Canine disseminated aspergillosis is treated with itraconazole, voriconazole, posaconazole, and/or amphotericin B. Terbinafine has been used in addition to azole therapy with limited success. At best, treatment leads to remission for months to more than a year, but usually antigen titers remain high and eventually relapse occurs, leading to euthanasia or death. Although expensive, voriconazole is a treatment of choice in humans with invasive aspergillosis, and has led to remissions of many months' duration in some dogs. *A. terreus* is resistant *in vitro* to amphotericin B, but clinical improvement still occurs after treatment of some dogs with lipid complexed amphotericin B. Caspofungin is also used to treat invasive aspergillosis in humans, but expense and the need for daily intravenous administration have limited its use in dogs.

Prognosis

Success rates for treatment of SNA have varied from less than 30% to 100%. Low success rates reflect extensive disease that is often present at diagnosis, together with irreversible turbinate loss. Dogs with turbinate loss are predisposed to recurrent bacterial infections of the nasal cavity, which lead to persistent nasal discharge and sneezing. Therefore, attempts should be made to reach a diagnosis as early as possible when SNA is on the differential diagnosis list. Treatment with antibacterial drugs without pursuing a diagnosis only leads to disease progression, and is inappropriate because primary bacterial infections of the nasal cavity are rare in adult dogs.

Many dogs with disseminated aspergillosis have advanced disease at diagnosis, sometimes with respiratory distress, pathologic fractures, vertebral subluxations, and cord compression. The prognosis for these dogs is poor.

Public Health Implications

Aspergillosis occurs in people who have significant immunosuppressive disorders, such as transplant recipients, and is usually due to *Aspergillus fumigatus* complex organisms. Infections are acquired from the environment, and transmission from dogs and cats has not been described.

Candidiasis

Etiology/Pathophysiology

Candida species are yeasts that belong to the normal gastrointestinal, urogenital, and cutaneous flora but can invade tissues and cause disease as a result of disruption of normal host defenses. *Candida* species can also be isolated from soil, inanimate objects, and hospital environments. The yeasts are small (3–6 µm), ovoid and reproduce by budding. Budding results in the formation of new yeast cells, pseudohyphae (chains of elongated yeast cells), and true septate hyphae.

Disease syndromes caused by *Candida* spp. that occur in dogs and cats include keratitis, cutaneous or mucocutaneous candidiasis, otitis, urinary tract infections (UTIs), gastrointestinal candidiasis, peritonitis, and disseminated infections. The most commonly isolated species is *Candida albicans*, and only *C. albicans* appears to cause disseminated disease in dogs and cats.

Epidemiology and Signalment

Predisposing factors in dogs or cats with local or disseminated candidiasis have included diabetes mellitus, treatment with immunosuppressive drugs or broad-spectrum antibacterial drugs, a history of gastrointestinal surgery, parvoviral infections, and/or underlying malignancy. Disseminated candidiasis has also been described in apparently immunocompetent animals, which may reflect an underlying genetic immunodeficiency. Urethrostomy or cystostomy tube placement may be in the history of some animals with *Candida* UTIs.

History and Clinical Signs

Lower urinary tract candidiasis may be subclinical or associated with signs of lower urinary tract disease. Cutaneous candidiasis may manifest as erythema, alopecia, erosions,

and crusting, often where disruption of cutaneous or mucocutaneous regions has occurred (such as a previous surgical site or around a feeding tube or cystotomy stoma). *Candida* peritonitis can follow intestinal surgery, treatment with broad-spectrum antibacterial drugs, and subsequent enterotomy site dehiscence. Mixed infections with *Candida* and intestinal flora may develop. Affected dogs are febrile, have abdominal pain, and may have other gastrointestinal signs such as vomiting and diarrhea.

Dogs with disseminated candidiasis frequently develop rapidly progressive clinical signs that include fever, inappetence, weight loss, and other clinical signs that reflect the specific organs involved. The latter can include the pancreas, liver, mesentery, spleen, kidneys, heart, lungs, lymph nodes, and less often the bone, intestinal tract, eyes, meninges, thyroid, and/or prostate gland. Ocular signs include keratitis, uveitis, chorioretinitis, and endophthalmitis. Thromboembolic disease may complicate disseminated infections.

Diagnosis

Definitive diagnosis of candidiasis requires visualization of *Candida* blastospores, pseudohyphae, and true hyphae within lesions by cytologic or histopathologic examination, as well as confirmation of its identity using fungal culture. Because *Candida* can be isolated from the skin and mucous membranes of healthy dogs and cats, infection must be confirmed with cytology or histopathology when *Candida* is isolated from these sites. A diagnosis of disseminated candidiasis should be considered whenever *Candida* is isolated from the eye, skin, or urinary tract of an animal that develops systemic illness, and aggressive treatment instituted without delay.

Isolation of *Candida* allows antifungal susceptibility testing. Some isolates (especially *C. glabrata* and *C. krusei*) are resistant to multiple antifungal drugs.

Therapy

Treatment of candidiasis should involve management of underlying immunosuppressive disorders and specific antifungal drug treatment. Systemic antibacterial drugs should be discontinued if not clearly indicated, or the spectrum of activity should be narrowed. Cutaneous and corneal infections are usually treated with a combination of topical antiseptics or antifungal medications and systemic antifungal drugs until lesions resolve. Dogs and cats with *Candida* UTIs should initially be treated with fluconazole, which concentrates in urine. Intravesicular treatment with 1% clotrimazole under anesthesia may be necessary in animals that fail to respond to treatment. Intravesicular treatment is continued weekly until *Candida* can no longer be isolated from the urine. Typically 1–4 treatments, spaced one week apart, are required.

Systemic candidiasis is treated aggressively with systemic antifungal drugs, especially fluconazole, and supportive care. One dog with *Candida* peritonitis was treated successfully with surgical lavage of the abdomen, abdominal drain placement, and intravenous fluconazole. Antifungal drugs other than fluconazole with activity against *Candida* include amphotericin B and caspofungin, both of which must be administered parenterally.

Prognosis

The prognosis for successful resolution of local *Candida* infections is good, but successful treatment of systemic candidiasis in dogs or cats is rarely described.

Public Health Implications

Human infections with *Candida* species result primarily from invasion by normal flora.

Sporotrichosis

Etiology/Pathophysiology

Sporothrix species are dimorphic, saprophytic fungi that cause disease that often results from cutaneous or subcutaneous inoculation of the organism through a puncture wound, but can also follow inhalation of the fungus. Direct contact with cats that have sporotrichosis, without an apparent break in the skin, can also result in transmission.

Sporothrix species prefer moist soil that is rich in decaying vegetation. The fungus is distributed worldwide in tropical and temperate zones, but is most prevalent in tropical or subtropical regions of the Americas. The *S. schenckii* species complex includes multiple *Sporothrix* species, the epidemiology of which is still incompletely understood.

Epidemiology and Signalment

Cats are more susceptible to sporotrichosis than dogs and are thought to facilitate spread of organisms in the environment. Contaminated claw or bite wounds are thought to be important modes of transmission. Male cats have been overrepresented. Sporotrichosis in dogs is uncommon, but tends to occur in hunting breeds. Introduction of the organism with plant foreign bodies may lead to infection in some dogs.

History and Clinical Signs

In dogs and cats, *Sporothrix* spp. most often cause focal or multifocal cutaneous lesions. These are crusted, thickened or nodular lesions that often ulcerate or drain serosanguinous fluid. Most cats have multiple cutaneous lesions. These lesions may develop as a result of autoinoculation during grooming or they may be a manifestation of a disseminated infection.

Transmission by inhalation is thought to occur in some cats that develop pulmonary and nasal cavity disease. Respiratory signs include sneezing, cough, tachypnea, increased respiratory effort, stertor, and/or nasal discharge. Cats also can develop generalized disease, with involvement of the lungs, liver, spleen, kidneys, lymph nodes, and/or testicles. Clinical signs of systemic involvement include fever, generalized lymphadenomegaly, anorexia, vomiting, and weight loss. Osteoarticular sporotrichosis has rarely been described in dogs.

Diagnosis

Cytologic examination or histopathology of affected tissues from cats reveals pyogranulomatous inflammation with large numbers of round to cigar-shaped yeasts, which can be found intracellularly within neutrophils or macrophages and extracellularly (Figure 109.7). The yeasts are 4–6 µm in diameter and typically exhibit a single bud with a narrow base.

Dogs tend to have very low numbers of organisms in skin lesions, which may not be readily detected. Definitive diagnosis of sporotrichosis can be made by fungal culture of aspirates or biopsies from lesions. Use of molecular assays to identify *Sporothrix* could also be considered.

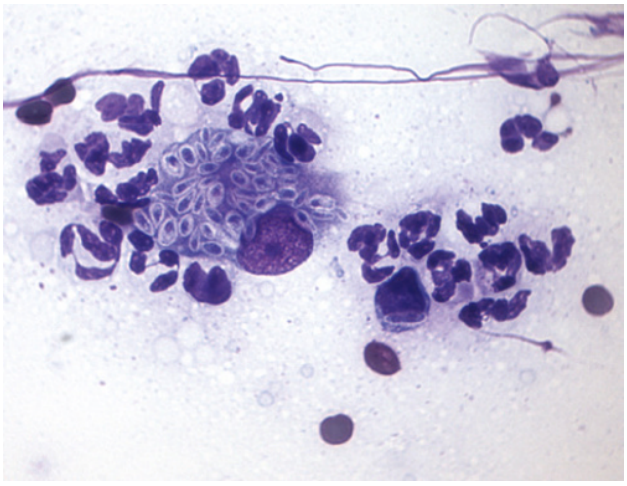

Figure 109.7 Cytology of an impression smear of a skin lesion from a cat with cutaneous sporotrichosis. Large numbers of intracellular pleomorphic yeasts are present.

Therapy

The treatment of choice for most dogs and cats with sporotrichosis is itraconazole. Alternative antifungal drugs for refractory disease include supersaturated potassium or sodium iodide, terbinafine, or amphotericin B. Unfortunately, potassium iodide formulations often lead to adverse gastrointestinal signs in cats. Localized hyperthermia has been used as adjunct therapy to treat fixed cutaneous lesions, because most strains of *Sporothrix* survive poorly at high temperatures. In this case, a thermal bag at a temperature of 40–42 °C is applied at least twice daily to lesions for 15 minutes.

Prognosis

In general, the prognosis for cure of sporotrichosis is good. Treatment durations of at least 4–6 months are generally required, but some cats require more than a year of treatment. Treatment should be continued for a month after complete resolution of lesions.

Public Health Implications

Inoculation from cat scratches, bites or direct contact with infected cats are important means by which people acquire sporotrichosis. Sporotrichosis should be considered as a differential diagnosis for any cat with a draining cutaneous lesion, and such cats should be handled with gloves and hands washed after contact. Owners of infected animals should minimize contact, and if contact is necessary, it should be recommended that they wear gloves and wash their hands immediately after handling the animal. Owners should also be warned of the risk of exposure to the organism in the environment. Needlestick injuries should be avoided and laboratory personnel warned of suspect cases.

