not considered a mandatory component of community trap-neuter-return programs.

Public Health Implications

Some strains of FeLV can be experimentally grown in human tissue cultures, leading to concerns of potential for transmission to people. Studies addressing this concern have shown no evidence that any zoonotic risk exists, and there are no known cases of zoonotic transmission.

Feline Immunodeficiency Virus

Tom Phillips, DVM, MS, PhD, †

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA, Deceased

Etiology/Pathophysiology

Feline immunodeficiency virus (FIV) is a member of the *Lentivirus* genus in the *Retroviridae* virus family. As such, it is an enveloped virus, has an icosahedral capsid, and a genome composed of two (nearly identical) linear, positive sense, single-stranded RNA molecules.

Much has been learned about FIV since it was first described in 1987, particularly in regard to its application as a model to study the closely related lentivirus human immunodeficiency virus (HIV). In particular, FIV and HIV share remarkable structure and sequence organization, utilize parallel modes of receptor-mediated entry, and result in a similar spectrum of immunodeficiency-related diseases due to analogous modes of immune dysfunction.

The disease course for FIV is variable, likely dependent upon the route of infection, strain of virus, age of the animal at time of infection, and the robustness of the immune response generated to the virus. Transmission is primarily through the bite of an infected cat, though sexual transmission has been shown to occur in experimentally infected cats. Infection by blood transfusion may also potentially occur. Initially, FIV is transported by tissue macrophages to lymphoid tissues, where it replicates in lymph nodes, thymus, spleen, bone marrow, brain, lung, gastrointestinal tract, and kidney. FIV gains entrance into the cell primarily through receptor mediation. The main cellular receptors for FIV are the chemokine receptor, CXCR4, and CD134, a receptor expressed by T lymphocytes and activated macrophages. Other mechanisms of virus entry may also be important, such as the use of other receptors and antibody-mediated entry through FC receptors.

Experimentally, virus is detected in the blood of animals usually by two weeks post infection, and remains easily detectable for up to six weeks post infection. Generally, FIV induces a strong but only partially effective immune response. However, there are reports of detectable levels of FIV DNA in cats without a detectable antibody response. Generally, antibodies to FIV are detected by two weeks post infection, and most cats develop antibody by 60 days post infection, although it may be delayed further in some cats. Over the next few weeks after antibody development, the virus levels in the blood are gradually reduced to undetectable quantities and become clinically latent. However, the virus is not truly latent, as it continues to replicate at low levels. During this clinical latent phase, the virus infection gradually is eroding normal immune function of the infected cat. FIV causes the T helper cell numbers to decrease with an inversion of the CD4:CD8 ratio. The effect of FIV on feline lymphocyte numbers is likely due to several mechanisms operating simultaneously: virus-induced lysis of infected cells, virus suppression of the ability of bone marrow and other lymphoid tissues to produce new lymphocytes, immune-mediated lysis of infected cells, and apoptosis. The ability of lymphocytes from FIV-infected cats to proliferate in response to both B and T cell mitogens is impaired, as is the expression of lymphocyte cell surface receptors that are important in control and proliferation of the immune response, such as cytokine receptors and MHC class II antigens.

The pathophysiology of FIV neurologic dysfunction is not completely understood as it occurs in the apparent absence of virus replication in neurons, with minimal inflammatory lesions in infected cat brains, and only low levels of replication in astrocyte and microglia cells. Infected astrocytes have impaired glutamate uptake function, which may lead to an increased susceptibility of glutamate toxicity, oxidative stress, and ultimately neuron loss. Additionally, FIV envelope protein is toxic

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

to rat neurons in culture and may play a role in neurologic disease pathogenesis. The neurologic disease is more prevalent with certain isolates of the virus, which may point to certain envelope protein sequences being more toxic and/or relate to the ability of virus to replicate in the feline nervous system.

Epidemiology

Feline immunodeficiency virus infection is common around the world. The incidence of FIV varies (from 4% to 47%) geographically, correlating with the percentage of free-roaming and feral cats in the population.

Signalment

Although it is possible for any cat to be infected with FIV, free-roaming, nonpure-bred, sexually intact, mature, male cats are more likely to contract an FIV infection. This is largely due to cat bites being the primary mode of virus transmission.

History and Clinical Signs

Acute clinical signs of the infection are generally mild and often consist of the nonspecific signs of lethargy, anorexia, pyrexia, diarrhea, and lymphadenopathy. Generally, these clinical signs coincide with the viremia. Once the viremia subsides, the virus appears to go into a clinical latent phase, with virus not detected in the blood and the apparent absence of most clinical signs. This clinical latent phase is of variable length but often lasts for years, as the virus slowly suppresses the immune system. The last phase of the infection is feline acquired immune deficiency syndrome (FAIDS). Clinical signs of FAIDS are the result of opportunistic infections, various neoplasias, and/or neurologic disease. Thus, clinical signs are variable depending upon how the immune suppression is manifested. Stomatitis is very common and can occur during any phase of the infection. Persistent diarrhea is also fairly common, as is respiratory disease. Neoplasia is common in FAIDS, with B cell lymphoma being the most frequent. Neurologic signs such as behavioral changes, disrupted sleep, impaired learning, paresis, and seizures have been reported. A wasting condition has also been described late in the FAIDS phase of the disease. Increased circulating immune complexes can result in immune complex disease manifested as uveitis and glomerulonephritis.

Diagnosis

Complete blood count (CBC) abnormalities may include anemia, lymphopenia, and neutropenia. Thrombocytopenia may sometimes occur. Hyperglobulinemia is the most common biochemical abnormality. Proteinuria may be seen in cats with glomerulonephritis.

Antibodies to FIV infection persist for life and thus patient-side ELISA antibody testing is recommended as a screen for FIV infection. However, false-positive and -negative results may occur. If a kitten under 6 months of age is antibody positive, it should be retested after 60 days, as maternal antibody could be the cause of the positive assay. If an animal is negative after a recent possible exposure, it should be retested after 60 days, allowing sufficient time for an active immune response to develop. Tests used to detect antibody cannot distinguish between infection and vaccination. Positive tests in healthy cats should be confirmed using ELISA from another manufacturer, western blotting, or PCR. In cases where the vaccination history is not known, real-time quantitative PCR should be considered, as this assay can detect a low-grade viremia, indicative of an active infection. However, sensitivity and specificity of PCR are variable. PCR may be negative due to low levels of viremia or mutations, and false-positive results have been reported in vaccinated cats.

Management

The best therapy for FIV is prevention. Keeping cats indoors and only allowing exposure to known FIV-negative cats is the best way to prevent the infection. The vaccine for FIV is controversial, as efficacy is variable. Additionally, using standard FIV screening assays, a vaccinated cat currently cannot be distinguished from an infected cat. Since shelters may not perform a confirmatory assay on an animal that is found FIV positive by a screening assay, it is advised to microchip the cat at the time of vaccination with a chip whose data are linked to vaccination status to assist shelter personnel in the interpretation of a positive result.

The use of the routine feline vaccines in FIV-positive cats is controversial due to the suppressed immune system of the FIV-infected cat. Since it is best to keep infected cats indoors to reduce the risk of FIV exposure to other cats, the exposure of the infected cat to other common pathogens is also reduced, thereby decreasing the need for vaccination. Additionally, the duration of immunity to most of the vaccinatable feline pathogens likely lasts for years. If the cat has been vaccinated earlier in life, protective immunity likely still remains. If, however, vaccines are to be used,

killed vaccines are preferred. Even if they are kept indoors, housing cats in overcrowded conditions has been significantly associated with disease progression in FIV-positive cats. Therefore, reducing stress and limiting exposure to potential infectious agents are important husbandry practices that can decrease morbidity and mortality.

For cases of prolonged severe stomatitis, removal of all the teeth is the treatment of choice. Zidovudine (AZT) at a dose of 5–10 mg/kg PO or SC q12h has also been shown to be effective in some cases of stomatitis. AZT is also used, to some effect, in cases with neurologic signs of disease. AZT can cause bone marrow suppression. CBCs should be monitored closely. AZT should not be used in cats with myelosuppression. Alfaferone (natural human alpha-interferon) has been reported to increase the survival of FIV-infected cats. Recombinant feline IFN-omega may improve clinical signs and reduce inflammatory cytokine production but does not appear to affect viral load. A recent publication demonstrated that an analog of tenofovir, a widely prescribed anti-HIV drug in human medicine, may also be effective as a therapy for FIV, though further investigation is needed. Griseofulvin treatment of fungal disease should be avoided as bone marrow suppression has been reported in FIV-infected cats.

Prognosis

Though the virus can never be cleared from an infected cat, most infected cats have long life spans. While many die from conditions that are unrelated to the infection, many ultimately succumb to an FIV-related disease.

Public Health Implications

Feline immunodeficiency virus infection of humans has never been documented, even in veterinarians or individuals who have been bitten multiple times by FIV-infected cats. However, FIV has been shown to replicate in human cells *in vitro* and cause disease in monkeys experimentally infected with FIV-infected autologous cells. Thus, caution is still advised.

Feline Viral Upper Respiratory Tract Disease

Yvonne Drechsler, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Feline viral infectious upper respiratory tract disease is primarily caused by two viruses: feline herpesvirus (FHV-1) and feline calicivirus (FCV). Infection is common in multicat environments, and most cats have been exposed. FHV-1 is an enveloped single-stranded DNA virus belonging to the alpha-herpesvirus family. As such, the virus exists in a latent form in the trigeminal ganglia after initial infection and can be reactivated by stressors. This leads to shedding via secretions from oral, nasal, and conjunctival membranes. Viral replication is usually restricted to the upper respiratory tract, due to viral preference for lower temperatures. However, in young kittens and possibly immunosuppressed cats, more severe systemic disease can occur.

Feline calicivirus belongs to the Caliciviridae family, and consists of a single-stranded positive RNA genome. This genome structure has a high mutation rate and therefore the isolates are highly variable. Strains can vary in their pathogenicity. Like FHV-1, transmission occurs via secretions from oral, nasal, and conjunctival membranes. FCV persists in tonsillar and other oropharyngeal tissues, leading to a carrier state, but the mechanism of persistence is not well understood. In addition to causing upper respiratory disease, FCV can be associated with lameness due to acute synovitis, possibly due to antigen-activated macrophages residing in the synovial membrane. Rarely, FCV can cause virulent systemic disease (VSD). Lesions associated with VSD are severe and include oral and dermal ulcerations, bronchointerstitial pneumonia, necrosis of the liver, spleen and pancreas, and death. The pathogenesis of VSD is not fully understood.

Epidemiology

Infection with both FHV-1 and FCV is widespread in the general cat population. The prevalence of infection and clinical disease is higher in multicat households, colonies, catteries or shelters. Viral reactivation may occur in latently infected cats when they are stressed or if their immune system is compromised. FHV-1 is short-lived in the environment, and transmission occurs mainly by direct contact with an infected cat. However, transmission through fomites in crowded environments is also important.

Cats infected with FCV may be carriers who shed virus while appearing clinically healthy. Virus may be shed in the urine and feces in addition to respiratory secretions. FCV survives in the environment much longer than FHV-1 and is resistant to quaternary ammonium compounds. Therefore, in addition to direct and aerosol contact with respiratory secretions, fomites are a very important means of transmission for FCV.

Signalment

Cats of any sex and age can develop respiratory disease caused by FHV-1 or FCV, with kittens being more susceptible.

History and Clinical Signs

Cats from multicat households, colonies, catteries or shelters are commonly infected. A history of stress or immune suppression may be noted. FHV-1 may cause severe respiratory disease, especially in

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

immune-compromised animals. Nonspecific signs of FHV-1 infection may include depression, anorexia, and pyrexia. Respiratory signs include sneezing and conjunctivitis associated with serous ocular and nasal discharge. Nasal turbinate destruction can lead to recurrent rhinitis and sinusitis. Coughing and dyspnea can develop in more severe cases. Ocular and nasal discharge that becomes mucoid or purulent may signal secondary bacterial infection. In addition to conjunctivitis, keratitis and corneal ulcerations also occur with FHV-1 infection. Dendritic corneal ulcerations are considered pathognomonic for infection with FHV-1. FHV-1 might also play a role in other forms of ocular disease. Skin ulceration and herpetic dermatitis may also be caused by FHV-1.

Feline calicivirus causes a range of clinical signs due to strain variability. Similar to FHV-1, upper respiratory signs predominate. Sneezing and ocular discharge associated with conjunctivitis are common. In contrast to FHV-1 infection, corneal ulceration does not typically occur with FCV infection. However, oral ulceration is common, making FCV a top differential diagnosis for oral ulcerations in cats. Stomatitis may be severe, and lead to excessive ptyalism. Other signs of FCV infection include depression, pyrexia, anorexia, enlarged lymph nodes, and acute lameness. Infection with highly virulent strains of FCV causing VSD results in severe signs such as high fever, cutaneous edema, jaundice, other signs of multiorgan failure, and death.

Diagnosis

History, clinical signs, and evidence of possible immunosuppression (due to retroviral infection, stress or drug administration, for example) should increase the index of suspicion for infection with one or both viruses. For cats with signs of upper respiratory disease, diagnosis is usually made based on clinical signs alone. Specific laboratory tests documenting infection or exposure may be used to help confirm infection, particularly in patients with more severe or atypical clinical signs, although each has limitations. Complete blood count (CBC) and serum chemistry findings are not specific in cats with upper respiratory disease caused by FHV-1 or FCV, although cats with stomatitis caused by FCV may be hyperglobulinemic. Cats with VSD may have anemia, thrombocytopenia, neutrophilia, and lymphopenia. Hypoalbuminemia, elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST), elevated bilirubin, and increased creatine kinase (CK) also occur.

Direct testing for the presence of virus may include culture, polymerase chain reaction (PCR), histopathologic examination, and immunofluorescence staining. False-negative results may occur with any of these assays as virus may not be present in specimens. Laboratories should be contacted for appropriate sample acquisition and transport techniques for culture. The sensitivity and specificity of PCR may vary depending on the laboratory and design of the test. It should also be kept in mind that PCR may not detect all strains, particularly for calicivirus, due to variability in nucleic acid target sequences. Positive PCR results may occur in healthy cats, so a positive result does not necessarily mean that clinical signs may be attributed to infection. In addition, vaccination with attenuated virus may cause false-positive PCR results. Serologic testing is also available, but it is not easily interpreted as vaccination and previous exposure are common for both viruses and the presence of antibody may not indicate active infection.

Therapy

In cases of acute respiratory disease, supportive care including fluid therapy and/or nutritional support may be indicated. Clinical signs resolve within 2–3 weeks. Judicious administration of appropriate antibiotics is indicated if evidence of secondary bacterial infection or co-infection with *Chlamydia*, *Mycoplasma* or *Bordetella* is present. For more severe or recurrent disease, or if keratoconjunctivitis or stomatitis is present, more aggressive specific therapy may be indicated, including antiviral or immunomodulating agents, and for stomatitis, dental extractions, antimicrobial treatment, and antiseptic mouthwashes.

Most antiviral therapies developed for human herpesviruses are too toxic for oral administration in cats, although the use of famciclovir appears promising. Topical use of idoxuridine, vidarabine, and other select nucleoside analogs appears beneficial for treatment for ocular disease. The therapeutic potential of feline interferon-omega on FHV-1 replication is under investigation. The use of oral L-lysine to decrease clinical signs or infection with FHV-1 infection has shown conflicting results.

Prognosis

In general, cats will recover but both viruses persist, with reactivation of FHV-1 occurring due to stressors. FCV carriers can shed virus continuously, increasing the likelihood of infecting other cats. FCV infection with strains associated with VSD has been associated with greater than 50% mortality.

Prevention

Vaccination information and guidelines are available for free online from the American Association of Feline Practitioners (https://catvets.com/guidelines/practice-guidelines/feline-vaccination). Vaccination, stress reduction, avoiding overcrowding and implementing strict disease prevention techniques in shelters and kennels are important to prevent infection and associated clinical signs (see Chapter 117).

Public Health Significance

These viruses are not known to infect people.

Rabies in Dogs and Cats

Emily Beeler, DVM, MPH and Karen Ehnert, DVM, MPVM, DACVPM

Veterinary Public Health Program, Los Angeles County Department of Public Health, Los Angeles, CA, USA

Etiology and Pathophysiology

The rabies virus is an enveloped, single-stranded RNA virus in the family Rhabdoviridae and the genus *Lyssavirus*. There are 16 known lyssaviruses worldwide capable of causing rabies-like symptoms in mammals. Bats are the reservoir for most of them. Rabies virus itself is by far the most prevalent lyssavirus, and the only one known to exist in the Americas. Rabies has the highest mortality rate of all known infectious diseases.

Rabies is usually transmitted by the bite of a rabid animal. It may also be transmitted when virus-laden saliva is introduced into mucous membranes. Theoretically, scratches may transmit the virus, if the claws are contaminated with fresh infectious saliva, but this mode of spread is very rare in people. Because the virus may be present in tissues throughout a rabid animal, exposure may occur during necropsy. Rabies has occasionally been spread by corneal and internal organ transplantation, transplacentally, through aerosolization in closed spaces such as caves, and by ingestion of infected tissues. Because it is readily destroyed by UV light, desiccation, and most disinfectants, the rabies virus is not effectively transmitted by fomites.

When the rabies virus first enters the body, it multiplies at a very low rate in a small amount of muscle cells and fibrocytes, and curtails the local immune reaction by inhibiting type I interferons. The majority of the incubation period, which can last for 3–12 weeks or more in dogs and cats, likely passes with the virus localized at the site of entry. The virus then enters the nervous system through a peripheral motor nerve, and is drawn up the axon at a rate of about 100 mm per day. Once the virus reaches the neuronal cell body, it multiplies and disseminates rapidly, although unevenly, throughout the central nervous system (CNS). Histologic analysis of brains from rabies victims typically reveals little tissue damage. When increased inflammation and damage do occur in the CNS, they are usually found in patients in which paralytic clinical signs predominated. The total amount of virus in the brain tends to be significantly higher in cases of encephalitic, "furious" rabies than in cases of paralytic, "dumb" rabies.

Some details of what happens at the molecular level of rabies pathogenesis remain a mystery. The rabies virus has an uncanny ability to evade early recognition and clearance by the immune system, and to preserve the health of cells of the nervous system throughout most of the infection. In laboratory studies, rabies virus strains that stimulate a significant immune response are less pathogenic than those that suppress it.

Epidemiology

Over 60 000 people die worldwide from rabies each year. The vast majority of rabies victims are children who were infected by bites from rabid dogs. Most cases occur in countries where rabies vaccination rates for dogs are below 50%, primarily in Asia and Africa.

The human death toll from rabies is much lower in countries where animal control policies are well established and vaccination of pets is widespread. Over the past two decades in the United States, an average of three people per year died from rabies. Typically, the cases occurred after a person failed to obtain timely rabies postexposure prophylaxis, often due to lack of awareness about the risk of rabies. About 70% of the cases were caused by bat bites, and most others were caused by a dog bite inflicted while the person was visiting another country.

The primary reservoirs for rabies are bats, domestic dogs, raccoons, skunks, foxes, mongooses, and jackals. In the past decade, 6000–7000 rabid animals per year

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

were detected in the US. Over 90% were wild animals, with raccoons, bats, and skunks constituting over 80% of the total. Rabid foxes add another 5%. The island of Puerto Rico has consistently reported about 30–40 rabid mongooses each year.

Rabid cats (4% of rabid animals) have outnumbered rabid dogs (1%) for many years, most likely because of better vaccination coverage in dogs. In North America, rabies cases are more frequent in spring and summer. The number of rabid animals reported typically reflects only those confirmed by laboratory testing; it is thought that the number of undiagnosed rabies cases in wild animals is far higher.

There are multiple rabies virus substrains (aka variants), that are uniquely adapted to their reservoir hosts. Rabies variants tend to be found in identifiable geographic locations. This phenomenon is very useful for investigating the source of individual rabies cases. As an example, if a stray dog in the US was found to be rabid, analysis of the variant could reveal the source of the infection. Finding a North American bat, skunk, or raccoon variant in the dog would reveal that it caught the virus from indigenous wildlife. Finding a Thai dog variant would suggest the dog had recently been imported from Thailand, or had been bitten by a rabid dog from Thailand.

In the Americas, insectivorous bat rabies variants are widely distributed. Vampire bat variants are found in certain areas in South America, Central America, and southern Mexico. The canine rabies virus variant has been eradicated from the US but is still present in parts of Central and South America. So far, no feline variant has been reported. The pathogenicity and virulence of the variant, the behavior of the reservoir species (natural behavior and behavior when rabid), and the degree of overlap in habitat between the reservoir species and other mammals all affect the risk of rabies transmission to pets and people.

The risk of rabies exposure for domestic animals is higher in areas where variants associated with terrestrial animals (i.e., not just insectivorous bat variants) are prevalent. The risk is highest where the canine variant is enzootic (example: India), and much lower in areas where only insectivorous bat rabies variants are found (example: southern California). Many islands in the world, such as Hawaii, are considered completely rabies free.

The raccoon variant is found throughout the eastern quarter of the US and in parts of eastern Canada. Multiple variants of skunk rabies are found in large areas in the center of North America, California, and parts of Mexico. Fox variants have been found in Alaska, Arizona, New Mexico, and Texas in the US, and in Ontario, Canada. One variant found periodically in southern Texas and northern Mexico appears to be adapted to both dogs and coyotes.

Humans have spread rabies variants in the US by moving infected animals. Before the late 1970s, the raccoon variant had been limited to the southeastern area of the US. It was translocated to the mid-Atlantic states by people shipping raccoons from south to north for hunting purposes. The canine variant of rabies, which was considered officially eliminated from the US in 2007, could be reimported at any time from countries where canine rabies is still enzootic. Rabid dogs have been imported into the US many times but fortunately were quickly detected, isolated, and euthanized. If imported rabid dogs were released into populations of unvaccinated dogs, such as into a city with a significant stray dog population, canine rabies could become reestablished in the US.

Mice, rats, and rabbits can be experimentally infected with rabies, but rabies is very rare in them in nature. Rabies has been detected in larger rodents in the US, such as woodchucks, groundhogs, and beavers, usually in areas where the raccoon variant is enzootic. It has also been rarely seen in rabbits attacked by raccoons.

Opossums are partially resistant to experimental rabies infection. So far, no marsupial has been found to be a rabies reservoir. Nonetheless, opossums can become infected. In California (where skunk and bat rabies variants are enzootic), 11 rabid opossums were detected between 1983 and 2012 (data from Dr Curtis Fritz, California Department of Public Health). The omnivorous nature of opossums would make it natural for them to investigate a dying, rabid animal, and to potentially be bitten.

Practitioners should have full understanding of the rabies variants that are common in their area. However, since rabies may be imported, a thorough travel history for all patients should also be taken, with special focus on the previous six months. The Centers for Disease Control and Prevention (CDC) maintains an online list of nations that present a higher risk for importation of rabies in animals.

Signalment

Any breed of dog or cat may present with rabies. Rabies is highly unlikely in animals less than 4 weeks of age.

History

Taking a thorough history is vital for clinical diagnosis. The risk of rabies depends on the geographic area where the pet lives or has spent time, especially in the previous six months. Knowledge of the clinical course of illness before presentation is also essential for diagnosis.

A history that *increases* the likelihood of rabies may include the following.

- *Travel*. Pet imported within the last six months from a country where canine rabies is enzootic (includes many countries in Africa, Asia, and Central and South America). Imported strays or street animals present especially high risk. See the Public Health Implications section below for more information.
- *Unvaccinated*. No rabies vaccination in pet's history. Dogs and cats that were vaccinated only once or twice against rabies may not be fully protected. Repeated vaccination (>2 times) significantly reduces the risk of rabies.
- *Exposure to wild animal or suspected rabid pet*. History of interaction with a wild animal (especially a known rabid animal or rabies reservoir species) 10 days to six months before presentation. Bite from the wild animal will likely be healed by the time rabies signs begin. Bites inflicted in thick fur or in the oral cavity, or bites from bats, may have gone unrecognized.
- *Onset of clinical signs is gradual and steady*. Once clinical signs begin, they worsen over days or hours. Animals are *unlikely* to be rabid if they have a peracute onset of neurologic signs, stabilization or improvement, or have survived through more than 10 days of overt illness.

Clinical Signs

Rabies is rarely recognized on physical exam alone. The initial clinical signs mimic other diseases and may not seem neurologic. The most consistent finding is a steadily worsening clinical course over hours or days, with an accumulation of signs that eventually reveal their neurologic origins. The pet will not respond to therapy, and will usually die within 10 days. Close monitoring, with the patient kept in isolation, is the most important premortem clinical tool.

The incubation length is highly variable. Most dogs and cats develop clinical signs within six months after exposure, but some may become ill in as few as 10 days. The most common incubation period is 3–12 weeks.

In general, the clinical signs of rabies may be divided into a prodromal phase, followed by a furious (excitatory or encephalitic) phase, then a dumb (paralytic) phase, then death. However, the clinical course can vary considerably. Phases may be absent or overlap. The majority of cases are associated with a prominent furious phase, followed by a short paralytic phase before respiratory arrest and death. Approximately 20% of cases lack a furious phase (i.e., dumb or paralytic rabies).

Clinical signs in the prodromal phase are nonspecific. Dogs and cats may have fever, lethargy, dehydration, anorexia, vomiting or diarrhea. The animal may withdraw and hide, or may appear to become more sociable than usual. They may lick or chew at the site of the original bite wound. Activation of the autonomic nervous system may lead to piloerection, drooling, and dilated pupils.

Furious (excitatory) phase clinical signs may include the following.

- *Restlessness*. When confined, animals may pace or constantly readjust their body posture. When crouching, they may continuously shift the front paws. Unconfined animals may walk or run for miles.
- *Hyperreactivity* to sounds, movements, and touch.
- *Bizarre behavior*. The animal may bite or strike at unseen things, or stare at things in an unsettling manner. Dogs may lick their own urine or eat unusual objects (pica), and may present with gastrointestinal foreign bodies.
- *Vocalization*. Dogs or cats may repeatedly howl, with a noticeable change in voice because of alterations in laryngeal function. Cats may make aggressive screeching sounds, especially in response to stimuli.
- *Aggression*. Bites from rabid dogs usually occur without warning or behavioral cues (i.e., without snarling, growling or posturing). Cats may combine striking and biting. Confined rabid animals may repeatedly bite and gnaw at cage doors and walls. Rabies has sometimes been associated with spectacular levels of aggression, with the rabid animal repeatedly attacking even while receiving grave injuries from the bite victim. Bites are often firmly inflicted, with the rabid animal latching onto the object or individual.
- *Grand mal seizures*.
- *Fine muscle tremors*, especially in cats.

Dumb (paralytic) phase clinical signs may include the following.

- *Persistent lethargy*.
- *Cranial nerve deficits*. Pharyngeal paresis may cause a change in voice and dysphagia, leading to accumulation of saliva in the mouth and drooling. The animal may repeatedly lap at water in unsuccessful attempts to drink. Dogs often develop a dropped jaw and hanging tongue, and may gag and cough, causing them to appear to be choking on an object.
- *Ataxia*.
- A *stiff or hunched gait*.
- *Paresis*, usually beginning in the body part where the original bite was inflicted. May be unilateral at first, and the animal may present with an apparent limp. Progresses as an ascending flaccid paralysis.

Rabid animals may exhibit a combination of excitatory and paralytic signs, in which disorientation and anxiety may be coupled with restlessness and weakness. Some animals die acutely. Most rabid animals eventually progress to generalized paralysis, respiratory arrest, and death.

Diagnosis

There is no validated test available for diagnosing rabies in a clinically ill, living animal. The direct fluorescent antibody (DFA) test is the gold standard for diagnosing rabies, and is performed on brain tissue. This test is almost always performed by a public health laboratory, and is the test that must be used when human rabies exposure is possible. For most species, the DFA test requires submission of the head or whole brain. When decapitation or debraining is required, only trained, rabies-vaccinated staff should perform the procedure. Keep the specimen fresh and refrigerated; *fixation with formalin renders it untestable by DFA*. Freezing the sample will delay testing and complicate performance of the test. For bats, the entire body may often be submitted. The laboratory should be contacted in advance for requirements on specimen preparation, shipping, and submission.

Serology is not useful in the diagnosis of clinical rabies in animals. Patients previously vaccinated against rabies before the illness may have positive titers. Young, unvaccinated animals may have measurable maternal antibodies against rabies, clouding interpretation.

Fixed brain tissue may be examined for rabies through immunohistochemistry (IHC) by certain laboratories. Histopathology may reveal Negri bodies in rabies-infected neurons, but they are not consistently present.

Polymerase chain reaction (PCR) testing is used as an antemortem test for rabies in people. The test is usually performed on saliva and on skin from the back of the neck of the human patient. The sensitivity of PCR testing on tissue outside the CNS is too low to be used to make decisions in managing a potential rabid animal, and is not routinely used in animals because of the risk to public safety. PCR testing may be used to supplement DFA testing on brain matter.

A direct, rapid immunohistochemical test (DRIT) is used during surveys of rabies in wildlife.

There is no test available for evaluating healthy animals for exposure to rabies, primarily because the virus usually remains localized and undetected by the immune system during much of the incubation period.

Therapy

If an animal is rabid, all clinical interventions will fail and the animal will die. No antivirals have been shown to be effective against rabies. Secure isolation and observation, or euthanasia, of the suspect rabid animal is the primary clinical intervention.

Prognosis

Grave – rabies is fatal.

Prevention

A robust immune response is the only effective defense against rabies. Standard rabies vaccination, when administered through proper protocols, affords protection against all variants. Vaccine failure does occur, but is very rare.

Numerous vaccines are licensed for use in the US. Vaccines are either inactivated (killed) or recombinant, in which a live canarypox virus expresses rabies proteins. Most rabies vaccines are first administered at age 3 months, boostered a year later, and then every one or three years thereafter. The vaccine label should be reviewed carefully for the exact protocol required. Adult dogs or cats being vaccinated for the first time should have a booster a year later. An animal is considered immunized about four weeks after its first rabies vaccination, or immediately after a booster.

Indoor-only cats should be vaccinated against rabies. Insectivorous bats, an important rabies reservoir in North America, are sometimes found inside buildings. In Los Angeles County (where the authors work), at least one rabid bat is identified indoors every year.

The risk of injection-site fibrosarcoma exists when vaccinating cats. Recombinant vaccinations appear to be associated with a lower risk than killed vaccines.

All states require rabies vaccination for dogs, and several require vaccination of cats. Individual cities or counties may require vaccination of cats even when their state does not require it. Some states allow exemption from rabies vaccination in cases where it may present a severe risk to the health of the animal. The criteria for granting exemption, and the protocol for obtaining one, vary by state and locality. Note that rabies serologic testing is *not* accepted in lieu of vaccination in most areas of the US.

Vaccination is not the only way to reduce the risk of rabies exposure. Encourage clients to keep dogs leashed when off property, and to keep cats indoors. Clients can reduce the attractions for wildlife on their property by keeping all pet food (and other consumables) and water indoors, by bat-proofing their home, and by keeping crawl spaces and the underside of decks sealed off.

Clients who rescue stray, feral or wild animals, and especially those who may participate in international rescue efforts, may face a higher risk of rabies exposure.

They should be given detailed information about rabies, and be encouraged to budget for thorough veterinary examination as part of the processing of each animal. Rescue groups that import animals should be educated about associated legal requirements (see later).

Public Health Implications

Veterinarians routinely face rabies-related circumstances in which they are called upon to protect not only their patient but also people and other animals. National guidelines on rabies control are routinely published by the National Association of State Public Health Veterinarians (http://nasphv.org/documentsCompendia.html). Local animal control and public health agencies usually play the most prominent role in rabies control. Contact your local agencies in advance for information on rabies-relating reporting, testing, and other protocols. Ask for the phone number to call in case of an emergency. Place the information in an easy-to-find location and review it with clinic staff.

Four rabies-related circumstances occur routinely in small animal practice.

- *Dog or cat bit a person*. Legally reportable. Rabid dogs and cats can potentially shed rabies virus in their saliva for a few days before clinical signs of rabies begin. Quarantine and/or testing are typically required regardless of the rabies vaccination status of the animal. The quarantine protocol may vary depending on the severity of the bite and the requirements of the jurisdiction. If the dog or cat remains healthy for 10 days or longer, the risk of rabies for the bite victim is negligible. If the animal dies or is euthanized during this 10-day period, it should be tested for rabies. The pet should not be vaccinated for rabies during this 10-day quarantine.
- *Dog or cat vs wild mammal*. Legally reportable in many areas. (Note that certain wild mammal species may be exempt – for example, in California, bites from wild rabbits and small rodents are not reportable.) Bite wounds from the wild animal exposure may or may not be obvious. Pets found unattended near a wild mammal may have wounds hidden in the fur or mouth. Bite wounds from bats are especially hard to see, even on human skin. Pets with unexplained bite wounds may also have been exposed to a rabid animal. Ask the pet owner about the location of the biting wild mammal. If it is deceased, its body should be retrieved for testing – *a negative rabies test on the wild mammal eliminates concerns about rabies*. If the wild mammal is not available for testing, or tests positive for the virus, the pet is considered exposed to rabies. Regardless, the bite wound should be thoroughly cleaned to remove virus particles. The next steps depend on the pet's rabies vaccination status.
  - **Pet's rabies vaccination was current before incident**. Revaccinate the pet immediately. The owner should be advised that there is a risk of the pet becoming rabid. The postexposure quarantine and observation period in this case is usually 30–45 days, depending on the jurisdiction. The quarantine may potentially be performed at the pet owner's home or may require a more secure setting, depending on the risk of rabies and local requirements.
  - **Pet was not vaccinated at all before incident**. Tell the owner that there is an elevated risk of the pet becoming rabid, presenting risk to them and their family members. National guidelines call for the pet to be euthanized to prevent it from becoming rabid. Alternatively, the pet may be immediately vaccinated and then quarantined. In most states the quarantine period is 4–6 months. Texas requires only 90 days of quarantine, but also requires unvaccinated pets to be vaccinated three times while in quarantine: the first week, then three and eight weeks afterward. This three-vaccine postexposure "Texas Protocol" may provide some protection against the development of rabies, and is sometimes recommended in other localities.
  - **Pet overdue for rabies vaccine at time of incident**. These cases are often managed similarly to unvaccinated pets with a rabies vaccination being given immediately followed by a 4–6-month quarantine period (see earlier). However, the risk of rabies transmission is lower, especially if the pet has a lifetime history of multiple rabies vaccinations, and some jurisdictions may allow for a shorter quarantine of 45 days if there is proof of the earlier vaccination. If there is no proof of earlier vaccination, national guidelines suggest a procedure called prospective serologic monitoring to determine if the animal was likely vaccinated in the past. It involves documenting a very rapid rise in rabies antibody titers following boostering, by measuring antibody levels in serum samples drawn just before the booster and again 5–7 days later. This procedure may or may not be accepted as proof of earlier vaccination, depending on the state and local law.
- *Dog or cat suspected of being rabid*. Legally reportable. Isolate the animal. Create a list of all people who may have been bitten or exposed to the saliva of the animal, and refer them to physicians for consultation. After the animal dies or is euthanized, submit the head or brain to your local rabies control agency following its protocols. Inform all the exposed individuals of the rabies test result once available.
- *Pet imported from another country*. Over the past decade, the globalization of the puppy trade and animal

rescue efforts has led to dramatic increases in animal translocation. Rabid dogs have been imported into the US several times. As a result of the increasing number of imported dogs and an increase in noncompliance with import regulations, dog import requirements in the US were modified in 2014 to reduce the risk of importing rabies.

CDC Requirements

As of 2019, a health certificate is not required to import a dog or cat, but the imported pet must appear healthy on arrival. Importers of dogs must provide proof of rabies vaccination when the dog is imported from countries designated as high-risk for rabies importation (see www.cdc.gov/importation/bringing-an-animal-into-the-united-states/rabies-vaccine.html). The vaccination must have been given 28 days or more before entry, when the dog was at least 3 months of age.

Unvaccinated dogs may only be imported if they have lived in a country with a very low risk for rabies exposure for the past six months or longer, are being imported for research purposes, or on a rare case-by-case basis. See www.cdc.gov/importation/bringing-an-animal-into-the-united-states/index.html.

USDA Requirements

The US Department of Agriculture (USDA) requires dogs and cats to be at least 8 weeks old when shipped without their mothers. Dogs imported specifically for resale or adoption (i.e., importation by international dog rescue groups) must be healthy, at least 6 months old and be accompanied by a health certificate, rabies certificate, and proof of vaccination against distemper, leptospirosis, parvovirus, and parainfluenza (DHLPP). See www.aphis.usda.gov/aphis/pet-travel/bring-pet-into-the-united-states.

Federal, state, and local regulations regarding pet importation may vary over time, and can include additional requirements depending on the animal's country of origin. Veterinarians are recommended to check the latest information on the websites for both CDC and USDA-APHIS as well as any additional requirements from US Customs and Border Protection (https://help.cbp.gov/app/answers/detail/a_id/3695/kw/3695) and from the state where the animal is arriving.

Unfortunately, many imported dogs and cats are not physically inspected on arrival, so it is still possible that sick animals, or those incubating rabies, will be imported. Private practice veterinarians play a crucial role in detecting imported cases of rabies, since they may the first person to examine the pet after arrival. If a clinician suspects an imported pet has rabies or any other unusual disease, they should immediately contact their local authorities.

Bats and Public Health

Bats represent a special case when it comes to rabies. Rabid insectivorous bats may transmit rabies via very shallow bites, even bites that do not bleed. In fact, two bat variants appear to have greater ability to infect through shallow bites than the canine variant. Clinic staff may hear about clients or staff who have handled bats. They should urge such people to seek public health or medical consultation. Bats found near pets, children or sleeping people, or people with lowered levels of consciousness, may have bitten a person or pet, and *rabies testing of the bat should be prioritized*. If the bat is not tested, it should be assumed to have been rabid for the sake of safety, and the exposed person needs to be referred for medical care.

Oral Rabies Vaccination and Public Health

Clients and their pets may encounter oral rabies vaccines (ORVs) that are intended for wildlife. ORVs distributed in wildlife habitats in North America and Europe have been very successful in controlling the spread of rabies in raccoons, coyotes, and foxes. Government agencies typically work to alert the local population as to when and where the baits are being distributed. These vaccines contain a live, attenuated *Vaccinia* virus-vectored rabies recombinant liquid vaccine in a packet surrounded by a flavored bait. There is no live rabies virus in the vaccine. The *Vaccinia* virus may cause illness in immunocompromised people if the liquid vaccine comes into contact with abraded skin or mucous membranes. Human exposure to ORVs is rare. During 10 years of distribution of over 86 million ORVs in 18 states, only 296 incidents of human exposure were reported, with six illnesses. Most people were exposed when trying to remove the bait from their dog's mouth. Clients should be advised to keep their dogs leashed when in areas that are part of an ORV baiting program. If a client may have had direct contact with the liquid vaccine inside the bait, they should wash their hands, and collect the vaccine without touching it directly, such as by wearing gloves or covering their hand with a bag. There is a toll-free phone number printed on the side of the ORV bait that the person should call to report the incident and seek medical consultation.

Rabies Preexposure Prophylaxis for Humans

The CDC recommends preexposure vaccination for all people who routinely handle animals. Clinical staff, such as veterinarians and veterinary technicians, should be prevaccinated against rabies. The preexposure vaccine series consists of three intramuscular human rabies vaccinations given on days 0, 7, and either 21 or 28. Antibody titer levels should be checked every two years to insure

that the body is still producing antibodies against the virus. Preexposure vaccination alone is not considered protective in the event of a rabies exposure.