Miscellaneous Fungus-Like Infections (Pythiosis and Rhinosporidiosis)

Etiology/Pathophysiology

A variety of fungus-like organisms that reside in aquatic environments and are thought to invade damaged host tissues can cause disease in dogs and cats. These include *Pythium insidiosum*, *Lagenidium* spp. and *Rhinosporidium seeberi*. *Pythium insidiosum* and *Lagenidium* are oomycetes (water molds), whereas *R. seeberi* is an aquatic protistan parasite (class Mesomycetozoea) that is taxonomically located between animals and fungi. *Pythium insidiosum* causes severe, progressive gastrointestinal or cutaneous disease in dogs

and rarely cats that is often fatal. In the US, pythiosis most often occurs in the Gulf Coast states but has also been recognized in other parts of the USA, including California and Arizona. *Lagenidium* is found primarily in the southern United States and causes ulcerative cutaneous lesions or systemic lymphadenopathy in dogs. *Rhinosporidium seeberi* is most often found in warm, wet environments such as the southeastern and south-central USA, where it causes polypoid masses in the rostral nasal cavity of dogs and rarely cats.

Epidemiology and Signalment

Pythiosis, lagenidiosis, and rhinosporidiosis most commonly occur in young, large-breed dogs that are apparently immunocompetent.

History and Clinical Signs

Gastrointestinal pythiosis in dogs is characterized by severe, focal intestinal wall thickening, often with mesenteric lymphadenopathy. Clinical signs include weight loss, anorexia, vomiting, diarrhea, and sometimes hematochezia. Cutaneous pythiosis in dogs occurs most often at the base of the tail, on the extremities, or the perineum, and is characterized by ulcerated mass lesions with draining tracts. Generally, gastrointestinal and cutaneous pythiosis do not occur concurrently.

Dogs with lagenidiosis are typically evaluated for cutaneous lesions that resemble those of cutaneous pythiosis. Local lymphadenopathy occurs in some dogs, and may occur in the absence of obvious cutaneous lesions. Dogs with lagenidiosis may also have intrathoracic or intraabdominal lesions, which may involve the great vessels, tracheobronchial, sublumbar and/or inguinal lymph nodes, lung or cranial mediastinum.

In dogs and cats, infection by *R. seeberi* leads to formation of pedunculate to sessile masses within the rostral third of the nasal cavity. The polyps range in size from a few millimeters to several centimeters. Clinical signs consist of subacute to chronic progressive sneezing with or without epistaxis, snuffling, and sometimes a serous, mucoid or serosanguinous unilateral nasal discharge.

Diagnosis

Diagnosis of pythiosis, lagenidiosis, and rhinosporidiosis is often initially based on the results of cytology or histopathology, which reveals broad, poorly septate hyphae that resemble zygomycete hyphae. Culture and/or PCR and sequencing can be used to distinguish between these organisms. Serologic assays that detect antibody are also available to assist diagnosis, but these do not discriminate between pythiosis and lagenidiosis.

Cytologic examination of smears, brushings or biopsies of *R. seeberi* polyps reveals pyogranulomatous inflammation with numerous *R. seeberi* endospores. Histopathology reveals abundant sporangia in various stages of development (Figure 109.8).

Therapy and Prognosis

Aggressive surgical resection is the treatment of choice for these infections. A combination of high-dose itraconazole (10 mg/kg PO q24h) and terbinafine (5–10 mg/kg PO q24h) should be used to treat dogs with nonresectable pythiosis or lagenidiosis, or when there is concern that not all margins have been cleared of disease. Dogs with nonresectable gastrointestinal pythiosis may also benefit from treatment with antiinflammatory doses of glucocorticoids. Prognosis is guarded to poor, but some dogs can be cured with aggressive therapy. To monitor for recurrence, ELISA serology can be performed at surgery and 2–3 months later. If serum antibody levels drop by more than 50% within three months, medical therapy can usually be discontinued.

Because *Rhinosporidium* polyps are often rostrally located, surgical excisions can often be extended caudally from the nares in order to remove the polyps. Many dogs have no recurrence of clinical signs thereafter, but some experience disease recurrence within months of surgery.

Public Health Implications

Human infections with *P. insidiosum* are rare and are acquired from the environment. However, routine precautions when handling infected tissues or exudate should be followed.

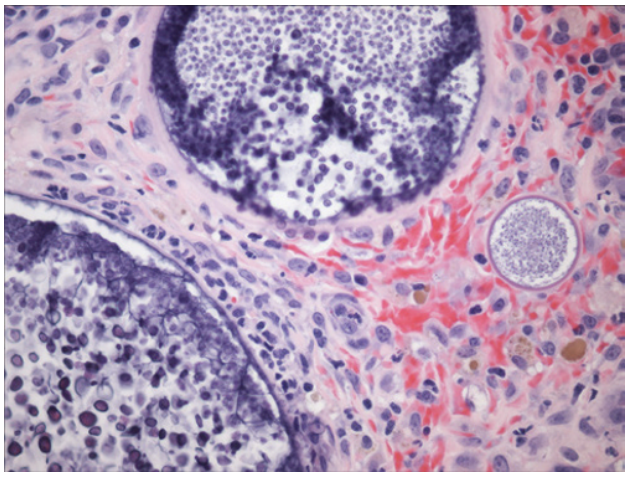

Figure 109.8 Histopathology of a polyp caused by *Rhinosporidium seeberi*. Sporangia that contain endospores are seen in various stages of development.

Parasites are responsible for some of the most important and widespread diseases of domestic dogs and cats. Some of these parasitic infections are also zoonotic and can infect humans. A thorough understanding of the pathogenesis and epidemiology of these parasitic diseases is required in order to treat infected pets and prevent the spread of disease efficiently. This chapter focuses on important protozoal diseases in dogs and cats with emphasis on etiology, pathophysiology, clinical manifestations, diagnosis, treatment, and prevention.

Toxoplasmosis

Etiology and Pathophysiology

Toxoplasma gondii is a tissue coccidian protozoon with a sexual life cycle in the intestine of felids, the definitive host, and an asexual phase in intermediate hosts. The intermediate hosts of *T. gondii* include all warm-blooded vertebrates including humans. Cats and intermediate hosts can be infected by bradyzoites in meat or by sporulated *T. gondii* oocysts from cat feces. Cats shed *T. gondii* oocysts in their feces within 3–10 days after infection by bradyzoites from tissue cysts and excretion continues for approximately 7–21 days (median eight days) with massive shedding which can reach hundreds of millions of oocysts per cat during the shedding period. After that initial period, risk of further oocyst shedding is limited. Oocysts in cat feces undergo sporulation in the environment and develop sporocysts containing infective sporozoites within 1–5 days in appropriate humidity, temperature, and oxygenation conditions [1].

After oral infection, *T. gondii* sporozoites release from the oocysts and can invade the gut, multiply as tachyzoites, disseminate systemically and localize in internal organs, the nervous system, and muscle tissues. In most cases, infection is subclinical and parasites are eventually encysted as tachyzoites in tissues, but severe and fatal disease can occur due to acute infection or reactivation of parasites in tissue cysts. In addition, in some host species and in humans, infection can cross the placenta and infect embryos intrauterinely.

Several *T. gondii* genotype strains have been described with variable virulence and host predilection. These include the more common genotypes I, II, and III described in North America and Europe as well as several atypical genotypes [2].

Epidemiology

Exposure to *T. gondii* in cat populations is widespread and positive serology may be detected in up to 74% of cats in domestic feline populations worldwide. Dogs have also been reported to have high exposure to *T. gondii* with seroprevalence rates ranging from 30% to 64% in different countries and populations. Most *T. gondii* infections are subclinical and hosts may remain chronically infected without developing clinical disease. Cats are often infected by preying on infected rodents and it has been shown that *T. gondii* infection can alter rodent behavior and make them less alarmed, consequently increasing their likelihood of falling prey to domestic cats. Toxoplasmosis is one of the most common zoonotic infections in humans and is responsible for human abortions, birth defects, encephalitis, and generalized disease [1,3].

Signalment

Cats and dogs of any age or gender can be affected. Young and immunosuppressed animals tend to develop more severe disease. Congenital infection is usually associated with more severe disease than infection of adult cats, often affecting the liver and respiratory tract.

History and Clinical Signs

Clinical signs in cats are rarely related to the gastrointestinal stage of *T. gondii* development which is usually subclinical. Cats affected by systemic infection may show a variety of clinical signs including fever, anorexia, abdominal pain, respiratory distress, ocular inflammation, lethargy, and central nervous system disorders. These are associated with tachyzoite dissemination and their cytotoxicity with generation of local and systemic inflammation. Acute disease in dogs may be accompanied by neuromuscular, central nervous system (CNS), respiratory, gastrointestinal, hepatic, and more rarely ocular manifestations. Myositis and myocarditis are also prevalent in canine toxoplasmosis. Disease in both cats and dogs may result from new infection or from reactivation of latent infections by immune suppression such as cyclosporin treatment, distemper infection in dogs or feline immunodeficiency virus (FIV) in cats [4].

Diagnosis

Cats and dogs with acute systemic toxoplasmosis may develop nonregenerative anemia, leukopenia with lymphopenia, or neutrophilic leukocytosis, monocytosis, and eosinophilia. Serum biochemistry abnormalities during acute toxoplasmosis may include hypoproteinemia with hypoalbuminemia. Increased activities of alanine aminotransferase (ALT), creatinine kinase (CK), and aspartate aminotransferase (AST) are found in animals with hepatic or muscle necrosis.

Excretion of oocysts by cats during the limited shedding period can be detected by fecal examination or polymerase chain reaction (PCR). Oocysts are relatively small (10 µM) and can be concentrated by fecal flotation with centrifugation using sugar solutions such as Sheather's sugar solution. *Hammondia hammondi* and *Besnoitia* spp. produce oocysts which are morphologically indistinguishable from *T. gondii* occysts in cat feces.

Diagnosis of clinically ill cats and dogs is based on compatible clinical signs and laboratory abnormalities and by the detection of specific serum antibodies, demonstration of parasite DNA by PCR, or visualization of tachyzoites by cytology in clinical samples. *T. gondii* tachyzoites may be detected by cytology during acute toxoplasmosis in peritoneal and ascitic fluids, and more rarely in cerebrospinal fluid (CSF), blood and bronchoalveolar lavage washings or other tissues. PCR performed on CSF, aqueous humor, or any other body fluid or internal organ tissue is confirmative of infection with *T. gondii*.

Serology is carried out by the enzyme-linked immunoabsorbent assay (ELISA), immunofluorescence assay (IFA) (Figure 110.1), agglutination assays, and immunochromatographic kits.

Subclinically infected animals may display antibody levels, and therefore positive serologic results may only indicate previous infection, which is not necessarily acute. The demonstration of increased IgG levels by at least fourfold in paired sera taken at least two weeks apart or high IgM levels suggests active acute infection, although this is often not observed. Immunoblotting and ELISA assays have been developed for the measurement of specific *T. gondii* IgM, IgG, and IgA antibody classes in an effort to discern the kinetic pattern of antibody formation in feline infection.

About 80% of healthy cats experimentally infected with *T. gondii* develop detectable specific IgM antibodies within 2–4 weeks post infection and most become IgM seronegative by 16 weeks. However, some cats, particularly those with FIV or ocular toxoplasmosis, may have

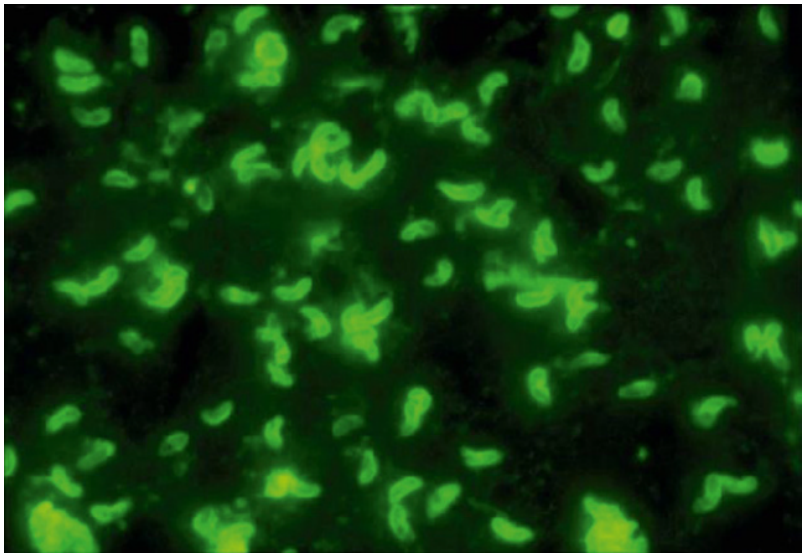

Figure 110.1 A positive indirect fluorescent antigen test serologic response to *Toxoplasma gondii* antigen. *Source*: Courtesy of Dr Monica Leszkowicz Mazuz, Kimron Veterinary Institute, Israel.

persistent IgM levels. Since some cats never develop a detectable IgM response and others have persistent IgM antibodies, it is not possible to accurately use IgM serology to predict recent infection, although a positive antibody titer can be suggestive of it. Furthermore, *T. gondii*-specific IgG can be detected by serum ELISA in healthy cats from 3–4 weeks after experimental infection. By this time, oocyst shedding has usually been completed and therefore IgG seropositive cats are usually considered of low risk to public health. However, *T. gondii*-IgG antibodies usually persist in the sera of infected cats for years or even for their lifetime due to the persistence of tissue infection.

In addition, anti-*T. gondii* antibodies can be measured in the CSF and aqueous humor to demonstrate local production of antibodies as an indication of organ infection. This local antibody production can be compared to the serum antibody concentration using an antibody coefficient to differentiate whether local production of antibodies is present or if antibodies have diffused from the circulation.

Therapy

Clindamycin is the current treatment of choice in dogs and cats with clinical toxoplasmosis. It is administered at 10–20 mg/kg PO q12h for at least two weeks to dogs and at 12.5 mg/kg PO q12h for 2–4 weeks to cats. Azithromycin at 10 mg/kg PO q24h for four weeks is an additional treatment choice for cats and trimethoprim-sulfonamide at 15 mg/kg PO q12h for 2–4 weeks is an alternative treatment for animals with intolerance to clindamycin. Uveitis due to toxoplasmosis is treated with 1% prednisolone acetate ophthalmic drops.

No vaccine is currently available commercially for the prevention of *T. gondii* infection in cats and dogs, or the prevention of oocyst shedding in cats. Avoiding exposure of cats and dogs to *T. gondii* infection includes prevention of hunting and feeding of raw or undercooked meat. Cat feces should be discarded properly every day to prevent exposure to sporulated oocysts.

Prognosis

Acute toxoplasmosis often starts improving 24–48 hours after initiation of clindamycin treatment. Ocular and CNS infections tend to respond more slowly and disease in immunocompromised patients usually has a poorer prognosis.

Neosporosis

Etiology and Pathophysiology

Neospora caninum is a coccidian parasite which is an important cause of abortion in livestock worldwide and can also cause neurologic disease in dogs. *Neospora caninum* can infect several domestic animal species including dogs, cattle, sheep, goats, horses, and chickens, and wild animal species including deer, rodents, rabbits, coyotes, wolves, foxes, and birds. Dogs, wolves, coyotes, and foxes are the definitive hosts of *N. caninum* [5].

The sexually reproductive stage of the parasite's life cycle occurs in the intestine of a canine definitive host which passes unsporulated oocysts in the feces. Infective oocysts are ingested by an intermediate host, such as cattle, following sporulation in the environment which happens within 24 hours. Tachyzoites of *N. caninum* develop in the infected intermediate host during acute infection followed by the development of bradyzoites walled off in tissue cysts as infection becomes chronic. Dogs acquire the infection mainly by ingesting parasite cysts from tissues of infected intermediate hosts, in particular cattle, and shed oocysts approximately five days after bradyzoite ingestion. In addition, transplacental transmission during pregnancy has been shown to occur in dogs, sheep, and cattle.

Epidemiology

The prevalence of *N. caninum* varies in different dog populations and has been reported to be associated with the dog's environment and lifestyle. Free-roaming dogs living in rural areas are more likely to be seropositive than urban dogs with less access to infected prey, bovine placentas, aborted fetuses or other potentially infected tissues. High seroprevalence rates of above 50% have been reported in beef farm dogs in South America, whereas populations of healthy dogs in Europe and the USA typically have seroprevalence rates below 15%.

Signalment

Dogs of any age or gender can be affected by *N. caninum* but disease is more common in dogs under the age of 1 year.

History and Clinical Signs

The clinical manifestations of canine neosporosis are due to inflammation and necrosis caused by cellular destruction induced by tachyzoites. As for *T. gondii*, disease by *N. caninum* can be caused by new infection, or by reactivation of parasites in cysts during host stress or immune compromise. Immune-suppressive treatment for other disease by cyclosporin, steroids or azathioprine may activate latent *N. caninum* infection. *Neospora caninum* may replicate in the lower respiratory system, skin, liver, and nervous system. Disease is mostly associated with the neuromuscular predilection of this parasite. Neurologic disease is especially severe in congenitally infected puppies and may be apparent shortly after birth or delayed and manifested months after birth, usually before the age

Figure 110.2 A young puppy with hindlimb paresis due to *Neospora caninum* infection. *Source*: Courtesy of Dr Monica Leszkowicz Mazuz, Kimron Veterinary Institute, Israel.

of six months. Typical signs in pups include ascending hindlimb paresis and ataxia which becomes progressively more severe (Figure 110.2), polymyositis, muscle atrophy, muscular back pain, head tilt, ocular abnormalities, urinary incontinence and dysphagia.

Infected adult dogs may suffer from encephalomyelitis, polymyositis, focal cutaneous nodules or ulcers, pneumonia, hepatitis, peritonitis, or myocarditis.

Diagnosis

The hematologic and serum biochemistry findings in clinical neosporosis are nonspecific. Increased serum activities of CK and AST may be evident in dogs with myositis due to neosporosis. CSF abnormalities include mild increase in protein and nucleated cells concentrations with predominantly mononuclear cells including monocytes and lymphocytes and occasionally neutrophils and eosinophils [6].

The diagnosis of canine neosporosis can be based on clinical signs and positive serology by ELISA or IFA. Pups usually seroconvert 2–3 weeks after infection and antibody levels are frequently high in clinically sick dogs. A fourfold increase in antibody levels is associated with recent infection and IFA titers of 1:800 or greater in conjunction with compatible clinical signs suggest clinical neosporosis. Serologic cross-reactivity between *N. caninum* and *T. gondii* antibodies is present in some assays but not expected in sera from dogs with medium to high titers. No correlation has been found between antibody level and clinical severity in dogs with neosporosis and subclinically infected dogs may also have high antibody levels to *N. caninum*. Suspicion of canine neosporosis can be confirmed by demonstrating the presence of the parasite's DNA by PCR of CSF or muscle biopsies [7]. *Neospora caninum* tachyzoites can occasionally be detected in the CSF by cytology.

Therapy

Clindamycin at 10–12 mg/kg PO q8h for at least one month is the main drug used for the treatment of canine neosporosis. Trimethoprim-sulfa at 15 mg/kg PO q12h alone or in combination with pyrimethamine at 1 mg/kg PO q24h for at least a month is another treatment option. Pyrimethamine may be combined also with clindamycin at the same doses. Ponazuril has been shown to be effective in cattle and mice but there are insufficient data on its efficacy against canine neosporosis. Treatment of neosporosis may only be partially effective or not effective at all and long-term treatment of two months or more is often required, until no further improvement is noted.

Prevention should be aimed at avoiding the ingestion of bovine placentas and raw bovine or prey meat by dogs, and also elimination of fecal contamination of ruminant feed by dog and wild canid feces.

It has been recommended to test all littermates of a puppy with neosporosis by serology for infection and treat all those who are positive, or further consider treatment of the whole litter for the sake of prevention, regardless of seropositivity. Bitches who have given birth to infected puppies should be tested for infection and not be bred. Immunosuppressive therapy should preferably not be administered to seropositive dogs due to potential reactivation of tissue cysts.

Prognosis

The prognosis for treated dogs with cutaneous neosporosis is more favorable than for those with CNS and neuromuscular disease. Young dogs with muscle contracture and rigid hyperextension of the back legs have a poor prognosis and often do not improve with treatment. Older juvenile dogs above 4 months of age and mature dogs with neurologic disease often respond to long-term treatment but may not return to complete function and cure. Untreated dogs with clinical neosporosis usually die.

Trypanosomiasis

Trypanosomiasis is a group of diseases caused by flagellated protozoans of the genus *Trypanosoma* which are mostly arthropod borne and transmitted by hematophageous insects. The life cycle of trypanosomes is shared by two hosts: a vertebrate animal and an arthropod vector. Trypanosomes are divided to two main groups. The Salivaria (including *T. brucei*, *T. conglonese*, and other species, develop in the anterior part of the vector's digestive tract and salivary glands, and are transmitted in saliva through biting. In contrast the Stercocaria

(*T. cruzi*), develop in the posterior gut of the vector and are transmitted in the fecal excretion of the vector. The Salivaria species cause African trypanosomiasis, mainly transmitted by tsetse flies (*Glossina* spp.), whereas the Stercocaria *T. cruzi* causes American trypanosomiasis and is transmitted by *Triatoma* bugs ("kissing bugs"). *Trypanosoma evansi*, which is closely related genetically to the tsetse-transmitted *T. brucei*, is transmitted mechanically by biting flies without development in the fly gut. The life cycle of African trypanosomes includes an epimastigote stage which develops in the tsetse fly and a trypomastigote stage found in the fly's saliva and in the blood and tissues of the animal. The life cycle of the American trypanosome *T. cruzi* includes an additional intracellular life stage in the animal host, the amastigote (also found in *Leishmania* spp.).