Rabies Postexposure Prophylaxis

For people with a known, or suspected, exposure to rabies, postexposure treatment is recommended. In healthy, previously unvaccinated people, treatment includes a dose of human anti-rabies immune globulin (HRIG) injected into the bite wound (with the excess given intramuscularly) plus a series of four rabies vaccines over two weeks (on days 0, 3, 7, and 14). A fifth vaccine dose may be needed for immunosuppressed individuals on day 28. The HRIG should not be injected in the same muscle as the rabies vaccine. Previously vaccinated people only need a series of two vaccinations, on days 0 and 3, after an exposure.

West Nile Virus

Tracey McNamara, DVM, DACVP

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

West Nile virus (WNV) is a mosquito-borne viral disease that causes disease primarily in birds, humans, and horses. Sporadic disease has also been reported in a number of other species including squirrels, chipmunks, bats, dogs, cats, white-tailed deer, reindeer, sheep, alpacas, alligators, and harbor seals during periods of intense local viral activity. WNV is a zoonotic mosquito-transmitted arbovirus belonging to the genus *Flavivirus* in the family Flaviviridae. The virus can cause inapparent infection, mild febrile illness, meningitis, encephalitis or death. Dogs and cats are susceptible to WNV infection and may become infected through the bite of a mosquito, but they are significantly more resistant to disease than horses, humans, and some species of birds. It is unlikely that healthy dogs or cats will become ill. Limited information is available on WNV infections in dogs and cats but experimental studies have shown that the virus targets the meninges, dorsal horn, brainstem, cerebellar Purkinje cells, and cerebral cortex. In two naturally occurring cases in a dog and a wolf cub, myocarditis was also a finding.

Epidemiology

Like other arboviruses, WNV is maintained in nature by cycling through birds and mosquitoes. Migratory birds are thought to be primarily responsible for virus dispersal. Serologic studies of dogs and cats have shown high seroprevalence but little evidence of disease, suggesting that dogs and cats suffer little to no ill effect. In a 2002 study in Louisiana, the incidence of seropositivity was 19 times higher in outdoor dogs than in indoor dogs. Another study suggested that stray dogs and cats may serve as better sentinels than chickens. There is a single report of WNV being isolated from a sick dog in Botswana in 1982 and in a 3-month-old wolf cub and older dog with immune-mediated disease. There are three reports of naturally occurring WNV illness in cats, including one cat in New Jersey in 1999 and two cats in New York City in 2000. Experimentally infected dogs did not develop clinical signs of illness or infectious levels of viremia. Experimentally infected cats did develop brief episodes of febrile illness, lethargy or decreased appetite of short duration. Cats develop slightly higher levels of virus in their bloodstream but it is unclear if it is sufficient to infect mosquitoes. Cats fed infected mice developed viremias similar to those caused by a mosquito bite, suggesting that prey animals may serve as an important source of infection for carnivores and that outdoor cats are at greater risk of WNV infection. All dogs and cats cleared WNV from the bloodstream within days and mounted an antibody response. No evidence of prolonged or persistent infection was found. Neither dogs or cats are likely to serve as an important amplifying host epidemiologically.

Signalment

Clinical signs of WNV infection are nonspecific and diagnosis cannot be made on clinical presentation alone. Based on a small number of naturally occurring cases, dogs may present with lethargy, depression, ataxia, difficulty rising, weakness or paresis, muscle tremors or twitching, abnormal head posture, fever, and nonlocalizable pain. Other differential diagnoses for these signs would include bacterial meningitis, distemper, rabies, fungal or rickettsial infections, and primary neurologic disease. Cats develop nonspecific mild febrile illness.

© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

Diagnosis

Diagnosis of WNV in the live patient requires paired acute and convalescent serum samples for neutralizing antibody. Due to the widespread seropositivity, single serum samples are nondiagnostic. If a necropsy is performed (with appropriate biocontainment gear or facilities), the following tissues should be collected and submitted chilled, not frozen, for WNV polymerase chain reaction (PCR), immunohistochemistry and/or virus isolation: heart, kidney, brain/brainstem, a section of spinal cord.

Therapy

There is no specific therapy for WNV infection. Supportive care should be provided. An experimental recombinant canarypox vectored WNV vaccine protected dogs and cats against mosquito challenge but is not commercially available.

Prognosis

Full recovery is likely.

Public Health Implications

As WNV is a biologic safety level (BSL) 3 pathogen, anyone performing a necropsy should wear protective apparel and, if possible, work in a laminar flow hood. In most cases, it would be preferable to send the body to a diagnostic laboratory with appropriate facilities for testing. There is no documented evidence of dog- or cat-to-person transmission of WNV. WNV has not been detected in the saliva of dogs so dog bites would not appear to be a risk factor for human infection. Neither dogs or cats are considered epidemiologically important amplifying hosts, although peak viremias in cats may be high enough to infect mosquitoes at low efficiency.

Suspect cases should be reported to your state veterinarian, state diagnostic laboratory or reference laboratory. Positive cases should be promptly reported to your local Department of Health. Clients may ask about methods of mosquito protection in dogs and cats. It is important to emphasize that DEET-containing products are not approved for use in pets and should not be used. The same holds for citrus-based oils that have been found to cause contact dermatitis. Owners should be advised to eliminate mosquito habitat and avoid outdoor exposure of pets during peak mosquito feeding activity (early morning and dusk).

Ebola Virus

Linda Kidd, DVM, PhD, DACVIM

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Ebola virus is an enveloped, negative-sense RNA virus belonging to the genus *Ebolavirus* in the family Filoviridae. Filoviruses cause severe lethal hemorrhagic disease in people. The Ebola viral genome encodes a nucleoprotein (NP), a glycoprotein (GP), an RNA polymerase (L), and four structural proteins (VP 24, VP30, VP 35, and VP 40). A soluble form of GP thought to be important in evading humoral immunity is produced through receptor editing.

The primary target cells of Ebola virus are dendritic cells (DC) and macrophages. Other cells, including hepatocytes, endothelial cells, fibroblasts, and cells of the adrenal gland, can be infected.

Ebola virus can both inhibit and evade innate and adaptive immunity. For example, the virus inhibits interferon (IFN)-alpha, IFN-beta, and IFN-gamma production. Infection also inhibits DC expression of CD 40, CD 80/86, and MHC II, co-stimulatory molecules that are important in the induction of adaptive immunity. Examples of evasion tactics include shielding of GP epitopes that may be recognized by the immune system, and releasing soluble GPs that act as "decoys" that bind protective antibodies.

Despite being able to avoid immune recognition, infection is associated with massive production of proinflammatory cytokines. Thus, additional cells are recruited and available for the virus to infect. The systemic effects of cytokines cause systemic inflammatory response syndrome (SIRS). Increased vascular permeability and endothelial cell activation associated with infection are in part mediated by GP. Disordered hemostasis may arise from endothelial cell dysfunction and damage. Tissue factor expression induced by virus or cytokines appears to play a major role in activation of coagulation and induction of disseminated intravascular coagulation (DIC).

Epidemiology

Ebola was first discovered in 1976 near the Ebola River in what is now the Democratic Republic of Congo. Several epidemics have occurred in Africa. The largest outbreak began in 2014 and involved several West African countries. It was considered ended in 2016. Infection has been reported in healthcare workers returning from Africa in a few countries, including the United States, Spain, and the United Kingdom. Further spread in these countries has not occurred.

Handling of dead infected animals or consumption of infected primates was thought to be the mechanism of entry into the human population. Human-to-human spread is the primary means of infection in people. Infection occurs by exposure to bodily fluids through mucous membranes or broken skin, or inoculation via needle sticks. Importantly, fomites may also play a role in transmission. The incubation period is thought to be 2–21 days.

Bats are believed to be the reservoir host in Africa but this has not been confirmed. A summary of surveillance studies of naturally infected species in outbreak areas detected virus in nonhuman primates and bats and an ungulate. Recovered human patients can still shed the virus in semen and virus has been amplified from bodily fluids in patients with uveitis and meningoencephalitis after recovery.

Antibodies have been detected in additional species, including dogs; 27.2% of dogs had formed antibodies to the virus in a survey of a 2001–2002 outbreak of Ebola in people in Gabon. Dogs in the study were not ill. The dogs were thought to be exposed to Ebola virus by eating carcases of dead infected wild animals (bush meat) and vomit of infected people. No virus was amplified from the blood samples. A recent *in vitro* study suggested that both canine and feline cells are less susceptible to infection than primate and human cells.

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

At the time of this writing, whether Ebola can cause viremia and be shed by or cause clinical signs in dogs and cats is not known. As a precautionary measure, during the 2014 Ebola outbreak, a healthy dog owned by an infected Spanish nurse was euthanized by officials without testing. Global public outcry was significant given that it had not been shown that dogs can be infected with or shed the virus and that the risk was unknown. A call for testing and not automatic euthanasia was made by the World Small Animal Veterinary Association. Shortly thereafter, a dog owned by an infected nurse in Texas was quarantined and tested rather than euthanized. Reverse transcriptase polymerase chain reaction (RT PCR) testing of blood, urine, and feces was negative, and the dog showed no evidence of illness during the 21-day quarantine.

Clinical Signs

Ebola causes severe disease in humans and nonhuman primates. Whether the virus causes clinical signs in dogs and cats is not yet known. In people, flu-like symptoms occur, including fever, headache, and muscle pain. Gastrointestinal signs also occur. Dramatic signs of disordered hemostasis such as maculopapular rash, petechiae, conjunctival hemorrhage, epistaxis, and hematemesis are common. Encephalopathy also occurs.

Diagnosis

Diagnosis in people depends on the phase of infection. Direct detection of the virus is attempted if clinical signs have been present for a short period of time. Detection techniques include virus isolation, antigen-detecting ELISA, immunohistochemistry, and RT PCR. RT PCR is used in the emergent clinical setting. Detection of IgM antibody or demonstration of seroconversion can facilitate diagnosis of acute infection.

Therapy

Treatment of infection in people is primarily supportive. Experimental therapies that appear to hold promise were utilized in some cases in the 2014 outbreak. Vaccines are in development.

Prognosis

The mortality rate in people and nonhuman primates is high. Prompt and adequate supportive care appears to be important for survival.

Public Health Implications

In the fall of 2014, the AVMA Ebola Companion Animal Response Plan Working Group developed recommendations regarding dog and cat quarantine after exposure to a human with confirmed Ebola virus disease. These recommendations are available at www.cdc.gov/vhf/ebola/pdf/dog-cat-quarantine.pdf. Public health officials and state veterinarians should be contacted immediately on an emergency basis if a pet is exposed to a person with Ebola virus infection. Regardless of whether infection occurs in dogs and cats, recommendations for people with exposure to Ebola virus include avoiding contact with their pets due to the potential risk of fur acting as a fomite.

Ehrlichiosis and Anaplasmosis

Pedro P. Vissotto de Paiva Diniz, DVM, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Ehrlichiosis and anaplasmosis are tick-borne diseases caused by a group of gram-negative intracellular bacteria belonging to the family Anaplasmataceae, order Rickettsiales (Figure 93.1). These organisms are capable of causing an array of clinical signs and even death in dogs. Some bacterial species from this family are capable of infecting cats, horses, other animals, and humans. Cats are generally subclinically infected so this chapter will focus on infection in dogs.

Ehrlichia and *Anaplasma* preferentially parasitize leukocytes or platelets and form intracytoplasmic clusters called morulae (Figure 93.2). Understanding the differences in the target cell type, clinical signs, primary vectors, and geographic distribution can help clinicians differentiate the likely infecting organism, which has therapeutic and other clinically relevant implications. For dogs, *Ehrlichia canis* is the most pathogenic organism (see Figure 93.2a,b), targeting monocytes and rarely lymphocytes. *Ehrlichia canis* is transmitted by the brown dog tick, *Rhipicephalus sanguineus*, which has a ubiquitous distribution (Figure 93.3).

Like *E. canis*, *E. chaffeensis* also targets monocytes but causes comparatively mild to moderate signs, and is transmitted in the United States by *Amblyomma americanum* (the Lone Star tick), which has a more limited geographic distribution (see Figure 93.3). *Ehrlichia ewingii* and *Anaplasma phagocytophilum* target granulocytes (see Figure 93.2c,e,f) and often cause acute lameness or polyarthritis in dogs. These organisms are transmitted by different ticks (*A. americanum* and *Ixodes* spp., respectively) with distinct but overlapping areas of distribution in the United States (see Figure 93.3). *Anaplasma platys* is the only organism from this family to target platelets (see Figure 93.2d), causing cyclic thrombocytopenia and bleeding tendencies. *A. platys* is probably transmitted by the brown dog tick so co-infections with *E. canis* are not uncommon and result in more severe clinical disease than either agent alone. A summary of the species of importance in dogs and cats, their associated vectors, target cell, and geographic distribution is given in Table 93.1.

With advances in molecular methods of diagnosis, a growing number of species of *Ehrlichia* that infect humans have been documented in dogs, including *E. muris* and Panola Mountain *Ehrlichia* sp.

After transmission via tick saliva, the incubation period for *E. canis* and *A. phagocytophilum* ranges from one to three weeks. The acute phase of the disease can last 1–4 weeks, when the organism rapidly multiplies within the targeted blood leukocytes and, in the case of *E. canis*, tissue macrophages (spleen, liver, lungs, and lymph nodes). Intracellular multiplication is achieved by impairing the antimicrobial activity of host monocytes or granulocytes by inhibiting lysosome fusion, decreasing the formation of reactive oxygen species, and inhibiting phagocytosis. The organisms also increase host cell survival by inhibiting apoptosis and leukocyte migration to tissues. In addition, *Ehrlichia* and *Anaplasma* spp. avoid the immune system by repressing the early innate immune response, and by antigenic variation of outer membrane proteins. Consequently, infected monocytes or granulocytes remain in circulation longer, facilitating subsequent transfer to ticks. Genetic analyses have demonstrated that multiple strains of *E. canis* and *A. phagocytophilum* exist, which may be associated with differences in pathogenicity. In addition, host susceptibility, size of the inoculum, and concurrent infection with other tick-borne diseases transmitted by the same tick affect the clinical presentation.

An exacerbated host immune response against the infection is likely an important mechanism of the disease. Dogs infected with *E. canis* may develop polyclonal

or monoclonal hypergammaglobulinemia. Immune-mediated consumption of platelets is thought to contribute to thrombocytopenia in dogs infected with these organisms. Other mechanisms of thrombocytopenia such as splenic and vascular sequestration may also be involved. Thrombocytopathia may also occur due to antiplatelet antibodies. Deposition of immune complexes and infected cells in the vascular endothelium of kidneys, joints, and eyes may predispose to glomerulonephritis, polyarthritis, and uveitis. Systemic inflammation associated with *E. canis* infection may also contribute to myocarditis, meningitis, thrombosis, hyperviscosity, and vasculitis. The development of high circulating levels of antibodies against *Ehrlichia* or *Anaplasma* spp. does not promote protective immunity against reinfection.

The progression of the disease appears to vary according to the cell type targeted by the parasite. Granulocytic anaplasmosis caused by *A. phagocytophilum* appears to be an acute illness in naturally infected dogs that can be self-limiting. However, chronic persistent infection has been shown in experimentally infected dogs, and has been suspected in some naturally infected dogs. Similarly, granulocytic ehrlichiosis caused by *E. ewingii* appears to be self-limiting, but persistent infection was detected in experimentally infected dogs.

In contrast, monocytic ehrlichiosis associated with *E. canis* infection causes an acute illness, which may vary from mild to severe depending upon the pathogenicity of the parasite, followed by subclinical phase of months to years in duration. It is unclear if dogs are able to eliminate E. *canis* or if the organism remains sequestered in the spleen, bone marrow or other primary niche indefinitely. Some dogs develop a chronic phase characterized by hyperglobulinemia and bone marrow suppression, which is more difficult to treat. *E. chaffeensis* also appears to cause chronic infection in dogs, but dogs are generally asymptomatic.

Epidemiology

The presence of *Ehrlichia* and *Anaplasma* spp. primarily follows the geographic distribution of their vectors and mammalian reservoir hosts (see Figure 93.3). *E. canis* has worldwide distribution, being one of the most common tick-borne pathogens in dogs in tropical and subtropical regions. The ubiquitously distributed brown dog tick (*R. sanguineus*) is well adapted to urban environments. Consequently, dogs with no access to wooded areas are still at risk of *E. canis* infection. In contrast, the Lone Star tick (*A. americanum*), vector for *E. ewingii* and *E. chaffeensis*, is most frequently found in woodland habitats, especially where a high number of white-tailed deer are present. The geographically limited distribution of dogs

Table 93.1 Species of *Ehrlichia* and *Anaplasma* of importance to dogs and cats

Disease	Monocytic ehrlichiosis		Granulocytic ehrlichiosis	Granulocytic anaplasmosis	Cyclic thrombocytopenia
Organism	Ehrlichia canis	Ehrlichia chaffeensis	Ehrlichia ewingii	Anaplasma phagocytophilum	Anaplasma platys

exposed to *E. chaffeensis* and *E. ewingii* in the United States has recently been described (Figure 93.4).

A. phagocytophilum is transmitted by the blacklegged tick (*Ixodes scapularis* or *I. pacificus*) in the United States and by the castor bean tick (*I. ricinus*) and the taiga tick (*I. persulcatus*) in Europe and Asia. In the United States, *A. phagocytophilum* is more prevalent in the Northeast and upper Midwest regions, and in northern California. Updated prevalence maps of canine ehrlichiosis (*E. canis* and *E. chaffeensis* combined) and anaplasmosis (*A. phagocytophilum* and *A. platys* combined) in the United States are available at the Companion Animal Parasite Council website (https://capcvet.org/maps/#2019/all/anaplasmosis/dog/united-states/). A detailed world map of vector-borne diseases and vectors by country is available at the Canine Vector-Borne

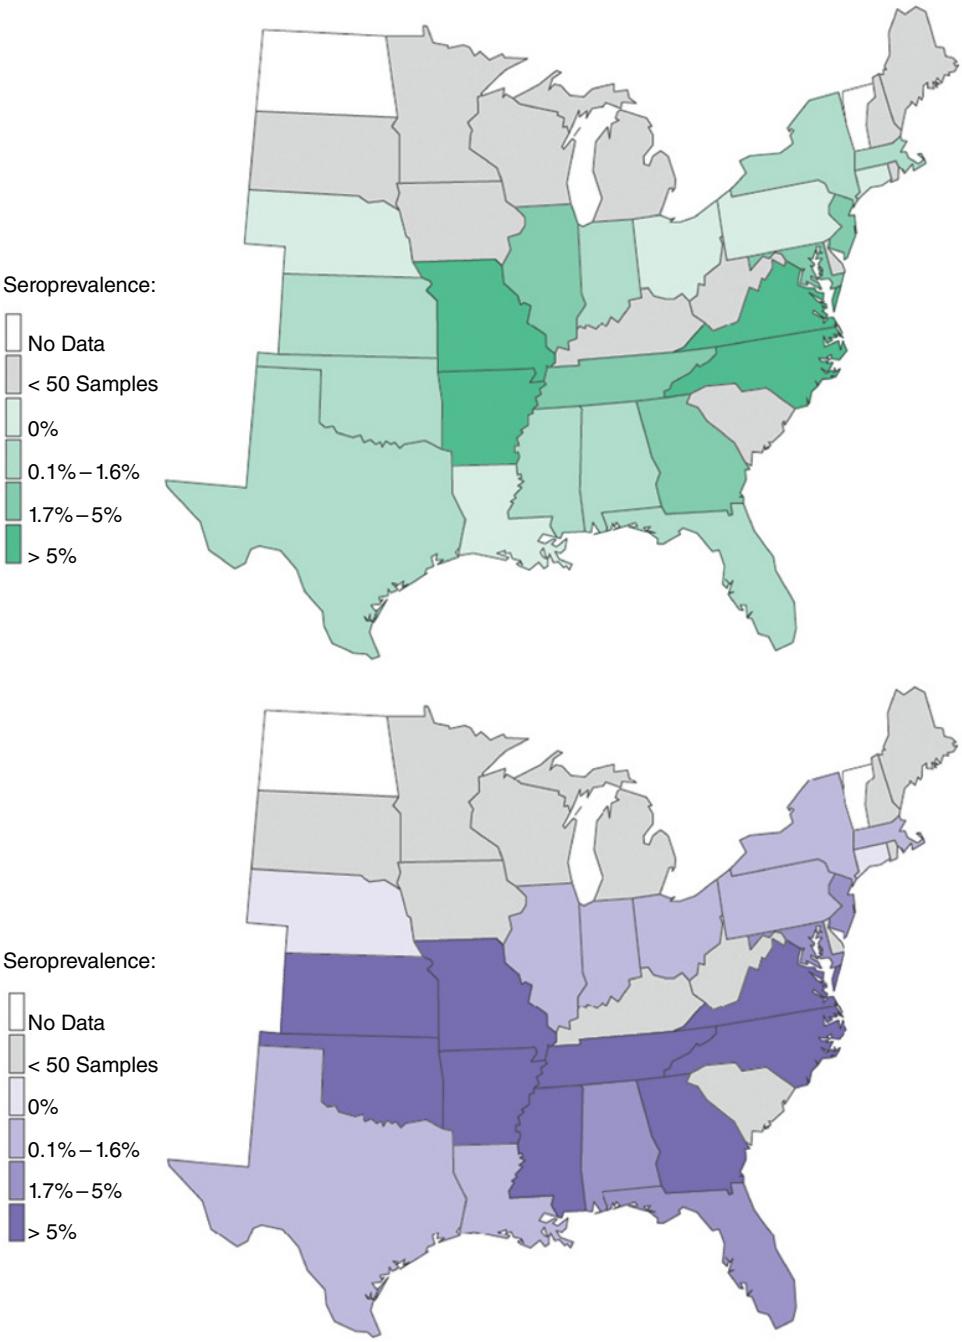

Figure 93.4 Seroprevalence by state of *E. chaffeensis* (*green*) and *E. ewingii* (*purple*) in dogs. *Source: Beall MJ, Alleman AR, Breitschwerdt EB, et al*. Seroprevalence of *Ehrlichia canis*, *Ehrlichia chaffeensis* and *Ehrlichia ewingii* in dogs in North America. *Parasites Vectors* 2012; **5**(29): 1–11. Disease World Forum website (www.cvbd.org/en/occurrence-maps/world-map/).

Recently, two new species of *Ehrlichia* have been described in dogs in the United States: *E. muris* from a sick dog in Minnesota, and Panola Mountain *Ehrlichia* (PME) from a sick dog in North Carolina. *E. muris* is believed to be transmitted by *I. scapularis* in the United States, with wild rodents as reservoir, whereas PME is transmitted by *A. americanum*, with white-tailed deer as the probable vertebrate reservoir in the United States.

Signalment

Male or female dogs at any age can develop the disease. German shepherd dogs are predisposed to a more severe illness during *E. canis* infection. Despite the fact that cats are naturally exposed to *Ehrlichia* and *Anaplasma* spp. infection, clinical manifestations are rarely reported.

History and Clinical Signs

The classic presentation in dogs is characterized by depression, lethargy, mild weight loss, and anorexia. Frequently, pet owners will not recall tick exposure, since infection may have occurred weeks to months prior to illness. Canine monocytic ehrlichiosis is more frequently associated with history of epistaxis and signs of pallor, petechiation, and uveitis (Table 93.2, Figure 93.5). Canine granulocytic ehrlichiosis and anaplasmosis are more frequently associated with history of reluctance to stand or walk and signs of joint effusion and lameness (see Table 93.2).

Anaplasma platys infection rarely causes clinical signs in the United States, but moderate to severe manifestation has been described in Europe, the Middle East, and South America. Fever, lymphadenopathy, and splenomegaly are common findings in monocytic or granulocytic ehrlichiosis. Severe cases of monocytic ehrlichiosis caused by *E. canis* may present with central nervous system (CNS) signs, retinal hemorrhage and detachment, and/or cardiac arrhythmias. The hallmark of the chronic phase of *E. canis* infection is pancytopenia from hypoplasia of all bone marrow cell lines, but protein-losing nephropathy, diffuse muscle wasting, and secondary infections, presumably due to immunosuppression, have been described. Chronic illness associated with granulocytic ehrlichiosis/anaplasmosis has not yet been well documented in naturally infected dogs.

Table 93.2 Main features of ehrlichiosis and anaplasmosis in dogs

Disease	Monocytic ehrlichiosis	Granulocytic ehrlichiosis/anaplasmosis	Thrombocytic anaplasmosis
Disease course	Acute, subclinical, chronic	Acute	Acute, subclinical
History	Lethargy, depression, inappetence, weight loss, epistaxis	Lethargy, depression, inappetence, weight loss, weakness, reluctance to stand or walk, lameness, stiff or stilted gait	Generally asymptomatic. Weight loss, epistaxis
Common signs	Fever, lymphadenopathy, splenomegaly, petechiae, pallor, uveitis	Fever, lymphadenopathy, splenomegaly, joint effusion	Fever, lymphadenopathy, petechiae
Less common signs	Ecchymosis, bleeding gums, melena, ocular and nasal discharge, scleral congestion, hyphema, retinal detachment, ataxia, seizures, vestibular signs, peripheral edema, muscle atrophy, cardiac arrhythmias, vomiting, diarrhea, erythema multiforme	Pallor, scleral congestion, uveitis, head tilt, tremors, anisocoria, vomiting, diarrhea	Pallor, uveitis
Common laboratory findings	Thrombocytopenia, neutropenia, nonregenerative anemia, lymphocytosis or lymphopenia, monocytosis, eosinophilia, hyperglobulinemia (polyclonal or monoclonal), increased ALT and ALP activities, proteinuria, pancytopenia	Thrombocytopenia, lymphopenia, eosinopenia, mild nonregenerative anemia,spherocytes, polyclonal hyperglobulinemia, increased ALT and ALP activities, proteinuria, neutrophilic polyarthritis	Thrombocytopenia, mild nonregenerative anemia, mild hypoalbuminemia
Main differential diagnoses	Rocky Mountain spotted fever, idiopathic immune-mediated hemolytic anemia, multiple myeloma, lymphocytic leukemia, systemic lupus erythematosus	Lyme disease, idiopathic immune-mediated polyarthritis, idiopathic immune-mediated hemolytic anemia, systemic lupus erythematosus	Idiopathic immune-mediated thrombocytopenia

ALP, alkaline phosphatase; ALT, alanine aminotransferase.

Diagnosis

No single laboratory test is capable of detecting *Ehrlichia* or *Anaplasma* infection in all cases, so clinicians should be aware of the limitations of each diagnostic test (Table 93.3).

Diagnosis is generally based on clinical and hematologic abnormalities, response to therapy and presence of specific antibodies against *Ehrlichia* and *Anaplasma* spp. Common hematologic abnormalities are listed in Table 93.2. In addition, it is worth noting that *E. canis* is an important differential for lymphocytic leukemia or multiple myeloma, as infection has occasionally been associated with marked granular lymphocytosis and monoclonal, rather than polyclonal gammopathy. *E. canis* infection may also be associated with positive Antinuclear Antibody (ANA) tests, so it should be ruled out in suspected cases of systemic lupus erythematosus.

Table 93.3 Features of diagnostic assays available for ehrlichiosis and anaplasmosis in dogs

Assay	Advantages	Disadvantages	Recommended testing time
Morulae detection	• Fast and cost-effective • Can be performed in practice	• Sensitivity and specificity are low • Requires trained operator	Acute phase (first days of illness)
IFA serology	• Gold standard, widely used • Antibodies can be quantified (titer) • *E. canis* antigens cross-react with Panola Mountain *Ehrlichia* • Can be used to monitor therapy (decrease in titers generally associated with successful therapy)	• Cannot be performed in practice • Procedure not standardized among veterinary laboratories • Indicates exposure, not infection • Four-fold increase in titer is required for definitive diagnosis • Assay not available for *A. platys*, *E. ewingii* and *E. muris* as they cannot be cultured • Lack of antibody titer in the first weeks does not rule out exposure	After 2–3 weeks post infection. Low antibody titers may be detected as early as 7 days
ELISA serology: SNAP 4Dx Plus	• Fast and cost-effective • Can be performed in practice • Procedure is standardized • *E. canis* spot cross-react with *E. chaffeensis* • A. phagocytophilum spot cross-react with A. platys • Detects five *Ehrlichia* and *Anaplasma* spp., including *E. ewingii*	• Does not quantify antibody response • Intended to be a screening test, not a diagnostic test • Indicates exposure, not infection • Negative results in the first weeks do not rule out exposure • May not detect Panola Mountain *Ehrlichia* • Unknown sensitivity for *E. muris* • Limited use for monitoring therapy, as it remains positive for months after exposure	After 2–3 weeks post infection • *A. phagocytophilum* and *E. canis*: after 7–21 days post infection • *A. platys*: after 10–21 days post infection • *E. ewingii*: 3–4 weeks post infection

(*Continued*)

Table 93.3 (Continued)

Assay	Advantages	Disadvantages	Recommended testing time
Spinning-disc interferometry serology: Accuplex4 Bio-CD	• Detects antibodies against *E. canis* and *A. phagocytophilum* • May detect *E. canis* antibodies earlier than the ELISA	• Cannot be performed in practice • Indicates exposure, not infection • Does not quantify antibody response • May have less accuracy and reproducibility than the ELISA for *Anaplasma* spp. • Unclear if detects antibodies against *A. platys*, *E. chaffeensis*, *E. ewingii*, Panola Mountain *Ehrlichia*, and *E. muris*	Currently unknown. Recommended after 3–4 weeks post infection
Western immunoblotting	• Detects specific antibody response to ehrlichial species • Less cross-reactivity among species than other serology methods	• Cannot be performed in practice • Technically difficult • Not widely available • Primarily used on research	Subclinical or chronic phases
Polymerase chain reaction	• Early detection of active infection • Highly sensitive for acute phase • Identifies pathogens at the species level, and even new species or strains • Can test a wide variety of samples (whole blood, buffy coat, cavitary effusions, synovial liquid, tissue aspirates or fragments, and ectoparasites) • Can test frozen historical samples • Widely available	• Cannot be performed in practice • Procedure not standardized among veterinary laboratories • Sensitivity and specificity depend on assay design • Risk of false-positive results if laboratory quality control is not implemented • Limited sensitivity for chronic infection • Negative results do not rule out infection, even after therapy, as bacteria levels may be lower than limit of detection of assay • Not recommended as a single screening test for blood donors	Acute phase. May detect carrier state and chronically infected, but sensitivity ranges from 25% to 68%

ELISA, enzyme-linked immunosorbent assay; IFA, immunofluorescent antibody.

Visualization of morulae in blood smears using light microscopy can facilitate diagnosis, but it is insensitive. In addition, stain artifacts or basophilic precipitates can be confused with inclusions so other diagnostic techniques are recommended. Serology based on assays such as immunofluorescent antibody (IFA), enzyme-linked immunosorbent assay (ELISA), spinning-disc interferometry or western blotting is the most common method used for diagnosis. Most of the serology methods cannot precisely identify the species of *Ehrlichia* or *Anaplasma* involved due to serologic cross-reactivity. Serology only documents exposure to, not infection with, one or more organisms, so previous exposure or self-limiting infection should be considered in a patient with a positive result. Results of serology should be interpreted in light of clinical signs, laboratory abnormalities, and other potential differential diagnosis. A single positive serology result in a healthy dog with no clinical, hematologic or biochemical abnormalities or proteinuria may not require therapy. Because serology depends upon production of specific antibodies, false-negative results may occur in the first 1–2 weeks post infection. Seronegative dogs with compatible clinical signs should be retested 2–3 weeks later to demonstrate seroconversion, and alternative methodologies, including polymerase chain reaction (PCR), should be utilized. Continuous decrease in antibody titers after antibiotic therapy may suggest clearance of infection; however, it may take several months to years for titers to decrease. In addition, dogs with chronic infection may be seronegative due to the ability of the pathogen to evade the immune system.

Generally speaking, in contrast to serologic assays, PCR assays are very sensitive during the acute phase of infection when organisms are circulating in high numbers. PCR panels are widely available, and many can identify the species of the pathogen(s) involved. Some PCR panels can also detect and differentiate new species or strains. Bodily fluids, effusions, cytology aspirates, tissues, and ectoparasites may all be tested using PCR. However, a negative PCR result never rules out infection. PCR assays have low to moderate sensitivity for subclinical or chronic infections because the pathogen may be sequestered in the spleen or bone marrow, or be circulating in the bloodstream at very low levels, below the limit of assay detection. Since the length of time since infection is generally unknown for a given patient, it is recommended that serology and PCR assays are used in combination (see Table 93.3).

Therapy

Doxycycline remains the treatment of choice for ehrlichiosis and anaplasmosis. In this author's experience, a dose of 5 mg/kg PO q12h is associated with fewer gastrointestinal (GI) adverse effects (vomiting, anorexia) but has the same clinical efficacy as 10 mg/kg PO q24h. For cats and small dogs, liquid formulations are preferred, because tablets may become stuck in the esophagus and cause esophageal damage and stricture. Alternatively, at least 6 mL of liquid should be given PO following each tablet.

The optimum duration of therapy is unknown. Since tetracyclines are bacteriostatic, it may require several weeks of therapy. A *minimum of 28 days* is recommended for acute and subclinical monocytic ehrlichiosis, and a *minimum of 14 days* for granulocytic ehrlichiosis and anaplasmosis for dogs and cats. Chronic cases may require much longer treatments, and consequences of long-term infection such as bone marrow suppression may not resolve despite appropriate antibiotic therapy. Because clinical improvement generally occurs as early as 24–48 hours after the beginning of therapy, clients should be reminded not to interrupt or terminate the therapy early. Aggressive tick control should be implemented. After appropriate treatment of a dog with acute or subclinical infections, the pathogen should no longer be detected in the bloodstream by PCR or culture, but dogs with chronic infections may remain intermittently positive. Decrease of antibody titers within 6–9 months post infection may indicate clearance of the pathogen, but titers can remain elevated for more than 30 months after infection.

If the patient does not tolerate oral antibiotics, IV doxycycline, oxytetracycline (7.5–10 mg/kg IV q12h) or chloramphenicol (25–50 mg/kg IV or SC q8h) can be used until GI signs subside. Of note, chloramphenicol should be avoided in dogs with severe anemia and pancytopenia. The use of enrofloxacin is associated with initial clinical improvement, but it is not recommended as single therapy due to antibiotic resistance by *E. canis*. Imidocarb dipropionate should be avoided due to limited efficacy.

Supportive therapy may be crucial for survival in advanced cases. IV fluids and blood transfusions are frequently used in severe anemic and thrombocytopenic cases. Granulocyte colony-stimulating factor and recombinant human erythropoietin were used with success in one case of bone marrow suppression. Desmopressin acetate (DDAVP), a synthetic vasopressin analog, has been successfully used to treat bleeding associated with ehrlichiosis when used at 1 µg/kg SC q24h for three days. In addition, low immunosuppressive doses of prednisone (1–2 mg/kg PO q24h for 2–7 days) are recommended when thrombocytopenia fails to resolve with antibiotic therapy, or when severe or life-threatening thrombocytopenia is present. Treatment of seropositive dogs without clinical or laboratory abnormalities is currently not recommended.

Prognosis

Acute ehrlichiosis and anaplasmosis have very good prognosis if antibiotic therapy is initiated immediately. Dogs with severe anemia, severe leukopenia, hypokalemia, prolonged activated partial thrombin time (APTT) and protein-losing nephropathy have a higher risk of mortality. Prognosis is guarded in cases of bone marrow hypoplasia or aplasia.

Public Health Implications

Several ehrlichial species have been detected in humans worldwide. Most human cases are presented with acute evolution of fever, malaise/fatigue, myalgia and arthralgia, and fully respond to doxycycline therapy. No direct transmission from dogs to humans has ever been documented, but dogs can serve as environmental sentinels, as well as natural reservoirs of some species. Blood from infected dogs should be handled with caution and needle sticks should be avoided.

Humans get infected by the bite of an infected tick so measures to prevent exposure to ectoparasites are fundamental to avoid disease in humans. *E. chaffeensis* is the etiologic agent of human monocytic ehrlichiosis, while *A. phagocytophilum* is the etiologic agent of human granulocytic ehrlichiosis, and *E. ewingii* causes human

monocytic ehrlichiosis. They are considered emerging diseases in the United States, with over 7400 human cases reported in the United States in 2017. Human ehrlichiosis is most frequently reported in the southeastern and south-central regions of the United States. Three states (Oklahoma, Missouri, and Arkansas) account for 30% of all reported cases. Conversely, human anaplasmosis is most frequently reported in the upper midwestern and northeastern US, with six states (New York, Connecticut, New Jersey, Rhode Island, Minnesota, and Wisconsin) accounting for 90% of all reported cases. Additionally, *E. chaffeensis* has been documented in Africa, Asia, the Middle East, Central and South America, while *A. phagocytophilum* has been documented in Europe, Asia, and South America. The fatality rate of human ehrlichiosis and anaplasmosis ranges from 0.2% to 3.7%. *Ehrlichia canis* infection in humans has been documented by molecular methods, but only in Venezuela (named Venezuelan human ehrlichiosis). In 2008, Panola Mountain Ehrlichia was first detected from a sick human in Georgia. In addition, infection with E. muris eauclairensis, formerly E. muris-like agent (EMLA), has been reported in 115 human cases in the upper Midwest. No deaths have been described.

Salmon Poisoning Disease

Pedro P. Vissotto de Paiva Diniz, DVM, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Neorickettsia helminthoeca, also known as salmon poisoning disease (SPD), belongs to the family *Anaplasmataceae* (Figure 94.1). The organism causes an acute febrile and often fatal disease in dogs. In contrast to other pathogens of this family, *N. helminthoeca* does not depend on blood-sucking ectoparasites for transmission. Dogs acquire the infection by ingesting fish infected with the SPD vector, the trematode *Nanophyetus salmincola*. In order to complete its life cycle, this trematode requires a snail (*Oxytrema silicula*), a fish (salmon, trout, lamprey, goldfish, stickback, among others), and a mammal or a bird (human, dog, coyote, raccoon, fox, river otter, bobcat, rat, heron, merganser, among others). Once the trematode matures and attaches to the gastrointestinal (GI) tract of the dog, *N. helminthoeca* is transmitted, initially multiplying in the epithelial cells and intestinal lymphoid tissue and then spreading systemically to visceral and somatic lymph nodes, where proliferation within macrophages occurs. After 8–12 days post infection, the organisms circulate in high numbers in the bloodstream, spreading to brain, liver, lungs, and spleen, causing systemic signs. Death of the dog occurs around 18 days post infection. The disease also occurs in other canids (foxes, coyotes) and bears, but it has not been described in domestic cats.

Epidemiology

Salmon poisoning disease is endemic in the Northwest Pacific of the United States (coastal regions of northern California, Oregon, and Washington) and southern British Columbia in Canada. A similar syndrome has been described in dogs from south Brazil.

Signalment

Dogs from any breed, age, and sex can be infected with *N. helminthoeca* and develop SPD. In one study, intact male dogs and Labrador retrievers were overrepresented, probably associated with the popularity of this breed.

History and Clinical Signs

History of consumption of raw or improperly cooked fish, obtained by fishing or purchased at the supermarket, is very common among sick dogs. However, dogs can also be infected by swimming in rivers and lakes where contaminated cercaria are present.

Inappetence and depression are usually the first findings, followed by progressive weight loss. Fever and peripheral lymphadenopathy are frequently seen during initial physical exams. Because of the multiplication of the pathogen in mesenteric and ileocecal lymph nodes, with consequent inflammation and tissue edema, vomiting, diarrhea, and dehydration are present in over 70% of the cases. Melena, hematemesis, and abdominal pain may occur in one-third of cases. The hemorrhagic gastroenteritis may be indistinguishable from canine parvoviral enteritis in some dogs. Less frequently, polyuria, polydipsia, serous to purulent ocular discharge, neurologic signs, tachypnea, peripheral edema, hyphema, splenomegaly, scleral injection, and epistaxis may be seen. If left untreated, the illness progresses quickly,

which can cause severe hypotension, mucosal pallor, cardiac arrhythmias, and death.