African trypanosomes infect a large variety of animals, with some species causing severe disease in humans, such as *T. brucei gambiense* which is responsible for the chronic debilitating disease sleeping sickness and *T. brucei rhodesiense* which causes a more acute severe form of human trypanosomiasis. Dogs and cats are not known to develop disease from these two important human pathogens. However, dogs do suffer from severe disease due to *T. congolense,* and both dogs and cats suffer from disease due to *T. evansi*. American trypanosomiasis is a zoonotic disease caused by *T. cruzi* which has both wildlife and domestic animal hosts. It induces acute or chronic disease associated with myocarditis and neuromuscular degeneration in dogs and humans.

Trypanosoma caninum is a newly discovered species that has been found in the skin and other tissues of dogs in Brazil. No apparent clinical signs have been attributed to this infection and the relatedness of this species to *T. cruzi* or African trypanosomes has not been determined [8].

American Trypanosomiasis

Etiology and Pathophysiology

Trypanosoma cruzi, the zoonotic agent of Chagas disease or American trypanosomiasis, can cause acute or chronic disease in dogs. Trypomastigotes of *T. cruzi* are shed in the triatomine vector feces onto the skin of a vertebrate host. The parasite crosses the skin in bruised areas or through rubbing or scratching and enters the bloodstream. Trypomastigotes that invade macrophages or myocytes transform into amastigotes which multiply intracellularly. Amastigotes transform back to trypomastigotes and are released from destroyed host cells into the blood and are ingested during a blood meal by the vector. Trypomastigotes are transformed to epimastigotes in the triatomine's gut and replicate until eventually transferring to the posterior gut where they transform back into infectious trypomastigotes before excretion in the insect's feces. The triatomine vectors defecate shortly after feeding on blood thereby infecting animals and humans. Dogs may also be infected orally by ingesting triatomine bugs, their excretions or infected animal tissues. This route of infection is also prevalent in humans. Furthermore, transplacental infection and transmission from contaminated blood transfusion products are additional modes of transmission which enable the parasite's spread.

Invasion of cells by *T. cruzi* trypomastigotes, replication as amastigotes and then transformation back to trypomastigotes result in cell rupture and tissue damage. Parasitemia with *T. cruzi* can be detected by examining canine blood smears three days post infection, reaching its peak 14 days later, and becomeing undetectable cytologically 30 days post infection. Acute cardiac disease may develop as early as 14 days after infection and resolve by one month. Chronic disease can develop after a long subclinical phase with progressive myocarditis and cardiomyopathy directly induced by the parasite or by an autoimmune reaction which is unrelated to the intracellular amastigote parasite load.

Epidemiology

Trypanosoma cruzi infects a large number of animal species in the American continent and Caribbean islands. These include wild animals such as armadillos, opposums and raccoons, and also dogs and humans. Cats may also be infected but less frequently than dogs and without apparent clinical disease. The disease is prevalent in humans in southern and central American countries from Argentina to Mexico. It has also been reported in the southern, United States, especially in Texas. Dogs are considered the main domestic reservoir for human infection in several areas, whereas wildlife hosts are the main reservoirs in others. Canine infection is more prevalent than its human counterpart in the United States where the seroprevalence in dogs in Texas and Louisiana ranges from 12% to 22% [3].

Signalment

Puppies and dogs younger than 1 year of age develop more severe, acute, and frequently fatal disease compared with older dogs.

History and Clinical Signs

Chagas disease myocarditis has three stages: acute, intermediate (latent), and chronic. The main findings of acute disease in puppies include lethargy, fever, lymphadenomegaly, pale mucous membranes, hepatosplenomegaly, and loss of appetite. This stage of the disease results from direct myocardial cell injury by trypomastigotes and the associated inflammatory response.

Meningoencephalitis due to parasite invasion of the CNS may also develop during the acute disease. Dogs older than 6 months of age develop less severe clinical signs of infection which may be inapparent. Survival of acute infection may be preceded by a long subclinical latent infection with no clinical signs and no apparent parasitemia. Some dogs develop the chronic form of the disease within 8–36 months after the acute phase. These dogs suffer from cardiac failure that often begins as right-sided and may progress to left-sided. Exercise intolerance, ascites, pleural effusion, pulse deficits and hepatomegaly can occur due to myocarditis, dilated cardiomyopathy and arrhythmias.

Diagnosis

Dogs with acute *T. cruzi* infection may have hematologic abnormalities that include anemia, thrombocytopenia, neutrophilia, monocytosis, eosinophilia, and lymphocytosis. Serum biochemical abnormalities during acute *T. cruzi* myocarditis may include increased muscle enzyme activity and prerenal or renal azotemia. Changes in cardiac electrical conductivity including arrhythmias and atrioventricular blocks will be evident on ECG during acute *T. cruzi* myocarditis.

Trypomastigotes may be evident in stained blood smears, and sensitivity can be improved by examining a Giemsa-stained thick buffy coat smear. Concentration of trypomastigotes by centrifugation of plasma is also more sensitive than examining blood smears. The parasite pellet from plasma may be examined microscopically following staining or used for DNA extraction and PCR. *Trypanosoma cruzi* trypomastigotes or rarely intracellular amastigotes may be demonstrated by examining lymph node cytology.

Serologic detection of antibodies to *T. cruzi* by IFA, ELISA, or immunochromatography is the most common diagnostic technique for the detection of latent and chronic infection. Antibodies are detectable three weeks after infection and persist for the lifetime of the dog irrespective of whether it remains in latent infection or develops chronic disease. Serologic cross-reactivity between *T. cruzi* and *Leishmania* is a considerable problem in settings where these infections overlap. PCR assays for the detection of *T. cruzi* are specific but are often not sensitive during the latent and chronic stages of the disease when parasitemia is rare.

Therapy

Benznidazole at 5–10 mg/kg PO q24h for 60 days or nifurtimox at 2–7 mg/kg PO q6h for 3–5 months often in association with prednisone are used at the acute disease stage. These drugs, particularly nifurtimox, have severe side-effects, are not FDA approved for dogs and are often difficult to obtain. Furthermore, infection may persist despite treatment.

Prognosis

Infected dogs should be monitored for cardiac dysfunction and are at risk for sudden death. Specific treatment for cardiac failure is often indicated.

Prevention

Prevention consists of limitation of exposure to triatomine vectors and access to potentially infected prey. Blood donors should be screened for *T. cruzi* infection in and around endemic regions.

African Trypanosomiasis and *T. evansi*

The African trypanosomes are a multitude of species for which some distinct strains have been reported. All the species that belong to the *T. brucei* complex and *T. evansi* are similar morphologically and indistinguishable by light microscopy, whereas *T. congolense* differs from the *T. brucei* complex by the length and shape of its flagella. All the African trypanosomes are strictly extracellular and develop in the form of trypomastigotes in the vertebrate host, which transform to epimastigotes in the tsetse vector. *T. brucei* is able to avoid elimination from the mammalian host by periodic change of antigenicity and evading the host's immune system.

Epidemiology

Tsetse flies, the vectors of *T. brucei* and *T. congolense*, are found only in sub-Saharan Africa and therefore the prevalence of diseases caused by these parasites is limited to this part of Africa. Because *T. evansi* is transmitted mechanically by tabanids and possibly by other insects present also outside Africa, it was able to spread away from Africa and be prevalent also in major parts of Asia and South America.

Signalment

European breeds of dogs and cats imported into Africa are considered more susceptible to clinical disease caused by species of African trypanosomes, compared with local domestic dogs and cats.

History and Clinical Signs

The clinical signs described in dogs with African trypanosomiasis include fever, anorexia, lethargy, lymphadenomegaly, hepatosplenomegaly, edema, ascites, petechial hemorrhages, uveitis, oculonasal discharge, corneal edema reminiscent of blue eye caused by canine adenovirus infection, and neurologic signs associated with meningoencephalitis.

Diagnosis

Dogs may have anemia, leukocytosis or leukopenia and thrombocytopenia. Serum biochemistry abnormalities

include increased activities of liver enzymes, azotemia, hypoalbuminemia, and hyperglobulinemia.

The diagnosis of African trypnosomiasis in dogs and cats involves detection of trypomastigotes by cytology of blood, body fluids or tissues using microscopy (Figure 110.3). PCR with sequencing is useful for detection of low parasitemias and for species determination. The flagella of *T. congolense* trypomastigotes does not extend separately beyond the body of the parasite whereas the flagella of *T. brucei* and *T. evansi* extends posteriorly after overlapping the parasite's body. ELISA, IFA, and the card agglutination trypanosomiasis test (CATT) are available for the detection of antibodies against *T. evansi*.

Therapy

Trypanosoma congolense infection in dogs can be treated with isometamidium chloride at 0.5 mg/kg injected deep intramuscularly. *Trypanosoma brucei* infection of dogs is apparently more resistant to drug therapy than *T. congolense* and its treatment consists of a higher dose of 1 mg/kg isometamidium chloride intramuscularly or diminazene aceturate at 3.5 mg/kg IM or SC [9]. *Trypanosoma evansi* in dogs and cats can be treated with diminazene aceturate at the same dose for dogs as for the treatment of *T. congolense* [10,11].

Prognosis

Dogs infected with *T. congolense* have been reported to be treated successfully, unless infection involved the CNS. Untreated disease is often fatal.

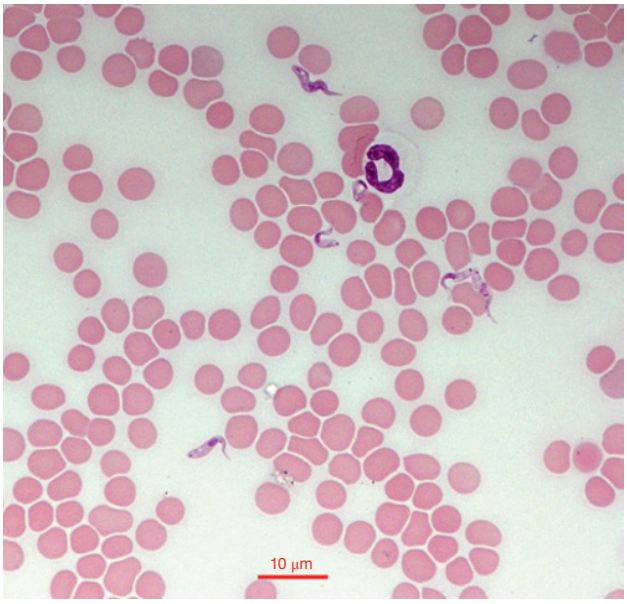

Figure 110.3 Trypomastigotes of *Trypanosoma congolense* in a blood smear from a naturallyinfected dog (May Grunwald–Giemsa stain).

Prevention of African trypanosomiasis can be achieved by eliminating dog contact with vectors by using deltamethrin-impregnated collars, or by injections of isometamidium chloride every 2–3 months.

Leishmaniosis

Etiology and Pathophysiology

The leishmanioses are a group of infectious diseases that affect humans and domestic and wild animals worldwide caused by diphasic protozoans of the genus *Leishmania* (Kinetoplasta, Trypanosomatidae). Most transmission cycles are zoonotic, involving reservoir hosts such as rodents, marsupials, edentates, monkeys, domestic dogs, and wild canids.

Canine leishmaniosis (CaNL) due to *Leishmania infantum* is a major zoonotic disease endemic in more than 70 countries. It is present in regions of southern Europe, Africa, Asia, South and Central America and has emerged in the United States mainly in foxhounds. In Europe, the domestic dog is a reservoir host of major veterinary and human importance [12].

Natural transmission of *L. infantum* infection between animals and from animals to humans occurs by the bite of a phlebotomine sand fly species (Diptera, Psychodidae, Phlebotominae) of the genera *Phlebotomus* (Old World) and *Lutzomyia* (New World). *Leishmania* completes its life cycle in the phlebotomine sand fly vector, which harbors the flagellated extracellular promastigote form, and in a mammal where the intracellular amastigote forms develop. A female sand fly ingests *Leishmania* while feeding on blood and then transmits the infective stages (metacyclic promastigotes) during a subsequent blood meal. The infective promastigotes inoculated by the sand fly into the skin of animals are phagocytosed in the mammalian host by macrophages and other phagocytic cells, in which they transform to amastigotes. In susceptible dogs or cats, amastigotes multiply and disseminate to internal organs.

The immune response elicited by susceptible animals is mainly an overwhelming humoral response that does not control infection. This robust humoral immune response coupled with a high parasite load leads to immune complex formation and deposition which causes a type III hypersensitivity reaction in several tissues and is associated with uveitis, polyarthritis or glomerulonephritis. In subclinical resistant animals, a protective T cell-mediated immune response predominates and controls the infection, preventing it from causing clinical disease.

Proven modes of non-sand fly transmission in dogs include infection through transfused blood products

from carriers and vertical transplacental transmission, as documented in foxhounds in North America, and venereal transmission.

Epidemiology

At least 2.5 million dogs are estimated to be infected in southwestern Europe alone, and the disease is spreading north into the foothills of the Alps and the Pyrenees. The number of infected dogs in South America also is estimated in millions, and there are high infection rates in some areas of Venezuela and Brazil, where a high prevalence of canine infection is associated with high risk of human disease.

The seroprevalence reported in dogs in the Mediterranean basin ranges from 5% to 30%, depending on the region. Surveys employing other detection methods to estimate the prevalence of *Leishmania* infection by amplification of *Leishmania* DNA from different tissues or by detection of specific anti-*Leishmania* cellular immunity have revealed even higher infection rates, approaching 70% in some foci. Most dogs in these areas appear to have chronic infection that may be lifelong, but only a low proportion of dogs develop severe disease.

In cats, serologic and PCR surveys in southern Europe indicate that *Leishmania* infection is more widespread than clinical disease. Epidemiologic studies have described rates ranging from 0.4% to 30% based on serologic and molecular techniques. However, it is important to highlight that clinical illness in cats is less frequently reported than in their canine equivalents.

Signalment

Dogs and cats of either gender can suffer from clinical leishmaniosis. Some dog breeds such as the boxer, Rottweiler, cocker spaniel and German shepherds appear to be more susceptible to the disease and other breeds (Ibizan hound) are more resistant. Disease is most common in young adult (>6 months of age), adult, and older dogs. Cats of any breed can be affected by this infection. Disease is most common in adult or older cats [13].

History and Clinical Signs

The clinical manifestations of this infection are very broad and variable, mainly due to the various types of immune responses which may be elicited in the dog in response to the parasite, the different organs affected and the different types of pathogenic mechanisms of disease that can be activated. Infection with *L. infantum* causes chronic infection, which can sometimes occur in a subclinical or mild self-limiting illness, or as a moderate or severe illness in dogs which can be fatal. Four clinical stages of the disease have been described based on the severity of the disease (clinical and laboratory abnormalities) and serology results, establishing different therapeutic regimens and forecast for each stage of the disease.

The main clinical findings found on physical examination in classic CaNL include skin lesions, local or generalized lymphadenomegaly, loss of body weight, exercise intolerance, decreased appetite, lethargy, splenomegaly, polyuria and polydypsia, ocular lesions, epistaxis, onychogryposis, lameness, vomiting, and diarrhea [12,13].

Skin lesions are the most frequent manifestation of CaNL in dogs brought for treatment due to suspicion of the disease. Several dermatologic lesion patterns have been described: exfoliative dermatitis with alopecia which can be generalized or localized over the face, ears and limbs; ulcerative dermatitis; nodular dermatitis; mucocutaneous proliferative dermatitis; and papular dermatitis.

The most common ocular manifestations of CaNL are anterior uveitis, blepharitis (exfoliative, ulcerative, or nodular), and keratoconjunctivitis, either common or sicca. About 25% of dogs with clinical leishmaniosis have ocular and periocular lesions including keratoconjunctivitis and uveitis. Ocular consequences of systemic hypertension such as retinal detachment and/or hemorrhages, retinal arterial tortuosity, and hyphema are present in the disease but not diagnosed frequently.

Some degree of renal pathology is present in most dogs with CaNL and subsequent renal disease due to immune-complex glomerulonephritis eventually develops and is believed to be the main cause of death in dogs with CaNL.

The most common clinical signs and clinical-pathologic abnormalities compatible with feline leishmaniosis (FeL) include lymph node enlargement and skin lesions such as ulcerative, crusty or nodular dermatitis mainly on the head or distal limbs, ocular lesions mainly with uveitis, feline chronic gingivostomatitis (FCGS) and mucocutaneous ulcerative or nodular lesions. Clinical illness is frequently associated with impaired immune competence, such as retroviral infections or immunosuppressive therapy.

Diagnosis

The most common laboratory findings in CaNL are hyperglobulinemia mainly with polyclonal gammaglobulinemia, hypoalbuminemia, decreased albumin:globulin ratio, mild to severe proteinuria, mild to moderate nonregenerative anemia, renal azotemia, elevated liver enzyme activities, thrombocytopenia, and thrombocytopathy. Hypergammaglobulinemia and mild normocytic normochromic anemia are commonly reported in FeL.

The pathologic findings observed by cytology or histology in CaNL and FeL are macrophagic, neutrophilic-macrophagic and lymphoplasmacytic inflammation in affected tissues and reactive hyperplasia of lymphoid organs.

The clinical diagnosis of leishmaniosis could be complex because of the broad spectrum of clinical and clinicopathologic abnormalities which are often not specific. For this reason, it is important to separate the diagnosis of *Leishmania* infection from clinical disease and to apply different diagnostic techniques for each situation [14]. Accurate diagnosis of CaNL and FeL often requires an integrated approach consisting of a clinicopathologic assessment and specific laboratory tests. The detection of *L. infantum* infection in dogs and cats includes parasitologic (cytology, histology, immunochemistry, and culture), molecular (conventional, nested, and real-time PCR) and serologic methods (qualitative and quantitative antibody tests). Detection of specific serum antibodies to *L. infantum* should preferably be based on quantitative serologic techniques, such as the IFA and ELISA.

The challenges of serology include cross-reactivity with other pathogens such as other *Leishmania* and *Trypanosoma* species, and with antibodies elicited by vaccination against CaNL. High antibody levels are associated with severe parasitism and moderate to severe disease. However, the presence of low antibody levels is not necessarily indicative of disease and further work-up is necessary to confirm CaNL and FeL by other diagnostic methods such as cytology, histopathology, and PCR. Information provided by PCR should not be separated from the data obtained from clinicopathologic and serologic evaluations. These should all be combined for a comprehensive assessment. It is essential to know the terms and limitations of each diagnostic test and make an adequate clinical interpretation [12–14].

Therapy

Treatment for CaNL depends on the severity of disease. Different therapeutic regimens have been established for each stage of CaNL. The drugs most frequently used in moderate to severe CaNL (stage 2 and 3) are a combination of meglumine antimoniate at 75–100 mg/kg q24h or 40–75 mg/kg BID for four weeks SC and allopurinol at 10 mg/kg/BID/PO for at least one year. Alternatively, a combination of miltefosine at 2 mg/kg/ PO q24h for four weeks and allopurinol at the same dose described above is also employed. Other drugs have been proposed for the treatment of CaNL but their efficacy or safety are limited.

Clinical cure in CaNL is often obtained and is associated with reduction in the parasite load and infectiousness to sand flies, but infection may persist and clinical relapse might occur and therefore life-long follow-up post therapy should be maintained.

The most common drug used for FeL is allopurinol administered alone at a dose of 10 mg/kg/BID/PO for at least six months. Treatment with meglumine antimoniate alone has been reported in rare cases of FeL. Most cats recover clinically following prolonged treatment and as for dogs, follow-up with routine laboratory tests, serology, and PCR is essential for the prevention of clinical relapses [12–14].

Prognosis

The prognosis of dogs and cats with leishmaniosis depends mainly on the severity of disease. Different prognosis is expected for each stage of CaNL with generally poor prognosis observed in dogs with renal insufficiency or severe renal disease associated with profuse proteinuria. The prognosis in cats is generally fair and a poorer prognosis is associated mainly with the presence of concomitant diseases and immune suppression.

Prevention

Several preventive measures are available for CaNL. The use of individual topical pyrethroid insecticides in collars or spot-on formulation has been shown to be effective in reducing *L. infantum* infection and, therefore, they are commonly applied to dogs in endemic areas to prevent infection.

Vaccination is also considered a promising tool for controlling CaNL. Second-generation vaccines for CaNL are commercially available in Europe and Brazil, with different efficacy rates in reducing the incidence of the clinical illness in field. Domperidone, a hyperprolactinemic immunomodulatory drug, has recently been licensed in some European countries for preventive use against CanL. However, limited studies exist regarding its efficacy in preventing the disease.

Dog culling practiced in Brazil as a control measure has been reported to have little impact on the incidence of human and canine leishmaniosis [15].

To date, preventive measures for this infection in cats are not commercially available.

Hepatozoonosis

Etiology and Pathophysiology

Hepatozoonosis is an arthropod-borne infection caused by apicomplexan protozoa of the family Hepatozoidae which are phylogenetically related to the piroplasms (*Babesia*, *Theileria*, and *Cytauxzoon*). Two different species of *Hepatozoon* infect dogs: *Hepatozoon canis* globally and *Hepatozoon americanum* in some parts of

the United States, mainly the southeastern states. *Hepatozoon canis* infects the hemolymphatic tissues and causes anemia and lethargy whereas *H. americanum* primarily infects muscular tissues and induces severe myositis and lameness [16,17]. Feline hepatozoonosis is caused by *H. felis*, which is prevalent in the Mediterranean basin, Asia, Africa, South, Central and North America. It infects muscle tissues including the myocardium and has not been associated with severe clinical disease [18]. Recently, *H. canis* and *H. silvestris* infections have been described in cats in Europe.