Diagnosis

Thrombocytopenia, anemia, lymphopenia, and neutrophilia with a left shift are the most consistent hematologic abnormalities. Hypocalcemia, hypoalbuminemia, hyponatremia, and hypokalemia are frequent abnormalities in the serum biochemistry. Urinalysis may reveal bilirubinuria and proteinuria. Coagulation testing may indicate evidence of disseminated intravascular coagulation.

Fecal microscopy for the detection of *N. salmincola* is a fast, cost-effective, and specific diagnostic procedure that can be performed in practice. Both the sedimentation and the zinc sulfate centrifugal flotation tests should be performed for better sensitivity. Light brown operculated eggs are present in fecal samples 5–8 days after ingestion of infected fish. However, eggs may not be detected in the feces of every infected dog. Fine needle aspirates from peripheral and mesenteric lymph nodes or spleen may reveal intracytoplasmic neorickettsial bodies within macrophages and histiocytic inflammation. However, the absence of morulae does not rule out the disease.

Currently, serologic assays for *N. helminthoeca* are not available from commercial diagnostic laboratories. However, due to acute presentation of the disease and the time needed for production of specific antibody, serology tests may not help the diagnosis. Polymerase chain reaction (PCR) assays are available for the specific detection of *N. helminthoeca* DNA from blood, aspirates of lymph nodes, spleen or liver, tissue samples, and feces. Because PCR assays can be specific and highly sensitive, they may aid the diagnosis of SPD if the laboratory has a short turnover time. Due to the high mortality of SPF, clinicians should not wait for laboratory confirmation before starting appropriate antibiotic therapy.

Therapy

Tetracyclines are the antibiotic class of choice, and clinical improvement is seen within 24–72 hours. If the patient can receive oral medication, doxycycline 5 mg/kg PO q12h for 1–2 weeks is recommended. Vomiting dogs should receive doxycycline (5 mg/kg IV q12h) or oxytetracycline (7–10 mg/kg IV q8h) until GI signs subside. Trematode infection should be treated with praziquantel (10–30 mg/kg PO q24h for 1–2 days). For complicated cases, hospitalization and intensive care may be required.

Prognosis

Survival is directly related to early diagnosis and introduction of appropriate antibiotic therapy and support care, achieving >85% success rate. Most untreated animals die within 6–10 days of the onset of clinical signs. In contrast to other pathogens in the family *Anaplasmataceae*, infection with *N. helminthoeca* generates protective immunity against the same strain; however, alternate strains can still cause illness.

Public Health Implications

No confirmed case of human infection has ever been reported, although humans can be naturally infected with the trematode *N. salmincola*, which may cause abdominal discomfort and GI signs.

Wolbachia pipientis Infection

Pedro P. Vissotto de Paiva Diniz, DVM, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Wolbachia pipientis is a gram-negative bacteria belonging to the family *Anaplasmataceae*. The organism is found in all developmental stages of *Dirofilaria immitis*, the filarial helminth that causes heartworm disease in dogs and cats. *Wolbachia* is an endosymbiont of *D. immitis* (Figure 95.1) and supports the nematode's survival, maturation, and reproduction. It is transmitted by the mosquito vector along with the nematode, and is released into the bloodstream in large numbers during parasite molts, microfilaremia, and upon death of the parasite.

It was originally believed that *Wolbachia* was not pathogenic to mammals. However, in recent years, studies have shown that components of their surface membranes stimulate production of inflammatory and vasoactive cytokines from neutrophils and endothelial cells, resulting in inflammatory lesions and pulmonary artery vasoconstriction. Experimental infection with *D. immitis* free of *Wolbachia* results in a reduced inflammatory response after anthelminthic therapy. Furthermore, antibiotic therapy that targets *Wolbachia* results in a significant reduction in inflammatory reactions when anthelmintic drugs are used to kill *D. immitis* in infected dogs. It has been shown that cats naturally infected with *D. immitis* and seropositive for *Wolbachia* surface proteins (WSP) have a greater acute inflammatory response at bronchial, vascular, and parenchymal levels when compared to healthy cats. WSP have also been detected in glomerular capillaries and may contribute to the glomerulonephropathy seen in heartworm disease. It is currently unclear if *Wolbachia* can cause disease in animals without the presence of *D. immitis*, because the bacterium has never been cultured *in vitro*.

Companion website: www.wiley.com/go/bruyette/clinical

Epidemiology

Wolbachia is ubiquitous in *D. immitis*, being present in 100% of the helminths. Therefore, the distribution of *Wolbachia* follows the presence of *D. immitis*, which is endemic in North, Central, and South America, the coastal regions of Africa, southern Europe, India, north, central-east and south China, Southeast Asia, and Australia. Updated prevalence maps for heartworm are available at the Canine Vector-Borne Disease World Forum website (www.cvbd.org/en/occurrence-maps/world-map/).

Signalment

Because of the life cycle of *D.* immitis, clinical signs are generally detected in animals older than 1 year. Dogs are more frequently affected than cats.

History and Clinical Signs

While *Wolbachia* may collaborate in the pathogenesis of *D. immitis* infection, clinical signs are indistinguishable from heartworm disease.

Diagnosis

Wolbachia DNA can be detected using polymerase chain reaction (PCR) on EDTA–anticoagulated blood samples. Interestingly, using PCR to detect *Wolbachia* has been proposed as a tool to detect early *D. immitis* infection. WSP can also be detected using serology, but because all *D. immitis* stages are infected with *Wolbachia*, the presence of the organism is assumed in a dog with a positive test for occult heartworm antigen. Interestingly, one study suggested that dogs infected with *D. immitis* and seropositive for WSP were more likely to have proteinuria than WSP-seronegative dogs.

Therapy

Because of the symbiotic relationship between *Wolbachia* and *D. immitis*, decreased bacterial load affects embryogenesis, maturation, and survival of heartworm. Treating dogs infected with *D. immitis* with an antibiotic that targets *Wolbachia* results in a decrease in microfilaremia, and when combined with ivermectin, fewer pathologic pulmonary lesions are observed compared to adulticide therapy alone (melarsomine). Therefore, the current therapeutic recommendation from the American Heartworm Society is to administer doxycycline at 10 mg/kg PO BID for four weeks in combination with ivermectin prior to adulticide therapy. Doxycycline eliminates >90% of the *Wolbachia* organisms from the nematode for at least three months.

Prognosis

Because all *D. immitis* are infected with *Wolbachia*, the prognosis of *Wolbachia* infection follows the prognosis for treatment of heartworm infections. Patients with no abnormal physical examination findings or radiographic changes have an excellent prognosis. Those with mild clinical signs and mild thoracic radiograph abnormalities have a good prognosis if adequately treated. Patients with moderate to severe disease, including caval syndrome, have a poor prognosis.

Public Health Implications

Dirofilaria immitis is able to infect humans, where it generally causes granulomatous lesions in lungs and subcutaneous tissue. Similar to what has been documented in dogs and cats, inflammatory reactions to these parasites in humans may be associated with their co-infecting *Wolbachia*, but it is unclear if *Wolbachia* can cause disease without the presence of filarial nematodes.

Bartonellosis

Pedro P. Vissotto de Paiva Diniz, DVM, PhD

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Bartonellosis is a complex syndrome caused by gram-negative bacteria of the genus *Bartonella*, which are transmitted by blood-sucking arthropods and have tropism for mammalian erythrocytes, endothelial cells, and bone marrow progenitor cells. There are at least 14 species, subspecies or species candidatus of *Bartonella* capable of infecting dogs, with at least six species capable of infecting cats (Table 96.1).

Most species of *Bartonella* reported from dogs and cats can also infect humans. Few *Bartonella* spp. are host specific, such as *B. bacilliformis* in people, with the vast majority of species having a preferred host but being capable of infecting other terrestrial mammals and even some marine animals. *Bartonella* spp. cause absent to minimal clinical manifestations in their preferred hosts. However, when a *Bartonella* sp. infects a nonadapted incidental host, clinical abnormalities are commonly seen. Severe illness is more frequently seen in immunosuppressed hosts or when co-infection with other vector-borne disease agents occurs. *Bartonella* causes chronic infections in dogs, cats, and humans, many of which are misdiagnosed and misreported.

Unlike some other vector-borne disease agents, species of *Bartonella* that infect dogs and cats do not form intracytoplasmic morulae. Therefore, they cannot be seen on blood smears or cytologic specimens without the use of special staining. Based on genetic analysis and presence of virulent factors, *Bartonella* spp. are divided into four lineages, with *B. bacilliformis* being the ancestor of all other species. The vast majority of *Bartonella* spp. capable of infecting dogs and cats (lineages 3 and 4) have virulence factors that mediate erythrocyte adhesion in a host-specific manner (Trw type IV secretion system [T4SS]) and transfer effector proteins into host cells (VirB T4SS) to promote chronic infection. Consequently, *Bartonella* can invade and multiply in erythrocytes and endothelial cells and evade the host's immune system. Other virulence factors also participate in the pathogenesis of the infection. These include adhesion molecules, regulatory systems and a factor capable of inhibiting proinflammatory responses mediated by Toll-like receptor IV. *Bartonella* spp. also infect dendritic cells, microglial cells, monocytes, macrophages, and CD34+ progenitor cells in the bone marrow. From these primary niches, *Bartonella* spp. are periodically shed into the bloodstream.

Like bacteria belonging to the family Anaplasmataceae, *Bartonella* spp. inhibit apoptosis of host cells. This allows infected cells to remain in circulation longer, and increases the likelihood of acquisition by a blood-sucking arthropod vector. The pathogen often establishes subclinical bacteremia that can last from weeks to several months. It is still unclear why some dogs or cats may develop clinical manifestations while other animals infected with the same *Bartonella* species are asymptomatic. Factors such as host immune response, species virulence, predisposing factors (congenital valvular disease), infection chronicity, and concomitant infections may play a role in disease manifestation.

Epidemiology

Bartonella spp. can be transmitted by an increasing number of arthropod vectors. In dogs and cats, cat fleas (*Ctenocephalides felis*) have been well defined as the major mode of transmission. However, epidemiologic evidence also supports the role of ticks in transmission to companion animals. Other suspected vectors include *Pulex* flea species, lice, and biting flies.

The prevalence of *Bartonella* infection differs significantly between dogs and cats, being generally low in dogs and high in cats. There are also differences in infecting species, with the most common species detected in dogs being *B. henselae* and *B. vinsonii* subsp. *berkhoffii*, and the most common species in cats being *B. henselae*,

B. washoensis	Squirrel	Dog, human, rat	Unknown
Candidatus *B. merieuxii*	Dogs and other canids	Unknown	Unknown

followed by *B. clarridgeiae* and *B. koehlerae*. It is believed that infection with these *Bartonella* species in dogs and cats has a worldwide distribution, but epidemiologic data are limited. *Bartonella* spp. are more frequently documented in temperate regions of the world, especially in warm and humid areas.

Bacteremia documented by polymerase chain reaction (PCR) ranges from 1% to 17% in sick or healthy dogs, depending upon the geographic location evaluated. In the United States, up to 10% of sick dogs with clinical manifestations compatible with tick-borne diseases are infected with *Bartonella* spp. Exposure to *Bartonella* spp. in dogs, documented by serology methods, is generally ≤10% of tested dogs, with higher prevalence detected in sick dogs and in some tropical countries. Conversely, bacteremia prevalence in cats ranges from 5% to 40%, with prevalence of ≥ 80% in some populations (feral cats, colonies with frequent flea infestation). Seroprevalence is also frequently high, with some colonies having over 90% of cats seroreactive to *Bartonella* species. Because of its ubiquitous presence in cats, establishing a causal relationship between *Bartonella* infection and illness is challenging in this species.

Signalment

Dogs from any breed, sex, and age can be infected but in one study, over 95% of dogs bacteremic for *Bartonella* spp. were older than 12 months. Outdoor access, residence in a rural environment, and tick exposure are considered risk factors for infection in dogs. Similarly, cats from any breed and sex can become infected with *Bartonella* spp. Young cats (≤1 year) are more likely to be bacteremic, while older cats are more likely to be seropositive. Stray or feral cats are more likely to be infected than pet cats.

History and Clinical Signs

Bartonella spp. have been associated with a wide range of diseases in dogs and cats (Box 96.1). Endocarditis is the most commonly reported manifestation in dogs (Figure 96.1).

In one study, *Bartonella* spp. infection was confirmed as the cause of culture-negative endocarditis in 20% of canine cases presented at a US tertiary hospital. Aortic valve involvement and congestive heart failure are more frequent in dogs with endocarditis from *Bartonella* spp. infection despite most of these patients having no fever.

Because of the cyclic shedding of the pathogen into the bloodstream, several other organs can be affected. Consequently, the most frequent signs in dogs are nonspecific, including fever (40% of cases), lethargy (40%), weight loss (34%), anorexia (32%), and lymphadenopathy (30%). In one study, weight loss was significantly associated with *Bartonella* when compared to other dogs suspected of vector-borne diseases. Although Bartonella spp. DNA has been detected in dogs and cats with diverse signs and syndromes (see Box 96.1), causal relationships have mainly been confirmed in dogs and cats with endocarditis, myocarditis, fever of unknown origin, and specifically in cats, fetal reabsorption and stillbirth. (see Box 96.1).

Box 96.1 Clinical signs and syndromes potentially associated with *Bartonella* infection in dogs and cats

Reported from dogs and cats
Endocarditis
Fever of unknown origin
Hepatitis
Lameness
Lymphadenopathy
Myocarditis
Skin lesions
Uveitis

Only reported from dogs
Bacillary angiomatosis
Cavitary effusion
Chronic erosive polyarthritis
Epistaxis
Granulomatous hepatitis
Hyperviscosity syndrome
Meningoradiculoneuritis
Peliosis hepatis
Polyarthritis
Systemic pyogranulomatous disease

Only reported from cats
Cholangitis
Diaphragmatic myositis
Gingivitis
Hepatitis
Interstitial nephritis
Lower urinary tract disease
Neurologic signs (nystagmus, focal motor seizures, behavior changes)
Osteomyelitis
Reproductive failure (fetal reabsorption, stillbirth)
Stomatitis

Chronic infection in dogs is associated with pyogranulomatous disease, which can be located in several sites, including lymph nodes, liver, and the central nervous system (Figure 96.2). Consequently, clinical signs vary depending upon the extent of damage caused in one or more organs. *Bartonella* infection in humans is associated with vasculoproliferative disease (bacillary angiomatosis and peliosis hepatis), which has been also described in dogs (Figure 96.3).

Despite the growing number of reports of sick dogs infected with *Bartonella* spp., two recent studies failed to reproduce clinical signs in dogs that were experimentally infected with *B. henselae*, *B. vinsonii* subsp. *berkhoffii*, and *B. rochalimae*. In addition, another study documented that 18% of asymptomatic dogs carry *Bartonella* DNA in the blood or lymph nodes. In one study, 8% of *Bartonella*-infected dogs were seropositive for at least one other vector-borne pathogen. Therefore, the pathogenesis of bartonellosis in dogs is still unclear, and clinicians should rule out other relevant differentials before considering this diagnosis.

In naturally infected cats, clinical signs are rarely reported. Similarly, experimental infection often causes mild and transient clinical signs such as fever, lethargy, and lymphadenopathy in less than a third of infected cats. However, more severe manifestations have been reported from experimental studies, including mild neurologic signs (nystagmus, intermittent tremors, and focal motor seizures), epaxial muscle pain, reproductive failure, and severe myocarditis (respiratory distress, cardiac murmurs, and arrhythmias). As seen in dogs, *Bartonella* infection in cats can be associated with granulomatous lesions in several organs. Osteomyelitis (Figure 96.4), uveitis, hepatitis, gingivitis, and stomatitis, among other syndromes (Table 96.2), have been associated with natural *Bartonella* spp. infection in cats.

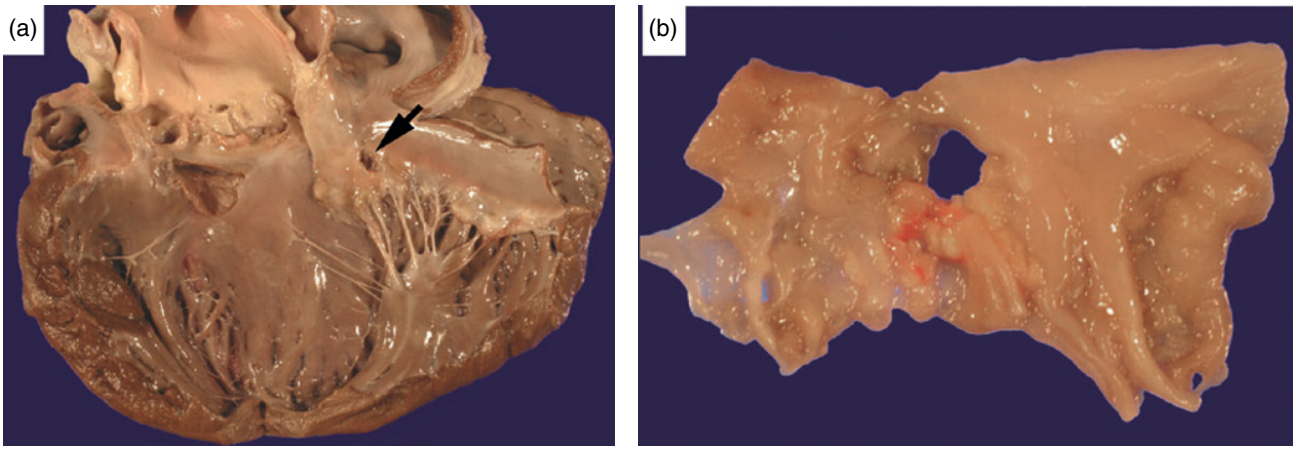

Figure 96.1 Endocarditis caused by *Bartonella vinsonii* subsp. *berkhoffii* in a dog. (a) Heart of a dog with mitral valve perforation (*black arrow*). Diagnosis

The most common laboratory abnormalities in dogs with endocarditis caused by *Bartonella* spp. are leukocytosis (78%), hypoalbuminemia (67%), thrombocytopenia (56%), and elevated liver enzymes (56%). Commonly, dogs infected with *Bartonella* spp. have laboratory abnormalities indistinguishable from other vector-borne diseases. Interestingly, although hyperglobulinemia occurs in dogs with bartonellosis, in one study, the presence of hypoglobulinemia was more frequent in *Bartonella*-infected dogs than dogs suspected of other vector-borne disease. In cats, laboratory abnormalities, when present, are limited to transient mild anemia, inflammatory leukogram, and/or eosinophilia in most cases. Hyperglobulinemia, particularly polyclonal gammopathy, is associated with *Bartonella* spp. in cats.

Because of the diversity of clinical presentations, the lack of an in-clinic rapid diagnostic test, and the limited diagnostic value of serology, diagnosis of canine or feline bartonellosis is a great challenge. For life-threatening illnesses such as endocarditis, myocarditis, and neurologic disease, clinicians should promptly investigate the presence of *Bartonella* spp. and presumptively treat for this infection, because specific antibiotic therapy is required for adequate management (see therapy section). The diagnostic approach of nonlife-threatening cases is based on ruling out other illnesses, including other vector-borne pathogens present in the area, submitting samples for microbiologic tests, banking samples, and evaluating response to antibiotic treatment, since laboratory test results may take weeks to months to become available. This author strongly recommend clinicians to bank samples at –20 °C (EDTA-blood, serum, plasma, tissues, etc.) collected prior to antibiotic therapy, which can be later tested by DNA and culture methods, because antibiotic therapy rapidly decreases the chances of detection of *Bartonella* spp. by these laboratory methods.

The microbiologic diagnosis of *Bartonella* infection is based on detection of *Bartonella* from whole blood,

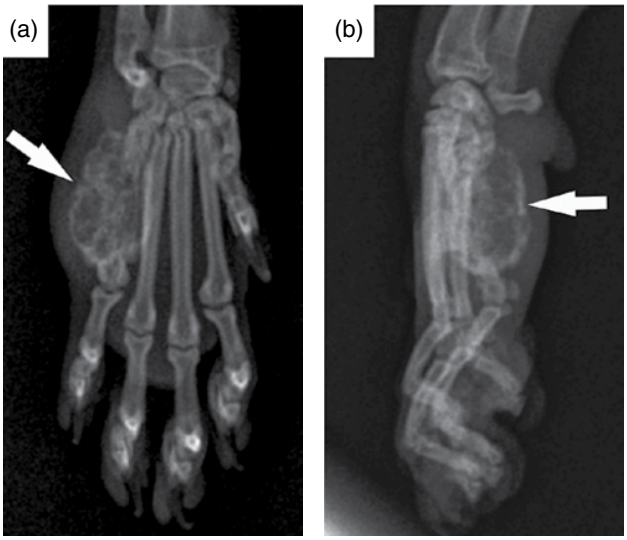

Figure 96.4 Radiograph images of the right forelimb of a cat with osteomyelitis due to *Bartonella vinsonii* subsp. *berkhoffii*. other body fluids (cavitary effusions, synovial fluid, cerebrospinal fluid, etc.) or tissue specimens by specific polymerase chain reaction (PCR) assays or isolation by blood culture. While isolation remains the microbiologic gold standard, standard blood culture has limited diagnostic use because *Bartonella* spp. are fastidious bacteria that take months to grow in standard culture media. In addition, *Bartonella* bacteremia levels in dogs are very low (see Table 96.2) when compared to cats. Therefore, sensitivity of standard blood culture is very low in dogs. Consequently, preenrichment techniques are required in dog samples to increase the number of organisms to detection levels of PCR assays. Currently, the most sensitive diagnostic technique combines preenrichment culture in an insect-based liquid media (BAPGM) coupled with isolation in blood-based solid media and specific PCR testing of samples pre- and postenrichment culture, with DNA sequencing to confirm the species of *Bartonella* involved (so-called "enrichment PCR" platform). This approach is capable of detecting more than twice the number of infected dogs than the direct PCR from clinical specimens. In addition, using this platform allows initial results to be obtained as early as two weeks, with a number of new *Bartonella* species being detected in dogs. This assay is available at one commercial laboratory (www.galaxydx.com).

The direct detection of *Bartonella* DNA by PCR from blood, other body fluids or tissues is also available through commercial laboratories. Depending upon the assay design, this test may have high specificity but sensitivity is always limited by the magnitude of bacteremia (see Table 96.2). Therefore, direct PCR is a good diagnostic tool for feline samples, but it has limited sensitivity for canine samples. In a recent study, direct PCR from clinical specimens only detected 44.7% of dogs infected with *Bartonella* spp. Therefore, negative PCR results should never be used to rule out *Bartonella* spp. infection in dogs. It is important that clinicians choose a diagnostic laboratory that offers PCR testing for the entire *Bartonella* genus, not only for selected species, because a growing number of new *Bartonella* species has been described in sick and healthy companion animals recently.

Serology assays are available through veterinary laboratories, but have limited diagnostic use in dogs and cats because presence of antibodies does not correlate with infection. Only one-third to one-half of infected dogs and cats have detectable antibodies against *Bartonella* spp. Therefore, negative serologic testing does not rule out infection with *Bartonella* spp. Also, seropositivity does not indicate infection because only one-third of seropositive animals are bacteremic. When seropositive dogs are detected, serology may be helpful to monitor therapy progression, because many dogs that experience resolution of disease manifestation have decrease in antibody titers within 3–6 months following treatment. Serology has better diagnostic use in *Bartonella* endocarditis, which is usually associated with high antibody titers. There is some level of cross-reactivity among *Bartonella* spp. but multiple species-specific assays should be performed, including specific assays for *B. henselae*, *B. vinsonii* subsp. *berkhoffii*, *B. koehlerae*, and *B. clarridgeiae* (which cross-reacts with *B. rochalimae*).

Therapy

The optimal treatment protocol for *Bartonella* spp. infection in dogs and cats is unknown. Similar to other vector-borne infections, elimination of *Bartonella* may

not be achievable in all cases despite long-term use of antibiotics. Clinicians should focus on resolution of clinical abnormalities and monitor therapeutic success with serologic testing, PCR, and culture. Antibiotic therapy is recommended for two weeks past clinical resolution, which may require more than three months in some cases.

In dogs, while single therapy with doxycycline or azithromycin has been previously used with moderate success, rapid development of resistance has been documented. The current recommendation for clinically stable dogs is doxycycline at 5 mg/kg PO q12h for seven days, adding a second antibiotic such as a fluoroquinolone (enrofloxacin at 5 mg/kg PO q12h for 4–6 weeks) or rifampin (5 mg/kg PO p24h for 4–6 weeks). This stepwise approach is recommended in order to decrease the risk of Jarisch–Herxheimer reaction, which is caused by rapid death of bacteria and release of endotoxins with consequent increase of inflammatory cytokines in the bloodstream. Dogs that experience this reaction show lethargy, vomiting, and signs resembling bacterial sepsis that can last for a few days, and can be misinterpreted as an adverse drug event. Therefore, clinicians should not interrupt antibiotic therapy if a Jarisch–Herxheimer reaction occurs. Empirically, corticosteroids at antiinflammatory doses generally alleviate these signs.

Life-threatening diseases associated with *Bartonella* spp. infection in dogs (such as endocarditis, myocarditis, meningoencephalitis, etc.) should be treated with a combination of a fluoroquinolone or doxycycline with an aminoglycoside (amikacin at 15–20 mg/kg IV/IM/SC q24h), with constant monitoring of renal function. When discharged, these patients should receive doxycycline and enrofloxacin as described above.

In cats, administration of antibiotics generally limits bacteremia but does not eradicate the infection in all cats. The current recommendation from the American Association of Feline Practitioners (AAFP) is based on doxycycline at 5 mg/kg PO q12h or 10 mg/kg PO q24h for a minimum of four weeks. If a poor clinical response is observed in the first seven days of therapy, enrofloxacin at 5 mg/kg PO q24h or pradofloxacin at 3–5 mg/kg PO q24h should be used. It is currently unknown if these fluoroquinolones should be used in addition to doxycycline or as monotherapy in cats, as is recommended in dogs. Pradofloxacin has been shown *in vitro* to have superior activity against feline and human *Bartonella* isolates than enrofloxacin. Therefore, it is currently recommended for bartonellosis in cats. However, no information is currently available about the efficacy of pradofloxacin for canine bartonellosis.

Prognosis

Prognosis of bartonellosis in dogs and cats varies with the organ or system affected. For nonlife-threatening bartonellosis, anecdotal reports indicate moderate to good prognosis when adequate antibiotic therapy is instituted. *Bartonella* endocarditis has guarded prognosis, with dogs having shorter survival time than those with other causes of endocarditis.

Public Health Implications

Human bartonellosis ranges from benign self-limiting manifestation of cat scratch disease (CSD) to devastating hemolytic anemia seen in Oroya fever. The most common manifestation of human bartonellosis is cat scratch disease, followed by bacillary angiomatosis in immunocompromised patients and blood culture-negative endocarditis. Recent reports have associated *Bartonella* spp. infection with chronic neurologic disease, rheumatic signs, and small vessel syndrome. Direct transmission from infected dogs has not been documented, but they can be a reservoir for vector-mediated transmission to humans. Conversely, since *Bartonella* spp. can survive in flea feces for several days, cats can transmit *Bartonella* spp. to humans through scratching when cat claws are contaminated with infected flea feces.

The Centers for Disease Control and Prevention and the AAFP currently recommend the following steps to avoid human infection.

- Flea control should be initiated and maintained year round.
- If a family member is immunocompromised and a new cat is to be acquired, adopt a healthy cat >1 year of age and free from fleas.
- Immunocompromised individuals should avoid contact with cats of unknown health status.
- Be cautious about adding stray cats or cats from shelters to the household without controlling fleas.
- Cat claws should be trimmed regularly, but declawing of cats is generally not required.
- Scratches and bites should be avoided (including rough play with cats).
- Cat-associated wounds should be washed promptly and thoroughly with soap and water and medical advice sought.
- While *Bartonella* spp. have not been shown to be transmitted by saliva, cats should not be allowed to lick open human wounds.
- Keep cats indoors to minimize hunting and exposure to fleas and other possible vectors.

Hemotropic *Mycoplasma*

Séverine Tasker, BSc, BVSc (Hons), PhD, DSAM, DACVIM-CA, PGCertHE, MRCVS

Bristol Veterinary School, University of Bristol, Bristol, UK

Etiology/Pathophysiology

The hemotropic mycoplasmas (hemoplasmas) are unculturable bacteria that parasitize red blood cells and can induce hemolysis, causing anemia. Commonly recognized feline and canine hemoplasma species are shown in Table 97.1. *Mycoplasma haemofelis* is the most pathogenic of the feline and canine species described, and can cause significant hemolytic disease in immunocompetent cats.

In cats, *Mycoplasma haemofelis* appears to be most pathogenic during acute infection, whereas chronic infection is not usually associated with significant anemia. *Candidatus* Mycoplasma haemominutum and *Candidatus* Mycoplasma turicensis infections are not usually associated with clinical signs, unless concurrent disease or immunusuppression exist in the host cat, such as feline leukemia virus (FeLV) infection, neoplasia. However, anemia due to these agents has occasionally been reported in immunocompetent cats. *Ca.* M. haemominutum has also been associated with the development of myeloproliferative diseases in cats with concurrent FeLV infection.

In dogs, *M. haemocanis* and *Ca.* M. haematoparvum infections are not often associated with hemolytic anemia unless infection occurs in a splenectomized host (particularly for *M. haemocanis*) or in association with concurrent disease or immunosuppression.

Asymptomatic carrier status can exist with all of the hemoplasma species, and so the detection of hemoplasma infection is not always indicative of clinical disease associated with that species.

Epidemiology

The prevalence of the commonly recognized feline and canine hemoplasma species is shown in Table 97.1; these vary considerably due to the differing populations of cats and dogs sampled in studies used to generate these data. Retroviral-infected cats are also usually found to be at increased risk in studies, although results are variable for FeLV and feline immunodeficiency virus (FIV). A recent study in the United States reported a low prevalence of canine hemoplasma infection in dogs.

The prevalence of feline hemoplasma infections is increased in cats that are male, non-pedigree and with access outdoors.

The natural route of transmission of hemoplasma infection in the field has not yet been determined but the clustered geographic distribution of infection in some studies supports the role of an arthropod vector in hemoplasma transmission. The cat flea, *Ctenocephalides felis*, has been implicated in feline hemoplasma transmission, but this has not been definitively proven in experimental studies, and transmission of *M. haemocanis* by the brown dog tick, *Rhipicephalus sanguineus*, has been suggested.

Studies have successfully transmitted feline hemoplasma infection via subcutaneous inoculation of blood containing low numbers of organisms, suggesting that transmission by aggressive interaction (e.g., fights) in the field is possible. Blood transfusion is another potential route of transmission, and blood donors should be screened for hemoplasma infection. Vertical transmission may also occur.

Signalment

Older cats are more likely to be infected with *Ca.* M. haemominutum whilst younger cats are more likely to show disease due to *M. haemofelis* infection. Canine hemoplasma infections appear to be more common in kennel-housed dogs, younger dogs, and dogs with mange.

Table 97.1 Hemoplasma species, their prevalence and pathogenicity

Hemoplasma	Prevalence	Pathogenicity summary
Mycoplasma haemofelis	0.4–46.6%	Can result in hemolytic anemia in immunocompetent cats
Candidatus Mycoplasma haemominutum	8.1–46.7%	Can result in a drop in erythrocyte parameters but not usually severe enough to cause anemia unless cat has concurrent disease or is immunocompromised, e.g., retrovirus infection
Candidatus Mycoplasma turicensis	0.4–26%	
Mycoplasma haemocanis	0–45%	Hemolytic anemia primarily seen in splenectomized dogs, and occasionally in immunocompromised dogs (e.g., with neoplasia)
Candidatus Mycoplasma haematoparvum	0–33%	

History and Clinical Signs

When anemia results from hemoplasma infection, historical features can include lethargy, inappetence, pallor, weakness, pica, and weight loss. In immunocompromised hosts, evidence of concurrent disease is present. Dogs may have a history of splenectomy.

Clinical signs can include pyrexia, weakness, pallor, tachypnea, tachycardia (sometimes with a hemic murmur), bounding pulses, dehydration, cardiac murmurs, sometimes splenomegaly (in nonsplenectomized hosts) and, occasionally, jaundice.

Diagnosis

Acute hemoplasma infections are typically associated with a regenerative anemia with reticulocytosis, macrocytosis, polychromasia, and anisocytosis. However, the anemia may be nonregenerative if the animal is sampled early in the disease process (i.e., during the preregenerative phase) or if concurrent disease is present that inhibits regeneration (e.g., concurrent FeLV infection, neoplasia).

Acute *M. haemofelis* and *M. haemocanis* infections can be associated with the presence of persistent saline autoagglutination or positive Coombs' testing, indicating the presence of erythrocyte-bound antibodies. Autoagglutination may be noted on blood smear examination but the contribution of such antibodies to the development of hemoplasma-associated anemia has not been confirmed.

Serum biochemistry may reveal elevated liver parameters (ALT and AST) due to anemia-associated hypoxia, mild to moderate hyperbilirubinemia due to hemolysis, and prerenal azotemia due to dehydration. Hyperproteinemia may occur. Hemoplasmas are currently unculturable *in vitro*.

Cytologic detection of hemoplasma organisms on blood smears is occasionally possible but this is known to be very insensitive and shows poor specificity, and cytology cannot differentiate between hemoplasma species. When organisms are visible, they appear as small basophilic organisms on the surface of erythrocytes with Romanowsky-based stains (e.g., Wrights', Diff-Quik™). *M. haemocanis* has a tendency to form chains on the surface of erythrocytes, and so may be easier to differentiate from stain artifacts and other erythrocyte inclusions with which hemoplasmas are confused.

Polymerase chain reaction (PCR) assays are usually sensitive and specific, if designed appropriately, for the diagnosis of hemoplasma infection, and species-specific assays exist for both dogs and cats. EDTA-anticoagulated blood is usually the appropriate sample type for PCR. Real-time PCR (qPCR) assays are now increasingly used, and these allow for quantification of hemoplasma organism numbers (Figure 97.1), as well as detection of infection. Organism numbers in feline hemoplasma infections are often high during acute infection but it should be noted that large fluctuations in blood organism numbers can occur over time in some *M. haemofelis*-infected cats, meaning that qPCR results may not be correlated with anemia.

In addition, PCR results may be negative in an infected cat if a sample is obtained when the number of circulating organisms is very low, below the limit of detection of the PCR assay. Furthermore, the existence of asymptomatic carrier cats for all hemoplasma species means that the PCR results should always be interpreted in conjunction with the patient's clinical signs, the degree and nature of the anemia present, and any concurrent signs or diseases that could be contributing to the clinical presentation.

Therapy

Therapy for hemoplasmosis is required if infection is diagnosed in an animal with clinical signs and clinicopathologic changes consistent with hemoplasma infection. However, no treatment regime has yet been described that consistently eliminates hemoplasma infection with all species and the aim of most treatment protocols is resolution of clinical signs associated with infection.

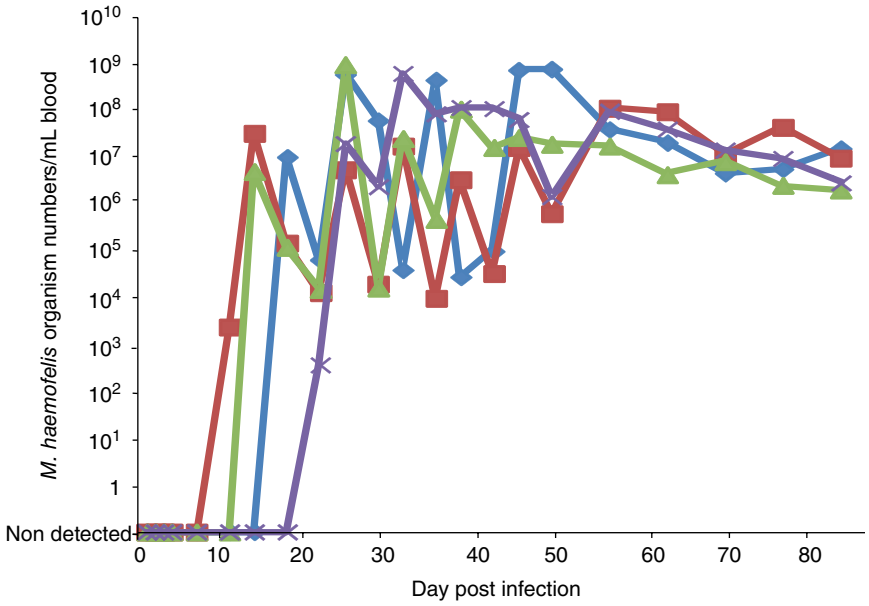

Figure 97.1 Hemoplasma organism numbers in the blood of four cats infected with 10^3 *M. haemofelis* organisms by subcutaneous inoculation on day 0 post infection. Cats infected with *M. haemofelis* often show marked fluctuations in blood organism numbers, especially during early infection. Such fluctuations, in the absence of treatment, should be considered when interpreting quantitative PCR results in *M. haemofelis*-infected cats. Longer term fluctuations in organism numbers in the blood are seen in some *M. haemofelis*-infected cats. In contrast, cats infected with *Ca.* M. haemomintum and *Ca.* M. turicensis do not show these blood organism number fluctuations at any stage of infection.

A number of antibiotics, notably tetracyclines (primarily doxycycline at 10 mg/kg once daily PO or 5 mg/kg twice daily PO; as some formulations have been associated with esophagitis following incomplete swallowing, all doses should be followed with food or water) and fluoroquinolones (e.g., marbofloxacin 2–5.5 mg/kg once daily PO, pradofloxacin 5 mg/kg once daily PO), have been shown to be effective in reducing feline hemoplasma (especially *M. haemofelis*) organism numbers and cause resolution of clinical signs. Courses of two weeks are usually recommended although some have suggested that longer treatment courses (up to six weeks) increase the likelihood of eliminating infection. Pradofloxacin may be more effective at clearing *M. haemofelis* than doxycycline. One recent study has suggested that clearance of *M. haemofelis* infection may be possible using 28 days of doxycycline followed by marbofloxacin for 14 days if the cats remained PCR positive.

Only limited information is available regarding the response of canine hemoplasma infections to antibiotic therapy. Tetracycline or fluoroquinolone treatments have both been associated with clinical improvement, but infection has sometimes persisted.

Ideally, response to antibiotic treatment in both cats and dogs should be monitored by qPCR to ensure organism numbers are decreasing with therapy but clinical improvement usually occurs within 2–3 days of effective treatment.

Affected dogs and cats may also require aggressive supportive treatment with crystalloids or blood products (blood transfusions).

Corticosteroids have been recommended as adjunct treatment for hemoplasmosis, to treat the immune-mediated component of anemia. However, the vast majority of hemoplasma-infected cats, including those that have erythrocyte-bound antibodies confirmed, respond to antibiotic treatment and supportive care alone without the need for corticosteroids. Indeed, immunosuppressive doses of corticosteroids have been used experimentally to exacerbate hemoplasma infection, so their routine use is not advised.

In view of the potential for vector transmission of hemoplasmas, control for fleas and ticks should also be instigated.

Prognosis

With prompt and appropriate therapy, the prognosis for feline and canine hemoplasmosis is good. However, the disease can be fatal if untreated, due to severe hemolytic anemia, collapse, and death.