In contrast to most tick-borne pathogens which are transmitted via the tick salivary glands, *Hepatozoon* spp. infect vertebrates when they ingest arthropod hosts containing infective sporozoites. The main vectors of *H. canis* are the ticks *Rhipicephalus sanguineus* and *R. turanicus* worldwide and *Amblyomma ovale* in South America, whereas the Gulf Coast tick *Amblyomma maculatum* is the vector of *H. americanum* in North America. The vector of *H. felis* has not been identified to date but transplacental transmission in the feline host has been shown. Transplacental transmission from dam to pups has also been demonstrated for *H. canis* infection but not for *H. americanum*. Transmission by carnivorism and predation of the canine host on intermediate or wildlife transport hosts with ingestion of parasite cyst forms from their tissues has been shown for *H. americanum* and is considered as a main route of dog infection with this parasite [19].

The life cycle of *H. canis* revolves between the canine and tick hosts. When dogs ingest the vector tick or tick parts, *H. canis* sporozoites are released from sporocysts in the intestine and penetrate the gut wall. The sporozoites invade mononuclear cells and disseminate hematogenously or via the lymph to hemolymphatic target organs that include the bone marrow, spleen, and lymph nodes and to other internal organs such as the liver, kidney, and lungs. Meronts in which asexually dividing merozoites develop are formed in the dog's tissues in the process of merogony and may cause cellular necrosis in tissues. Merozoites release from mature meronts, invade neutrophils and monocytes, and develop into gamonts. Alternatively, merozoites can produce secondary meronts in the target tissues. The tick, which serves as the definitive host, is infected by ingesting leukocytes containing gamonts when feeding on a parasitemic dog. Morphologically indistinguishable male and female *H. canis* gamonts are released from the dog leukocytes within the tick gut, associate in syzygy, and differentiate in the process of gametogenesis to distinct gametes. After fertilization, the zygote divides and sporogony takes place with the formation of oocysts that release into the tick's hemocoel. The oocysts are large, spherical forms consisting of a membrane that envelops multiple sporocysts in which the infective sporozoites are found.

The life cycle of *H. americanum* differs from that of *H. canis* particularly with regard to the parasite's target tissues in the dog, the formation of distinct large cysts and the inflammatory reaction formed in response to infection. Sporocysts of *H. americanum* sporozoites from the hemocoel of an infected vector tick ingested by dogs release infectious sporozoites following contact with bile in the gut. Sporozoites are thought to cross the gut wall, and then taken up by host macrophages and transmitted via the lymph system or hematogenously to the target organs consisting of skeletal and cardiac muscles. *Hepatozoon americanum*-infected macrophages lodge between striated muscle fibers in these tissues and form muscle cysts. Concentric layers of mucopolysaccharide material are deposited by the infected cell forming a cystic structure referred to as "onion skin cyst." The encysted zoite undergoes merogony and multiple merozoites are formed. Eventually, the cyst ruptures, releasing mature individual merozoites into the surrounding tissue and eliciting a strong local inflammatory response. The pyogranulomatous inflammatory response is associated with severe musculoskeletal pain. The merozoites are taken up by leukocytes and are thought to undergo additional merogonic cycles or enter the blood vasculature, develop into gamonts and circulate in monocytes.

Epidemiology

Hepatozoon canis infection is reported mainly from tropical, subtropical, and temperate climate regions where vector tick species are abundant. Infection with *H. canis* has also been reported in dogs in the southeastern United States, mainly in some regions where *H. americanum* is also prevalent, and co-infections of both species have been reported. In Europe, autochthonous dog infection is found mostly close to the Mediterranean basin. It has also been described in dogs imported into nonendemic countries such as Germany, in foxes in European countries where autochthonous canine infection is rare or has not been reported, and in Slovakia and Poland where *R. sanguineus*, its tick vector, is not present. The prevalence of *H. canis* infection differs between regions. The rates of infection based on blood smear examination or PCR range from 1% to 64%.

The presence of *H. americanum* infection in the United States has expanded north and east from Texas, where it was first detected in 1978. It is found in several southeastern states, and occasionally cases are reported in other locations including Nebraska, Vermont, Washington, and California. *Hepatozoon americanum* infects wild coyotes (*Canis latrans*) and in experimentally infected young coyotes, it causes similar disease to that seen in dogs. Surveys of free-ranging coyotes in Oklahoma showed that 40–50% were infected naturally with *H. americanum*.

Signalment

Infection with *Hepatozoon* species is more common in dogs and cats with frequent outdoor access and those with contact to tick vectors. *Hepatozoon americanum* is often detected in hunting and guard dogs in contact with prey and potentially infected wild mammals. No age or breed predilections have been reported.

The pathogenesis of *H. canis* infection is influenced by immunodeficient conditions including immunosuppressive treatment, an immature immune system in young pups, concurrent infectious diseases or debilitating concomitant diseases. Co-infections with *Toxoplasma*, *Leishmania*, *Babesia*, *Ehrlichia canis*, or viral infections might predispose to clinical illness.

History and Clinical Signs

Hepatozoon canis infection varies from being subclinical to a severe disease in which dogs present with lethargy, fever, cachexia, and pale mucous membranes due to anemia. In contrast to the generally mild disease usually found in *H. canis* infection, dogs diagnosed with *H. americanum* infection are presented with fever, gait abnormalities, muscular pain induced by myositis, generalized muscular atrophy and mucopurulent ocular discharge with decreased tear production associated with inflammation of the extraocular muscles. Clinical signs may start 4–6 weeks after infection due to the pyogranulomatous inflammatory response that occurs when the encysted parasite cyst ruptures in muscle tissue. American canine hepatozoonosis can have an acute presentation or a waxing and waning chronic pattern. Pain associated with disease may be generalized or localized in the lumbar and cervical spine, long bones, or joints. Gait abnormalities range from limb stiffness to complete recumbency and inability to rise. Chronic infections can be associated with polydipsia and polyuria due to renal amyloidosis or glomerulonephritis and an ophthalmic examination may reveal uveitis. *Hepatozoon felis* infection has not been associated directly with overt clinical manifestations but *H. silvestris* has been reported to cause severe disease in domestic cats.

Diagnosis

Subclinical infection or mild disease is the most common presentation of *H. canis* infection and it is usually found in dogs with a low level of parasitemia (1–5%) (Figure 110.4). Severe illness can be found in dogs and may be associated with white blood cell concentrations as high as 150×10^9 leukocytes/L. High parasitemia rates of up to 100% can accompany extreme neutrophilia. A case–control study of dogs with *H. canis* parasitemia

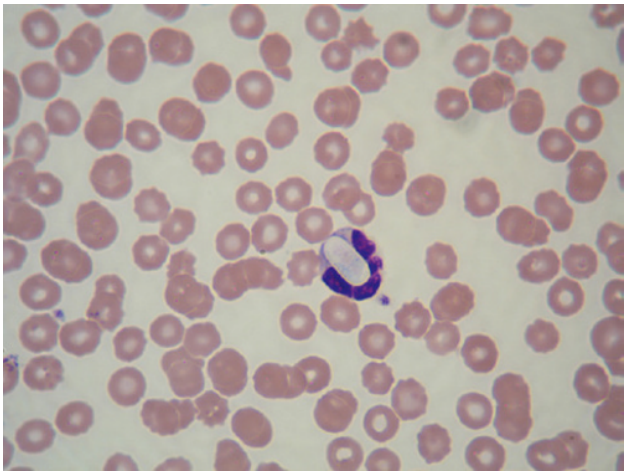

Figure 110.4 *Hepatozoon canis* gamont in a neutrophil from the blood smear of a naturally infected dog (May Grunwald–Giemsa stain 1000× magnification).

indicated that 15% had a high number of circulating parasites (>800 gamonts/μL) accompanied by elevated body temperature, lethargy, weight loss, anemia, and hyperglobulinemia. An association between the severity of clinical signs and the level of parasitemia was also found in a study of canine hepatozoonosis from Turkey. The most frequent hematologic abnormality reported in *H. canis* infection is mild to moderate normocytic normochromic nonregenerative anemia and, more rarely, regenerative anemia. Abnormalities in serum chemistry include hyperproteinemia with hyperglobulinemia due to polyclonal gammopathy, hypoalbuminemia and increased creatine kinase and alkaline phosphatase activities. Meronts of *H. canis* are commonly found in the spleen, bone marrow, and lymph nodes by cytology and histopathology. Although lesions of the periosteum are more frequently associated with *H. americanum* infection, periostitis has also been described as a rare finding in *H. canis* infection.

A marked neutrophilia is also one of the consistent hematologic findings in *H. americanum* infection with leukocyte counts of $30–200 \times 10^9$/L blood, although the level of parasitaemia is typically very low. A mild to moderate normocytic normochromic nonregenerative anemia is frequent. Serum biochemical abnormalities include increased alkaline phosphatase activity and hypoalbuminemia. Histopathology of skeletal muscles from dogs with *H. americanum* infections reveals pyogranulomatous myositis and large round to oval "onion skin" cysts (250–500 micrometer diameter). Radiography of the long bones or pelvis demonstrating periosteal proliferation can be used for screening suspected animals.

Hepatozoon canis infection is usually diagnosed by microscopic detection of intracellular *H. canis* gamonts in stained blood smears. Gamonts can be detected in the

blood at 28 days post infection. The gamonts are found in the cytoplasm of neutrophils and monocytes, have an ellipsoidal shape and are about 11 ×4 micrometers. In contrast, *H. americanum* parasitaemia usually does not exceed 0.1% of the leukocytes and rare gamonts may be detected in the blood from 32 days post infection. The confirmation *of H. americanum* infection can be achieved by muscle biopsy and demonstration of typical parasite cysts and granulomas or by PCR. PCR of blood for *H. canis* or *H. americanum* is a sensitive and specific diagnostic option. Diagnostic real-time PCR assays that can also quantify the parasitic load are able to detect both *H. americanum* and *H. canis* and distinguish between the two species. *Hepatozoon felis* infection is usually associated with a low parasitaemia and is best detected by blood PCR.

Serologic testing for *H. canis* or *H. americanum* by an IFA test or ELISA is used in epidemiologic studies but not commonly employed for clinical diagnosis in practice.

Therapy

The current treatment for *H. canis* is the administration of imidocarb dipropionate at 5–6 mg/kg IM or SC every 14 days until gamonts are no longer present in blood smears. The decrease of parasitemia is slow and usually requires several imidocarb treatments. Studies with follow-up by evaluation of buffy coat smears and sensitive PCR indicated that complete elimination of the parasite may frequently not be achieved with imidocarb dipropionate alone and also with combinations of imidocarb dipropionate and toltrazuril/emodepside, or imidocarb dipripionate with clindamycin [20].