Public Health Implications

Polymerase chain reaction methods have recently documented human hemoplasma infections and some have documented infection with veterinary hemoplasma species such as *Ca.* M. haematoparvum. In view of this, blood from potentially infected animals should be handled with care and vector control initiated. Future studies should evaluate the zoonotic potential and transmission of these emerging pathogens.

Nonhemotropic *Mycoplasma*, *Ureaplasma*, and L-Form Bacteria

Joachim Spergser, Dipl.Tzt., Dr. Med. Vet., DECVM

Institute of Microbiology, University of Veterinary Medicine, Vienna, Austria

Etiology

Mycoplasmas (general name for members of the class *Mollicutes*) are unusual bacteria representing the smallest and simplest self-replicating organisms. They are distinguished from ordinary bacteria by their complete lack of a cell, resulting in cellular pleomorphism and resistance to cell wall-inhibiting antimicrobials. The lack of a protective cell wall also makes mycoplasmas fragile outside their hosts. Due to their extremely small genome size, mycoplasmas possess limited anabolic and metabolic capabilities and maintain intimate parasitic lifestyles, depending on nutrients from their host cell environment. To keep this parasitic mode of life, mycoplasmas have developed sophisticated mechanisms to colonize their hosts and resist host defense. A highly dynamic, versatile membrane surface architecture appears to be crucial for their survival, and for establishing and maintaining a subtle relationship with their host. Certain mycoplasmas are capable of entry into nonphagocytic cells, providing them with the ability to resist host defenses or antibiotic treatment, which may contribute to chronic infection.

Nonhemotropic mycoplasmas usually exhibit a rather strict host and tissue specificity with predilection for mucous membranes of the respiratory and urogenital tract. Pathogenic mycoplasmas are not considered highly virulent and mostly cause mild, slowly progressive, chronic infections. Host cell damage and the resulting clinical manifestations appear to be mainly due to host immune reactions and inflammatory responses rather than to direct toxic effects of mycoplasma components.

Nonhemotropic mycoplasmas that have been isolated from cats and dogs include species within the genera *Mycoplasma*, *Ureaplasma*, and *Acholeplasma*. Some canine and feline mycoplasmas are considered mere commensals, but certain members are proven pathogens or play an etiologic role as opportunists in miscellaneous conditions (Table. 98.1).

Little is known about the virulence factors of canine and feline mycoplasmas so far. However, the availability of the complete genome of two canine *Mycoplasma* species (*M. canis, M. cynos*) will certainly increase understanding of their pathogenic properties in the future. Recently, a hemagglutinin that is probably involved in cytadherence to host cells has been identified and characterized in *M. cynos*. Furthermore, a secreted sialidase that presumably promotes colonization and tissue invasion has been proposed as a candidate virulence factor of *M. canis* and *M. cynos*. Its expression in canine mycoplasmas varies significantly among strains which may contribute to the variable spectrum of clinical manifestations and disease outcomes. Intracellular localization of *M. canis* has also been demonstrated which may contribute to chronicity of infection or perturbation of cell function and integrity.

L-forms are cell wall-deficient morphotypes of normal bacteria that resemble mycoplasmas. L-forms can be generated from many bacterial species by treatment with lysozyme or by exposure to beta-lactam antibiotics or host immune responses. Knowledge of the clinical significance of L-form bacteria is fragmentary and their role as a cause of disease is still under debate.

Epidemiology

Mycoplasmas are common inhabitants of the oropharynx and upper respiratory tract of dogs and cats wherein they are thought to be part of the normal bacterial flora. Mycoplasmas have been isolated from lungs of dogs and cats with pneumonia, are shown to be absent in the lungs

Table 98.1 Nonhemotropic mycoplasmas frequently isolated from domestic dogs and cats

Species	Primary host	Primary colonization site	Diseases associated with or caused by mycoplasmas isolated from domestic dogs and cats
Mycoplasma cynos	Domestic dogs (canine mycoplasmas)	ONP, RT, UGT	CIRD, tracheobronchitis, bronchopneumonia, pyothorax
Mycoplasma canis		ONP, RT, UGT	Urethritis, epididymitis, orchitis in male dogs; endometritis, metritis, adverse pregnancy outcomes in female dogs
Mycoplasma edwardii		ONP, RT, UGT	Polyarthritis[a], meningoencephalitis[a]
Mycoplasma molare		ONP, UGT	ND
Mycoplasma maculosum		ONP, RT, UGT	ND
Mycoplasma opalescens		ONP, UGT	ND
Mycoplasma mucosicanis		ONP, RT, UGT	ND
Mycoplasma spumans		ONP, RT, UGT	Polyarthritis[a]
Ureaplasma canigenitalium		UGT	Infertility in male dogs[a]
Mycoplasma felis	Domestic cats (feline mycoplasmas)	C, ONP, RT	Conjunctivitis, keratitis[a], URTD, bronchopneumonia, pyothorax, polyarthritis, meningoencephalomyelitis[a]
Mycoplasma gateae		ONP, RT	Polyarthritis, bronchopneumonia[a]
Mycoplasma feliminutum		ONP, RT	ND
Ureaplasma felinum		ONP	ND
Ureaplasma cati		ONP	ND
Mycoplasma arginini	Various (ubiquitous mycoplasmas)	ONP, RT, UGT	ND
Acholeplasma laidlawii		UGT	ND

C, conjunctiva; ND, not defined, likely to be a commensal; ONP, oro- and nasopharynx; RT, respiratory tract; UGT urogenital tract.
[a] Single reports.

of healthy cats but can be isolated from the lungs of healthy dogs. Younger, group-living animals with syndemic viral/bacterial infections or underlying diseases that impair defense mechanisms are more likely to be infected by mycoplasmas. They are efficiently transmitted through oronasal contact with aerosolized respiratory secretions or contact with freshly contaminated fomites.

Mycoplasmas are among the recognized normal flora of the vagina and prepuce of dogs but are rarely isolated from the feline urogenital tract. They have been associated with canine urogenital diseases in subpopulations of colonized individuals. Reasons and risk factors for disease development and progression are unknown. Canine genital mycoplasmas may be transmitted via sexual intercourse, artificial insemination or orogenital contact. Mycoplasmas may also be transmitted vertically to fetus or offspring by ascending intrauterine infection, hematogenously acquired placental infection, or during passage through the birth canal.

Signalment

Younger, immunosuppressed dogs and cats are more likely to be affected by mycoplasmas and develop more severe diseases.

History and Clinical Signs

Ocular *Mycoplasma* Infections in Cats

Mycoplasma felis is considered a major pathogen in conjunctivitis of cats. The prevalence rate of the agent in ocular swabs taken from cats displaying conjunctivitis was 9.6% or 25% which is significantly higher than the respective rates of 2.3% or 0% present in clinically healthy cats. In contrast, *M. arginini* and *M. gateae* more often exist on the conjunctival surface of healthy cats. Experimental infections of *M. felis* have produced conjunctivitis only in young cats or when a large inoculation

dose was used. Natural *Mycoplasma* conjunctivitis predominantly occurs when infected cats are housed in groups or in kittens soon after weaning. The clinical signs observed may vary in severity and have been described as blepharospasm, conjunctival hyperemia, chemosis, and serous discharge followed by mucoid to sticky exudate. The cornea is usually not involved; however, *M. felis* and *M. gateae* have been occasionally associated with ulcerative keratitis and/or keratomalacia.

Respiratory *Mycoplasma* Infections in Cats

Mycoplasmas have been associated with chronic and acute feline upper respiratory tract disease (URTD) by epidemiologic evaluation, but available data are more inconclusive hypotheses than definite proofs of causality. Studies have also suggested that approximately 22% of cats with lower airway disease may have a concurrent *Mycoplasma* infection.

Experimental challenge with *M. felis* induced pneumonia in kittens, emphasizing its role as a primary pathogen in the lower respiratory tract. Naturally occurring infections with *M. felis* have been increasingly reported in the feline host associated with suppurative bronchitis and/or pneumonia. Radiographic or computed tomography (CT) findings may include diffuse interstitial pulmonary disease similar to that observed in adult human patients with *M. pneumoniae* pneumonia. Cats with concurrent pleural effusion show minimal signs of dyspnea and a nonodorous fluid is expected with uncomplicated *Mycoplasma* pyothorax.

Respiratory *Mycoplasma* Infections in Dogs

Mycoplasmas have been isolated from 78% of tracheobronchial lavages of younger dogs with pulmonary disease but may also be present in the lower respiratory tract of healthy individuals (20–25%). Consequently, the role of certain canine *Mycoplasma* species as pathogens in canine pulmonary disease is still a subject of controversy. Experimental infection with *M. canis*, *M. gateae*, and *M. spumans* failed to produce pulmonary disease. However, *M. cynos* has been consistently associated with canine respiratory diseases, including tracheobronchitis and bronchopneumonia, conditions that have been reproduced experimentally. A more recent study noted a correlation of *M. cynos* with canine infectious respiratory disease (CIRD) in younger dogs (<1 year). Dogs acquired infection during the first two weeks after being kenneled and seroconversion to *M. cynos* was correlated with the development of clinically respiratory disease. Further evidence of the primary pathogenic role of *M. cynos* was its isolation as sole pathogen from a litter of pups with severe respiratory disease. Clinical findings were fever, productive cough, and leukocytosis with a left shift. Radiographs featured alveolar and bronchointerstitial pulmonary densities and mild pleural effusion. Infection was fatal for some pups and necropsy findings were mucopurulent airway exudates and hemorrhagic fibrinous necrotizing bronchopneumonia. *M. cynos* was abundantly demonstrated at neutrophilic inflammatory sites using immunohistochemistry.

Urogenital *Mycoplasma* Infections in Dogs

Mycoplasmas are commonly present in the lower urogenital tract of dogs. They have occasionally been associated with canine reproductive diseases including poor conception rates, early embryonic death, fetal resorption, abortion, weak pups, and neonatal death. *M. canis* and *U. canigenitalium* are the species most consistently associated with canine genital mycoplasmosis. *Mycooplasma canis* has been isolated from dogs with urogenital disease and infertility, despite prolonged antibiotic therapy. It has also been cultured from the prostate, epididymis, and chronically inflamed bladder wall. Experimental infection with *Mycoplasma canis* produced urethritis, prostatitis or epididymitis in males and endometritis or metritis in females. In a single study, *U. canigenitalium* was associated with infertility in male dogs. Nevertheless, as conclusive evidence is lacking, further studies are required to establish whether *M. canis* or *U. canigenitalium* is linked to genital tract infections and infertility.

Arthritis in Cats and Dogs Caused by Mycoplasmas

Only a few cases of naturally occurring mycoplasma mono- and polyarthritis in cats (*M. felis*, *M. gateae*) and dogs (*M. edwardii*, *M. spumans*) have been documented so far. In most cases, predisposing factors such as immunosuppressive therapy, acquired immunodeficiency or traumatic bites have been identified. The pathogenic potential of *M. gateae* in cats, however, has been substantiated by intravenous injection resulting in polyarthritis.

Mycoplasma Central Nervous System Infections in Cats and Dogs

Mycoplasma felis has been isolated from brain and spinal cord sections of a young cat with meningoencephalomyelitis. A similar infection has been documented in a young dog with suppurative meningoencephalitis caused by *M. edwardii*, and a penetrating wound close to the skull was suspected as the source of infection.

Abscesses and Cellulitis in Cats Caused by Mycoplasmas and L-Form Bacteria

Abscess formations caused by mycoplasmas presumably introduced by bite wounds have been reported in cats. Nonodorous, nondegenerate, neutrophilic, gram stain-negative exudates are characteristic for *Mycoplasma* abscesses. L-form bacteria have been isolated from cats with persistently draining cellulitis and synovitis. Usual sources of infection with L-form bacteria have been penetrating bite wounds or surgical incisions. Spread of infection can occur manifested by polyarthritis or distant abscess formation.

Diagnosis

The fragile nature of mycoplasmas mandates careful attention to specimen collection, inoculation of transport medium, and proper transportation and shipping conditions. Laboratory diagnosis of canine and feline mycoplasmas is commonly achieved by cultivation (Figure 98.1) which also allows quantification or by polymerase chain reaction (PCR) if a particular *Mycoplasma* species is sought.

Cultivation is, however, expensive and requires specialized media and expertise not commonly available at all laboratories. Culture results are usually available within 2–4 days for most canine and feline mycoplasmas, but definitive species identification requires additional tests which traditionally include serologic methods depending on specific antisera to each individual *Mycoplasma* species. Such specific antisera are not readily available in most diagnostic laboratories and multiple cross-reactions may occur.

To circumvent the limitations of serologic differentiation methods, more accurate and rapid identification schemes employing PCR-restriction fragment length polymorphism (RFLP) of the 16S-23S intergenic region have been developed. Alternatively, PCR-denaturing gradient gel electrophoresis (DGGE) may be applied, enabling primary detection and differentiation of mycoplasmas in clinical material even if mixed infections occur. Recently, matrix-assisted laser desorption/ionization time of flight (MALDI TOF) mass spectrometry has become an excellent method for the identification and differentiation of animal mycoplasmas, representing a promising alternative to the currently practiced cumbersome diagnostics. No serologic assays for the detection of immune responses to canine or feline mycoplasmas have been standardized and made commercially available so far.

Therapy

In most diagnostic laboratories, susceptibility testing of mycoplasmas to antimicrobials is not available. As is known, mycoplasmas are inherently resistant to beta-lactam antibiotics. Treatment with nonbeta-lactams such as macrolides, tetracycline, chloramphenicol, clindamycin or fluoroquinolones should be effective against most canine and feline mycoplasmas providing that animals are treated for an extended period. For example, in cats with URTD, *M. felis* was eliminated with either pradofloxacin or doxycycline treatment for 42 days. No vaccines are currently available to prevent *Mycoplasma* infections in dogs and cats although they are successfully used in other animals.

Public Health Implications

Due to their rather strict host specificity, mycoplasmas of the dog and cat are not considered a major public health risk. Zoonotic infections have only been occasionally documented, predominantly involving immunosuppressed individuals.

Spotted Fever and Typhus Group Rickettsia

Linda Kidd, DVM, PhD, DACVIM

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Spotted Fever Group (SFG) and Typhus Group (TG) *Rickettsia* are alpha-proteobacteria belonging to the genus *Rickettsia*, family Rickettsiaceae, order Rickettsialis. There are over 20 species of SFG *Rickettsia*, whereas the TG *Rickettsia* include only *R. typhi* and *R. prowazekii*. The division of *Rickettsia* into groups is based on phenotypic and, more recently, genotypic characteristics.

One of the clinically important phenotypic characteristics that differentiates the SFG and TG *Rickettsia* is their vectors. Members of the SFG *Rickettsia* are primarily transmitted by ticks whereas *R. typhi* is transmitted by fleas, and *R. prowazekii* is transmitted by lice and other ectoarasites. Interestingly, *R. felis,* a *Rickettsia* that has characteristics of both TG and SFG, is transmitted by both fleas and ticks.

Spotted Fever Group *Rickettsia* have both pathogenic and nonpathogenic species. The two most pathogenic and well-studied members of the SFG *Rickettsia* are *R. rickettsii*, the cause of Rocky Mountain and Brazilian spotted fever, and *R. conorii*, the cause of Mediterranean spotted fever (MSF) in people. Infections with many other species of SFG *Rickettsia* have been described in people with spotted fever-type illness in recent years. Some of these new rickettsioses are caused by newly discovered species while others have been associated with species previously thought to be nonpathogenic endosymbionts of ticks. Discovery of the pathogenicity of atypical species has been greatly facilitated by advances in molecular biology that allow easy and accurate differentiation of species.

Illness caused by *R. rickettsii* is very well characterized in dogs and is quite similar to Rocky Mountain spotted fever (RMSF) in people. Recently, a spotted fever-type illness associated with *R. conorii* infection was also described in dogs. Many recent studies have shown that exposure to and infection with additional species of SFG *Rickettsia* occur in dogs. The ability for these additional species to cause illness has not been well characterized to date. However, it is important for practitioners to be aware of their potential as disease-causing agents.

The ability of SFG *Rickettsia* to cause disease in cats is not known. Antibodies to several SFG *Rickettsia* have been detected in cats and recently, DNA from some SFG *Rickettsia* species most closely resembling *R. massiliae* Bar29 and *R. conorii* has been amplified from naturally infected cats. Although antibodies to *R. rickettsii* are detected in cats in endemic areas, active infection and associated clinical signs have not been documented. Thus, whether RMSF occurs in cats is not known.

Rickettsia felis, a SFG *Rickettsia* transmitted by the cat flea (*Ctenocephalides felis*), is an important cause of illness in people. *Rickettsia felis* has been amplified from the blood of dogs and experimentally infected cats. Although the organism has been detected in the gingiva of naturally infected cats, bacteremia in naturally infected cats has not been documented. No association between infection or seropositivity and illness in cats or dogs has been documented.

The ability of TG *Rickettsia* to cause disease in cats and dogs is also not known. However, *R. typhi*, the cause of murine typhus in people, infects cat fleas and has been detected in the blood of cats and dogs. Cats and dogs in domestic areas commonly have antibodies to *R. typhi*. Whether the organism causes disease in dogs or cats remains to be determined.

Because it is well characterized and the most common cause of illness caused by *Rickettsia* species in small animals, canine RMSF caused by *R. rickettsii* is the focus of the remainder of this chapter. However, practitioners should keep in mind that infection and illness with other SFG and TG *Rickettsia* could occur in cats and dogs. Importantly, the flea and tick vectors that transmit these organisms must be controlled on pets to protect their human companions.

Rickettsia rickettsii in Dogs

Rickettsia rickettsii is a tick-transmitted obligately intracellular coccobacillus that infects endothelial cells. Because it is endotheliotropic, vasculitis is a major clinical manifestation of infection. This results in disordered primary hemostasis, tissue edema, hypovolemia, and microthrombosis. Thrombocytopenia is common in dogs, and occurs due to vasculitis and antibody-mediated platelet destruction. Increased vascular permeability and associated edema and hypovolemia result from disruption of endothelial cell adherens junctions and endothelial cell death, and expression of inflammatory cytokines. Organisms also induce changes in platelet adherence to endothelium, increased tissue factor expression, and increased plasminogen activator inhibitor, and cause the release of von Willebrand factor, all of which likely contribute to microthrombosis.

Epidemiology

Rickettsia rickettsii is transmitted by several hard (ixodid) ticks including *Dermacentor variabilis* (American dog tick), *Dermacentor andersoni* (Rocky Mountain wood tick), *Amblyomma americanum* (Lone Star tick), *Amblyomma cajennense* (Cayenne tick), and *Rhipicephalus sanguineus* (brown dog tick). Historically, the geographic distribution of RMSF in the US has primarily followed that of its primary tick vectors, *D. variabilis* and *D. andersoni*. In endemic areas, most cases of canine and human RMSF are reported from April through October, months of peak tick activity. Dogs living outdoors, particularly those with access to shrubs and high grass, are at increased risk.

Increasing travel and the effects of climate change on tick populations and habitat are changing the geographic distribution of RMSF and other emerging infectious diseases. For example, a recent fatal outbreak of RMSF in people occurred in a nonendemic area of Arizona. The outbreak was caused by the ubiquitously distributed tick *R. sanguineus*. Retrospectively, it was shown that infection existed in the dog population before the fatal outbreak in people. *Rhipicephalus sanguineus* is the primary vector of *R. rickettsii* in Mexico. In South America, *Amblyomma* species are the main vectors. Recently, *A. americanum* was implicated in the transmission of *R. rickettsii* to a person in North Carolina. In fact, the importance of *D. variabilis* as a vector for RMSF in endemic areas of the US has recently come into question. Veterinarians should consider the possibility of transmission by novel vectors if dogs present with clinical signs of RMSF in nonendemic areas or at an unusual time of year.

Dogs are sentinels for spotted fever rickettsioses in people. RMSF in dogs can occur before, or coincide with, outbreaks of RMSF in people in the same household or community. Similarly, there is an increased risk of RMSF in people living near seropositive dogs in endemic areas. It is likely that as more species of SFG *Rickettsia* are shown to infect dogs, they will play a role as sentinels for these novel rickettsial infections as well.

Signalment

Young and pure-bred dogs are overrepresented in some but not other studies. Although some studies suggest male dogs may be at increased risk, no definitive sex predilection has been documented.

Diagnosis

Clinical Signs

The clinical signs and response to therapy for canine RMSF are very similar to RMSF in people. It is very important to be familiar with clinical signs of the disease because treatment must begin prior to diagnostic confirmation. RMSF is primarily an *acute* disease. Chronic infection has not been documented in naturally infected dogs. However, a recent experimental study documented an apparent relapse of clinical signs and bacteremia in a dog after treatment. Low numbers of SFG *Rickettsia* typically circulate in blood free or in detached endothelial cells for a short period of time after infection (13 days). This is the time when clinical signs are observed. Coinfection with other vector-borne agents is common and should be considered if the clinical presentation is atypical, there is an incomplete response to doxycycline therapy or clinical signs have been present chronically.

Because *R. rickettsii* infects endothelial cells, *vasculitis* is the major clinical sign associated with infection. However, due to variation in the extent and severity of vascular injury among dogs, a range of signs can occur and disease manifestations are initially mild and nonspecific. The nonspecific nature of the clinical signs makes diagnosis difficult. This is very important because a delay in diagnosis and appropriate antimicrobial therapy dramatically increases morbidity and mortality in people and dogs. Therefore, the clinician must have a high index of suspicion in order to correctly diagnose and treat this disease. This can be difficult because often there is no known history of a tick bite. Lethargy and anorexia are common, and may be the only clinical signs. Vomiting and diarrhea occur frequently. Melena may also occur. Central nervous system (CNS) abnormalities including

vestibular disease and seizures may be observed. Dramatic and rapid weight loss has been described.

On physical examination, fever and ocular abnormalities are common. Ocular signs may include mucopurulent discharge, scleral and conjunctival injection and hemorrhage, conjunctivitis, uveitis, retinal hemorrhage, and retinitis. Lymphadenomegaly, splenomegaly, nasal discharge, epistaxis, tachypnea, dyspnea, petechiae, ecchymosis, peripheral edema, hyperemia, and necrosis may occur. Cutaneous lesions are not always present in dogs or people. Orchitis and scrotal edema, hyperemia, and epididymal pain are common in intact male dogs. Generalized myalgia and arthralgia can be observed. CNS abnormalities can be focal or generalized and include paraparesis, tetraparesis, ataxia, hyperesthesia, central or peripheral vestibular signs, stupor, seizures, and/or coma. Arrhythmias may be noted. Microvascular hemorrhage, thrombosis, hypotension, oliguric renal failure, cardiovascular collapse, and brain death occur terminally. Thoracic radiographs may show an unstructured interstitial pattern.

Laboratory Testing

Complete blood count (CBC) commonly shows thrombocytopenia but it does not occur in all dogs with RMSF. Leukopenia or leukocytosis may be observed. Neutrophils may have toxic change. Nonregenerative anemia may be present. Serum biochemical abnormalities may include hypoalbuminemia, elevated alkaline phosphatase, hyponatremia, and mild hyperbilirubinemia. Prolonged activated partial thromboplastin time (APTT), prothrombin time (PT), and elevated fibrinogen and fibrin degredation products may occur. Disseminated intravascular coagulation (DIC) is uncommon. Urinalysis results are variable and may include proteinuria, hematuria, bilirubinuria, and pyuria. Granular casts can be observed. Cerebrospinal fluid (CSF) analysis may reveal a mixed cellular, neutrophilic, or lymphocytic pleocytosis. Arthrocentesis may reveal a neutrophilic polyarthritis. Cytologic examination of enlarged lymph nodes is consistent with reactive lymphoid hyperplasia.

Active infection with a SFG *Rickettsia* is confirmed in a patient with compatible and clinical signs and demonstration of the organism using polymerase chain reaction (PCR) or immunohistochemistry, or documentation of seroconversion. Importantly, serology and PCR can be negative at the time of testing because clinical signs can occur before seroconversion, and organisms circulate transiently in blood in low numbers. Repeat testing using PCR can increase sensitivity. Infection also cannot be definitively diagnosed by documenting a single positive titer because of cross-reactivity with nonpathogenic SFG *Rickettsia*, and the potential for long-lived antibody levels after infection. Therefore, documenting a fourfold change in titer is necessary to confirm acute infection with SFG *Rickettsia* using serology. That said, a single high titer in the context of acute and compatible clinical signs and an appropriate response to therapy is suggestive of infection.

Of note, most antibody-based diagnostic tests do not differentiate among species of SFG *Rickettsia*. Some PCRs can differentiate among species of infecting *Rickettsia* while others only amplify rickettsial DNA targets conserved among several species. Veterinarians should check with their laboratory regarding the sensitivity and specificity of a given PCR, keeping in mind that *in vitro* (absolute) sensitivity is higher than *in vivo* sensitivity due to low circulating copy numbers of *Rickettsia* in blood. Therefore, PCR can enable definitive diagnosis but a negative PCR does not rule out infection. It is also important to note that PCRs that specify that they target SFG *Rickettsia* may not detect TG *Rickettsia*.

Therapy

Appropriate antibiotic therapy must be instituted immediately based on clinical suspicion, before diagnostic tests confirm infection. Inappropriate or delayed antibiotic therapy may increase morbidity and mortality. Treating with an antibiotic that is not effective allows rapid progression. Some antibiotics such as trimethoprim sulfa may worsen disease in people. Doxycycline (5 mg/kg PO or IV q12h) is the treatment of choice. It is highly effective at eliminating *R. rickettsii*. Furthermore, it provides effective empiric therapy for *A. phagocytophilum*, *Ehrlichia* spp., and *Borrelia burgdorferi*, agents that are differential diagnoses or may co-infect patients with RMSF. Enrofloxacin has been shown to be effective against *R. rickettsii* in experimentally infected dogs. Chloramphenicol was effective in experimentally infected dogs but may be less effective in treating RMSF in people. The duration of therapy for RMSF is short, with 7–14 days being adequate in most cases. Treatment a few days past defervesence is recommended. A longer course of (doxycycline) therapy is recommended for patients co-infected with an *Ehrlichia* sp. or *B. burgdorferi*.

Many patients require hospitalization. Intravenous antibiotic therapy may be necessary in debilitated patients. Aggressive supportive care for complications such as thrombosis, CNS deficits, and gastrointestinal signs may be necessary. Due to the loss in vascular integrity, fluids should be administered with caution and colloids may be warranted in some cases. The use of corticosteroids in dogs with RMSF is controversial. Antiinflammatory and immunosuppressive doses did not affect overall outcome in experimentally infected dogs, but rickettsemia was prolonged in dogs concurrently treated with doxycycline and immunosuppressive

doses of corticosteroids. Antiinflammatory doses of corticosteroids have been used in dogs with severe CNS manifestations and may be necessary topically or systemically for treatment of ocular abnormalities.

Response to appropriate antibiotic therapy is very rapid (24–48 hours). Co-infection with *B. burgdorferi*, *Ehrlichia* spp., *Babesia* spp., and *Bartonella* spp. should be considered in dogs with severe or prolonged clinical signs and those that fail to respond to doxycycline. Residual CNS and other deficits may occur in severely affected patients. A convalescent serum sample should be drawn 2–3 weeks after the initial serologic sample in PCR-negative patients.

Prognosis

The prognosis is good to excellent if the disease is diagnosed and treated with appropriate antibiotics and supportive care early in the course of illness.

Public Health Implications

Rocky Mountain spotted fever is reportable in people in the US. It is also a reportable disease for dogs in some counties in the US. Because direct inoculation into blood or aerosolization can cause infection, all specimens should be handled with care and marked clearly as biohazards. Avoid needle sticks, contact with cuts in the skin, and aerosolization of rickettsemic blood.

It is important for veterinarians to communicate with owners and physicians that infection in a dog may precede tick-transmitted infection to owners or neighbors. Instruct clients to remove ticks properly and avoid crushing to prevent exposure to infected hemolymph. Refer to www.cdc.gov/ticks/removing_a_tick.html. Educating owners with regard to the importance of tick control and prevention for both people and pets and the environment is critical. In cases where *Rh. sanguineus* is the vector, environmental control is particularly important. The veterinarian should keep in mind that novel and well-characterized species of SFG *Rickettsia* are important causes of emerging infectious disease. Furthermore, *R rickettsii* is considered a potential bioterrorist agent. Because dogs are sentinels for infection, veterinarians can play an important role in detecting, defining, and preventing illness in their canine patients and their human companions.

Lyme Borreliosis

Meryl P. Littman, VMD, DACVIM (SAIM)

University of Pennsylvania, School of Veterinary Medicine, Philadelphia, PA, USA

Etiology/Pathophysiology

Lyme borreliosis is caused by gram-negative spirochetes of the *Borrelia burgdorferi* sensu lato complex, including 21 species and at least 30 strains of *B. burgdorferi* sensu stricto in North America and Europe, and *B. afzelii*, *garinii*, and others in Europe. At least 52 *Borrelia* spp. exist; some 29 cause relapsing fever or rash in people, mimicking Lyme disease (e.g., *B. andersonii*, *B. hermsii*, *B. lonestari*, *B. miyamotoi*, *B. parkeri*, *B. recurrentis*, *B. turicatae*). Fever, lameness, anterior uveitis, splenomegaly, thrombocytopenia, and spirochetemia were associated with *B. turicatae* in dogs in Florida and Texas; *B. hermsii* was isolated in a febrile spirochetemic pancytopenic dog in Washington.

Lyme spirochetes are mainly transmitted via *Ixodes* tick bites after two days of host attachment, as outer surface protein A (ospA, the organisms's attachment to tick midgut) is downregulated and other antigens (e.g., ospC) become expressed. The organisms live extracellularly, associated with fibroblasts and collagen. Disease signs are due to immune-mediated reactions, not bacterial toxins or cellular damage by the organisms. Although many exposed people develop acute signs of illness (rash, flu-like signs) and later possible arthritis, neurologic, and/or cardiac manifestations, most exposed dogs and cats seroconvert without illness. The experimental model in 6–12-week-old beagle puppies showed no illness until 2–5 months after infected tick exposure. Carrier status and antigenic variation account for recurrent self-limiting episodes of anorexia, fever, and lameness. Only <5% of seropositive dogs in the field show Lyme arthritis. In some endemic areas, 70–90% of healthy dogs are seropositive. Canine Lyme nephritis is rare (<2% of those exposed), even among seropositive retrievers (predisposed breeds). Other manifestations in dogs are not well documented. Lyme arthritis is rare in seropositive cats; signs may be due to co-infection with *Anaplasma phagocytophilum*.

Lyme nephritis in dogs is not due to spirochetal renal invasion but rather Lyme-specific antigen–antibody complex deposition and immune-mediated glomerulonephritis, with secondary changes of tubular necrosis/regeneration and interstitial nephritis. There is no experimental model of Lyme nephritis, but genetic predisposition appears to play a role.

Epidemiology

Ixodes ticks are the main vector of *B. burgdorferi*. The main reservoirs are mice, small mammals, and birds. In the US, 95% of human cases are seen in the Northeast, MidAtlantic, and Midwest states. Bird migration and climate changes are extending the habitat of infected ticks to adjacent areas.

Signalment

Most affected dogs are middle-aged, large-breed dogs with outdoor lifestyles exposing them to field ticks questing in leaf litter, hedges, bushes, and tall grasses. Lyme nephritis can occur in any breed, but Labrador and golden retrievers appear predisposed.

History and Clinical Signs

Lyme Arthritis

The experimental tick exposure model shows that dogs seroconvert and become nonclinical carriers of spirochetes for many years, based on positive spirochetal cultures and polymerase chain reaction (PCR) tests of skin and subcutis biopsies from tick bite sites. Very young (6–12 weeks old) puppies showed signs of illness 2–5

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

months after infected tick exposure, starting with a four-day episode of self-limiting anorexia, fever, lameness, and local lymphadenopathy in the leg closest to tick attachment, followed sometimes by several additional short episodes in the same or different leg(s) every two weeks, resolving without treatment. Older exposed puppies (13–26 weeks old) showed fewer signs and episodes, and adult dogs (>26 weeks old) seroconverted without illness. Antibiotic therapy cleared 85–90% (but not all) experimental dogs, based on skin biopsy culture and PCR test results.

In clinical cases in the field, dogs with suspected Lyme arthritis may show lameness in one leg with a hot swollen painful joint and joint effusion. Dogs with polyarthropathy (e.g., hocks/carpi) may have co-infections, immune-mediated arthritis or perhaps had multiple tick attachment sites affecting multiple limbs/joints. Dogs with Lyme arthritis typically respond quickly (within 1–2 days) to antibiotics, and if they do not, other causes of signs should be sought. Response to treatment may be coincidental, due to responsive co-infections (e.g., anaplasmosis), or due to the antiarthritic, antiinflammatory properties of doxycycline.

Lyme Nephritis

There is no experimental model for Lyme nephritis so the incubation, progression, best treatment, or whether Lyme vaccine prevents or promotes aggravates the illness are unknown. It is suspected to be a chronic manifestation, since it is associated with seropositivity and circulating immune complexes at presentation. Retriever dogs are predisposed, so an underlying genetic immunodysregulation and/or podocytopathy may exist. Dogs with early or mild glomerulonephritis may have occult proteinuria; more severely affected dogs present with signs of protein-losing nephropathy (PLN), such as edema/effusions, thromboembolic events (e.g., pulmonary, saddle, portal, neurovascular), hypertensive damage (e.g., blindness, epistaxis, neurovascular events), and eventually renal failure (e.g., anorexia, weight loss, emesis, polyuria/polydipsia, and potentially oliguria/anuria).

Diagnosis

Serology

The organism migrates interstitially (exception: *B. mayonii*, a cause of Lyme borreliosis in humans, may travel hematogenously) and is difficult to find by cytology with special stains, culture, or PCR testing, so serologic testing is used for antibodies directed against natural exposure antigens. Older tests such as whole-cell enzyme-linked immunosorbent assay (ELISA), indirect immunofluorescence assay (IFA), immunoglobulin (Ig) G, IgM, and western immunoblot show cross-reactivity with antibodies from vaccines and other infections, and are no longer preferred.

The C_6 peptide antibody test is sensitive and specific for natural exposure antibodies against part of the VlsE antigen, which is only expressed by the spirochete after infecting the host and is not in Lyme vaccines. Antibodies against the C_6 peptide rise 3–5 weeks after infection and persist in carriers. Qualitative in-house C_6 peptide testing is combined with tests for heartworm antigen and antibodies against multiple *Anaplasma* and *Ehrlichia* spp. (e.g., SNAP-4Dx Plus, IDEXX Reference Laboratories). Quantitative C_6 peptide antibodies (Lyme Quant C_6, IDEXX) usually wane 50% by six months post treatment. The new baseline result is useful for comparisons should future signs of illness suggest relapse or reinfection. The AccuPlex®4 test (Antech Diagnostics Reference Laboratories) tests for heartworm antigen and antibodies against *Anaplasma phagocytophilum* and *Ehrlichia canis*; its qualitative Lyme antibody test uses an algorithm comparing the magnitude and responses to five markers, including those usually found in vaccinates (ospA) vs after natural exposure (ospC, VlsE, ospF), and for recent exposure (ospC antibody rises 2–3 weeks post exposure and wanes within 3–5 months) vs past/chronic infection (ospF antibody rises 6–8 weeks post exposure and persists). The Multiplex test (Cornell University) quantitates ospA, ospC, and ospF antibodies. The in-house Abaxis/Zoetis qualitative tests for only Lyme (VetScan) or for Lyme/*A. phagocytophilum*/*E. canis*/heartworm (FLEX4) tests for Lyme antibodies directed against proprietary antigens mimicking VlsE, ospC, and p41 (flagellin).

Compromised interpretation of the Lyme test results above may be due to ospA antibodies possibly present in nonvaccinates after natural exposure (acutely or in carriers), ospC antibodies induced by new Lyme vaccines (bacterins and chimeric recombinant), and cross-reacting flagellin antibodies from other infections/vaccines. The magnitude of any natural exposure Lyme antibody titer does not predict illness, but may validate exposure.

Lyme Arthritis

Many causes for lameness or inability to rise need to be considered. Overdiagnosis is a problem; one study showed that 40% of Lyme arthritis cases were misdiagnosed and signs were due to other causes – for example, Lyme seropositivity was coincidental. Blood tests (complete blood count [CBC]/biochemical profile) are not abnormal but other tick-borne or other illnesses may cause changes such as cytopenias, hypoalbuminemia, hyperglobulinemia, azotemia, etc. All seropositive dogs

should be checked for proteinuria. Joint tap cytology shows a neutrophilic inflammatory response without bacteria, but morulae may be seen due to co-infections.

Lyme Nephritis

Abnormalities may include elevated blood pressure measurement, proteinuria/cylindruria, ± glucosuria, ± decreased concentrating ability, hypoalbuminemia, hypercholesterolemia, azotemia, hyperphosphatemia, anemia, thrombocytopenia, and abnormal (hypercoagulable) thromboelastography. Diagnostic work-up of PLN also includes screening for other infectious, inflammatory, genetic, and neoplastic diseases that cause proteinuria (e.g., serologic testing, urine culture, chest radiographs, abdominal ultrasonogram). Renal imaging is usually unremarkable. Renal biopsy by experienced personnel with thin section light microscopy, special stains, immunofluorescence, immunohistochemistry, and transmission electron microscopy shows immune-complex glomerulonephritis (staining techniques for Lyme-specific complexes are not validated), and possible secondary tubular necrosis/regeneration and interstitial nephritis.

Therapy

Therapy for nonclinical nonproteinuric dogs is not warranted. For Lyme arthritis signs, doxycycline (10–20 mg/kg/day for 30 days) or minocycyline is recommended because of possible responsive co-infections. Other antispirochetal antibiotics include amoxicillin, erythromycin, azithromycin, cefovecin, and ceftriaxone. Management for Lyme nephritis includes longer antibiotic regimes (perhaps until the Quant C_6 result has waned), a modified low-protein diet, renin-angiotenin-aldosterone system inhibitors (e.g., angiotensin-converting inhibitors and/or angiotensin receptor blockers), omega-3 fatty acids, antithrombotics, antihypertensives, drugs for renal failure (e.g., antiulcer medications, phosphate binders), and possibly immunosuppressives if renal biopsy shows glomerular immune-complex deposition or, in rapidly progressive cases, even without biopsy confirmation (compassionate care). The best protocol is unknown but may include single or combined mycophenolate, cyclophosphamide, steroids, chlorambucil, cyclosporin, and/or azathioprine.

Prognosis

The prognosis for Lyme arthritis is excellent as the course is self-limiting or responsive to antibiotics within 1–2 days. If unresponsive, consider other causes. The prognosis for Lyme nephritis is guarded to poor if the dog presents in renal failure, but may be better in earlier stages. Monitoring abnormalities frequently with treatment adaptation is essential.

Prevention

Tick control year round (ticks are active when temperature is >40 °F or 4 °C) is most important, since ticks in Lyme-endemic areas may transmit borreliosis as well as anaplasmosis, babesiosis, ehrlichiosis, mycoplasmosis, and Rocky Mountain spotted fever, and possibly bartonellosis. Some of these are transmitted within the first day of tick attachment so products which prevent tick attachment (e.g., permethrins or amitraz) or kill ticks fast after attachment (e.g., isoxazolines) are preferred.

There are five Lyme vaccines available: three killed adjuvanted bivalent bacterins (LymeVax, Zoetis; Duramune Lyme, Elanco; Nobivac Lyme, Merck Animal Health) including ospA and ospC, a nonadjuvanted recombinant subunit ospA vaccine (Recombitek Lyme, Merial), and a chimeric recombinant adjuvanted vaccine which includes ospA plus ospC from seven strains (Vanguard crLyme, Zoetis). Even in endemic areas, Lyme vaccination is controversial because:

- tick control is important to protect dogs from other tick-borne diseases in these areas
- most exposed dogs do not become ill or they respond quickly to commonly used antibiotics
- Lyme vaccines may interfere with some diagnostic tests
- Lyme vaccines are costly, have inconsistent efficacy, produce weaker/shorter duration of immunity that may require six-month boostering, and cause more postvaccinal adverse events than other canine vaccines.
- the most serious forms of Lyme disease have an immune-mediated pathogenesis, so theoretically it may not be a good idea to introduce Lyme antigens to genetically predisposed dogs, lest sensitization or aggravation of immune-complex deposition in glomeruli or joints may occur.

These last possibilities may not appear temporally associated with vaccination and are difficult to study without an experimental model of Lyme nephritis. Most concerns are anecdotal and theoretical, and because owner compliance to using adequate tick control may be problematic, many veterinarians recommend Lyme vaccinations in addition to tick control.

Public Health Implications

A seropositive dog has exposure to wildlife, may be a carrier for infection with other tick-borne diseases or leptospirosis, and is a sentinel for Lyme exposure in the environs. Educate owners about landscaping, tick prevention on their pets and themselves, and that physicians in Lyme-endemic areas may prescribe humans a single day's preventive dose of doxycycline to be taken within 72 hours of removing an engorged *Ixodes* tick.

Leptospirosis

Katharine F. Lunn, BVMS, MS, PhD, MRCVS, DACVIM (SAIM)

College of Veterinary Medicine, NC State, Raleigh, NC, USA

Etiology/Pathophysiology

Leptospirosis is a zoonotic bacterial disease affecting the health of animals and humans throughout the world. In small animals, clinical leptospirosis is a significant problem in dogs, but the role of leptospires in feline disease is still poorly understood. Leptospiral organisms are typically divided into serovars, based on antibody responses to surface proteins. Serovars are further classified into antigenically related serogroups. Canine leptospirosis is caused by several serovars of the pathogenic species *Leptospira interrogans* sensu latu. Examples of serovars that have been implicated in canine disease include Grippotyphosa (serogroup Grippotyphosa), Pomona (serogroup Pomona), and Bratislava (serogroup Australis).

Leptospiral organisms enter the host through intact mucosal surfaces or damaged skin. During the first week of infection, organisms multiply and spread throughout the vascular space, leading to vascular damage and invasion of many organs and tissues. During this initial leptospiremic phase, organisms can be isolated from the blood. The immune phase of infection begins in the second week, with the appearance of serum antibodies. This leads to clearing of leptospires from the blood and many organs; however, organisms may be protected from the systemic antibody response in sites such as the renal tubules and the eye. Leptospiruria develops in the second week after infection and can persist for days to months, depending on the species of the mammalian host and the infecting serovar.

Pathologic changes associated with leptospirosis include vasculitis and endothelial cell damage. The precise mechanisms by which leptospires cause tissue damage and disease are not well understood, but several toxins and enzymes produced by the organisms likely contribute to disease pathogenesis. The pathogenicity of leptospires may also be related to their motility and their ability to adhere to, and penetrate, cells.

Epidemiology

Pathogenic leptospires are maintained in the environment through the shedding of organisms in the urine of a wide variety of endemically infected mammalian reservoir hosts. These reservoir hosts usually do not develop clinical disease, but serve as a source infection for incidental hosts, such as dogs and humans. In some locations, there appears to be an increased incidence of leptospirosis in late summer and fall, perhaps associated with weather conditions and wildlife behavior. Leptospires survive, but do not replicate, in warm and wet environments, whereas freezing, ultraviolet radiation, and dehydration all reduce survival. Transmission to incidental hosts is usually indirect, through exposure to contaminated water, soil, food or bedding, although direct contact through ingestion, bite wounds, or direct contact with urine is possible.

Reservoir hosts that likely contribute to environmental contamination include the raccoon, opossum, fox, skunk, mouse, rat, vole, squirrel, and deer. Clinicians should note that many of these reservoirs co-exist with humans in urban, suburban, and periurban environments, thus leptospirosis is not confined to large-breed, working, predominantly outdoor dogs or rural dogs. Many clinicians routinely diagnose leptospirosis in small-breed indoor dogs. Indeed, two different recent studies have demonstrated that dogs in some urban areas are at increased risk for leptospirosis, and that small dogs (<15 lb) were more likely to be diagnosed with the disease. Case reports and serologic surveys have demonstrated both clinical leptospirosis and subclinical exposure to the organisms in dogs from many locations in the US and Canada, and it is likely that only desert regions are truly free of the disease. Unfortunately, it is difficult to determine which serovars predominate in different geographic regions, as diagnosis is usually based on antibody titers, and these cannot identify the infecting serovar. Further studies are needed to

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

isolate and genetically type the organisms in order to better understand the epidemiology of leptospirosis in different hosts and regions of the world.

Signalment

Any age, breed, and sex of dog is susceptible to leptospirosis, and the diagnosis should not be ruled out on the basis of signalment. A recent study of the Veterinary Medical Database demonstrated signalment changes in canine leptospirosis from 1970 to 2009. In the most recent decade studied, the highest prevalence of disease was in the 7–9.9 year age group, and in dogs <15 lb. The terrier group had the highest prevalence in this decade, and Yorkshire terriers had the highest prevalence among small breeds. Other sources have suggested an increased susceptibility in German shepherd dogs, although this has not been rigorously evaluated.

There are few reports of clinical leptospirosis in cats, but it has been shown that cats can seroconvert to leptospiral organisms, and there is some evidence that cats may shed leptospires in the urine. However, it has not been clearly demonstrated that leptospirosis is a significant clinical problem in domestic cats.

History and Clinical Signs

The manifestations of leptospirosis in dogs range from peracute disease to subclinical infection, and include sudden death, acute kidney injury (AKI), liver disease, vasculitis, and uveitis. Because this is a zoonotic disease, it is essential that veterinarians maintain a high index of suspicion for this infection, particularly in cases with atypical clinical signs.

Typical clinical signs in acute or subacute leptospirosis include lethargy, anorexia, fever, muscle pain, abdominal pain, signs of shock, dehydration, vomiting, diarrhea, bleeding, jaundice, polyuria, oliguria, and anuria. While AKI has been the most common presentation for canine leptospirosis in recent years, affected patients may also present with a combination of renal and hepatic disease, or hepatic disease alone.

Acute kidney injury in leptospirosis may be anuric, oliguric, or polyuric. Dogs that survive AKI due to leptospirosis may progress to chronic kidney disease (CKD). Acute kidney injury may be undetected in subclinically infected animals, and those patients may eventually be diagnosed with CKD of unknown cause. Leptospirosis should also be considered in any dog with previously diagnosed CKD that develops unexplained "acute-on-chronic" kidney disease. Other manifestations of renal disease in canine patients with leptospirosis include glucosuria in the absence of hyperglycemia, nephrogenic diabetes insipidus, and renal tubular acidosis. Liver disease associated with leptospirosis is predominantly cholestatic in nature, with minimal histopathologic changes.

Clinicians should be aware that patients with leptospirosis may present with unusual signs, including respiratory distress, bleeding disorders, effusions, and uveitis. Pulmonary disease in dogs with leptospirosis is probably more common than previously suspected, and has been attributed to pulmonary hemorrhage, a known serious complication of leptospirosis in people. Bleeding disorders may manifest as petechiae, epistaxis or gastrointestinal bleeding, and are most likely due to vasculitis, although the mechanisms are poorly understood.

Diagnosis

Common but nonspecific laboratory findings in dogs with leptospirosis include azotemia, hyperphosphatemia, metabolic acidosis, hyper- or hypokalemia, hyperbilirubinemia, increased serum alkaline phosphatase (ALP) activity, and increased serum alanine aminotransferase (ALT) activity; the latter is usually less markedly increased than ALP activity. Mild to moderate thrombocytopenia is relatively common, although the platelet count is seldom low enough to directly cause spontaneous bleeding. Urine specific gravity can be hyposthenuric in patients with nephrogenic diabetes insipidus; it may also be isosthenuric or concentrated, depending on the extent of renal involvement. Urinalysis may reveal hematuria, cylindruria, proteinuria, or glucosuria.

Imaging findings are also nonspecific, and may include reticulonodular pulmonary interstitial or alveolar opacities on radiographs, and ground-glass nodules or diffuse opacity and peribronchovascular interstitial thickening on thoracic computed tomography (CT). Abdominal ultrasound examination has been reported to reveal renal and hepatic changes, perirenal and peritoneal effusions, intestinal wall thickening, and lymphadenopathy.

Diagnostic tests for leptospirosis rely on detection of the organism, or detection of an antibody response in the infected patient. It is recommended that both types of tests be utilized to maximize the chance of diagnosing this zoonotic disease. It is essential that the results of any diagnostic test be interpreted in light of the patient's clinical signs, clinicopathologic findings, and vaccination history.

The microscopic agglutination test (MAT) is still the most widely used antibody detection test for the diagnosis of leptospirosis. Advantages of this test are that it is widely available and provides a numerical titer that allows

comparison of paired acute and convalescent titers. Most authors recommend that an initial titer of ≥1:800 is consistent with a diagnosis of leptospirosis in an unvaccinated dog. If initial titers are low, or the patient has an unknown vaccine history, convalescent titers can provide further information. Although a 2–4-week period between acute and convalescent titers is often recommended, it is not always necessary to wait that long. When performing paired acute and convalescent titers, a fourfold change (usually an increase) in titer supports the diagnosis of leptospirosis. Most laboratories that perform the MAT will test patient sera against multiple serovars (representative of serogroups) and often report seropositivity to more than one serogroup, due to significant cross-reactivity. For this and other reasons, it should be noted that MAT results cannot identify the infecting leptospiral serovar in an individual patient. However, for most clinicians this is of little importance, as there is currently no evidence that clinical signs, treatment, or prognosis are serovar or serogroup specific. When paired titers are performed, the MAT is a highly sensitive and specific test for leptospirosis.

More recently available serologic tests for the diagnosis of canine leptospirosis include an enzyme-linked immunosorbent assay (ELISA) test that detects antibodies to the lipoprotein LipL32 found on the surface of pathogenic leptospires, available both at a reference laboratory and as a point-of-care test (SNAP® Lepto Test, IDEXX), and a patient-side lateral flow device test that detects IgM antibodies to a whole-cell antigen from Grippotyphosa and Bratislava serovars (WITNESS® Lepto, Zoetis). These tests give qualitative positive or negative antibody results, with proposed advantages including lower cost and shorter turn-around time, compared to the MAT. In one study, SNAP Lepto demonstrated similar performance to the MAT for the detection of antibodies to *Leptospira* spp., with agreement being greater in MAT-positive samples with higher titers. In a more recent study comparing MAT, SNAP Lepto, and WITNESS Lepto in experimentally infected dogs, the WITNESS test detected seroconversion to common leptospiral serovars in all 32 dogs by day 10 after infection, the MAT detected seroconversion in 30 of 32 dogs by day 14, and the SNAP test detected antibodies in only three of 32 dogs in the 14-day follow-up period. However, it is important to note that the challenge infection in these dogs did not result in clinical illness, and the comparative performance of these tests may be different in a clinical setting in which patients are sick and potentially presented later in the course of infection.

Advantages of the point-of-care tests include that they potentially allow earlier diagnosis of leptospirosis, thus facilitating early institution of safe patient handling protocols and appropriate medical therapy. However, these tests cannot reliably distinguish vaccinal titers from natural infection, and they do not provide numerical titers to allow comparison of acute and convalescent titers. These disadvantages are particularly important in dogs with low initial titers, vaccinated dogs, or dogs with an unknown vaccination history.

If a negative result is obtained on either point-of-care test, additional serum samples should be obtained for acute and convalescent MAT titers (or the point-of-care test can be repeated in 1–2 weeks), polymerase chain reaction (PCR) testing should also be performed (see later), and leptospirosis should not be ruled out unless an alternate diagnosis is confirmed, or acute and convalescent serologic tests are negative. If a positive result is obtained on a point-of-care test and the patient is vaccinated, or has an unknown vaccine history, acute and convalescent MAT titers should be performed to distinguish between vaccinal titers and natural infection.

Bacterial culture of pathogenic leptospires is very rarely used as a diagnostic test in dogs, because it is technically demanding, of limited availability, and requires several months of incubation. Dark-field microscopy and fluorescent antibody tests have been used to demonstrate the presence of organisms in urine samples but sensitivity is poor, and these tests have largely been replaced by PCR-based assays. Blood or urine samples from canine patients can be tested by PCR for the presence of DNA from pathogenic leptospires.

A variety of different PCR tests are available, with quantitative tests such as real-time PCR likely to be more sensitive. Despite the wide availability and frequent use of PCR-based assays, there are relatively few published studies that evaluate their sensitivity and specificity. Potential causes of false-negative results include low leptospire numbers in the sample collected, intermittent shedding of organisms in the urine, or the presence of PCR inhibitors in the sample. False-positive results on the PCR assay may be due to sampling from a subclinically affected carrier, the presence of dead organisms, or contamination of the sample during collection, handling, or processing in the laboratory. If leptospirosis is suspected, obtaining both blood and urine samples for PCR testing may increase the chances of detecting the organism. Positive or negative results from the PCR should be further followed up with acute and convalescent MAT titers, and should always be interpreted in light of the patient's clinical signs.

Therapy

There are no prospective studies that provide data regarding the best antibiotic protocols for treatment of leptospirosis in dogs. There are many studies that address

antibiotic therapy in other species, including experimental models of leptospirosis, and large animals such as pigs and cows. Antibiotics used to treat leptospirosis should terminate leptospiremia and eliminate the carrier state. Doxycycline is often used as it is generally believed to achieve both of these goals. Doxycycline is also used prophylactically in humans who have a high risk of exposure to leptospirosis. Penicillins are often used to clear leptospiremia, which should also reduce the risk of organ damage. Penicillin, ampicillin, and amoxicillin all appear to be effective.

The choice of antibiotic to be used in the acute phase of the disease is generally dictated by the clinical status of the patient. In general, injectable antibiotics are used in acutely ill patients that are vomiting or not eating. Patients that tolerate oral medications may be started on amoxicillin and then changed to oral doxycycline, or oral doxycycline may be used as the sole therapy if the patient tolerates it. Again, there are no published data that address the duration of antibiotic therapy in dogs with leptospirosis. Most clinicians treat with a penicillin for 1–2 weeks, followed by doxycycline for two weeks, or treat with doxycycline alone for 2–3 weeks.

For dogs with AKI due to leptospirosis, supportive care is essential for a successful outcome. Patients with leptospirosis that remain oliguric or anuric are candidates for extracorporeal therapies such as hemodialysis.

Prognosis

The prognosis for dogs with leptospirosis likely depends on which body systems are affected, and the extent and severity of organ damage. If suspected or diagnosed promptly, and appropriate specific and supportive therapy is initiated, the majority of dogs with leptospirosis will recover from the disease. The prognosis is expected to be guarded for patients with oliguric or anuric AKI, unless renal replacement therapy is initiated. Patients with less severe AKI may progress to CKD or return to normal. In a recent German study of 99 dogs with leptospirosis, dogs that did not survive were more likely to have severe dyspnea, oliguria, azotemia, hyperbilirubinemia, and severe radiographic pulmonary changes, with the latter being specifically associated with high mortality.

Vaccination

Most of the canine leptospirosis vaccines currently used in the US include the serovars Icterohaemorrhagiae, Canicola, Pomona, and Grippotyphosa. It is not known whether these vaccines protect against additional serovars. Contemporary vaccines are purified by subunit technology or microfiltration processes, and they appear to be associated with fewer vaccine reactions compared to the whole-cell cultures that were commonly used in the past.

Vaccination against canine leptospirosis continues to be an area of controversy, despite a growing body of work regarding vaccine efficacy in dogs. In particular, it has been convincingly shown in several studies that vaccination against leptospirosis confers protection against challenge for at least one year, and also confers significant protection against urine shedding. It should be noted that there is little correlation between protection against clinical disease and antibody titers in vaccinated dogs. Postvaccination MAT titers generally fall by four months after vaccination, and rarely persist for one year. This should be kept in mind when interpreting MAT titers in vaccinated dogs. It has been shown that vaccination does not cause false-positive results in a PCR-based assay for canine leptospirosis.

As noted above, leptospirosis is not a disease that is confined to large-breed, outdoor, rural, or working dogs. This author recommends that the risks and benefits of vaccination against leptospirosis be discussed with every dog owner. It is important to bear in mind that leptospirosis is one of the most commonly diagnosed causes of canine AKI, and that the disease can be seen in dogs of any age, breed, sex, or lifestyle. It is also important to bear in mind that currently available vaccines appear to be both safe and efficacious.

Public Health Implications

Leptospirosis is a zoonotic disease. It is essential that veterinary personnel understand how the organism is spread and that infection can occur through damaged skin or intact mucus membranes. In this author's opinion, all dogs with unexplained acute azotemia (including acute-on-chronic) should be treated as leptospirosis suspects until an alternate diagnosis is obtained. It is not necessary to place these dogs in isolation, but it is essential to avoid human and animal contact with the urine of suspects. Direct contact with blood should also be avoided. Leptospirosis suspects should have a urinary catheter placed, or should only urinate in a dedicated area that can be cleaned and disinfected. Dogs that urinate in their cages should have a urinary catheter placed with a closed collection system. This is also often a valuable procedure in the management of AKI patients. If placement of a urinary catheter is not possible, for example in a small dog, absorbent pads can be used in the cage to collect urine. These can also be weighed to monitor urine output.

All personnel nursing a dog with leptospirosis should wear gowns, gloves, and shoe covers while handling the patient. Immunosuppressed individuals should not handle leptospirosis suspects. Facemasks and eye protection should be worn when cleaning cages or runs, or handling wet bedding. Laboratory personnel should wear gloves and a mask when handling body fluids from a leptospirosis suspect. Gloves should always be worn when handling canine urine, as dogs can be asymptomatic carriers of leptospirosis. Fortunately, leptospires are sensitive to most detergents and disinfectants, and are also killed by drying and sunlight. Owners of dogs with leptospirosis should be advised to avoid contact with the dog's urine. If the dog urinates in the house, they should wear gloves and use household detergents or disinfectants to clean up the urine. How long these dogs will shed leptospires is unknown, but appropriate antibiotic therapy should reduce the risk. Owners should contact their own physician with questions about human leptospirosis.

Yersiniosis

Maria Grazia Pennisi, DVM, PhD

University of Messina, Messina, Italy

Etiology/Pathophysiology

Yersinia pestis is the agent of a rare, highly contagious, and often fatal zoonosis. Known since ancient times as plague or "black death," *Y. pestis* devastated medieval Europe with widespread epizootics. Today, *Y. pestis* is enzootic in some foci in the Americas, Africa, the Middle East, and Asia.

Yersinia pestis is a gram-negative, facultatively anaerobic coccobacillus that belongs to the family *Enterobacteriaceae*. The bacterium can survive for weeks in the environment as it is resistant to low temperatures and freezing. However, it is sensitive to high temperatures and desiccation. *Yersinia pestis* is a vector-borne pathogen transmitted by many flea species. *Xenopsylla cheopis* (Oriental rat flea) and some other flea species such as *Oropsylla montana* (the ground squirrel flea) are very efficient vectors whereas others, such as the dog and cat fleas (*Ctenocephalides* spp.), are much less efficient. Fleas acquire the organism from bacteremic mammals. *Yersinia pestis* can infect a wide range of mammals, including humans. Host species have variable susceptibility to development of the disease due to various factors. Less susceptible hosts such as mice, rats, squirrels, and prairie dogs usually develop prolonged bacteremia and therefore act as natural reservoirs. Due to high flea infestation rates and a communal lifestyle, burrowing mammals facilitate transmission of the organism by fleas to a high number of hosts.

Within the flea midgut, the bacterium replicates. Aggregates of the organism block the digestive tract, which causes the flea to suck blood with increased effort and regurgitate organisms into the bite wound it inflicts on subsequent hosts. Cats and dogs can acquire the infection from fleas but they may also become infected by ingesting infected prey. Although less common, transmission through aerosolization or contact with mucous membranes or skin wounds also occurs.

In susceptible mammalian hosts like the cat, *Y. pestis* is able to evade host innate immune defenses. It can infect macrophages wherein it abundantly multiplies inside phagolysosomes, causing cell lysis. In more resistant hosts such as dogs, *Y. pestis* is susceptible to macrophage killing inside phagolysosomes. When transmitted by a flea bite, the bacterium is carried by mononuclear cells to regional lymph nodes where it causes a suppurative lymphadenitis with a marked lymph node swelling (the bubo). Fistulae drain thick purulent exudate from the affected lymph nodes. When transmission occurs via ingestion of infected prey, mandibular and retropharyngeal lymph nodes are involved. Clinical disease characterized by lymphadenitis is called bubonic plague. Dissemination via lymphatic vessels or the bloodstream can follow lymphadenitis. After bacteremia, other lymph nodes, the lungs, and many other organs and tissues can be affected. Abscesses, hemorrhagic and necrotic lesions may occur in many organs. Sepsis may also occur. Bacteremia and multiple organ involvement is referred to as septicemic plague. Dissemination occurs more quickly after ingestion of infected prey or inhalation of the organism from contaminated aerosol droplets. The pulmonary form, known as pneumonic plague, can occur in cats due to hematogenous spread or inhalation of organisms.

It has been established that cats are the domestic species most susceptible to plague. Reinfection is possible and seropositive cats are not protected from bacteremia or death but may have a more prolonged course of the disease.

Similar to the presentation in cats, three different clinical forms of plague are described in humans: bubonic, pneumonic, and septicemic. Bubonic plague is the consequence of flea transmission while pneumonic plague develops after inhalation of the bacterium or hematogenous spread. Septicemic plague may arise from the other two forms.

Companion website: www.wiley.com/go/bruyette/clinical

Epidemiology

One of the oldest diseases known to man, plague is still endemic in many natural foci in the Americas (western USA, Peru, Brazil, Argentina, Ecuador), Africa (Algeria, Libya, Congo, Madagascar, Malawi, Mozambique, Uganda, Tanzania, South Africa) and Asia (China, Mongolia, Vietnam, India, Indonesia, Kazakhstan, Iran). Recent outbreaks have occurred in previously endemic areas after prolonged periods of absence. Countries belonging to the World Health Organization are obliged to notify officials when plague is diagnosed in humans, but underreporting likely occurs.

Each endemic focus is linked to the presence of a specific mammalian reservoir and flea vector. Variability in annual incidence is linked to climatic variability, specifically to rainfall because humidity favors both flea reproduction and increased food availability for rodent hosts. Enzootic hosts of *Y. pestis* are resistant to the development of disease and have prolonged bacteremia, thereby maintaining the flea–host–flea cycle in the wild. In endemic areas, outbreaks of recurrent or sporadic plague epizootics rapidly involve individuals of a particularly susceptible (epizootic) host species. These animals are easily infected when a highly competent flea vector species is more abundant.

Most cases of human plague result from exposure to fleas or activities that result in contact with reservoir hosts, such as skinning rabbits. Exposure to domestic cats accounts for approximately 10% of human plague cases. Veterinary staff and owners of free-roaming cats are at increased risk for *Y. pestis* infection in endemic areas. In some cases, human patients reported being bitten or scratched by infected cats but sometimes just handling or caring for a sick cat was the only contact reported. In one human case, the infecting scratch was obtained by a healthy cat which had fought with a cat suffering from bubonic plague. Importantly, human infection from cats commonly results in the pulmonary form of the disease (pneumonic plague) which is associated with rapid progression and a higher fatality rate.

Dogs rarely develop clinical signs. Infection results in people primarily due to contact with the *Yersinia*-infected fleas they carry. Dogs and other carnivores may serve as sentinels for *Y. pestis* because infection results in the transient production of antibody, peaking 3–4 weeks post exposure and lasting 4–8 months.

Signalment

Yersiniosis is diagnosed in dogs much less frequently than in cats. The disease is reported in cats (3 months to 15 years old) and dogs (1–14 years) of any age, but it seems to be more frequent in adults. No gender or breed predilection is known.

History and Clinical Signs

Free roaming in rural areas and hunting activity are the main risk factors for dogs and cats in endemic areas. In experimental infections, the incubation period lasts 24–48 hours but after natural exposure it may be up to a few days.

Fever, lethargy, and anorexia occur in cats associated with the development of the "bubo," a swollen painful lymph node. This swelling can be confused with abscesses that commonly arise from cat fights. Buboes may involve any superficial lymph node but mandibular and retropharyngeal nodes are more frequently affected because infection is commonly acquired by the oral route as a result of predation. Ulcerative or necrotic lesions may be observed on lips or oral mucosa. The white blood cell count is usually elevated with increased neutrophils and bands. In benign cases, drainage of the primary bubo is followed by resolution of fever and progressive recovery. In other cases, fatal septicemia rapidly occurs and may evolve to distributive shock and multiple organ dysfunction syndrome (MODS). MODS associated with *Y. pestis* is manifested by persistently high fever, depression, hypotension, rapid capillary refill time (CRT), bradycardia, hypodynamic peripheral pulses, hypoalbuminemia, hypoglycemia, and increased bilirubin, liver enzymes, blood urea nitrogen (BUN), and creatinine. Oliguria and metabolic acidosis are also observed. Disseminated intravascular coagulation (DIC) may also occur and is responsible for a hemorrhagic diathesis. Suspicion of DIC is increased in patients with thrombocytopenia, prolongation in activated partial thromboplastin time (APTT) and prothrombin time (PT), increased fibrin degradation products (FDPs) and/or D-dimer, and decreased antithrombin. In some septicemic cases a primary bubo is not found.

Primary pneumonic plague is not a typical presentation in cats because infection is rarely caused by inhalation. Pulmonary involvement is usually due to dissemination from a bubonic primary lesion. Cough and dyspnea represent the clinical manifestation of a pulmonary disease and thoracic radiographs may show the presence of poorly defined focal patchy and coalescing opacities due to pulmonary abscessation. Pleural effusion may also be found.

Few case reports of plague in dogs have been documented. Clinical signs include mild to severe hyperthermia, lethargy, anorexia, stomatitis, painful enlargement of the superficial lymph nodes (mandibular, retropharyngeal, superficial cervical or inguinal), vomiting, diarrhea,

respiratory signs, and abscesses. Leukocytosis and neutrophilia are often recorded.

Diagnosis

In endemic areas, bubo-like lesions and hyperthermia should immediately prompt consideration of *Y. pestis* in free-roaming or hunting cats and dogs. Public health officials should be notified immediately. Standard operating procedures for handling potentially infectious animals or materials should always be followed. Such procedures include isolation of the patient, and wearing surgical masks, gloves, and eye protection when performing physical examination and any clinical or laboratory procedures. Laboratories should be contacted for proper collection and submission protocols prior to collecting and submitting samples from an animal suspected of being infected.

Cytologic evaluation on both Gram- and Giemsa-stained smears from draining lesions may quickly show the presence of a large number of monomorphic Gram-negative (Gram staining) organisms with a bipolar safety pin shape (Giemsa staining). The diagnosis is confirmed by culture, direct fluorescent antibody test (DFA) or polymerase chain reaction (PCR). The DFA is performed by approved laboratories on tissue imprints on slides, smears of lymph node aspirate, or samples from draining pharyngeal or cutaneous lesions. Isolates can be made from cultures of oral swabs, blood or swollen lymph nodes if samples are obtained before starting antibiotic therapy. However culture can be insensitive, and takes several weeks. It should be noted that culture of *Y. pestis* can only be performed at approved laboratories due to its zoonotic potential, and public health authorities should be contacted to obtain information on collection and submission guidelines. Molecular diagnostic methods from clinical samples are also available from select laboratories. Negative immunofluorescence assay (IFA), culture or PCR does not rule out infection.

Diagnosis can also be confirmed by serologic methods. Antibodies against the organism's F1 capsular antigen can be detected many days after the onset of clinical signs and last many months after the infection. Dogs and cats may test seronegative at presentation, as illness may occur prior to seroconversion. A fourfold or more rise in antibody titer against F1 antigen (15 days minimum apart) or a single titer of 1:32 or more by hemagglutination in a cat or dog with signs suggestive of plague is diagnostic. ELISA tests or semiquantitative rapid lateral flow immunochromatographic tests using recombinant antigens have also been developed for humans and mammal reservoirs. Tests for antigen detection in mammals, fleas, and environmental samples are also available.

Therapy

Rapid appropriate therapy should be started as soon as possible without waiting for the confirmatory test result when infection is suspected. Strict isolation measures and personal protection measures should be followed and antiflea treatment applied. Public health authorities should be contacted immediately for notification and guidelines. Treated cats and dogs are considered noninfectious after three days of therapy when fever wanes and clinical recovery occurs but a minimum of three weeks of therapy is required. Many antibiotics have *in vitro* efficacy or are effective in experimental mouse studies. Gentamicin is a first-choice antibiotic for dogs and cats at a dose of 6–8 mg/kg q24h IM, SC or IV. Doxycycline is a second choice for less severe cases. Oral administration of this antibiotic poses a higher risk for caretakers and should be avoided in the initial treatment period. Draining of buboes is recommended (adopting the appropriate operating procedures for avoiding infection as explained earlier). Chlorhexidine is used for flushing fistulae.

Prognosis

In an experimental trial which reproduced oral transmission, 37% of 16 infected cats died. A minority of cats (19%) experienced a subclinical infection and 44% recovered after a clinical disease. Poor prognosis was associated with persistently high fever (≥40 °C, 105 °F). None of the cats in this experimental trial were treated with antibiotics or other measures and in natural disease a fatal course is observed in about half of feline clinical cases. Most cats promptly treated with antimicrobial drugs survive and drainage of cutaneous abscesses improves prognosis. Conversely, abscess development in the lung is considered a negative prognostic factor in cats.

Experimental studies show that dogs have only a mild febrile syndrome and a benign course with no fatality, and this appears to be the case in naturally infected dogs as well. Co-infection with other agents such as *Ehrlichia canis* may result in more severe clinical manifestations. In treated dogs, clinical cure is obtained in 1–21 days.

Prevention

Several types of vaccines have been produced for use in people at risk who are exposed to *Y. pestis* due to professional activities. However, these vaccines are no longer available in the US. Under experimental conditions, vaccination with a killed vaccine did not protect cats from

infection or death. This is consistent with the fact that after infection, seropositive cats are not protected from bacteremia or death.

Doxycycline (10 mg/kg SID PO for seven days) is administered to exposed animals to prevent development of disease.

Public Health Implications

Humans can acquire *Y. pestis* from cats through bites, scratches or aerosolization of respiratory secretions. Fleas on pets also expose humans to the disease. Personnel working in veterinary practices where plague is enzootic should be aware that plague occurs in cats and dogs. Veterinary staff handling potentially infectious animals or materials should be adequately protected from *Y. pestis* infection by wearing a well-fitted surgical mask, gloves, and eye protection. Exudates should be considered infectious, and any material used for treating suspect cats should be disinfected, autoclaved, or incinerated.

In plague-affected areas, owners should be advised to prevent their cats and dogs from roaming freely and to strictly follow flea control programs. Other general advice includes avoiding sleeping with pets, avoiding handling sick or dead animals without adequate protection, and preventing rodent infestations by eliminating food sources and available shelter. Owners of an animal diagnosed with plague should be instructed to contact their physician immediately for prophylactic antibiotics and other treatment as indicated.

Tularemia

Linda Kidd, DVM, PhD, DACVIM

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Tularemia is a rare but severe zoonotic illness caused by *Francisella tularensis*, a small gram-negative non-spore-forming, aerobic coccobacillis bacterium. The organism infects a number of mammals although some, such as rabbits and hares, rodents, cats and sheep, appear to be particularly susceptible to disease. The organism is classified into subspecies (also referred to as types), with *F. tularensis tularensis* (type A) and *F. tularensis holarctica* (type B) causing most disease in cats and people. Disease caused by type A appears to be more severe and is diagnosed more commonly in cats and people than that caused by type B.

Francisella tularensis is very stable in the environment and is transmitted to people and other mammals by a number of mechanisms. These include through biting flies, mosquitoes, fomites, aerosols, and water. Aquatic protozoa may also play a role in transmission. Fleas are considered potential but inefficient mechanical vectors. Several tick species also transmit *F. tularensis.* Transstadial and transovarial transmission have been documented in ticks so they are true biologic rather than mechanical vectors.

Francisella tularensis readily infects macrophages and cells of the reticuloendothelial system. It can also infect hepatocytes and other cells. In macrophages, it survives by inhibiting phagolysosomal fusion and the respiratory burst. After replicating, it induces a form of apoptosis known as pyroptosis. This releases the bacterium and allows it to be taken up by other phagocytic cells. Severe inflammatory responses in the host can cause serious morbidity.

After cutaneous infection, the bacteria may replicate locally and then migrate to local lymph nodes. Further dissemination and septicemia can follow. Lesions in the lungs, spleen, liver, lymph nodes, and skin may result. Systemic infection may also occur without prior localized infection. Pulmonary infection may also result directly from aerosolization. Infection may also be introduced by the oral or gastrointestinal route.

Immunity is T cell mediated, and natural killer cell secretion of interferon-gamma and subsequent activation of macrophages appears important in immunity.

Epidemiology

Type A occurs in North America, whereas type B occurs throughout the northern hemisphere. Types A and B cause disease in both cats and people. Type A is subdivided into types I and II, which appear to have relatively distinct geographic distributions and differences in pathogenicity, with type I causing more severe disease. *F. tularensis* is a reportable disease in the US, occurring in every state except Hawaii. The prevalence of the disease in people is highest in the south central US, the Pacific Northwest, and Massachusetts (Figure 103.1). The incidence of tularemia has been decreasing overall in the US in recent years.

In people, tularemia has classically been referred to as rabbit fever, because many reports of the disease have been associated with contact with rabbits. These include an outbreak associated with aerosolization of the organism while skinning rabbits after a hunt, and running over a rabbit nest with a lawn mower, among others. Recently, however, the importance of cats as a source of human infection has been illustrated. Due to predation on rabbits and rodents, and exposure to environmental sources such as water and ticks, free-roaming cats are believed to be at particular risk for exposure. In one serosurvey in the US, 12–24% of cats were seropositive. Alarmingly, it was recently reported that 48% of human cases in Nebraska were cat associated.

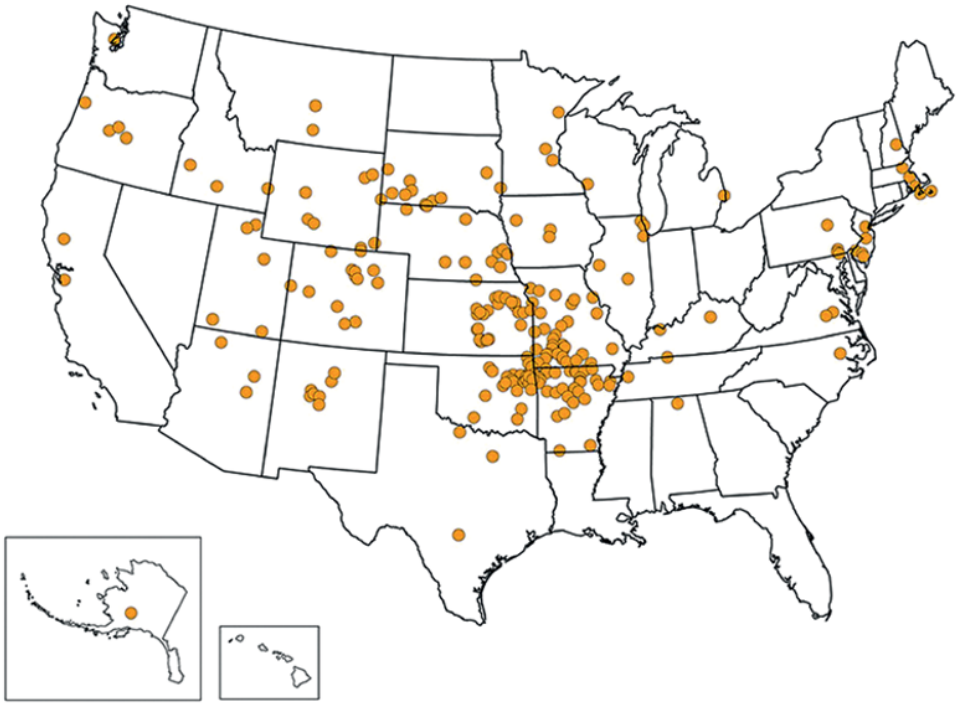

Figure 103.1 Reported tularemia cases in the United States, 2016. *Source:* www.cdc.gov/tularemia/statistics/map.html.

Because of its pathogenicity, the potential for aerosol transmission and other factors, *F. tularensis* is considered a Tier 1 bioterrorism agent. This is important for veterinarians to consider, as cats and possibly dogs could potentially serve as sentinels if such an attack were to occur.

Signalment

Infection in young adult cats and dogs has been reported most frequently, with natural infection in cats reported much more commonly than in dogs.

History and Clinical Signs

Clinical signs can range from minimal to severe disease and death. Severity of illness is likely determined by type and subtype of the organism and host immunity. Different clinical categories of disease, including ulceroglandular, glandular, pneumonia, and tonsillitis or pharangitis with cervical lymphadenopathy, are described in people. These disease manifestations are determined in part by route of inoculation.

Manifestations in cats appear to be similar to those found in people. In cats, clinical findings may include a more localized form that includes chronic subcutaneous draining abscesses, or generalized severe disease. In the severe form of the disease, fever, depression, lethargy, jaundice, splenomegaly, lymphadenomegaly, and hepatomegaly occur. Oral and lingual ulcerations may be present and might indicate ingestion as a route of infection. Embolic pneumonia associated with oral or gastrointestinal exposure has been described. Fever, lethargy, anorexia, lymphandenopathy, ocular changes, and tonsillitis have been described in dogs.

Diagnosis

Tularemia should be a differential diagnosis in cats with fever of unknown origin, chronic draining lesions/abscesses, lymph node enlargement and hepatosplenomegaly and oral ulcerations. Free roaming and hunting behaviors, especially predation of rabbits or rodents, should increase the index of suspicion for infection. Plague is an important differential diagnosis for tularemia.

Guidelines have been established by the European Advisory Board on Cat Diseases (www.abcdcatsvets.org/) for tularemia in cats. They state:

> When handling animals with suppurative or draining skin or lymph node lesions in endemic areas, gloves and goggles should be worn. Gloves should

also be worn when there is any direct contact with the oral mucosa. Handling of diagnostic samples by laboratory staff should follow biosafety procedures.

In addition to taking in-clinic precautions, laboratories and couriers should be warned that tularemia is a differential diagnosis before diagnostic specimens are submitted and appropriate precautions taken. Veterinarians should notify and consult public health authorities for guidance when tularemia is suspected.

Complete blood count may reveal thrombocytopenia, leukocytosis or leukopenia. Toxic change may be present in neutrophils. Serum chemistry may reveal elevations in alanine aminotransferase (ALT), alkaline phosphatase (ALP), and bilirubin. Lymph node aspiration may show reactive changes, pyogranulomatous inflammation or neutrophilic inflammation.

Pathologic findings include multiple foci of necrosis in lymph nodes, spleen, liver, and lung. Fibrinosuppurative to granulomatous inflammation may be present in many organs. It is difficult to demonstrate the organism in tissues with routine staining.

A fourfold increase in titer demonstrates acute infection, although it is important to note that animals may be seronegative early in the course of disease. Therefore, a negative titer does not rule out infection. Because antibody can be long-lived, a single positive titer is not diagnostic for active infection.

Antibodies may be used to directly demonstrate the presence of the organism in lymph node aspirates and tissue samples using direct immunofluorescent antibody assays. PCR verifies active infection. Culture is also a diagnostic method that demonstrates the presence of the organism. The laboratory must be notified that tularemia is a differential to protect laboratory workers and because the organism is fastidious and requires special media to grow. A negative result for immunofluorescent antibody assays, PCR or culture does not rule out infection.