Hepatozoon americanum is treated with a combination oral therapy of trimethoprim-sulfadiazine (15 mg/kg q12h), pyrimethamine (0.25 mg/kg q24h), and clindamycin (10 mg/kg q8h) for 14 days. Ponazuril (10 mg/kg PO q12h for 14–28 days) has been suggested as an alternative to the combination antiprotozoal treatment. After initial improvement of clinical disease signs is obtained, remission can be prolonged with the oral administration of the coccidiostat decoquinate at 15 mg/kg mixed in food q12h for two years. Relapse of clinical disease is frequent following discontinuation of treatment. Supportive therapy with nonsteroidal antiinflammatory drugs is effective in relieving pain and fever in dogs with *H. americanum* infection and administered initially with the combination antiprotozoal therapy.

No controlled trials have been published on the treatment of feline hepatozoonosis. Single cases have been treated with doxycycline, a single dose of 2 mg/kg primaquine PO or imidocarb at 2.5 m/kg IM with undetermined efficacy in eliminating the infection.

Prognosis

The prognosis of treated dogs with a low *H. canis* parasitemia is generally good even if decrease of parasitemia is slow and requires several imidocarb treatments. The prognosis for dogs with high parasitemia is good to guarded and sometimes associated with the outcome of a concurrent illness.

Hepatozoon americanum infection may be fatal without treatment within several months. Prognosis with antiprotozoal treatment followed up by long-term decoquinate therapy is guarded.

Prevention

Prevention of both *H. canis* and *H. americanum* infections consists of the use of topical acaricides and environmental parasiticides. Furthermore, avoidance of tick ingestion while scavenging or grooming, and of eating raw prey meat potentially harboring infectious tissue stages of the parasite is recommended [16].

To date, hepatozoonosis has not been shown to be established in recipient dogs following transfusion. Transfusion of the blood gamont stage is not likely to result in establishment of infection in the recipient dog as the gamont stage found in blood has to continue to the sexual parts of the parasite's life cycle in the tick before the parasite replicates.

Feline Cytauxzoonosis

Etiology and Pathophysiology

Feline cytauxzoonosis is an emerging tick-borne disease with an expanding geographic distribution caused by parasites from the genus *Cytauxzoon* (phylum Apicomplexa, class Piroplasmea, order Piroplasmida). Parasites of the genus *Cytauxzoon* are closely related to those of the genera *Babesia* and *Theileria*.

Cytauxzoon felis is a species infecting domestic cats and wild felids in the United States and South America and detailed clinical, parasitologic, and epidemiologic information is available on this infection. Other *Cytauxzoon* parasites which are genetically different and of decreased pathogenicity have been described in Europe in domestic cats and wild felids but limited information is available on these species.

Cytauxzoon felis is transmitted by the tick *Amblyomma americanum* in the United States. *Amblyomma cajennense* and other ixodid ticks have been presumed as vectors in South America. Other routes of transmission have not been well studied for this infection. The tick vector for *Cytauxzoon* spp. infection in felids in Europe remains unknown as well as other possible modes of transmission.

The wildlife animal reservoir for *C. felis* infection in the United States is the bobcat (*Lynx rufus*) where infection is mostly subclinical and a persistent erythroparasitemia is commonly found. Conversely, clinical illness is frequently found in infected domestic cats. *Cytauxzoon felis* infection in the cat varies in its clinical manifestation from a severe acute fatal disease to subclinical chronic infection.

Cytauxzoon species are detectable in two main forms in the mammalian host: schizonts in histiocytic cells and merozoites in erythrocytes. A phase of asexual schizogenous reproduction, within the host's mononuclear phagocytic cells, is responsible for the pathologic processes resulting in clinical illness. Large schizonts can occlude small blood vessels and cause thrombosis in the visceral organs and the brain. The onset of clinical disease occurs usually 1–3 weeks after tick-transmitted infection and the entire disease course is rapid, with cats frequently succumbing to infection within days.

Epidemiology

The geographic distribution and seasonality of cytauxzoonosis due to *C. felis* is largely correlated with relevant tick vector activity and presence of bobcats. This infection is present in the south-central, southeastern, and mid-Atlantic regions of the United States. Infected domestic cats are commonly from rural or suburban wooded areas. The prevalence of *C. felis* infection in domestic cats is variable in different published studies. In healthy cats, prevalence of *C. felis* infection ranged from 0.3% to 28%. Cytauxzoonosis accounted for 1.5% of all feline admissions to the veterinary teaching hospital at Oklahoma State University between 1998 and 2006 [21–23].

Signalment

Disease due to *C. felis* can occur in cats of any age and either gender with no identified breed predilections. Likewise, no signalment predispositions have been found in feline infections due to other species of *Cytauxzoon*.

History and Clinical Signs

Outdoor cats are more likely to be infected during spring and summer due to the presence of tick vector. Immune suppression has not been found to be a risk factor for infection with *C. felis*. *Cytauxzoon* spp. infection has been associated with living in a cat colony and outdoor lifestyle in domestic cats from Europe.

The clinical signs of *C. felis* infection are nonspecific and include an acute onset of anorexia, lethargy, and fever. Other clinical signs include increased vocalization, weakness, dehydration, icteric or pale mucous membranes, pigmenturia, mild to moderate lymphadenomegaly, splenomegaly and hepatomegaly, generalized pain, tachypnea and tachycardia with or without respiratory distress, dull mentation, and seizures.

Cytauxzoon spp. appear to mainly cause a subclinical infection with evidence of erythroparasitemia in domestic and wild felids in Europe. So far, evidence of clinical manifestations of a tissue schizogonic phase, as found for *C. felis*, has not been observed in *Cytauxzoon* spp. infection in Europe.

Diagnosis

Laboratory abnormalities due to *C. felis* infection include pancytopenia, hyperbilirubinemia, mild to moderate normocytic normochromic nonregenerative anemia, thrombocytopenia, lymphopenia, neutropenia, mild to moderate elevation of liver enzyme activities (ALT and ALP), prerenal azotemia, electrolyte disturbances (hypocalcemia, hypokalemia, and hyponatremia), hyperglycemia, mild hypoproteinemia with hypoalbuminemia and hypocholesterolemia.

Detection of *Cytauxzoon* in stained blood smears is useful in the diagnosis of erythroparasitemia. Infection may also be visualized by microscopic identification of schizont-laden macrophages in cytology of fine needle aspirates of lymph nodes, spleen or liver. PCR is a valuable tool to detect low parasitemia with higher sensitivity than blood smear. Furthermore, PCR and genetic characterization can distinguish between infection with *Cytauxzoon* and small *Babesia* spp. Serology is not used in the clinical setting.

Therapy

The combination of the antimalarial atovaquone (15 mg/kg PO q8h) and the macrolide azithromycin (10 mg/kg PO q24h) for 10 days is currently considered the best treatment option for acute cytauxzoonosis due to *C. felis*, with an approximately 60% survival rate in sick cats, while other treatments such as imidocarb dipropionate (3.5–5 mg/kg IM repeated at 14-day intervals if needed) have been reported to result in lower survival rates [23].

Medical management of this disease requires supportive treatments.

Prognosis

The prognosis for acute cytauxzoonosis in domestic cats due to *C. felis* is guarded to poor.

Prevention

So far, there is no vaccine commercially available for the prevention of *Cytauxzoon* infection. Prevention is focused

on avoidance of tick bites. A combination of tick control that targets the specific tick vectors and indoor lifestyle is the best strategy to reduce tick exposure.

Babesiosis

Etiology and Pathophysiology

Babesia are tick-borne protozoan parasites of erythrocytes that infect domestic and wild animals, and humans. *Babesia* belongs to the phylum Apicomplexa, class Piroplasmea, and order Piroplasmida [24].

Canine infections caused by different *Babesia* species are protozoal tick-borne diseases with worldwide distribution and global significance. Large-form *Babesia* spp. include *Babesia rossi*, *B. canis*, and *B. vogeli*. These species were previously considered subspecies of *B. canis*. They are identical morphologically but differ in the severity of clinical manifestations which they cause, their tick vectors, genetic characteristics, and geographic distribution. Therefore, they are currently considered separate species. Another yet unnamed large *Babesia* species most closely related to *B. bigemina* was found to infect immunocompromised dogs in the United States. The small *Babesia* spp. include *B. gibsoni*, *B. conradae*, and *B. vulpes* (formerly referred to as *B. microti*-like piroplasm and *Theileria annae*).

Babesiosis of domestic cats has mostly been reported in South Africa where infection is mainly due to *B. felis*, a small *Babesia* species that causes anemia and icterus. In addition, *B. cati* was reported from a cat in India and sporadic cases of infection in domestic cats by unnamed *Babesia* parasites have been reported in France, Germany, Thailand, and Zimbabwe. *B. canis* infection was reported from three cats in a study from Spain and Portugal in domestic cats with molecular evidence for infection. Additionally, infection of domestic cats with a genetically distinct species related to *B. canis* and named *B. canis* subsp. *presentii* was described in Israel [25].

Dogs and cats are infected when *Babesia* sporozoites are injected with saliva into the host's skin during a blood meal. The parasites invade the erythrocytes and form ring-shaped trophozoites which replicate within the erythrocyte and form merozoites observed as pairs of attached pear-shaped parasites in some *Babesia* species. Merozoites may further divide, forming eight or more parasites in the same erythrocyte and eventually lysing the cell, discharging into the blood to invade additional erythrocytes. Ticks feeding on infected blood take up merozoites and sexual parasite development in the tick gut is followed by sporogony in its salivary gland or ovaries. The parasite can be transmitted from the tick salivary glands during a tick bite or transovarially through its oocytes, as found in some *Babesia* species.

Babesia gibsoni infection has also been shown to be transmitted via blood transfusion and transplacentally. Furthermore, several studies have provided evidence that *B. gibsoni* is likely transmitted directly from dog to dog via bite wounds, saliva, or ingested blood [25,26].

Epidemiology

The geographic distribution of the causative agents and thus the occurrence of babesiosis is largely dependent on the habitat of tick vector species, with the exception of *B. gibsoni* where evidence for dog-to-dog transmission indicates that infection can be transmitted among fighting dog breeds independently of the limitations of vector tick infestation. *Babesia vogeli* and *B. gibsoni* have worldwide distribution, whereas *B. rossi* and *B. canis* have been mostly restricted to Africa and Europe, respectively. The unnamed large *Babesia* sp. most closely related to *B. bigemina* and *B. conradae* has been reported only from North America whereas *B. vulpes* was reported in Europe and North America.

Signalment

Puppies and dogs of any age with concomitant disease or immune suppression suffer clinical babesiosis due to *B. vogeli* more frequently compared to healthy adult dogs. Breed and gender do not appear to be predisposing factors.

Babesia canis, B. rossi, and *B. vulpes* have been reported to more frequently affect young to adult outdoor hunting and shepherd dogs. Breed and gender do not appear to be predisposing factors.

Disease due to *B. gibsoni* is found mostly in fighting dogs and breeds such as the pit bull terrier and tosa. Gender and age do not appear to be predisposing factors. Gender, breed, and age have also not been reported to be predisposing factors for *B. conradae* infection.