Therapy

Aminoglycosides are the treatment of choice. Doxycycline and fluoroquinolones are also effective treatments but may be associated with relapse, which may be ameliorated with a longer course of treatment (three rather than two weeks).

Prognosis

Specific information about prognosis in dogs and cats has not been published.

Public Health Implications

Public health authorities should be notified immediately when tularemia is suspected. Infected cats may transmit tularemia by bites, scratches or contact with or aerosolization of fluids or tissue specimens or potentially fur. Veterinary and laboratory personnel should take appropriate precautions as detailed earlier. To prevent tularemia, owners should be advised to keep cats from roaming and hunting, provide appropriate ectoparasite control and to seek medical care if they feel ill or if they have been scratched or bitten by a cat with suspected infection.

According to the US government, "an urban cluster of tularemia cases among persons with a common natural exposure could be the first sign of a bioterrorist attack." Cats may serve as sentinels for such an attack due to their apparent disease susceptibility and exposure to environmental sources of the organism. Veterinarians should be vigilant in considering tularemia as a differential diagnosis in cats or dogs with compatible clinical signs.

Q Fever

Linda Kidd, DVM, PhD, DACVIM

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Etiology/Pathophysiology

Q fever is caused by the gram-negative bacterium *Coxiella burnetii*. *Coxiella burnetii* is a gamma-proteobacteria currently classified in the order Legionellales. The organism exists in two forms: a large-cell variant that is the metabolically active form, and a small-cell variant which is spore-like. The small-cell variant is released into the environment where it is very resistant to destruction by chemicals, light, and desiccation, and can survive for long periods of time. The target cell of this obligately intracellular organism is the macrophage. Host factors may contribute to its ability to survive intracellularly as interleukin (IL)-10, an antiinflammatory cytokine, appears to inhibit phagosome maturation, while intracellular killing appears to be facilitated by interferon (IFN)-gamma. Cell-mediated immunity is important in controlling infection. Granulomatous inflammation occurs in infected hosts. In animals, the uterus and mammary glands are the most common sites of infection. The organism concentrates in the placenta during parturition, and large numbers of the organism are aerosolized from these membranes and also carried by dust and other environmental sources once contamination has occurred.

Epidemiology

Coxiella burnetii has a worldwide distribution. Many species of mammals, birds, and arthropods, including ticks, can be infected. Infection of mammalian hosts may occur through aerosolization, oral (ingestion) or tick transmission. In mammals, the organisms concentrate in placenta and are excreted in milk, urine, saliva, and feces. Cattle, sheep, and goats are the most important reservoirs for the organism. Serosurveys suggest free-roaming rural cats and dogs are at increased risk. Exposure to raw meat, particularly raw kangaroo meat, has been implicated as a possible risk factor in cats. Recently, infections have been identified in United States soldiers returning from Iraq where Q fever is endemic. In a recent serosurvey, 5% of wild canines in Iraq were seropositive, while no military working dogs (MWDs) in the region were seropositive. Diligent use of flea and tick control, and the fact that the MWDs in this study did not have access to local farm animals or food were hypothesized to contribute to the discrepancy. Serosurveys have shown that exposure in cats is common in many areas of the world, ranging from 2% to 61%. Interestingly, polymerase chain reaction (PCR) failed to amplify DNA from the organism from the vaginas of 50 intact female Colorado shelter cats while 4/47 uterine biopsy samples from client-owned cats were positive. A follow-up study showed a similar PCR-positive prevalence rate of 8.1% in the uterine tissues of cats with and without reproductive abnormalities.

Coxiella burnetii is primarily of importance in small animal medicine due to its zoonotic potential. Clinical disease in dogs and cats is not commonly recognized. Multiple reports of infection in people after exposure to periparturient cats and dogs have been described. Despite these reports, a study on pet ownership was not associated with increased risk of antibody formation in people. Cats and neonatal kittens have been reported as a source of infection in people more often than dogs. A recent report of an outbreak in a small animal veterinary hospital was associated with a female cat undergoing C-section; 8/9 infected personnel working at the veterinary hospital worked the day of the C-section while the ninth person cleaned equipment the morning after.

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

Signalment

Because infection is usually asyptomatic, a study on signalment of naturally infected cats and dogs has not been described. Most cases in the literature describe intact female dogs and cats undergoing parturition as a source of exposure. MWDs deployed in Iraq may be at increased risk for infection especially if they have exposure to farm animals.

History and Clinical Signs

Disease is usually subclinical in dog and cats. Fever, anorexia, and lethargy have been described in experimental infection. Abortion or neonatal death has been associated with infection but the organism's role in causing reproductive abnormalities in dogs and cats is not fully elucidated. In one report, lesions in affected kittens included granulomatous myocarditis, hepatitis, nephritis, and pneumonia.

Diagnosis

Serology has been used to document exposure, while isolation, histopathology, immunohistochemistry, fluorescence *in situ* hybridization (FISH), and PCR can document infection. Public health authorities should be contacted for guidance on sample submission for suspected cases. Animals may be seronegative in the acute phase of disease prior to seroconversion. Sensitivity also varies depending on the serologic assay, and assays are species specific. The inability to demonstrate the organism using PCR, culture, FISH, and histologic methods does not rule out infection. Because the organism is highly infectious to people and stable in the environment, taking precautions to prevent infection in clinical and laboratory workers and owners is important.

Therapy

Studies investigating efficacy of treatment in cats and dogs have not been reported. Doxycycline is the treatment of choice in people with acute infections. Doxycycline in combination with hydroxychloroquine is recommended for chronic infections in people. Doxycycline and chloramphenicol are suggested for treating cats by the European Advisory Board on Cat Diseases (www.abcdcatsvets.org/coxiellosis-q-fever/).

Prognosis

Because naturally infected dogs and cats are asymptomatic, prognosis for survival in these species is thought to be good. The possibility of chronic asymptomatic infection and reservoir potential should be considered.

Public Health Implications

Q fever is a reportable disease in the United States. Humans are very susceptible to Q fever. Farm workers, laboratory workers, and veterinarians are at increased risk. Acute and chronic infections occur in people and are associated with significant morbidity and mortality. Exposure to parturient cattle, sheep, and goats, and aerosolization of the organism from environmental contamination by their fluids and tissues has historically been the primary route of infection in people, although exposure to periparturient cats has been the primary risk in some studies. Human infection associated with exposure to cats and dogs is usually in the context of aerosolization of high concentrations of organisms in placental tissues during parturition.

Guidelines for prevention and management of *C. burnetii* in cats have been established by the European Advisory Board on Cat Diseases (www.abcdcatsvets.org/coxiellosis-q-fever/). *Wearing gloves and masks during parturition of ALL cats and dogs,* diligent use of tick control and preventing cats and dogs from roaming have been recommended. Direct mouth-to-mouth resuscitation of kittens and puppies after C-section should be avoided. More extensive guidelines to prevent infection in people, which include additional recommendations such as avoiding the consumption of raw milk or raw milk products, are available from the United States Centers for Disease Control and Prevention (www.cdc.gov/qfever/).

Brucellosis

Erin E. Runcan, DVM, DACVT and Marco A. Coutinho da Silva, DVM, MS, PhD, DACT

Department of Veterinary Clinical Sciences, Ohio State University, Columbus, OH, USA

Etiology/Pathophysiology

Canine brucellosis is caused by the aerobic, gram-negative, coccobacillus species *Brucella*. The most clinically relevant infection in dogs is caused by *Brucella canis*, although reports exist of infection with *B. abortus*, *B. melitensis*, and *B. suis* in individual animals. The bacterium is highly contagious, and often spreads rapidly in breeding kennels. Transmission is also possible via frozen semen and artificial insemination as the bacterium is resistant to cryopreservation.

The organism is best known for being venereally transmitted via vaginal and seminal secretions in sexually mature animals. Transmission also occurs *in utero*, at parturition, or during abortion through oronasal, conjunctival, or transdermal contact of aborted fetal tissues, placental tissues, urine, milk, or vulvar discharge. Aborted tissues are highly infectious, containing high numbers of organisms, and abortion often results in persistent vaginal discharge that can last for 4–6 weeks. Infection can also occur via artificial insemination with infected semen, and via fomites such as contaminated food and water bowls, equipment, and clothing. The bacterium is highly stable and can survive for months in moist soil in the environment.

Following contact, invading bacteria are able to survive phagocytosis and are taken up by lymphatic and genital organs where they rapidly reproduce. Bacteremia occurs 1–4 weeks post infection and can persist for up to six months. Bacteria can be intermittently detected in tissues and secretions for up to 64 months post infection. While the bacteria reproduce best in reproductive tissues, a variety of clinical signs can manifest as a result of hematogenous transmission to the eye, kidneys, and vertebrae.

Epidemiology

Canine brucellosis is widespread in domestic and feral dog populations throughout the southern United States, in Central and Southern America, and Asia. It is unclear how important wild canids or stray dog populations are in disease transmission. Sporadic cases have been reported in Europe. Recently, the disease has become more prevalent in breeding kennels due to their growing number, ease of buying/selling and trading infected dogs, and increased international semen shipment.

Signalment

There are no current recognized breed or age predispositions. As venereal transmission is most significant, sexually intact, reproductively mature dogs are most likely to become infected, but the disease has been readily identified in both neutered and intact individuals. There has been a case report of a child becoming infected as a result of contact with an infected 8-week-old puppy and thus, the disease is zoonotic, especially in immunocompromised individuals.

History and Clinical Signs

The majority of individuals infected with *B. canis* are asymptomatic. Fever is uncommon and there are no clinical signs that are pathognomonic. The classic clinical sign is late-term abortion in bitches, with abortion occurring at 45–55 days gestation. Deceased pups are often autolysed, and surviving pups are often weak, have peripheral lymphadenopathy, and may die months later as a result of bacteremia. A greenish-gray vulvar

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

discharge may persist in aborting bitches for up to six weeks. Some bitches may have perceived infertility due to early embryonic loss.

Males develop a characteristic epididymitis approximately five weeks after infection. Increased presence of neutrophils and teratozoospermia with sperm agglutination is often seen 18 weeks post infection. Over 90% of sperm are morphologically abnormal by week 20 post infection. The enlarged epididymis is often painful and scrotal dermatitis may also be seen due to increased licking of the scrotum because of discomfort. Chronic infection often leads to testicular atrophy. Concurrent prostatitis is common.

Dogs with systemic infection may also present with clinical signs outside the reproductive tract, depending on the site of infection. Discospondylitis, lymphadenitis, lameness, ataxia, recurrent anterior uveitis, and low-grade meningitis have all been reported in *B. canis*-infected animals.

Diagnosis

Direct detection of the organism in culture remains the only definitive diagnostic method available; however, the slow growth rate, intracellular location, and previous antibiotic therapy may affect the results. Therefore, a negative culture does not rule out disease. Positive blood cultures may occur starting at 2–4 weeks post infection up to several years following infection due to intermittent shedding of the organism. Placenta, fetus, lymph nodes, bone marrow, prostate, spleen, urine, vaginal discharge, and semen may all be potential sites for culture of organisms.

Due to the difficulty in growing the organism in culture, serology can be a helpful screening tool for the disease. Antibodies can be detected 3–4 weeks post infection and serology is most accurate as a screening test 8–12 weeks post infection. Serologic testing is highly sensitive, but has low specificity due to cross-reactivity with other bacterial species. Serologic tests include the rapid slide agglutination test (RSAT), which is available as a commercial, cage-side screening test, with or without the addition of 2-mercaptoethanol (2-ME). If a sample tests positive with the RSAT test, 2-ME should be added to prevent cross-reactivity with IgM antibodies to other bacteria species and increase the specificity of the test. A second serologic test, the tube agglutination test (TAT), is similar but is quantitative. Titers less than 1:200 should be retested approximately two weeks later. Any positive agglutination test should be validated with ancillary testing before the animal is considered to be truly positive.

Agar gel immunodiffusion (AGID) assays are frequently used as the confirmatory test of choice for other serologic assays, although positive cross-reactions are common. Enzyme-linked immunosorbent assays (ELISAs) detect antibodies to the organism and may be more rapid and specific than agglutination or AGID assays. Positive dogs can be detected within 30 days of infection using this test, but current availability of this test is limited commercially.

Most recently, real-time polymerase chain reaction (PCR) testing has become available as a rapid, sensitive, and specific assay for *Brucella* species. It also has the benefit of being able to directly detect *Brucella canis* DNA in blood and tissues. It is likely that PCR will be the diagnostic test of choice in the future as it becomes more widely available.

Therapy

Due to the intracellular location of *Brucella* bacteria, antimicrobial treatments are challenging. There is no vaccine currently available. While it is possible for aborting females to subsequently carry and produce litters without treatment, infection is likely to be transmitted to offspring and infected dogs remain a risk to other dogs and humans.

Infected animals should be quarantined and removed from the breeding population via surgical sterilization. In kennel situations where infected animals are identified, euthanasia may be recommended to prevent transmission of disease and resident animals should be tested monthly. New animals introduced to the kennel should be isolated until two negative screening tests are obtained at least 30 days apart. Breeding animals should be screened serologically every six months prior to breeding.

No single antimicrobial protocol has been shown to consistently eliminate the disease long term. Many believe that permanent cures may not be possible even with surgical sterilization and antimicrobial treatment. Combination protocols with aminoglycosides and tetracyclines (gentamicin 5 mg/kg SC q24h for seven days, repeated every three weeks for three months, and doxycycline 10 mg/kg orally q12h), or tetracyclines and streptomycin (tetracycline 30 mg/kg orally q12h for 28 days and streptomycin 20 mg/kg IV q24h for 14 days) show the most success, but even with treatment, titers may reappear much later after infection, especially during times of stress. A protocol using twice-daily oral enrofloxacin

(5 mg/kg q12h for 30 days) has been described as successful in preserving fertility in a kennel outbreak situation, although some dogs had persistently elevated antibodies and subsequent treatments were required.

Prognosis

As infected dogs rarely show clinical signs, prognosis for survival is excellent. However, since infected dogs remain a potential source for infection for other dogs and immunocompromised humans, they should be kept in isolation from these individuals. Infected dogs should not be used for breeding and infection may be devastating to a breeding kennel due to its rapid spread.

Public Health Implications

Due to zoonotic concern, *B. canis* is a reportable disease in most states. Human case reports are often limited to laboratory workers and immunocompromised individuals. Most infections in people are mild although serious illness can occur. The disease may be underreported in humans due to varying clinical symptoms, which may mimic other diseases. Krueger and workers showed in a 2014 study that based on serologic testing, kennel employees and dog breeders are most likely to be exposed and many may have experienced *Brucella*-associated illness without diagnosis. Fortunately, humans respond well to antibiotic therapy and the disease is cleared when treated appropriately long term.

Tetanus and Botulism

Andrea Fischer, DVM, Dipl. ECVN, Dipl. ACVIM (Neurology)

Department of Veterinary Clinical Sciences, Ludwig-Maximilians University, Munich, Germany

Tetanus

Etiology and Pathophysiology

Tetanus results from the effects of tetanus toxin (tetanospasmin) which is released by the anaerobic bacillus *Clostridium tetani*. Spores of *C. tetani* are ubiquitous, survive in soil, and can contaminate and infect wounds. Thus, tetanus is a true toxicoinfection in which the toxin is produced and released within the infected wound. Following binding to peripheral nerve surface ganglioside receptors, the toxin (L-chain of tetanospasmin) is internalized into the peripheral nerve terminals. Tetanospasmin undergoes retrograde axonal transport to the spinal cord or brainstem, where it migrates transsynaptically to its site of action, inhibitory interneurons which utilize glycine or gamma-aminobutyric acid (GABA) as neurotransmitters. Tetanospasmin acts as a metalloproteinase which cleaves and inactivates a vesicle-associated membrane protein (VAMP) called synaptobrevin. Synaptobrevin mediates fusion of vesicles with the neuronal membrane and release of neurotransmitter into the synaptic cleft. Interference with the release of glycine from inhibitory neurons in the spinal cord and brainstem results in stimulus-sensitive muscle rigidity and spasticity worsened by touching, stretching or noise.

Tetanus can be localized or generalized. With localized tetanus, the toxin migrates only to the inhibitory interneurons in the spinal cord segments which are closest to the injury site and there is no hematogenous spread to distant synapses or further transsynaptic migration as in generalized tetanus.

Epidemiology

Tetanus occurs in a worldwide distribution. Dogs are less sensitive to the effects of tetanus toxin than horses or humans, and cats are more resistant than dogs. Consequently, localized tetanus is more frequently reported in cats than in dogs.

Signalment

Any dog or cat of any breed or age can be affected, but younger animals appear to be more susceptible.

History

Many patients have a history of an infected wound within the previous 10 days (up to three weeks). Draining wounds, tracts or wounds of the feet are frequent causes. Rarely, tetanus may occur following non-sterile surgical procedures, intraabdominal (female reproductive tract) or dental infections. Occasionally, the initial site of infection may not be detectable. Previous paw wounds may be diifucult to detect and only mild swelling may be evident despite ongoing infection. Radiographs of the paws are often indicated to identify foreign bodies and ongoing osteomyelitis which may require surgical management.

Clinical Signs

Localized tetanus presents with rigidity or stiffness, often resulting in rigid extension of one or both limbs, usually the ones next to the infection site or injury. Generalized tetanus causes signs of generalized muscle stiffness and rigidity, which are exacerbated by excitement, touch, or noise. Generalized tetanus is always associated with characteristic head muscle spasms resulting in trismus, erect ears, which are drawn together, excessive wrinkling of the forehead, drawn-back muzzle (risus sardonicus), and episodic prolapse of the third eyelid. Initially, only salivation, miosis, enopththalmos, risus sardonicus, erect ears or trismus may be present (severity class I), but these may progress to severe trismus, dysphagia, and generalized extensor rigidity

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

presenting as a stiff gait and sawhorse stance (severity class II), or recumbency with rigid extension of all limbs, muscle fasciculations, spasms, seizures, and opisthotonus (severity class III). Severity class IV involves autonomic dysregulation of heart rate and blood pressure. Mental status is usually normal unless severe hyperthermia or a seizure develops. Trismus, pharyngeal and laryngeal muscle spasms impair food and water intake and increase the risk for aspiration pneuomonia. Complications in severely affected animals are respiratory distress and aspiration pneumonia, hyperthermia, gastrointestinal ulceration, multiple organ failure, and autonomic failure. Hiatal hernia, megaesophagus, and urethral sphincter spasms may occur. Autonomic failure results in bradyarrhythmias and blood pressure variability.

Diagnosis

Tetanus is one of the rare diseases in which diagnosis is solely based on a combination of characteristic clinical signs and history. Attempts to culture *C. tetani* from the wound are often not successful and do not prove toxin production. Real-time polymerase chain reaction (PCR) for detection of the neurotoxin gene fragments of *C. tetani* has been used to support the diagnosis in humans. Continuous motor unit activity in antagonistic flexor and extensor muscles and repetitive discharges following peripheral nerve stimulation during electromyography may suggest tetanus but these findings are not specific.

Therapy

Routine first line management consists of application of tetanus antitoxin, metronidazole TID, sedatives and thorough investigation for an infected wound, especially on the paws. Equine tetanus antitoxin (median dosage 100–300 U/kg IV, range up to 1000 U/kg, higher dose given to smaller patients, not to exceed 20 000 units) should be given once immediately upon hospital admission slowly over 5–10 minutes and also prior to any wound management. Tetanus antitoxin will neutralize any free unbound toxin in the circulation but is not effective against the toxin once it has been internalized. Intravenous administration of equine tetanus antitoxin is preferred to intramuscular application of human tetanus immunoglobulin. Intravenous administration achieves a rapid increase in circulating antitoxin, but is associated with risk of anaphylaxis. An intradermal or subcutaneous test dose is routinely recommended but its predictive value is poor. The antihistamine diphenhydramine may be given prior to tetanus antitoxin administration. Tetanus antitoxin (500–1000 units) should also be injected locally proximal and around the wound and prior to any surgical exploration. Intrathecal injection into the subarachnoid space (1000 units preservative-free antitoxin) has been beneficial in human patients.

Metronidazole 10 mg/kg TID IV is the preferred drug for treatment of clostridial infection. Penicillin G is also an appropriate choice, although the fact that it is a GABA antagonist should be considered. Antimicrobial treatment should be continued for 7–10 days. Surgical wound debridement may be necessary.

It is of the utmost importance to keep the animals in a quiet noise-protected environment and to avoid any unnecessary manipulations. Ear plugs should be considered. Diazepam, acepromazine (0.005 - 0.02 mg/kg/h CRI or repeated injections as needed), chlorpromazine or methocarbamol (5 - 10 mg/kg/h CRI or 30 - 60 mg/kg QID IV) alone or in combination may achieve sufficient muscle relaxation and sedation in milder affected cases (class I). Dexmedetomidine CRI (25 µg/m2/h) is very effective to provide a continuous state of sedation. Diazepam or midazolam constant rate infusion (CRI) and phenobarbital CRI, or even general anesthesia may be necessary to achieve muscle relaxation in severe generalized tetanus. Propofol or pentobarbital CRI may also be used. Magnesium sulfate CRI has been beneficial as an adjunctive treatment. Pain should be addressed aggressively. Opioids are preferred to non-steroidal analgesics e. g. butorphanol (0.1 - 0.2 mg/kg/h CRI) or fentanyl CRI. Rescue therapy in humans consists of intrathecal baclofen, anesthesia with neuromuscular blockade, and positive pressure ventilation.

Management of severe generalized tetanus requires intensive supportive care in the intensive care unit for up to three weeks. This is an essential part of the management of generalized tetanus and needs to be communicated to the clients. Parenteral nutrition or an esophagostomy tube may be necessary to address caloric needs and keep the animal hydrated if trismus develops. Urinary catheterization may be necessary. Patients need to be closely monitored for signs of autonomic failure (heart rate, blood pressure regulation) including life-threatening bradyarrhythmias and signs of aspiration pneumonia.

Glucocorticoids are contraindicated in the management of tetanus.

Prognosis

Patients can completely recover within 4–6 weeks. Published survival rates are from 50% to 80%. Prognosis varies with tetanus severity classification. Sleep disturbances are reported following recovery from tetanus.

Public Health Implications

Body fluids and tissues, urine, and feces should be handled with care and appropriately labeled before submitting to the laboratory as they may contain toxin. Animals with tetanus have the potential to cause bite wounds as well.

Botulism

Etiology and Pathophysiology

Botulism results from ingestion of spoiled food or dead carcases which have been contaminated with bacteria of the species *Clostridium botulinum*. Clinical signs of botulism are due to the effects of *C. botulinum* neurotoxins which are already present in the food. Unlike tetanus, botulism is a true intoxication, in which the preformed toxin is ingested with the food, rather than an infection. Up to now, seven types of neurotoxin have been identified (botulinum toxins A–G). In people, types A and B are identified in most intoxications, while type C remains the most commonly reported toxin in dogs and also in one case series describing occurrence of botulism in cats. Toxicoinfection, in which the toxin forms secondary to bacterial growth in the gut or a wound, is recognized in people (wound botulism in drug abusers) but has not been described in dogs.

Once the ingested toxin passes the gastrointestinal (GI) barrier and gains access to the systemic blood circulation, it binds to surface ganglioside receptors on the peripheral nerve endings of motor nerves, which utilize acetylcholine as the neurotransmitter. Following internalization, the L-chain of botulinum neurotoxin remains in the presynaptic motor nerve terminals. Unlike tetanospasmin, botulinum neurotoxin does not undergo retrograde axonal transport. Each type of botulinum toxin (L-chain) targets specific proteins of the SNARE protein family, which mediate neurotransmitter release in the synaptic cleft. Thus, all types of botulinum toxins result in a similar functional deficit, namely impaired release of acetylcholine into the synaptic cleft in response to arriving action potentials and influx of calcium. Functionally, botulism represents a presynaptic neuromuscular transmission disorder.

Epidemiology

Botulism can occur worldwide. Groups of animals may be affected if they share feeding habits, such as several dogs eating from a large animal carcase or when spoiled contaminated food is fed to several dogs. Outbreaks may also occur around polluted lakes when dogs ingest dead waterfowl harboring *C. botulinum* in their guts. Nevertheless, isolated cases of botulism may also occur

Signalment

Any dog of any age can be affected. There is only one report of botulism in cats.

History and Clinical Signs

A thorough dietary history is essential. Botulism is considered if ingestion of dead fish, dead waterfowl, other animal carcases or rotten meat is reported. Feeding a raw food and bones diet should be considered a risk factor.

Botulism has a rapid onset of action. Intoxicated animals present with acute onset of generalized lower motor neuron paresis or paralysis. In many cases, peak paralysis will be reached within a day. Uncommonly, a more protracted onset over several days has been reported. Neurologic examination shows normal mentation, flaccid generalized lower motor neuron paresis or paralysis with absent spinal reflexes of all limbs. Additional cranial nerve signs such as mydriasis, facial nerve paralysis, and/or tongue paralysis may occur in more severely affected dogs. Respiratory movements may be impaired due to diaphragmatic or intercostal muscle paralysis. Laryngeal paralysis may co-exist. There is no evident hyperesthesia on palpation of the spine or muscles. In people, prolonged autonomic impairment following recovery from botulism is a concern but has not been described in dogs.

Diagnosis

Clinical suspicion of botulism is based on the neurologic signs of acute lower motor neuron paresis or paralysis and a history suggestive of possible toxin uptake in the absence of other causes such as polyradiculoneuritis, raccoon bites, tick paralysis, myasthenia gravis (crisis), coral snake poisoning, and ionophore toxicity. Confirmation is obtained by the detection of botulinum neurotoxin (direct evidence) or botulinum toxin producing Clostridia (indirect evidence) in the serum or feces by mouse bioassay. Toxin-specific enzyme-linked immunosorbent assays (ELISAs) or PCR are increasingly available for toxin detection, but their sensitivity may be lower than the mouse bioassay. Serum antibodies against botulinum neurotoxins may appear during the recovery phase. Unless seroconversion or a significant rise in titers is demonstrated, they can only be considered as a rather nonspecific indicator of exposure because antibody may also be present in normal dogs. Notably, results of confirmatory tests (toxin assays, toxin-specific antibodies) are usually obtained with a significant time delay for up to seven days or more, and thus offer little help for the initial emergency management of the patient.

Electrodiagnostic examinations may facilitate diagnosis , because they offer a readily available bedside test. When performed within the first days after onset, EMG will be remarkably unremarkable. Distal peripheral nerve stimulation results in a compound action potential of normal morphology but with a reduced amplitude and area. Nerve conduction is commonly normal. In contrast to polyradiculoneuritis there is no temporal dispersion. Repetitive stimulation may show a decrement or increment or be normal. Consequently, high-frequency repetitive stimulation has been recommended. However, examination in normal dogs showed variable results,

limiting the value of this test due to a lack of specificity. Botulism may result in mild spontaneous electric activity from denervation in the second week after onset and also a mild decrease in nerve conduction velocity, but electrodiagnostic examination is rarely performed at that time due to the early disease peak followed by gradual recovery starting at day 5–7 after onset.

Therapy

The focus of therapy is to provide supportive care to the patient. Clinicians should not be reluctant to provide ventilator support if there is obvious respiratory impairment. Especially during the first two days after onset, the dog's respiration needs to be carefully monitored.

The use of botulinum antitoxin is controversial. First, botulinum antitoxin needs to be directed against the specific toxin type, which suggests that antitoxin CD should probably be used in dogs. There is a risk for anaphylaxis but this appears to be low. A subcutaneous test dose may be applied 30–45 minutes prior to IV application and pretreatment with diphenhydramine considered. Botulinum antitoxin will only be able to neutralize the free unbound fraction of toxin in the systemic circulation but not the bound and internalized toxin which is responsible for the observed clinical signs. Consequently, the goal behind the application of toxin type-specific botulinum antitoxin is to prevent further progression of the paralysis and specifically to avoid respiratory paralysis and the need for ventilatory support in cases with large amounts of circulating unbound toxin or ongoing GI absorption.

Supportive care should include adequate bedding, frequent turning, and intravenous fluids. Nutritional support is also needed if the dogs are unable to eat or drink on their own. Application of an eye lubricant is indicated if facial movements and lid closure are impaired. Any dog with botulism needs to assessed carefully for the presence of megaesophagus. Prolonged autonomic dysfunction as a consequence of botulism is a concern in humans, thus bladder emptying and GI motility should be closely monitored. Drugs that can impair neuromuscular transmission (clindamycin, aminoglycosides, neuromuscular blocking agents) and glucocorticoids should be avoided. In severely affected animals with respiratory distress, early intubation and ventilation should be considered as a life-saving tool.

Prognosis

Most dogs recover from botulism within 2–3 weeks if they do not die from respiratory arrest at the peak of the paralysis.

Public Health Implications

Botulism cannot be transmitted directly from dogs and cats to people but body fluids and tissues, urine, and feces should be handled with care and appropriately labeled before submitting to the laboratory as they may contain toxin.

Anthrax

Wayne E. Wingfield, MS, DVM, DACVS, DACVECC[1] and Jerry J. Upp, DVM[2]

[1] *Department of Clinical Sciences, Colorado State University, Fort Collins, CO, USA*
[2] *Midtown Animal Hospital, Gering, NE, USA*

Etiology/Pathophysiology

Anthrax is a life-threatening infectious disease that normally affects animals, especially ruminants (such as goats, cattle, sheep, and horses). Both the dog and cat appear to be relatively resistant to the inhalational and cutaneous forms of anthrax, but clinical disease associated with ingestion of contaminated carcases is reported. Because dogs and cats may theoretically act as sentinels for infection in people during bioterrorist attacks, familiarity with the disease is important for the small animal clinician.

The agent of anthrax is a bacterium called *Bacillus anthracis* and it possesses three known virulence factors: an antiphagocytic capsule and two protein exotoxins, called the *lethal* and the *edema* toxins. The role of the capsule in pathogenesis was demonstrated in the early 1900s, when anthrax strains lacking a capsule were shown to be avirulent. The capsule is composed of a polymer of poly-D-glutamic acid, which confers resistance to phagocytosis and may contribute to the resistance of anthrax through lysis by serum cationic proteins.The anthrax toxins, like many bacterial and plant toxins, possess two components: a cell-binding, or B, domain necessary for entry into the host cell, and an enzymatically active, or A, domain that has the toxic and, usually, the enzymatic activity. The two toxins are unusual in that the B protein, called *protective antigen* (molecular weight [MW] 83 000), is shared by both toxins. Thus, the lethal toxin is composed of the protective antigen combined with a second protein, which is known as the *lethal factor* (MW 90 000). The lethal toxin is lethal for experimental animals and also has been shown to possess similar structure and activity to metalloproteases, although no direct enzymatic activity has yet been discovered.

The edema toxin, consisting of the same protective antigen together with a third protein, *edema factor* (MW 89 000), causes edema when injected into the skin of experimental animals. The edema factor is a calmodulin-dependent adenylate cyclase, which elevates intracellular cyclic adenosine monophosphate, and which is likely to be responsible for the marked edema often present at the site of bacterial replication.

Each of the three toxin proteins – the B protein and both A proteins – individually is without biologic activity. The critical role of the toxins in pathogenesis was established when it was shown that deletion of the toxin-encoding plasmid or the protective antigen gene alone attenuates the organism. The lethal toxin also appears to be more important for virulence in a mouse model than the edema toxin.

Anthrax can infect humans in three ways. The most common is infection through the skin, which causes an ugly sore that usually goes away without treatment. Humans and animals can ingest anthrax from carcases of dead animals or contaminated soil/plant materials that have been contaminated with anthrax. Ingestion of anthrax can cause serious, sometimes fatal disease. The most deadly form is inhalation anthrax. If the spores of anthrax are inhaled, they migrate to lymph nodes in the chest where they proliferate, spread, and produce toxins that often cause death. Interestingly, the dog is quite resistant to inhalational anthrax. Experimental studies have shown it required over 150 times the dosage in dogs as compared to humans. Likely it is the long nose of the dog which serves as an effective filtration system in preventing the usual fatal inhalational form of anthrax.

Infection is initiated with the introduction of the spore through a break in the skin (cutaneous anthrax), through entry through the mucosa (gastrointestinal anthrax), or inhalation of spores 1–2 μm in diameter. After ingestion by macrophages at the site of entry, germination to the vegetative form occurs, followed by extracellular multiplication and capsule and toxin production. In the lungs, the

Companion website: www.wiley.com/go/bruyette/clinical

anthrax spores are deposited in alveolar spaces and from there are transported by lymphatics to regional lymph nodes where germination occurs up to 60 days later.

Signalment

Anthrax occurs throughout the world. *B. anthracis* exists in the soil as a spore. The question remains unsettled as to whether its persistence in the soil is due to significant multiplication of the organism in the soil or if it is due solely to cycles of bacterial amplification in infected animals whose carcases then recontaminate the soil. The form of the organism in infected animals is the bacillus. Only when the organism in the carcass is exposed to oxygen does sporulation occur.

Anthrax is most common in agricultural regions where it occurs in animals. It is primarily a disease of herbivores (Table 107.1); carnivores and humans are incidental hosts. Animals, domestic or wild, become infected when they ingest spores while grazing on contaminated land or eating contaminated feed. Environmental conditions such as drought, which may promote trauma in the oral cavity during grazing, are thought to increase the chances of acquiring anthrax. It is spread from animal to animal by mechanical means and biting flies. Spread from one environmental site to another appears to occur via nonbiting flies, rodents, and carrion-eating birds. Free anthrax spores can also be spread by water and wind.

Human anthrax victims can also theoretically spread anthrax spores that landed on their clothing and external body surfaces. Therefore, each victim should be decontaminated and issued new clothes *before* leaving the scene. Estimates have shown that ~90% of anthrax will be on the clothes of a person exposed to an anthrax aerosol. Affected clothing should either be destroyed or can be washed using a 0.5% hypochlorite solution. Wounded or discharged victims will create a possible vector if they are not properly decontaminated. Anthrax does not readily transfer from one person to another unless the spores are in the clothing/shoes and there is some method of moving the spores to another person. Once a rescuer walks in the anthrax, then the threat of "movement" to other areas is very real.

Bodies that are not immediately recoverable pose little threat. Anthrax doesn't "jump up and bite you or me"! As long as the bodies are not disturbed and/or wind movement is low, the anthrax will stay inside the bodies or in the clothing.

History and Clinical Signs

Anthrax in veterinary species may be peracute, acute or subacute, or chronic. The peracute form most frequently affects cattle, sheep, and goats. The acute or subacute form is common in cattle, sheep, and horses. Chronic anthrax is most often seen in less susceptible species such as swine but may also be seen in cattle, horses, dogs, and cats. Suspicions of anthrax are raised when livestock are found dead, bloated, and without rigor mortis. Blood is usually evident at body orifices.

Dogs and Cats

Both the dog and cat appear to be relatively resistant to anthrax. Dogs are supposedly 500–1000 times more resistant to anthrax infection than humans. The gastro-

D, moderate; S, severe.

intestinal form is most common. In most cases, consumption of tissue from infected livestock is considered the source of the infection. Inhalational and cutaneous anthrax have not been reported in dogs and cats. Their longer noses and dense hair coats are possible reasons for this.

Clinical signs of anthrax include respiratory distress and dysphagia resulting from swelling of the neck secondary to regional lymphadenopathy, hemorrhagic and ulcerative inflammation of the oral cavity and pharynx, hemoptysis, lingual swelling, enteritis, and enlargement of the kidneys, spleen, and liver. Sudden death with few premonitory signs has also been reported. The incubation period in naturally infected carnivores is often difficult to determine, but it is believed to be approximately 3–7 days with a range of 1–14 days.

Pets exposed to anthrax will likely be subject to the gastrointestinal problems listed above but may complicate matters for their owners/rescuers with their thick fur harboring *B. anthracis* spores. When petted or handled, these spores can be aerosolized and expose the pet owner or rescuer. Additionally, dogs and cats "wash" their feet/bodies with their tongue, which transfers the anthrax directly into the pet (possibly initiating either pharyngeal or gastrointestinal anthrax). These facts would seem to favor early decontamination and quarantine of exposed animals.

Birds

Birds are usually highly resistant to anthrax. Buzzards, vultures, and other carrion-eating birds may transmit the spores on their talons and beaks.

Humans

People are infected with anthrax in three ways: cutaneous, gastrointestinal, and inhalational.

Diagnosis

Bacillus anthracis is a large, gram-positive, encapsulated, spore-forming, nonmotile bacillus (1–1.5 µm × 3–10 µm), grows readily on sheep blood agar aerobically, and is nonhemolytic under these conditions. The colonies are large, rough, and grayish-white, with irregular, curving marginal outgrowths. Both *in vitro* in the presence of bicarbonate and carbon dioxide, and in tissue *in vivo*, *B. anthracis* forms a prominent capsule. In tissue, the encapsulated bacterium occurs singly or in chains of two or three bacilli. The organism does not form spores in living tissue; sporulation occurs only after the infected body has been opened and exposed to oxygen. Remember that samples are highly infectious! Extreme caution should be taken in collecting, preparing for shipment, or transporting any material suspected of being contaminated with this bacterial agent. Contact your state public health service for specific instructions. The spores are oval and occur centrally or paracentrally. They are very resistant and may survive in the environment for *decades* in certain soil conditions. Bacterial identification is confirmed by gram stain and culture techniques, immunofluorescence assays (IFA), enzyme-linked immunosorbent assays (ELISA), or polymerase chain reaction (PCR). Each of these tests has limitations, with the standard still being the direct identification of the organism.

Therapy

Anthrax is a reportable disease. That means that local or state health agencies must be notified if a case of anthrax is diagnosed in dogs, cats, and other veterinary species.

Treatment for anthrax in small animals is undocumented at this time. Natural strains of *B. anthracis* are usually susceptible to several antibiotics; most but not all natural strains are susceptible to penicillin (dogs: penicillin G potassium 20 000 U/kg IV, IM, SC q4h). Some strains, particularly those used in bioterrorist attacks, may be resistant to penicillin. For this reason, the Centers for Disease Control and Prevention (CDC) recommends other antibiotics (Table 107.2) as the initial treatment, particularly for systemic disease, until antibiotic

susceptibility has been determined. Antibiotics are effective only against the vegetative stage of *B. anthracis*, and not against spores. Treatment is continued for at least 60 days in people with inhalational anthrax, as spores may remain dormant in the lungs and germinate during that time.

The pulmonary form of anthrax in people is a medical emergency. Early and continuous intravenous therapy with antibiotics may be life-saving and ventilator support is often required. In a bioterrorism attack, humans exposed to anthrax will be given antibiotics before they become sick. A vaccine exists but is not yet available to the general public. Most experts think that the vaccine will also be given to exposed individuals who are victims of a bioterrorist attack. Supportive therapy may also be necessary, particularly for the inhalational and gastrointestinal forms.

Effective treatment depends on early recognition of the symptoms. Treatment for cutaneous anthrax is usually effective, but the inhalational and gastrointestinal forms are difficult to recognize early and the mortality rates are higher.

Public Health Implications

Anthrax in humans is associated with agricultural, horticultural, or industrial exposure to infected animals or contaminated animal products, and as a weapon of mass destruction disseminated by terrorists. In less developed countries, primarily in Africa, Asia, and the Middle East, anthrax occurs from contact with infected domesticated animals or contaminated animal products. This includes handling contaminated carcases, hides, wool, hair, and bones, and ingesting contaminated meat. Cases associated with industrial exposure are rarely seen today but may occur in workers processing contaminated hair, wool, hides, and bones. Direct contact with contaminated material leads to cutaneous disease, while ingestion of infected meat gives rise to oropharyngeal or gastrointestinal forms of anthrax. Inhalation of a sufficient quantity of spores, usually seen only during generation of aerosols in an enclosed space, is associated with processing contaminated wool or hair, or opening anthrax-laced letters, giving rise to inhalational anthrax.

In mail-handling sites, *B. anthracis* spores may be aerosolized during the operation and maintenance of high-speed mail-sorting machines, potentially exposing workers and other mail. In addition, these spores could get into heating, ventilating, or air-conditioning systems.

Unreliable reporting makes it difficult to estimate with accuracy the true incidence of human anthrax. It was estimated in 1958 that worldwide between 20 000 and 100 000 cases occurred annually. In more recent years, anthrax in animals has been reported from 82 countries, and human cases continue to be reported from Africa, Asia, Europe, and the Americas. In the United States, the annual incidence of human anthrax had steadily declined, from about 127 cases in the early years of this century to about one per year over the past 10 years. The vast majority of cases were cutaneous. Under natural conditions, inhalational anthrax is exceedingly rare, with only 18 cases having been reported in the United States in the 20th century.

Outbreaks of Weaponized Anthrax

Weaponized anthrax has caused two outbreaks of disease (key points from each are outlined in the sections below).

Sverdlovsk Outbreak – 1979

This outbreak in the Union of Soviet Socialist Republics resulted from accidental release of anthrax spores from a military microbiologic facility where weaponized anthrax was being produced.

Seventy-seven human cases were reported and 66 of the patients died, for a case–fatality rate of 86%; 75 cases were inhalational and two were cutaneous (one on the back of the neck and one on the shoulder). A recent statistical analysis of available data suggests that 250 cases with 100 fatalities may actually have occurred. The mean patient age for males was 42 and for females was 55 years, and interestingly no cases were reported in children.

United States – 2001

This outbreak predominantly involved direct exposure to mail that was deliberately contaminated with anthrax spores. Several contaminated letters were sent and one was reported to contain 2 g of powder, with 100 billion to 1 trillion anthrax spores per gram.

Twenty-two cases (11 inhalational and 11 cutaneous) were identified. Five of the patients with inhalational anthrax died, for a case–fatality rate of 45% among that group. The outbreak demonstrated several important points about weaponized anthrax: mail can be an effective vehicle for disseminating anthrax spores; cross-contamination of mail likely can occur within postal facilities; and persons who handle or process unopened contaminated mail are at risk of acquiring anthrax. Substantial environmental contamination can occur in facilities handling contaminated mail or in offices where contaminated mail is opened.

Prevention

Public health measures to prevent contact with infected animals are invaluable. There is a vaccine available for

people at high risk (such as veterinarians, laboratory technicians, employees of textile mills processing imported goat hair, and members of the armed forces). The Department of Defense and the Centers for Disease Control and Prevention are working hard to prevent a bioterrorist attack and to be prepared to deal with the consequences if one occurs. For anthrax, vaccines with greater efficacy and fewer side-effects are under development. Currently, most vaccines are given by injection. Early studies in experimental animals are showing promise for an oral vaccine for anthrax.

Actinomycosis, Nocardiosis, and Mycobacterial Infections

Joanna Whitney, BSc, BVSc, PhD, MVetStud, MACVS (SMAnimMed, ECC)[1] and Vanessa R. Barrs, BVSc (Hons), MVetClinStud, MACVSc (Small Animal), FACVSc (Feline), GradDertEd (Higher Ed)[2]

[1]*Small Animal Specialist Hospital, North Ryde, NSW, Australia*
[2]*University of Sydney, Sydney, Australia*

Actinomyces, *Nocardia*, and *Mycobacteria* belong to the order Actinomycetales. All are bacilli that form branching filaments and cause pyogranulomatous infections. However, differences in antimicrobial susceptibility patterns, zoonotic implications, and prognoses make an understanding of how the organisms are differentiated clinically important.

Actinomycosis

Etiology/Pathophysiology and Epidemiology

Actinomyces spp. are facultatively anaerobic or microaerophilic, Gram-positive, nonacid-fast, nonsporulating, and nonmotile bacilli. These opportunistic pathogens are commensals of the mucous membranes, especially the oral cavity but also the gastrointestinal and genitourinary tracts. *Actinomyces* are often involved in polymicrobial infections that enhance their pathogenicity. *A. viscosus*, *A. hordeovulneris*, *A. bowdenii*, *A. canis*, *A. catuli*, *A. turicensis*, *A. weissii*, and *A. odontolyticus* have been isolated from canine infections. *A. viscosus*, *A. meyeri*, *A. odontolyticus*, *A. hordeovulneris*, and *A. bowdenii* have been isolated from infections in cats. *Actinomyces pyogenes* was recently reclassified based on 16S rRNA gene sequencing to be included in the genus *Arcanobacterium*. This organism has been reported to produce actinomycosis-like infections in both dogs and cats.

Actinomyces cause disease following inoculation of body tissues, frequently in conjunction with other bacteria. Portals of entry include oral mucosa damaged by chronic gingivitis and periodontal disease, foreign body migration, subcutaneous inoculation via bite wounds or plant material, and aspiration of oropharyngeal material or grass awns. Infections occur primarily in immunocompetent individuals.

Actinomyces form histopathologic lesions characterized by pyogranulomatous inflammation with areas of central necrosis surrounded by macrophages, neutrophils, and plasma cells. Subacute and chronic infections result in granulation tissue formation, extensive fibrosis, and sinus tracts. Exudates and effusions are often malodorous. *Actinomyces* may form bacterial colonies in infected body fluids, commonly referred to as "sulphur granules," that grossly appear tan or white.

Signalment

Young, male, large-breed outdoor dogs are overrepresented. Hunting and working animals are often affected, particularly with soft tissue abscesses or pyothorax associated with plant material foreign bodies. Young, male cats are also at increased risk from aggressive interactions involving scratches and bite wounds resulting in inoculation of oral bacteria.

History and Clinical Signs

In both dogs and cats actinomycosis is most commonly associated with subcutaneous and soft tissue abscesses and intrathoracic disease. Clinical findings may include pneumonia, lymphadenopathy, intra- or extrapulmonary masses or pyothorax. Central nervous system (CNS), periodontal, ocular, peritoneal, urinary bladder, cardiac, and orthopedic infections have also been reported in dogs. In cats, less common presentations include abdominal granulomas, intracranial/spinal empyema, and cholecystitis.

Cervicofacial actinomycosis occurs in both cats and dogs associated with extension of oral bacteria into the soft tissues of the head and neck secondary to periodontal

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

disease, oral trauma, and bite wounds. Lesions most commonly develop around the jaw and neck.

Cutaneous and subcutaneous actinomycosis manifests as flocculent to firm masses often with draining sinus tracts typically on the thoracic wall, flanks or limbs. These lesions in dogs are often secondary to migrating grass awns. In cats, they are associated with bite wounds.

Thoracic actinomycosis can present as pneumonia, lymphadenopathy, intra- or extrapulmonary masses or pyothorax. Thoracic actinomycosis in cats occurs secondary to aspiration of oral flora whereas canine infections are secondary to inhalation and migration of grass awns. Clinical signs may be nonspecific, such as lethargy and weight loss, or can include tachypnea, dyspnea, and coughing. Foreign bodies in dogs can migrate further into the retroperitoneum, resulting in abscessation in this area.

Abdominal, visceral, and central nervous system infections can develop from extension of subcutaneous infections, foreign body migration or hematogenous spread. Osseous infections can result from extension from other locations or contamination of orthopedic implants.

Diagnosis

A provisional diagnosis of actinomycosis is based on the identification of Gram-positive, nonacid-fast filamentous organisms on cytologic examination of fluid or tissues from suspicious lesions using a modified Ziehl–Neelson (Kinyuon) method. A definitive diagnosis requires either isolation and phenotypic identification of the causative agent using biochemical methods, chemotaxonomy, and serology or identification using molecular methods. Molecular methods, most commonly 16S rRNA gene sequencing, are now the diagnostic techniques of choice for identifying the infecting species as they provide accurate and rapid results. It is important to note that culture and polymerase chain reaction (PCR) can be negative in some cases. Furthermore, culture or detecting organisms using PCR without compatible clinical signs may not be clinically significant since *Actinomyces* are commensals.

Therapy

The combination of surgery and antimicrobial treatment is generally superior to antimicrobial treatment alone in resolving *Actinomyces* infections in which a foreign body is suspected. Thoracotomy and debridement are recommended in dogs with pyothorax, while cats generally require only tube thoracostomy in addition to medical therapy. This likely reflects the difference in etiologies in which canine infections generally result from foreign body migration and feline infections are caused by aspiration of oral flora. Prolonged antimicrobial therapy for several months is often required to resolve infection. *Actinomyces* spp. are susceptible to high doses of penicillins as well as other antibiotics (Table 108.1). As actinomycosis often occurs as a component of a mixed bacterial infection, identification, susceptibility testing, and treatment of the co-infectious agents are also imperative for resolution.

Prognosis

The prognosis for dogs and cats with subcutaneous and soft tissue actinomycosis and for cats with pyothorax is generally good when treated for sufficient time. However, reported survival rates in dogs with thoracic disease are variable and CNS actinomycosis is invariably fatal.

Table 108.1 Antimicrobials used to treat *Actinomyces* and *Nocardia* infections

	Canine	Feline
Actinomyces spp.	Penicillins • Ampicillin (10–20 mg/kg IV/IM/SC q6–8h) • Amoxicillin (10–30 mg/kg IM/SC/PO q12h) Macrolides/Lincosamides • Clindamycin (5 mg/kg IV/IM/SC/PO q12h) • Erythromycin (10 mg/kg PO q8h) Chloramphenicol* (50 mg/kg IV/IM/SC/PO q8h)	Penicillins • Ampicillin (10–20 mg/kg IV/IM/SC q6–8h) • Amoxicillin (10–30 mg/kg IM/SC/PO q12h) Macrolides/Lincosamides • Clindamycin (5 mg/kg IV/IM/SC/PO q12h) • Erythromycin (10 mg/kg PO q8h) Chloramphenicol* (50 mg IV/IM/SC/PO/cat q12h)
Nocardia spp.	Sulfonamides • Trimethoprim-sulfonamide* (30 mg/kg PO q12h) Amikacin (10–30 mg/kg IV/IM/SC q24h)* Imipenem-cilastatin (3-10 mg/kg slow IV q8h) Cefotaxime (25–50 mg/kg IV/IM/SC q6h)	Sulfonamides • Trimethoprim-sulfonamide* (30 mg/kg PO q12h) Amikacin (10–15 mg/kg IV/IM/SC q24h) Imipenem-cilastatin (3-10 mg/kg slow IV q8h) Cefotaxime (22 mg/kg IV/IM/SC q6–8h)

* Potential severe adverse drug effects.
For all medications please consult comprehensive formularies for potential adverse drug effects, interactions, and contraindications.

IM, intramuscular; IV, intravenous; PO, by mouth (*per os*); SC, subcutaneous.

Public Health Implications

Humans bitten by dogs or cats can develop actinomycosis. However, there have been no reports of transmission from infected animals to humans.

Nocardiosis

Etiology/Pathophysiology and Epidemiology

The genus *Nocardia* consists of filamentous, branching, Gram-positive, variably acid-fast, catalase-positive, nonmotile aerobic bacilli. Unlike commensal *Actinomyces*, *Nocardia* species are ubiquitous soil saprophytes, involved in plant decomposition. Pathogenic species have been isolated from house dust, garden soil, beach sand, swimming pools, and tap water in different geographic regions. Pathogenic *Nocardia* species in dogs include *N. caviae*, *N. asteroides*, *N. abscessus*, *N. otitidiscaviarum*, *N. brasiliensis*, *N. cyriacigeorgica*, and *N. veterana*, while those in cats include *N. tenerifensis*, *N. africana*, *N. nova*, *N. farcinica*, *N. cyriacigeorgica*, *N.brasiliensis*, and *N. elegans*. The virulence of *Nocardia* spp. varies with the phase of growth associated with changes in composition of the cell wall.

Infection with *Nocardia* species occurs after inhalation of aerosolized environmental organisms or inoculation via puncture wounds. The host T cell response is essential in limiting dissemination of nocardial infection following inoculation, but it is also responsible for the development of the characteristic suppurative to granulomatous lesions of nocardiosis.

Nocardiosis is less common than actinomycosis and in contrast to *Actinomyces*, *Nocardia* infections are most common in immunosuppressed patients.

Signalment

Localized infections, particularly abscesses of the subcutaneous tissues, are most frequently seen in young outdoor dogs secondary to foreign body migration and inoculation during puncture wounds. Similarly, cats of any age with outdoor access more commonly develop superficial lesions.

Disseminated or systemic nocardiosis develops in young and immunosuppressed dogs and cats. The increasing use of immunosuppressive medications in veterinary patients has resulted in an increase in the incidence of such infections.

History and Clinical Signs

Nocardiosis is typically classified as subcutaneous, pulmonary and systemic, or disseminated. In immunocompetent companion animals, especially cats, disease most commonly manifests as cutaneous and pulmonary lesions. Disseminated disease, often involving the CNS, has been reported more commonly in young and immunosuppressed dogs. *Nocardia* spp. have been isolated sporadically from cases of hepatitis and cystitis.

Cutaneous nocardiosis is the most common manifestation of disease in cats, associated with inoculation via scratches from cat fights and punctures from plant material.

Dogs and cats with disseminated or systemic disease typically have a history of immunosuppressive disease or administration of immunomodulating drugs. In particular, nocardiosis has been shown to occur currently with canine distemper virus infection in endemic areas.

Pulmonary nocardiosis may occur in isolation associated with wound inoculation or foreign body migration, or as a component of disseminated disease. In dogs, the most common clinical signs of pneumonia include dyspnea, nasal discharge, fever, weight loss, and anorexia.

Diagnosis

A presumptive diagnosis of nocardiosis may be made based upon macroscopic and microscopic examination of clinical specimens. Organisms on Gram-stained slides will appear as Gram-positive, thin filamentous organisms within a background of lymphocytes and macrophages. Acid-fast stains may be used to demonstrate acid-fastness in samples that have revealed filamentous organisms with Gram staining. However, this reaction is unreliable in direct clinical samples and may be dependent on the growth media used and age of culture samples. Species identification has traditionally been performed based on biochemical methods, chemotaxonomy, and serology. Molecular methods, most commonly 16S rRNA gene sequencing, are now used preferentially for bacterial identification as these provide accurate and rapid results.

Due to the ubiquitous nature of *Nocardia* spp., the significance of isolation of these organisms from clinical samples should be assessed in light of the clinical findings. Identification of the sample organism in multiple samples also aids in determining significance.

Therapy

Treatment of nocardiosis relies upon debridement and drainage of the lesion and prolonged antimicrobial therapy. Most *Nocardia* spp. are susceptible to sulfonamide antimicrobials and these often form the basis of medical therapy. However, species differences in susceptibility have been reported and *in vivo* response to treatment does not always reflect *in vitro* results. In humans, a range of other antimicrobials (see Table 108.1) are efficacious

with protocols based on established species-specific susceptibility patterns advocated for treatment of persistent or disseminated infections. Six to 12 months of antimicrobial therapy is required in most cases for optimal results. Alternatives to sulfonamides should be considered for prolonged treatment of nocardiosis to minimize the risk of adverse drug reactions.

Prognosis

While cases of superficial nocardiosis may show initial response to treatment, most patients are euthanized due to deterioration or disease recurrence. Disseminated nocardiosis, especially with CNS involvement, has a grave prognosis. The poor outcome for these patients is likely associated with the underlying immunosuppressive disease.

Public Health Implications

There have been no cases of acquired infection from infected animals, but cat scratches have caused cutaneous nocardiosis in people. Immunocompromised individuals should take special precautions when interacting with infected dogs or cats.

Mycobacteriosis

Etiology/Pathophysiology

Members of the genus *Mycobacterium* are intracellular, aerobic, acid-fast, nonspore-forming, environmentally resistant bacilli. *Mycobacteria* spp. are generally saprophytic and nonpathogenic, but several are primary or opportunistic pathogens in dogs cats, and humans. Infecting bacteria are phagocytosed by host macrophages within which the organism replicates. Infected macrophages produce proinflammatory mediators and attract monocytes and other inflammatory cells to the site of infection, resulting in focal or disseminated granulomatous to pyogranulomatous disease.

Mycobacterial infections are recognized increasingly in companion animals because of improved diagnostic techniques and increased use of immunosuppressive medications. Recent evidence suggests that the prevalence of mycobacteriosis in companion animals, particularly in the United Kingdom, is underestimated due to nonspecific signs, a low index of suspicion, and difficult antemortem diagnosis.

The mycobacteria that cause companion animal infections are generally divided into tuberculous, saprophytic or opportunistic, and lepromatous groups. Generally, the tuberculous group includes members of the *Mycobacterium tuberculosis* (MTB) complex, the saprophytic group includes members of the *M. avium* complex (MAC) and other nontuberculous bacteria, and the lepromatous group includes bacteria that cause feline leprosy and canine leproid granuloma syndromes (Table 108.2). However, there is much overlap in these categories since different organisms cause similar clinical lesions and there is disagreement in the grouping of organisms. Organisms from all groups can cause cutaneous lesions whereas systemic or disseminated disease results from infection with tuberculous or saprophytic/opportunistic agents.

Epidemiology

Tuberculosis is caused by infection with members of the MTB complex, all of which are obligate pathogens (see Table 108.2). The prevalence of disease within a region and the causative agent are dependent on the presence of the primary host species. Humans are the reservoir host for *M. tuberculosis* so the incidence of *M. tuberculosis* infection in dogs follows the distribution reported for people, and includes areas of the US, Africa, France, and Switzerland. *M. bovis* infections in people occur in Great Britain and New Zealand and consequently most feline infections are also reported in these regions.

Mycobacterium tuberculosis infection typically results from close contact with infected humans. Disease transmission occurs via inoculation, ingestion or inhalation. Organisms in sputum and respiratory secretions are aerosolized and inhaled or ingested by in-contact pets. However, due to the chronicity of disease and potential for hematogenous dissemination, the route of infection may not be identifiable at the time of diagnosis. Although there are minimal reports of transmission of *M. tuberculosis* from pets to their owners the zoonotic potential of infected animals is of major concern, particularly for immunocompromised owners.

The primary reservoir of *M. bovis* is domestic cattle, with transmission to dogs and cats thought to be due to ingestion of contaminated meat or milk. Cats and dogs are considered to be potential amplifier hosts of *M. bovis* in endemic areas, meaning that they may act as a source of infection for other animals and people. Rodents, feral pigs, wild deer, badgers, and opossums are established reservoir hosts for *M. bovis* and/or *microti*.

The occurrence of peripheral primary cutaneous lesions in cats suggests that some infections may develop following inoculation of organisms via bite wounds. Hunting and catching small rodents are risk factors for *M. microti* infection in cats.

The saprophytic mycobacteria are the most common causes of mycobacteriosis in cats and dogs. This group includes the rapid-growing mycobacteria (RGM) and

slow-growing mycobacteria (SGM) groups, including the *M. avium-intracellulare* complex (see Table 108.2). The saprophytic mycobacteria are widely distributed in the environment. They have variable geographic prevalence likely associated with environmental factors such as warmer temperatures that support their growth. Infection with RGM usually follows cutaneous, pulmonary or gastrointestinal inoculation. Disseminated disease may develop in immunosuppressed animals.

Canine and feline leproid syndromes are characterized by discrete cutaneous lesions. The causative agents are fastidious and cannot be cultured readily. Feline leprosy results from infection with one of a number of saprophytic species (see Table 108.2). *M. lepraemurium* infection is thought to be transmitted to cats by rodent bites. Insect vector transmission has also been proposed but is unverified.

It is not clear whether canine leproid granuloma syndrome results from infection with one or more species. Partial characterization using gene sequencing has shown that genetically identical organisms have been associated with the disease worldwide; however, the causative species remains incompletely defined due to inability to culture it in the laboratory. Transmission of the canine agent via insect vectors seems likely. Case clusters of disease in related foxhounds suggest additional environmental or genetic factors may be involved.

Signalment

Younger animals tend to be more commonly affected by mycobacteriosis, particularly cutaneous forms of the disease. This may be associated with increased exposure to environmental organisms and precipitating injuries that allow infection. Patients that develop disseminated disease are often suspected to be immunocompromised although supportive evidence for this may not be apparent. Tuberculosis is most commonly observed in animals with prolonged close contact with an infected primary host. Adult nonpedigree cats with outdoor access are most commonly affected, although Siamese cats are also overrepresented. Feline leprosy is most common in young cats and in older cats that are immunosuppressed. Canine leproid granuloma syndrome is most common in large-breed, short-haired dogs, especially boxers. Bassett hounds, schnauzers, and Abyssinian cats are overrepresented in disseminated saprophytic mycobacteriosis, suggesting genetic immunodeficiencies in these breeds.

C, cutaneous lesions; D, disseminated disease; L, pulmonary disease; P, panniculitis.

History and Clinical Signs

Cutaneous lesions in mycobacteriosis vary. Leproid granulomas can be single or multiple nodules with or without ulceration and frequently occur on the head and limbs. The most common manifestation of tuberculosis and saprophytic mycobacterial infections in cats is the cutaneous form that results in the development of subcutaneous masses, often with draining sinuses and a regional lymphadenopathy. Skin lesions are usually mobile, firm, raised, moist, and without odor. The saprophytic mycobacterial agents have a predilection for adipose tissue and often cause a panniculitis of the ventral abdomen and inguinal area in cats (Figure 108.1). Ocular lesions are frequently reported in cats with the leproid syndrome. Pulmonary, gastrointestinal or disseminated granulomatous lesions can result from infection with tuberculous and saprophytic group organisms. Abdominal and pleural effusions often develop with progressive disease.

Diagnosis

Clinical pathologica results are generally nonspecific, and may include a neutrophilia with a left shift, nonregenerative anemia, decreased albumin:globulin ratio, and hypercalcemia. Where there is systemic involvement, diagnostic imaging findings are consistent with nonspecific infiltrative disease of the abdominal and/or thoracic cavities with possible organ and lymph node mineralization. Tuberculin intradermal testing in dogs and cats is generally unrewarding. However, immunodiagnostic assays for diagnosis of *M. bovis* in cats, including semiquantitative interferon-gamma production and point-of-care qualitative antibody detection tests, have shown positive results, although further evaluation is required.

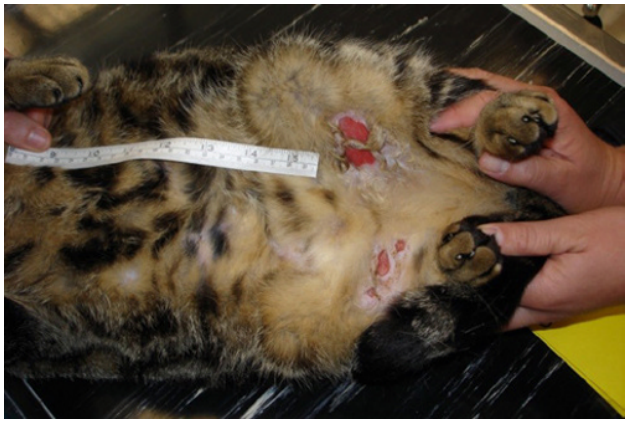

Figure 108.1 Inguinal panniculitis in a cat.

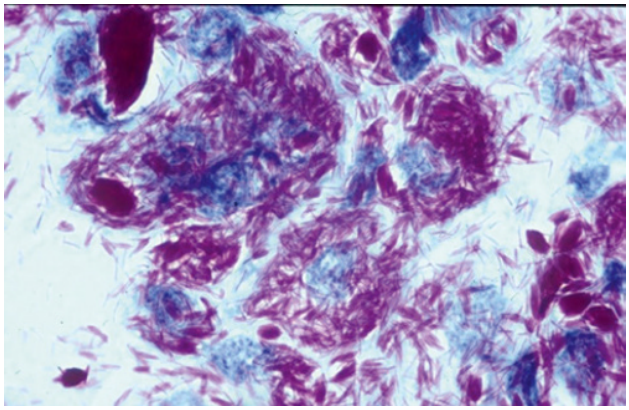

Figure 108.2 Acid-fast bacilli in a sample from a cat with feline leprosy.

Suspicion of mycobacteriosis should be raised in animals with consistent presenting signs whenever pyogranulomatous inflammation is identified on cytologic or histopathologic examination. Provisional diagnosis is based on the identification of acid-fast bacilli within tissue samples, exudates or blood smears (Figure 108.2). Definitive diagnosis requires organism identification and is imperative in mycobacterial infections in connection to their treatment and zoonotic potential. Like acid-fast staining, culture for mycobacteria must be specifically requested from the laboratory.

While RGM are often difficult to identify cytologically due to the scant number of organisms seen, they can generally be cultured within seven days. Conversely, SGM may be abundant on tissue cytology but cannot be cultured readily, if at all. Molecular techniques, particularly 16S rRNA sequencing, provide rapid and accurate identification of mycobacteria which is of particular importance in potential zoonotic infections. However, bacterial culture and susceptibility testing should still be attempted to determine appropriate antimicrobial therapy.

Therapy and Prognosis

The zoonotic potential and implications of treating infected animals must be considered before treatment (see later). Recommendations for treatment of tuberculous and saprophytic infections include triple agent antimicrobial therapy (a fluoroquinolone, a macrolide, and rifampicin) for three months followed by continued administration of two of these agents for an additional six months (see Table 108.3). Other antimicrobials, including doxycycline, aminoglycocides, third-generation cephalosporins, and chloramphenicol, have been reported to have been used in combination protocols or

Table 108.3 Antimicrobials used to treat mycobacterial infections

	Slow growing	Clarithromycin (5–15 mg/kg PO q12h) Clofazamine (4–12 mg/kg PO q24h) Rifampicin* (10–15 mg/kg, max 600 mg/day, PO q24h) Doxycycline (5–10 mg/kg PO q12–24h)	Clarithromycin (62.5 mg PO q12h) Moxifloxacin (10 mg/kg PO q24h) Clofazamine (8 mg/kg, max 25 mg) PO q24h) Rifampicin* (10–20 mg/kg PO q24h) Doxycycline (5–10 mg/kg PO q12–24h)
Leproid syndromes		Rifampicin* (10–15 mg/kg PO q24h) Clarithromycin (5–15 mg/kg PO q12h) Clofazamine (4–8 mg/kg PO q24h) Doxycycline (5–10 mg/kg PO q12–24h)	Rifampicin* (10–15 mg/kg PO q24h) Clarithromycin (62.5 mg PO q12h) Clofazamine (8 mg/kg, max 25 mg) PO q24h) Doxycycline (5–10 mg/kg PO q12–24h) Fluoroquinolones • Marbofloxacin (2 mg/kg PO q24h) • Moxifloxacin (10 mg/kg PO q24h) Amikacin (10–15 mg/kg IV/IM/SC q24h)

* Potential severe adverse drug effects.
Please see text for further information regarding treatment protocols and drug combinations.
For all medications please consult comprehensive formularies for potential adverse drug effects, interactions, and contraindications.
IM, intramuscular; IV, intravenous; PO, by mouth (*per os*); SC, subcutaneous.

have been shown to have *in vitro* efficacy. However, these are not recommended as first-line therapies. Similarly, protocols including isoniazid and pyrazinamide have been reported for treatment of resistant infections but should be used with care due to potential toxicities. It is important to note that *M. bovis* has natural resistance to pyrazinamide. While superficial infections hold a guarded prognosis for long-term resolution, the prognosis for systemic infections is grave.

Treatment of the leproid syndromes is not always required as spontaneous remission has been reported, especially in dogs. Refractory lesions should be treated with surgical resection with prolonged, dual or triple antimicrobial therapy comprising a combination of rifampicin, clarithromycin, and/or clofazamine (Table 108.3).

Public Health Implications

Although the risk of transmission from dogs and cats to humans is low, members of the tuberculosis complex and MAC have zoonotic potential. Infected animals may excrete organisms in sputum and respiratory secretions that are aerosolized and can be inhaled or ingested by humans in close contact. Euthanasia or aggressive treatment of

dogs and cats infected with these organisms is imperative to eliminate the risk of zoonotic transmission.

Infection of veterinary personnel with *M. tuberculosis* has been reported following necropsy of infected dogs. In one case, the organism may have been aerosolized during use of an electric saw. Cutaneous inoculation of mycobacterial bacilli has also been reported associated with needle sticks contaminated by laboratory and patient samples. Care should be taken in specimen handling and appropriate personal protective equipment must be worn to avoid aerosolization, inhalation, and inoculation of organisms.

Tuberculosis is reportable or notifiable in a number of countries. Regional and national health authorities should be consulted when tuberculous infections are suspected or diagnosed in dogs and cats to allow thorough epidemiologic investigation.

Fungal Infections

Jane E. Sykes, BVSc, PhD, DACVIM (SAIM)

Department of Medicine and Epidemiology, University of California-Davis, Davis, CA, USA

General Features of Fungal Infections

Etiology/Pathophysiology

Fungal infections can be classified as *superficial* (*cutaneous) mycoses* or *deep mycoses*. Superficial mycoses are limited to the skin and include dermatophytosis and *Malassezia* infections. Deep mycoses can be caused by:

- organisms that exist as molds (hyphal forms) in the environment, the conidia (spores) of which are typically inhaled by mammalian hosts and then transform into replicating yeasts in tissues (*dimorphic fungi*)
- organisms that exist as spore-producing molds in the environment, are inhaled by mammalian hosts and then continue to grow as molds in tissues, such as *Aspergillus*
- *Candida*, which is a commensal of mucous membranes and invades opportunistically.

With the exception of *Sporothrix*, infections caused by dimorphic fungi and molds are acquired from the environment, and disease transmission from one affected animal to another does not occur. Incubation periods are often several weeks to months in duration, because of the slow replication rate of many fungi.

Epidemiology and Signalment

In general, dogs and cats of any age, breed, and sex can develop deep mycoses, but dogs are often young adult, pure-bred dogs, suggesting that genetic factors predispose to infection. Most cats with deep fungal infections test negative for retroviruses, but some animals have concurrent diseases such as malignancy or a history of treatment with immunosuppressive drugs, including chronic low-dose glucocorticoid therapy. Some dogs and cats have evidence of concurrent opportunistic infections such as toxoplasmosis, neosporosis or papillomavirus. Cats housed exclusively indoors can develop soil-borne fungal infections such as histoplasmosis or cryptococcosis.

History and Clinical Signs

Many infections with dimorphic fungi are probably subclinical. Animals that develop systemic disease are often evaluated for vague signs such as lethargy, weight loss, inappetence, weakness, and low-grade fever, together with signs of respiratory involvement and/or dissemination to sites that commonly include the skin, bone, eye, and brain. Findings on routine hematologic and biochemical testing are also nonspecific and include nonregenerative anemia, mild leukocytosis, hypoalbuminemia, and hyperglobulinemia. In a smaller proportion of dogs with systemic mycoses, hypercalcemia secondary to granulomatous inflammation may be present. Although most infections are acquired through inhalation, radiographic evidence of pulmonary involvement can be absent in some dogs and cats with disseminated disease.

Diagnosis

Persistent disease in the face of antibacterial therapy, or progression in the face of glucocorticoid therapy, should raise suspicion for a fungal infection. Definitive diagnosis is based on clinical suspicion combined with cytology and/or histopathology, fungal culture, antibody or antigen testing, and/or real-time polymerase chain reaction (PCR) assays. Cytology and histopathology have variable sensitivity and specificity and a limited ability to identify fungal pathogens. The use of special stains such as periodic acid–Schiff or Gomori's methenamine silver can

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

highlight fungal elements in tissues. Most fungi grow within seven days in the laboratory, but occasionally several weeks elapse before growth occurs. Some dimorphic fungi (*Blastomyces*, *Histoplasma*, *Coccidioides*) grow as a mycelial form in the laboratory, which represents a laboratory health hazard. For these pathogens, culture should only be performed if a diagnosis cannot be established through other methods, and the laboratory should be warned that infection with a dimorphic fungus may be present, so that appropriate precautions are taken. Culture also allows antifungal susceptibility testing, although at this time, the clinical relevance of susceptibility test results is unclear for many fungi.

Antigen testing can be helpful for diagnosis and therapeutic monitoring of histoplasmosis (urine), blastomycosis (serum), cryptococcosis (serum or cerebrospinal fluid [CSF]), and disseminated aspergillosis (serum), although serologic cross-reactivity with other fungal pathogens is common with all assays except those for cryptococcosis. Serum antibody testing is helpful for diagnosis of coccidioidomycosis and pythiosis. At the time of writing, more information is needed on the clinical sensitivity and specificity of real-time PCR assays that are available for detection of fungal pathogens, but these may be useful when a fungal pathogen is suspected but cannot be detected or identified using other diagnostic tests.

Therapy

Treatment of fungal infections most often involves the use of orally administered azole antifungal drugs such as itraconazole capsules (usually 5 mg/kg PO q24h for dogs) or fluconazole tablets (5–10 mg/kg PO q24h). In general, fluconazole is less active than itraconazole, and itraconazole is preferred as first-line treatment for most infections, with the exceptions of *Cryptococcus* and *Candida*. Most molds are resistant to fluconazole. Topical antifungal drug preparations that contain azole drugs may be sufficient for treatment of the superficial mycoses. Liver enzyme activities should be monitored monthly during systemic treatment with azole antifungals in order to monitor for hepatotoxicity. Itraconazole solution (10 mg/mL) has higher bioavailability than the capsules and is administered at a lower dose (3 mg/kg PO q12h) and on an empty stomach. If itraconazole capsules are used, they should be administered with food. Compounded formulations of itraconazole should be avoided.

If clinical signs do not improve with azole treatment, measurement of serum drug concentrations could be considered. Serious systemic infections may require treatment with intravenous amphotericin B, with careful monitoring for evidence of nephrotoxicity before each infusion. Lipid complex amphotericin B preparations are not necessarily more effective than deoxycholate amphotericin B but are less nephrotoxic. Deoxycholate amphotericin B is administered to dogs at 0.5 mg/kg in 250–1000 mL of 5% dextrose over 4–6 hours on a Monday-Wednesday-Friday basis; the dose for cats is 0.25 mg/kg, which is given in 30 mL of 5% dextrose over one hour. Administration of 0.9% NaCl at 1.5–2 times maintenance for one hour prior to and after administration is recommended. Electrolytes cause amphotericin to precipitate so the line must be flushed with D5W prior to administration of the drug. Lipid complexed amphotericin B is administered to dogs at 3 mg/kg and cats at 1 mg/kg over two hours.

Voriconazole or posaconazole could also be considered for treatment of refractory deep fungal infections if client finances permit their use. Voriconazole (4–5 mg/kg PO q12h) has excellent central nervous system (CNS) penetration and so represents an option for dogs with fungal meningoencephalomyelitis. However, virtually all cats do not tolerate voriconazole due to gastrointestinal, neurologic, and cardiac adverse effects, so until a safe dose is known, voriconazole should not be administered to cats.

Other treatments that may be required for dogs or cats with serious pulmonary infections with or without dissemination are supplemental oxygen, nebulization and coupage, fluid therapy, and, in some cases, mechanical ventilation. Initially, clinical signs may worsen with treatment, possibly as a result of organism death and an associated inflammatory response. Nonsteroidal antiinflammatory drugs such as carprofen could be considered to control pyrexia, and systemic glucocorticoids may be required to control brain inflammation and edema in dogs and cats with CNS infections, although this is controversial. Topical antiinflammatory and antiglaucoma agents may be indicated if ocular involvement is present. In animals with endophthalmitis, enucleation may be necessary to control ocular pain and eliminate infection. Surgery may also be required for treatment of refractory fungal osteomyelitis (amputation) or large pulmonary granulomas (lung lobectomy).

Prognosis

Most fungal infections require several months of treatment at a minimum. Typically, treatment is continued until there is no evidence of disease remaining based on serial physical examinations, imaging, and antigen or antibody testing. Animals with disseminated fungal infections often require more than a year of treatment, or lifelong therapy. The prognosis is often poor when severe immunosuppression and dissemination are present at the time of diagnosis, but if immunosuppression can be

reversed and aggressive antifungal drug treatment is initiated promptly, complete recovery is possible.

Public Health Implications

Direct inoculation of yeast forms of fungi can potentially cause infection. The mycelial form of dimorphic fungi can pose significant zoonotic risk, although these are typically only present when the organisms are cultured in the laboratory. Appropriate precautions such as avoiding needle sticks and other traumatic wounds when working with animals that have deep fungal infections should be followed. Caution when performing necropsies, and cremating, rather than allowing burial of deceased patients are also important to prevent zoonosis from mycelial forms.

Dermatophytosis

Etiology/Pathophysiology

Dermatophytosis is caused by fungi that belong to the genera *Microsporum*, *Trichophyton* or *Epidermophyton*. These organisms secrete proteases that allow them to invade macerated or traumatized keratinized tissue. Infectious arthrospores persist in the environment for more than a year given optimal temperature and humidity, and are transmitted by close contact with other infected animals or contaminated fomites. The most common dermatophyte species that infect dogs and cats are *Microsporum canis*, *Microsporum gypseum*, and organisms that belong to the *Trichophyton mentagrophytes* species complex (especially *Arthroderma benhamiae*). *Microsporum canis* and organisms that belong to the *T. mentagrophytes* species complex are zoophilic dermatophytes (adapted to animal hosts), whereas *M. gypseum* is a geophilic dermatophyte (soil saprophyte).

Epidemiology and Signalment

Cats are more susceptible than dogs to dermatophytosis. The prevalence of infection is highest in regions with warm, humid climates. The risk of infection is higher in young animals and animals with concurrent immunosuppressive disorders, such as hyperadrenocorticism. Dogs that burrow in soil may also be at increased risk. Persian and Himalayan cats and Yorkshire and Jack Russell terriers appear to be predisposed.

History and Clinical Signs

Classically, dermatophytosis is characterized by one or more circular lesions of alopecia with an erythematous margin, superficial scale and crusts, and follicular papules and pustules. In dogs, lesions are most often on the face, distal limbs, and tail. When the claw is involved, there may be thickening of the ungual fold and deformity of the claw. Infection by *T. mentagrophytes* may result in widespread lesions with scar formation (Figure 109.1). Lesions in cats are extremely variable. In long-haired cats, dermatophytosis may simply be manifested as a poor hair coat with excessive shedding.

Figure 109.1 Fox terrier with dermatophytosis caused by *Trichophyton mentagrophytes* species complex organisms. *Source:* Image courtesy of the University of California, Davis Veterinary Dermatology Service.

Other forms of dermatophytosis include nodular inflammatory lesions known as kerions, and dermatophytic mycetomas, which are nodular lesions that coalesce and drain fluid. Persian and Himalayan cats appear to be prone to dermatophytic mycetomas.

Diagnosis

Diagnosis of dermatophytosis is based on clinical suspicion together with Wood's lamp examination, identification of hyphae and spores using skin and hair cytology, histopathology of skin biopsy specimens, and/or fungal culture. A positive Wood's lamp examination occurs when some strains of *M. canis* fluoresce within infected hair shafts. The sensitivity of Wood's lamp examination is low and false positives can occur when fluorescence of keratinized debris is misinterpreted as fungal fluorescence. The gold standard for diagnosis of dermatophytosis is fungal culture of hairs plucked from the edge of lesions, scrapings of crusts, or brushings of the haircoat (using a new toothbrush). Use of a microbiology laboratory is recommended whenever possible in order to properly distinguish dermatophyte growth from that of saprophytic molds and to prevent contamination of the practice environment.

Therapy

Dermatophytosis often resolves spontaneously within three months in otherwise healthy animals. Treatment is recommended for animals that are immunosuppressed, those that live in multipet households, and those that live with immunocompromised owners or children. Treatment should consist of systemic antifungal drugs (itraconazole is the drug of choice, but fluconazole, ketoconazole, griseofulvin or terbinafine also have activity against dermatophytes), with or without twice-weekly topical treatment (preferably a 1:16 dilution of lime sulfur) and environmental decontamination. Ideally, all in-contact animals should be examined and cultured using a toothbrush technique. Animals with positive cultures (and those with clinical signs) should be treated both systemically and topically. All unaffected, culture-positive animals should be treated topically along with any in-contact animals. Long-haired cats should be clipped in order to remove contaminated hair and facilitate penetration of topical treatments, although this is controversial because of the potential for contamination of the environment and for disruption of the skin. Clippers must be disinfected with 10% bleach afterwards.

Potential fomites (bedding, collars, grooming equipment) should be discarded if possible. Disinfection of hard surfaces should be performed with a 1:10 dilution of bleach, 0.2% enilconazole, or an enilconazole fogger (if available). Carpets and furniture should be thoroughly vacuumed and then steam cleaned, after which vacuum cleaners may need to be replaced.

Treatment is usually needed for at least 10–12 weeks. Animals should be examined and a culture performed monthly (and no earlier than weekly) during treatment. Treatment should be continued until lesions resolve and two successive cultures are negative. For group-housed animals, at least three successive negative cultures are recommended. If serial cultures are not possible because of financial limitations, treatment should be continued for 2–4 weeks after clinical signs resolve.

Prognosis

The prognosis for resolution of clinical signs is generally good, especially in households with one or only a few animals. Dermatophytic mycetomas may require long treatment durations; in some cats, surgery may be required for lesion resolution.

Public Health Implications

Dermatophyte species that cause disease in dogs and cats have the potential to cause disease in people. Young children and immunocompromised people are most susceptible. Protective gloves and clothing should be worn when handling infected animals. Young children and immunocompromised people should avoid any contact.

Malassezia Infections

Etiology/Pathophysiology

Malassezia spp. are lipophilic yeasts that normally colonize animal and human skin. *Malassezia pachydermatis* is the most commonly isolated yeast species from the skin and ears of healthy dogs and cats, and is most commonly found in the ear canals, lips, axillae, interdigital spaces, anal sacs, and occasionally the nose and vagina. Other species can also colonize the skin of healthy cats.

Malassezia proliferate opportunistically, and commonly contribute to chronic dermatitis and otitis externa in dogs, and to a lesser extent in cats. Underlying diseases that predispose to proliferation of *Malassezia* spp. include allergic dermatitis, endocrinopathies, intertrigo, primary keratinization/cornification disorders, a history of prolonged treatment with antibacterial drugs or glucocorticoids, and, in cats, underlying neoplasia or retrovirus infections. In some animals, hypersensitivity reactions to yeast antigens may contribute to the inflammatory response that results.

Epidemiology and Signalment

Predisposed dog breeds include American cocker spaniels, West Highland white terriers, basset hounds, poodles, and Australian silky terriers. Sphynx and Devon Rex cats have high rates of *Malassezia* spp. colonization when compared with domestic short-hair cats.

History and Clinical Signs

Clinical signs of *Malassezia* infection include erythema, pruritus, alopecia, scaling, and a greasy exudate. The most commonly affected sites are the ear canals, skinfolds (periocular and perioral skin, ventral neck, axillae, inguinal regions, and perineum) and interdigital skin. Chronic infections can result in hyperpigmentation, lichenification, and stenosis of the ear canal, and affected animals may emit a pungent odor.

Diagnosis

The diagnosis of *Malassezia* infection is usually based on cytologic examination of tape preparations. The yeasts stain darkly basophilic and exhibit wide-based budding, resembling "footprints." Mean counts of ≥1 yeast per oil immersion field (1000× magnification) for dermatitis and ≥5 organisms per oil immersion field for otitis are

considered abnormal in dogs. More than 12 yeasts/high dry field is considered abnormal in feline ear canals. The ear canals of healthy dogs and cats have mean counts of ≤ 2 yeasts/high dry field (400× magnification).

Therapy

Therapy of *Malassezia* spp. infections requires identification and treatment of the underlying cause, in addition to antifungal drug treatment. Topical therapy is adequate for many infections. Topical otic preparations for treatment of *Malassezia* otitis are used twice daily until there is cytologic resolution of infection, typically 2–4 weeks. These contain antifungals such as clotrimazole, miconazole or posaconazole, which are usually combined with a glucocorticoid and an antibacterial compound. Some antiseptic ear cleaners, such as Epi-Otic, also have activity against *Malassezia* and should be considered as an alternative to reduce unnecessary use of antibacterials.

Cleaning is performed on a 12- or 24-hour basis for 5–7 days, and then every second or third day until clinical signs resolve. Subsequently, weekly maintenance cleaning may reduce the risk of recurrence. *Malassezia* dermatitis can be successfully treated with twice-weekly shampooing with a 2% miconazole/2% chlorhexidine shampoo for three weeks, which also serves to prevent recurrence. Systemic antifungal drugs such as ketoconazole, itraconazole, fluconazole or terbinafine (30–40 mg/kg PO q24h) may be needed to treat more severe infections or infections of the claw bed.

Treatment should be monitored through serial dermatologic examinations and cytologic evaluation of tape preparations, and at least three weeks of treatment is usually required.

Prognosis

If the underlying cause can be resolved and there is good client compliance, the prognosis for resolution of *Malassezia* infections is generally good.

Public Health Implications

Malassezia pachydermatis can occasionally be carried on human skin. The risk of disease transmission appears low, although it may occur. Hand washing may theoretically reduce the risk.

Blastomycosis

Etiology/Pathophysiology

Blastomycosis is caused by the dimorphic fungus *Blastomyces dermatitidis*, which grows as a thick-walled budding yeast in tissues. Hyphae within soil produce conidia that are aerosolized and inhaled by the host, where they transform into yeasts, trigger a pyogranulomatous inflammatory response, and produce localized pulmonary or disseminated disease.

Epidemiology and Signalment

Blastomyces dermatitidis prefers warm, moist, sandy soil that is rich in organic debris such as decaying vegetation. The fungus is primarily found in North America around the Great Lakes, along the Ohio and Mississippi river valleys, and in the southeastern states. A smaller focus of endemicity exists in the northeast that extends into Ontario, Canada. Occasionally disease appears in nontraveled dogs that reside in nonendemic parts of the United States.

Young adult, large-breed (>15 kg) dogs are predisposed. Most affected dogs are apparently immunocompetent. Overrepresented breeds include coonhounds, pointers, Weimaraners, retrievers, and Doberman pinschers. Residence close to water sources and exposure to sites of soil disturbance also increase the risk of infection. Blastomycosis is rare in cats.

History and Clinical Signs

Infection with *Blastomyces* may result in disease that is localized to the lungs and associated lymph nodes, or signs that are severe and progressive with dissemination to extrapulmonary sites, which include the skin, eye, bone, prostate, and testes, and the CNS. Infection has also been reported in the mammary glands, nasal or oral cavities, cardiac tissues, and very rarely in the kidneys, liver, spleen, peritoneum, gastrointestinal tract, and urinary bladder. Neurologic involvement secondary to extension of intranasal *Blastomyces* granulomas through the calvarium has also been described.

In addition to nonspecific signs of illness, affected dogs may show signs that include cough, exercise intolerance and tachypnea, peripheral lymphadenopathy, ocular manifestations such as uveitis, chorioretinitis or panophthalmitis, nodular or ulcerated cutaneous or mucocutaneous lesions, and lameness due to fungal osteomyelitis or arthritis. Gastrointestinal signs, polyuria or polydipsia, nasal discharge, sneezing and/or epistaxis, mammary or testicular masses, facial distortion, cardiac arrhythmias, and neurologic signs due to meningoencephalitis or ependymitis are less common. Clinical signs of blastomycosis in cats resemble those in dogs.

Diagnosis

Thoracic radiographic findings in dogs with blastomycosis include unstructured, miliary or nodular interstitial patterns, a bronchointerstitial pattern, alveolar or mixed

alveolar-interstitial patterns, pulmonary mass lesions, tracheobronchial lymphadenopathy, and/or single or multiple pulmonary nodules that resemble pulmonary neoplasia. Radiographs of affected bone typically show osteolytic lesions, often accompanied by periosteal proliferation and soft tissue swelling.

A diagnosis of blastomycosis is often confirmed through cytologic examination of affected tissues, lung washes or body fluids. The yeasts are 8–15 µm in diameter, have a thick, refractile cell wall, and exhibit broad-based budding, although occasionally organisms are not visualized. The organisms are usually accompanied by pyogranulomatous inflammation (Figure 109.2).

Other methods of diagnosis include histopathology (e.g., of bone or tissue biopsies), fungal culture, antigen testing, and molecular diagnosis with PCR-based assays. Serologic tests for blastomycosis that detect antibody currently have poor sensitivity and specificity, and so the use of these tests is not recommended for routine diagnosis. When performed on urine, assays for *Blastomyces* cell wall galactomannan antigen (MiraVista Diagnostics, Indianapolis, IN) have high sensitivity (93.5%) and specificity (98%) for diagnosis of canine blastomycosis, but due to serologic cross-reactivity, results may also be positive in dogs with other fungal infections, especially histoplasmosis.

Therapy

The most widely used specific therapy for blastomycosis in dogs is itraconazole or fluconazole. The duration of treatment should be based on serial monitoring of clinical signs, radiographic lesions, and urine antigen titers (i.e., every 4–8 weeks). For dogs with pulmonary involvement, radiographic lesions and clinical signs may initially worsen with treatment. Initial worsening of radiographic lesions does not appear to affect survival. Urine antigen concentration declines with effective treatment. Although a positive residual urine antigen titer at the time treatment is discontinued does not necessarily predict that relapse will occur, a negative urine antigen test is recommended before treatment is discontinued. Most dogs require at least 4–6 months of treatment, and some dogs may require treatment for more than one year, especially those with osteoarticular infections or widespread dissemination. Treatment with amphotericin B could be considered for dogs with severe disease with widespread dissemination, followed by azole therapy after there has been a satisfactory clinical response to the amphotericin B.

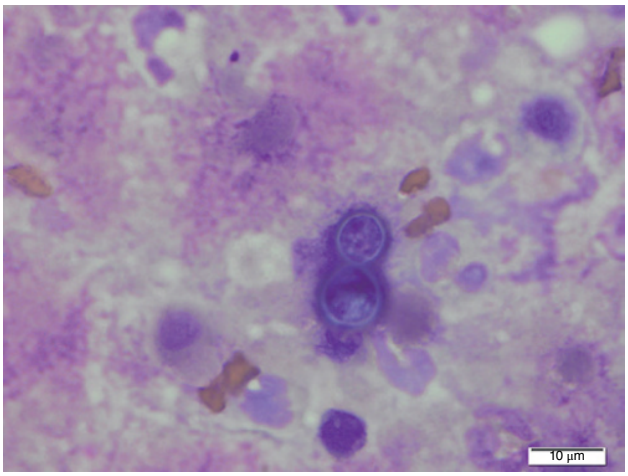

Figure 109.2 Cytology of a fine needle aspirate of a skin lesion from a dog showing a budding *Blastomyces* organism with associated pyogranulomatous inflammation. *Source:* Image courtesy of Dr Jed Overmann, University of Minnesota.

Prognosis

Cure rates of 50–75% have been reported in dogs with blastomycosis; an additional 20–25% of dogs experience disease recurrence after treatment is discontinued, which can occur as long as a year later. The most common radiographic sequelae to pulmonary blastomycosis are pulmonary bullae and persistent focal interstitial patterns, presumably as a result of pulmonary fibrosis. Involvement of the CNS, severe lung disease, and a high band neutrophil count are negative prognostic factors.

Public Health Implications

Blastomyces dermatitidis causes disease in people. Direct transmission between mammalian hosts does not occur, with the exception of inoculation of yeast via bite wound or needle sticks. Laboratory personnel are at risk if samples are cultured and should be warned that blastomycosis is suspected prior to submission. Bodies of deceased pets should be cremated rather than buried. Dogs are sentinels for human exposure.

Histoplasmosis

Etiology/Pathophysiology

Histoplasma capsulatum is a dimorphic, soil-borne fungus. Microconidia produced by the fungus are inhaled by mammalian hosts, and within the lungs transition to the yeast phase, which replicates by budding within alveolar macrophages. Some animals control the initial infection but remain latently infected with small numbers of yeasts. Subsequent immune suppression can lead to reactivation years later. Replication of *H. capsulatum* leads to a granulomatous inflammatory response, which

is sometimes accompanied by fibrosis. When a cell-mediated immune response is defective, yeast forms migrate to local lymph nodes (such as the tracheobronchial lymph nodes) and other tissues that contain mononuclear cells, such as the liver and spleen. Other common sites of dissemination include the bone marrow, small and/or large intestinal tract, pancreas, the skin, bones, central nervous system, and eyes.

Epidemiology and Signalment

Histoplasma capsulatum is found worldwide, but especially along the Mississippi, Missouri, Tennessee, and Ohio river valleys of the United States as well as in Latin America. *H. capsulatum* can be found in the intestinal tract and guano of bats, which constitute the primary reservoir of the organism and disseminate it geographically. *H. capsulatum* can also be found in high concentrations in decaying avian guano, but it is not shed in the feces of birds.

Cats are as susceptible, or slightly more susceptible, to histoplasmosis as dogs. Affected dogs and cats can be as young as several months of age, but most are middle aged, and geriatric animals can also be affected.

History and Clinical Signs

Approximately 40% of cats with histoplasmosis show respiratory signs such as dyspnea and tachypnea, and to a lesser extent cough and nasal discharge. Ocular signs such as chorioretinitis and/or uveitis occur in approximately one-quarter of cats, and around 20% of cats have evidence of osteomyelitis. Nodular or ulcerated and draining skin lesions, peripheral lymphadenopathy, vomiting, diarrhea, oral ulceration, and myelopathy have also been described.

Dogs appear to be particularly predisposed to gastrointestinal tract histoplasmosis. Involvement of the small and large intestines may result in malabsorption, diarrhea, dramatic weight loss, melena, dyschezia, tenesmus, and hematochezia. Profuse diarrhea may be chronic and persist for several months. Tracheobronchial lymphadenopathy is common and may contribute to cough through airway compression. Other signs include respiratory difficulty, icterus, vomiting, hepatomegaly, lymphadenomegaly, nasal discharge, ocular signs, polyuria and polydipsia, lameness due to osteomyelitis, cutaneous nodules, and neurologic signs such as seizures or paralysis/paresis.

Diagnosis

As with other deep mycoses, findings on routine laboratory testing are typically nonspecific and suggestive of inflammation. Dogs with acute progressive disseminated histoplasmosis may have increased band neutrophils, lymphopenia, monocytopenia, and thrombocytopenia. Increased liver enzyme activities, hyperbilirubinemia, and evidence of coagulopathies may be present in animals with hepatic involvement. In cats, plain thoracic radiographs can reveal diffuse, linear, nodular or miliary interstitial patterns. Alveolar, interstitial, and/or bronchial patterns, tracheobronchial lymphadenopathy, lung lobe consolidation, and/or rarely pleural effusion can be seen in dogs. Lesions in dogs can sometimes calcify. Abdominal imaging may show hepatomegaly, splenomegaly, abdominal lymphadenopathy or ascites. A thickened intestinal wall with architectural disruption of the bowel wall may be identified on ultrasound examination. Colonoscopic findings in dogs with colonic histoplasmosis include irregularity, ulceration, increased granularity, and friability of the colonic wall.

Cytologic examination of affected tissues or body fluids reveals pyogranulomatous or granulomatous inflammation. *H. capsulatum* yeasts are usually seen extracellularly and within mononuclear phagocytes, although they may not be identified within chronic, fibrosing lesions. The yeasts are 2–4 µm in diameter, oval, have a basophilic center and are surrounded by a clear halo due to shrinkage artifact (Figure 109.3).

Antibody assays for *H. capsulatum* have had poor clinical sensitivity and specificity, so are not recommended for routine diagnosis. An enzyme-linked immunosorbent assay (ELISA) for *H. capsulatum* antigen (MiraVista Diagnostics, Indianapolis, IN) is widely used in human patients for diagnosis of histoplasmosis, and as with blastomycosis, urine is the preferred specimen for testing

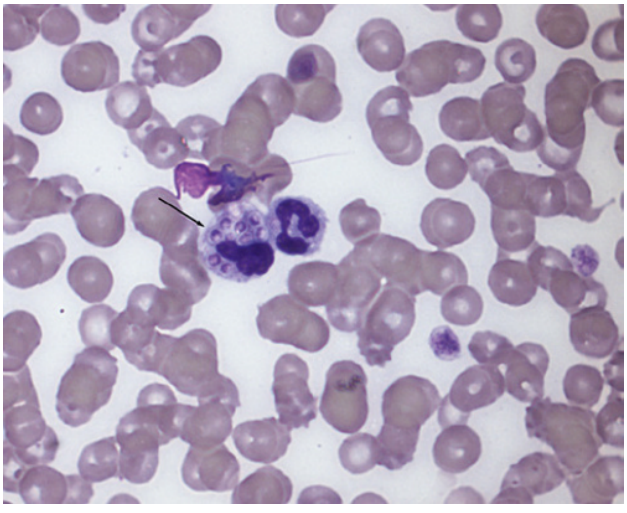

Figure 109.3 Cytology showing multiple intracellular *Histoplasma capsulatum* organisms within the cytoplasm of a circulating monocyte from a dog with disseminated histoplasmosis.

(sensitivity 95%). False positives occur as a result of serologic cross-reactivity in human patients with other disseminated mycoses, especially blastomycosis. Antigen levels become undetectable with successful treatment. This assay appears to have a similar performance in cats and dogs with histoplasmosis, although studies that evaluate large numbers of cats and dogs with confirmed histoplasmosis are required to fully establish the sensitivity and specificity of this assay.

Therapy

In human patients, itraconazole has consistently been more effective than fluconazole for treatment of histoplasmosis. Nevertheless, some animals can be cured with fluconazole monotherapy, so if funds or patient factors do not permit itraconazole treatment, fluconazole can be used. Amphotericin B should be used to treat dogs or cats with severe acute pulmonary, acute disseminated, or CNS disease, after which treatment should be continued with an azole. The decision to discontinue treatment should be based on lesion resolution and probably serial monitoring of urine antigen titers, although this requires further study.

Prognosis

The length of treatment and prognosis for histoplasmosis depend on the severity and chronicity of disease and the immune status of the host. At least six months of treatment is generally required. Many animals require treatment for 12 months or longer, and those with chronic disease may require treatment for more than two years.

Public Health Implications

Humans can be infected with *H. capsulatum* but direct transmission from cats and dogs has not been reported. Remains of infected animals should be cremated rather than buried.

Cryptococcosis

Etiology/Pathophysiology

Cryptococcosis is caused by dimorphic, basidiomycetous fungi that belong to the genus *Cryptococcus*. *Cryptococcus neoformans* and *C. gattii* cause the vast majority of infections. A filamentous form that produces basidiospores is thought to exist in the environment. Mammalian disease is believed to occur when basidiospores are inhaled, typically after an incubation period of several months, although in some cases, reactivation of subclinical infections may occur years after exposure. In animal tissues, the basidiospores are thought to convert to the yeast form, which is round to oval with a characteristic, variably sized polysaccharide capsule. Within tissues, *Cryptococcus* reproduces by narrow-based budding. After infection is established within the lung or nasal cavity, the organism can spread hematogenously to other sites, particularly the lymph nodes, eye, skin, and CNS. *Cryptococcus* has a predilection to invade the meninges, and typically causes meningitis or meningoencephalitis. In animals with nasal cavity involvement, extension of infection into the brain may also follow osteomyelitis of the cribriform plate.

Epidemiology and Signalment

Based on molecular methods such as multilocus sequence typing, cryptococcal strains worldwide have been divided into eight molecular types: VNI, VNII, VNIII, and VNIV (*C. neoformans*) and VGI, VGII, VGIII, and VGIV (*C. gattii*). Differences in epidemiology, pathogenicity, clinical features, and drug susceptibility have been associated with each molecular type. The environmental niche for *C. neoformans* is thought to be weathered bird (especially pigeon) guano, whereas *C. gattii* has been associated with *Eucalyptus* trees in Australia and a variety of other tree species on the west coast of North America.

The incidence of cryptococcosis in cats is eightfold higher than that in dogs. Siamese, Birman, and ragdoll cats have been predisposed in Australian studies but were not found to be at risk in the US. Similarly, German shepherd dogs, Doberman pinschers, and Great Danes appear to be predisposed in Australia, whereas American cocker spaniels are predisposed in the US.

History and Clinical Signs

Cryptococcosis is often a chronic infection in cats. Upper respiratory tract signs due to nasal cavity involvement are common, sometimes with associated mandibular lymphadenopathy. Single or multifocal ulcerated or nonulcerated cutaneous or mucocutaneous masses may also be present. Lower respiratory tract signs are uncommon, but can occur as a result of pleural effusion or severe mediastinal lymphadenomegaly. Neurologic signs vary depending on the location of lesions in the CNS. Optic neuritis and chorioretinitis develop in as many as one-third of affected cats, and almost always indicate CNS involvement. Other signs include peripheral lymphadenomegaly, lameness due to osteoarticular infection, and swollen digits. Rarely, involvement of the abdominal lymph nodes, kidneys, spleen, liver, and thyroid can occur in cats.

In contrast to cats, dogs often develop widespread dissemination with neurologic involvement. They may also present with signs relating to gastrointestinal or pancreatic involvement. Cryptococcal rhinosinusitis may be subclinical in dogs or may result in sneezing and mucopurulent nasal discharge. Cutaneous involvement is uncommon but, as in the cat, may be a marker for disseminated disease. Other clinical signs that are occasionally present in dogs include peripheral lymphadenomegaly or lameness (due to osteomyelitis or arthritis).

Diagnosis

Thoracic radiographs in dogs and cats with cryptococcosis are often normal, although interstitial to alveolar infiltrates or small nodular lesions may be present. Occasionally, pulmonary nodules, tracheobronchial lymphadenopathy, mediastinal masses, or pleural effusion are found.

Definitive diagnosis of cryptococcosis is based on evaluation of representative tissue specimens or body fluids (including cerebrospinal fluid) with cytology, culture, and occasionally histopathology (Figure 109.4), with or without serologic detection of cryptococcal antigen.

Latex agglutination assays for detection of cryptococcal polysaccharide capsular antigen are widely used in veterinary patients and are very (>85%) sensitive and specific, although false-negative and false-positive results can occur. ELISAs are also available. Serum antigen testing provides a rapid diagnosis when organisms cannot be visualized or cultured, and may prove advantageous when CSF collection is unacceptably risky. Even a titer as low as 1:2 can indicate cryptococcal infection.

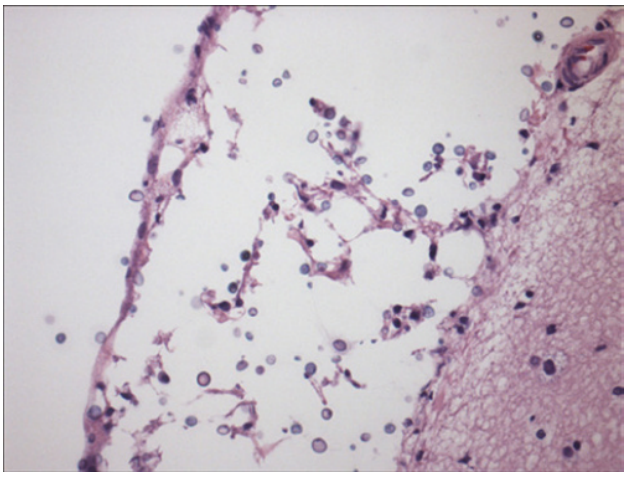

Figure 109.4 Histopathology showing large numbers of *Cryptococcus* organisms within the meninges of a 3-year-old domestic short-hair that died of disseminated cryptococcosis.

Because false-positive latex agglutination titers of up to 1:200 have been detected in cats, attempts to confirm infection using other diagnostic tests are recommended in animals that have titers <1:200. For dogs and cats suspected to have cryptococcal meningoencephalomyelitis that have negative serum antigen titers, CSF should be submitted for cytologic examination, antigen titers, and fungal culture.

Therapy

Some dogs and cats with cryptococcosis, especially those with lesions restricted to the skin, can be treated successfully with azole antifungal drug monotherapy. Fluconazole is a reasonable initial choice, because of its good penetration of the brain and eye. Generally, cats improve within 1–2 weeks of starting therapy. Treatment should be continued until there is complete lesion resolution and the cryptococcal antigen titer becomes negative. This typically takes 2–12 months, although longer periods of therapy may be required. For recovered animals that achieve an antigen titer of 0, the titer can be monitored every 3–6 months, so that relapse is diagnosed early. Some cats (especially those in California infected with molecular type VGIII) fail to respond completely to treatment, antigen titers persist at high levels, and relapse occurs after an initial treatment response. In some of these cats, prognosis is guarded and treatment with other azoles or combination therapy with amphotericin B may be necessary.

For cats with CNS cryptococcosis or those that fail to respond to azole antifungal drugs, a combination of amphotericin B and 5-flucytosine (250 mg PO q8h) or amphotericin B and fluconazole is recommended. Dogs with disseminated disease or CNS involvement should be treated initially with amphotericin B and fluconazole, because those treated with flucytosine often develop cutaneous necrosis 1–2 weeks after starting therapy. Treatment with 5-flucytosine and amphotericin B is continued for 2–4 weeks or until azotemia develops, after which treatment is continued with an azole. Anecdotally, administration of terbinafine to some dogs and cats that have failed azole or amphotericin B treatment has led to clinical improvement.

Prognosis

In studies from Australia, approximately 75% of cats with cryptococcosis were treated successfully. In one study, the median survival time of cats with CNS cryptococcosis was only 13 days (0–4050 days), but outcomes were more favorable if cats survived at least three days after diagnosis. The prognosis is guarded for dogs, with success rates that range from 30% to 55%. The median survival

time for dogs with CNS cryptococcosis in North America was seven days (0–3680 days).

Public Health Implications

Humans can develop cryptococcosis through environmental exposure. Notably, it is an important infection in people with AIDS. Direct transmission from animals to people has not been reported, but contaminated needlestick injuries may transmit the organism. *Cryptococcus* grows on routine fungal laboratory media as a yeast, so is less likely to represent a hazard to laboratory personnel than dimorphic fungi that grow as molds.

Coccidioidomycosis

Etiology/Pathophysiology

Coccidioides spp. (*Coccidioides immitis* and *C. posadasii*) are dimorphic fungi that exist in soil as chains of barrel-shaped arthrospores. The arthrospores are aerosolized and inhaled by animal hosts. This may be followed by localized pulmonary disease or dissemination to the tracheobronchial lymph nodes and then other anatomic sites in the face of an inadequate immune response. Infections often follow a pattern of moist conditions (required for growth of *Coccidioides* spp. in the soil), a dry period, then soil disruption, such as may occur with heavy rainfall, dust storms, or construction.

After inhalation, arthrospores are phagocytosed by alveolar macrophages. They then enlarge into a spherule (8–100 µm in diameter). Hundreds of endospores develop within the spherule, which are released when the spherule ruptures. This is associated with a pyogranulomatous inflammatory response.

Epidemiology and Signalment

In the environment, *Coccidioides* spp. are distributed in regions with arid soils, low elevations above sea level, and hot summers. Infections occur primarily in the southwestern United States, Mexico, and parts of Central and South America. In southwestern USA, highly endemic regions include the south-central valley of California ("Valley Fever") and Arizona. Latent infections occur in dogs and these can reactivate after treatment with immunosuppressive drugs. Coccidioidomycosis is rare in cats.

History and Clinical Signs

Development of clinical signs often follows a subacute to chronic course. Many dogs continue to otherwise appear healthy, with occasional periods of inappetence. Clinical signs of respiratory tract involvement include cough, tachypnea, and/or exercise intolerance. Rarely, diffuse pneumonia follows a more fulminant course, as reported in immunocompromised humans.

A small percentage of infected dogs develop disseminated infections. Sites of dissemination often include osteoarticular sites, the CNS, skin, peripheral lymph nodes, eye, testes, prostate, and pericardium. Rarely, other sites, such as abdominal organs, are affected. Dogs with skin involvement may have ulcerated skin lesions that drain serosanguinous fluid, or subcutaneous mass lesions. Neurologic signs result from fungal meningoencephalitis and include obtundation, blindness, nystagmus, ataxia, placing deficits, circling, cervical pain, tetraparesis, and seizures. Ocular manifestations include chorioretinitis, uveitis, optic neuritis, and endophthalmitis. Pericarditis may lead to signs of right-sided cardiac failure, with development of ascites and pleural effusion.

Diagnosis

Thoracic radiographs in dogs with disseminated coccidioidomycosis are often unremarkable. The most common radiographic finding in dogs with pulmonary coccidioidomycosis is tracheobronchial lymphadenomegaly. Although this may be the only finding, most dogs also have mild to moderate interstitial infiltrates. Nodular interstitial, interstitial-alveolar, bronchointerstitial infiltrates, and/or sternal lymphadenomegaly may also be present. Dogs with pericarditis may have cardiomegaly and pleural effusion, with hepatomegaly and decreased abdominal detail. Echocardiography in these dogs may reveal thickening and mass lesions of the pericardium, pericardial and pleural effusion, and cardiac tamponade.

A diagnosis of coccidioidomycosis is typically confirmed using serology for antibodies to *Coccidioides* spp., because of the low sensitivity of cytology and the fact that culture is hazardous to laboratory personnel and can have a long turnaround time. Cytologic examination of specimens from affected tissues or body fluids reveals granulomatous or pyogranulomatous inflammation. Occasionally, spherules can be identified as round, basophilic, double-walled, crinkled structures (8–70 µm in diameter) (Figure 109.5). Sometimes endospores (2–5 µm in diameter) can be seen in association with ruptured spherules.

Most diagnostic laboratories detect antibodies to *Coccidioides* using gel immunodiffusion. False-negative serologic test results are rare in dogs with coccidioidomycosis. Antibody titers typically range from 1:2 to 1:256. Dogs with active infection may have titers as low as 1:2, and healthy dogs in hyperendemic areas in Arizona have had titers as high as 1:16. As a result, positive titers of 1:16 or lower should always be interpreted in light of clinicopathologic abnormalities

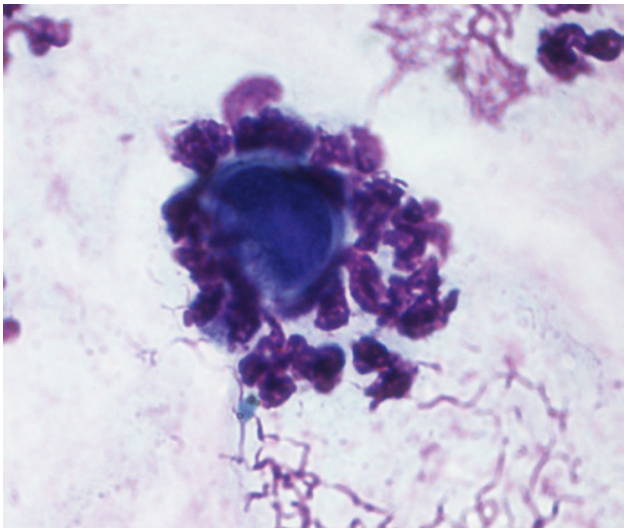

Figure 109.5 Cytology of a tracheal wash specimen showing a *Coccidioides* spherule surrounded by pyogranulomatous inflammation.

and, in hyperendemic areas, other diagnostic tests (such as cytology, histopathology or culture) should also be used to confirm the diagnosis.

Therapy

Dogs with pulmonary coccidioidomycosis often respond well to azole monotherapy with fluconazole or itraconazole. Treatment with amphotericin B is recommended either alone or in combination with an azole antifungal for dogs with refractory disease or those with severe clinical signs. Successful treatment of *Coccidioides* pericarditis has been reported after subtotal pericardiectomy and epicardial excision in conjunction with antifungal drug therapy. Referral to a specialist surgeon with experience in the technique is strongly recommended.

Prognosis

The prognosis for resolution for coccidioidomycosis depends on the severity of infection and the extent of dissemination. The duration of treatment ranges from six months (localized pulmonary coccidioidomycosis) to many years, and in some cases, life-long treatment is needed. IgG antibody titers decrease with successful treatment, which in general should be continued until lesions resolve and the titer is 1:2 or lower.

Public Health Implications

Coccidioidomycosis is an important and serious infection in people that is generally acquired from environmental exposure. Disease and death may occur from direct inoculation from needle-stick injuries and also from inhalation of the mycelial form, which can develop in tissues if they are stored for long periods after death of an infected animal. Physicians should be notified immediately in the case of inoculation or possible inhalation of a mycelial form. Necropsies should be performed with appropriate precautions and take place soon after death to prevent mycelial form growth. Bodies of infected animals should not be buried but should be cremated as soon as possible. Laboratories should be warned if coccidioidomycosis is suspected.

Aspergillosis

Etiology/Pathophysiology

Aspergillus are hyaline molds, the conidia of which are found commonly in soil, water, air, and decaying vegetation. *Aspergillus* spores are inhaled, and in the absence of adequate immune defenses, enlarge and germinate to form hyphae, subsequently leading to a variety of noninvasive to invasive disorders that include keratomycosis, fungal otitis externa, sinonasal aspergillosis (SNA), sinoorbital aspergillosis, bronchopulmonary and disseminated aspergillosis. Keratomycosis, otitis externa, feline sinoorbital aspergillosis, and bronchopulmonary aspergillosis in dogs are relatively rare conditions, and beyond the scope of this chapter. A variety of other molds less commonly cause infections in dogs and cats, including nonpigmented molds such as *Penicillium*, *Paecilomyces*, *Pseudallescheria*, and *Geotrichum* (hyalohyphomycoses); pigmented molds such as *Alternaria*, *Exophiala*, and *Cladophialophera* (phaeohyphomycoses); and zygomycetes such as *Basidiobolus*, *Conidiobolus*, and *Mucor*. The reader is referred elsewhere for detailed discussions of these pathogens.

Sinonasal aspergillosis is a subacute to chronic disease of the nasal cavity and sinuses that is most often caused by organisms that belong to the *A. fumigatus* complex. In most cases, affected dogs have no evidence of immune compromise, but sometimes SNA occurs as a result of implantation of a foreign body or other preexisting nasal disease, such as nasal neoplasia. SNA is a noninvasive disease, and the fungus does not extend beyond the mucosal epithelium. Production of toxins by the fungus and a profound host inflammatory response are thought to lead to extensive turbinate and bony destruction. Disseminated (invasive) aspergillosis in dogs is most often caused by *A. terreus* or *A. deflectus*, although other *Aspergillus* species have also been isolated.

Epidemiology and Signalment

Sinonasal aspergillosis in dogs is most common in large, nonbrachycephalic breeds. SNA uncommonly occurs in

cats, but diabetes mellitus has been identified in some affected cats.

Disseminated aspergillosis in dogs likely occurs as a result of an uncharacterized genetic immunodeficiency, because young adult female German shepherds are strongly predisposed, and immunosuppressive drug treatment is rarely present in the history of affected dogs. Disseminated aspergillosis is extremely rare in cats.

History and Clinical Signs

Clinical signs of SNA in dogs and cats consist of sneezing, serous to mucopurulent nasal discharge, depigmentation of the nasal planum (Figure 109.6), and, less commonly, epistaxis.

Nasal pain may be manifest in dogs as pawing at the face or withdrawal. Nasal airflow is usually normal or increased. Serous ocular discharge may occur as a result of destruction of the bones of the orbit. Rarely, palpation of the nasal bones or the hard palate reveals defects. Osteolysis of the cribriform plate occasionally leads to meningitis with neurologic signs such as obtundation or seizures.

Sites often involved in dogs with disseminated aspergillosis include the vertebral endplates and discs, renal pelvis, long bones, and lymph nodes. However, any organ may be affected, including the spleen, liver, heart, cardiac valves, pancreas, eyes, lungs, brain, meninges, small intestine, skin, spinal cord, thyroid, adrenal glands, prostate, and trachea. The most frequent clinical signs are lethargy, inappetence, pain, lameness, and ataxia and paresis secondary to discospondylitis.

Diagnosis

Imaging of the nasal cavity of dogs with SNA using plain radiography (open mouth view), computed tomography (CT) or magnetic resonance imaging (MRI) can reveal loss of turbinates, defects in the nasal septum, and/or increased soft tissue opacity within the nasal cavity. CT and MRI have increased sensitivity over plain radiography, and are the preferred imaging modalities. Osteolysis of the cribriform plate, orbit, and frontal bones may be identified using advanced imaging. In some animals, lesions are limited to the frontal sinus. Visualization of fungal plaques by rhinoscopy and sinuscopy confirms the diagnosis. Trephination or surgical exploration of the frontal sinuses may be necessary to visualize (and treat) this region. Cytologic examination of mucosal swabs, brush specimens of the nasal cavity, or nasal biopsies can reveal hyphae, which are septate and branch at 45° angles, and sometimes also conidia. Culture of *Aspergillus* from nasal biopsies supports the diagnosis, although negative culture results do not rule out SNA.

Figure 109.6 Nasal depigmentation and ulceration in a dog with sinonasal aspergillosis.

Disseminated aspergillosis may be suspected on the basis of signalment and clinical findings. In some cases, hyphae are visualized in tissue aspirates or urine sediment from affected dogs. Growth of a typical *Aspergillus* species (most commonly *A. terreus* or *A. deflectus*) from a normally sterile site confirms the diagnosis.

Both serum antibody and antigen assays have been evaluated for diagnosis of SNA and disseminated aspergillosis in dogs. Assays that detect serum antibodies to *Aspergillus* include ELISA and gel immunodiffusion (ID) assays. Different antibody assays vary in their sensitivity and specificity for diagnosis of SNA but in general, positive results suggest a diagnosis of SNA, but negative results do not rule out SNA. Dogs with disseminated aspergillosis frequently test negative, and so serum antibody testing is not recommended for diagnosis of this disease.

The sensitivity and specificity of serum *Aspergillus* galactomannan antigen ELISA (Platelia®) for diagnosis of SNA are low, and its use is not recommended for this condition. However, serum or urine antigen testing has high sensitivity for diagnosis of disseminated aspergillosis in dogs, and a high specificity when using a cut-off galactomannan index of 1.5. High-level false positives (>1.5) appear to occur only in dogs with other fungal infections, especially those caused by *Penicillium* or *Paecilomyces*, and dogs treated with Plasmalyte® fluid therapy.

In summary, a strong positive assay result in a dog with clinical abnormalities consistent with disseminated aspergillosis and no history of Plasmalyte administration supports a diagnosis of a mold infection, but fungal culture is required to confirm that *Aspergillus* is the causative agent. A negative result in a dog with disseminated disease suggests that *Aspergillus* is not the cause, but does not rule out the possibility of infection by another fungal species.

Therapy

Treatment of SNA requires thorough mechanical debridement of plaques with endoscopic biopsy forceps under anesthesia, followed by topical antifungal drug therapy. Frontal sinus trephination and curettage or open surgical debridement of the frontal sinus may be required. Provided the cribriform plate is intact, debridement is followed by lavage with 0.9% saline and suction, followed by topical therapy with clotrimazole or enilconazole. Several protocols for topical antifungal drug administration have been described. The reader is referred elsewhere for description of these protocols. Debridement and a second treatment are then performed one month later; sometimes, a third treatment may be necessary. Additional systemic treatment with antifungal drugs could also be considered, but it is not clear whether this improves outcome. Systemic azole antifungal drug therapy could be considered as an alternative to topical therapy in dogs with cribriform plate destruction, when topical treatment has the potential to lead to death or life-threatening neurologic signs.