Splenectomized and immune-compromised dogs are more susceptible to infection with any *Babesia* species.

History and Clinical Signs

The main clinical findings reported in dogs suffering from *B. canis* infection include dehydration, lethargy, anorexia and fever, *Babesia vogeli* usually causes a subclinical infection or mild to moderate clinical disease which often accompanies other concomitant diseases or immunosuppressive conditions or affects splenectomized dogs. Severe fatal hemolytic anemia has been reported in puppies.

The most virulent large-form *Babesia* is *B. rossi*. Babesiosis due to *B. rossi* can manifest with uncomplicated common clinical signs as described for other babesial species or with complicated clinical disorders

including acute renal failure with anuria, icterus, hypotension, acute respiratory distress syndrome (ARDS), vomiting, diarrhea, pancreatitis, myalgia, rhabdomyolysis, ascites, pulmonary edema, encephalomyelitis, and peracute shock. The clinical findings associated with *B. gibsoni* infection include fever, splenomegaly, lymphadenomegaly, hepatomegaly, and lethargy. *Babesia conradae* infection has been described as more virulent than *B. gibsoni* infection, resulting in higher rates of mortality. The most common clinical findings reported in dogs infected with *B. vulpes* from the northwest of Spain include fever, lethargy, weakness, and pigmenturia.

Diagnosis

The main clinicopathologic findings reported in dogs suffering from *B. canis* infection include mild to severe thrombocytopenia, hyperfibrinogenemia, mild to moderate normocytic-normochromic nonregenerative anemia, hemolysis and neutropenia. Hemoglobinuria has also been described in naturally infected dogs. Common laboratory abnormalities in dogs infected with *B. vogeli, B. gibsoni* and *B. conradae* are regenerative anemia and thrombocytopenia. Although they are both small *Babesia* species, more pronounced anemia occurs in *B. conradae* infection than with *B. gibsoni* infection. Dogs with *B. vulpes* infections in northern Spain have demonstrated moderate to severe regenerative anemia, thrombocytopenia and azotemia. Hyperglobulinemia and proteinuria can also occur in *Babesia* infected dogs. The hemolytic anemia and thrombocytopenia associated with *Babesia* infections appear to occur by multiple mechanisms including immune-mediated destruction. Positive Coombs' testing, spherocytosis, positive saline agglutination tests and anti-platelet antibodies can occur. Therefore, it is important to rule-out babesiosis in patients with suspected idiopathic immune-mediated hemolytic anemia and thrombocytopenia. Detection of large or small species of *Babesia* in stained blood smears has been the standard for diagnosis for many years. This method is reliable when a moderate to high parasitemia is present, but there is not always a correlation between the level of parasitemia and the severity of clinical signs. A fresh smear is recommended for the accurate diagnosis of infection. Serology can indicate past infection or a present persistent one. Some serologic cross-reactivity exists between *Babesia* species. False-negative results are likely in peracute or acute infection and therefore convalescent antibody titers are needed to prove acute infection. Some evidence suggests that seroconversion may not occur in immunocompromised or young animals. The PCR is particularly useful in the diagnosis of babesiosis in dogs with a low parasitemia level including suspected carrier dogs or chronically infected animals and for speciation of parasites. However, a negative PCR does not rule out infection. Several molecular methods including seminested PCR, reverse line blotting (RLB), and restriction fragment length polymorphism (RFLP) PCR permit discrimination between species.

Therapy

Large *Babesia* spp. infections of dogs and cats are commonly treated with one dose of imidocarb dipropionate at 5–6 mg/kg (dog) and 2.5 mg/kg (cat) IM or SC with good clinical response. *Babesia gibsoni* and *B. conradae* infections are often resistant to imidocarb dipropionate and diminazene aceturate. The treatment of choice for these small *Babesia* species is a combination of the antimalarial atovaquone and the macrolide azithromycin. This combination is also likely to be a good treatment option for *B. vulpes* infection. The most commonly used dose of atovaquone is 13.5 mg/kg, administered PO q8h with fatty food to maximize drug absorption, in combination with azithromycin at 10 mg/kg PO for 10 days. Clindamycin in combination with metronidazole and doxycycline for a minimum of three months has also been used for treatment of *B. gibsoni*, although its overall efficacy is uncertain. The use of clindamycin alone is not recommended by some authors given the potential for selection of resistance and may subsequently interfere with alternative treatments.

The treatment of choice for *B. felis* in cats is primaquine phosphate. Published dosages range from 0.5 to 1.0 mg/kg PO, IV, or IM once, or administered daily on three consecutive days. Clinical and parasitologic cure are commonly not achieved in small babesial spp. infections in dogs and cats and clinical relapses may occur frequently. Medical management of infection may require supportive treatments including blood transfusions, intravenous fluids, and the use of antiinflammatory drugs [24–27].

Prognosis

The prognosis of dogs and cats infected with large forms of *Babesia* is generally good with appropriate therapy. Canine infection with small *Babesia* spp. may be more resistant to treatment and have a poorer prognosis.

Prevention

The prevention of babesiosis relies mostly on topical and environmental acaricidal treatments aimed at reducing exposure to vector ticks and transmission of the pathogen to dogs and cats. As *Babesia* species are transmitted by blood product transfusions, it is recommended to screen canine blood donors for *Babesia* infection on a regular basis and consider screening cat blood in relevant areas. Nonvectorial dog-to-dog transmission of

babesiae by fighting is preventable and can be responsible for the spread of babesiosis into previously nonendemic areas. A vaccine against *Babesia* is commercially available in some countries in Europe.

Giardiasis

Etiology and Pathophysiology

The genus *Giardia* includes intestinal flagellated protozoan parasites that infect a large number of host species, ranging from mammals to amphibians and birds. The most important *Giardia* species, *G. duodenalis*, infects cats, dogs, livestock, and humans with a broad host range and considerable public health significance. *Giardia duodenalis* is currently considered a multispecies complex. Multigeneic sequence analyses have identified different genetic assemblages of *G. duodenalis* including assemblages A and B in man and animal species, assemblages C and D in dogs, assemblage E from ruminants and pigs, assemblage F from cats, and assemblage G from rodents. To date, no association has been made regarding specific assemblages and the induction of certain characteristic clinical signs or the degree of their severity [2,3].

The life cycle of *Giardia* is direct and has two stages: the trophozoite and a cyst. The infective stage of the parasite, the cyst, is encysted when released into the feces and is immediately infectious. Cysts remain infectious for months in cool, damp conditions and accumulate in the environment. When ingested by the host, cysts excyst in the duodenum, releasing motile trophozoites. The latter undergo repeated mitotic division and form environmentally resistant cysts. Cysts pass through the intestine in feces and are spread by contaminated water, food, and fomites, and by direct contact. *Giardia* is transmitted mostly by ingestion of cysts in contaminated food or water. Following the ingestion of cysts and their exposure to the gut environment, each cyst releases two trophozoites which attach to the villi of the small intestinal epithelium. Trophozoites multiply by binary fission and eventually form cysts which are shed in the feces. The parasite presence in the intestine induces diarrhea by hypersecretion and malabsorption with increased intestinal permeability. *Giardia* infection in most dogs and cats is subclinical, but some animals suffer from severe diarrhea and weight loss which can become chronic.

Epidemiology

Infection rates with *Giardi*a in dogs and cats vary in the 5–30% range. The infection rates found in a large multicountry study in Europe were 24.8% in dogs and 20.3% in cats. Shedding *Giardia* is often subclinical and has frequently not been associated with clinical signs in population surveys. However, diarrhea and illness due to *Giardia* infection have been associated with puppies and kittens of young age as well as immune-suppressed animals and pets living in crowded conditions.

The relationship between human and animal *Giardia* infection is not clear. Humans certainly infect each other frequently and although they share the same *G. duodenalis* assemblages with animals with whom they have close contact, such as household dogs, it is not known how frequently infection is actually acquired from household animal contact or whether both human and pets acquire it from a common source, such as contaminated water [2].

Signalment

There is no breed or gender predilection. Young, immune-suppressed animals or those living in crowded conditions are more predisposed to the disease.

History and Clinical Signs

Most feline and canine *Giardia* shedders are infected subclinically. Those affected clinically suffer primarily from diarrhea and weight loss if disease becomes chronic. Diarrhea can be acute, intermittent or chronic and is mucoid, soft to watery and rarely bloody. Diarrhea can worsen and become bloody in animals co-infected with other intestinal parasites such as *Ancylostoma* spp., *Coccidia* or *Tritrichomonas foetus*. Vomiting and fever are rare. Reinfection with *Giardia* after successful treatment may occur.

Diagnosis

Giardia infection can be diagnosed by stool examination to identify cyst and trophozoite stages in direct fresh stool smears or by flotation for cysts. Sheather's sugar centrifugation and zinc sulfate centrifugation can be used for concentrating cysts. Rapid detection of *Giardia* antigen can be made using immunochromatographic kits, or by immunofluorescence, ELISA, and PCR in the parasitology laboratory [28].

Therapy

Dogs and cats can be treated with febendazole at 50 mg/kg PO q24h for 3–5 days, or with combined febantel, pyrantel, and praziquantel according to the febantel component at 37.8 mg/kg PO q24h for 3–5 days, or with metronidazole at 15–25 mg/kg PO q12–24h for 5–7 days. Since *Giardia* strains may have different antiprotozoal

susceptibilities, treatment with one of these drug options should be replaced by another if it is not successful in effectively relieving clinical signs. Furthermore, co-infections should be diagnosed and treated and sanitary management with quaternary ammonium disinfectants should be instituted to prevent reinfection.

Prognosis

The prognosis of treated dogs and cats is usually good and clinical signs are ameliorated, although some animals could suffer from persistent or recurrent infection.

Prevention

Disinfection of kennels, cages, and the animal's direct environment, boiling or filtering drinking water and removal of feces are important for controlling the spread of infection among animals that live in close proximity. Bathing of dogs and cats in infected kennels may decrease transmission of giardiasis between individual animals.

Miscellaneous Infections

Amebiasis

Amoebas are unicellular protozoal organisms with motile cytoplasm and a flexible cell wall. Molecular phylogenetic studies have shown that amoebas do not form a single taxonomic group and are found in many lineages of eukaryotic organisms. In older nomenclature classifications, most amoebas were placed in the class or subphylum Sarcodina, a group of single-celled motile organisms that possess pseudopods or move by protoplasmic flow. However, the amoeboid organisms are not classified together in one group any longer. Amoebas can be classified as enteric and residing in the gastrointestinal tract or nonenteric and associated with visceral and CNS invasion. Amoebas of different species are a rare cause of disease in dogs and cats. Different species of *Acanthamoeba*, *Balamuthia*, *Hartmannella*, and other amoebic genera and species may infect dogs and cats and colonize various organs, causing pneumonia, meningoencephalitis, renal disease, gastrointestinal disease of the small or large bowel, dermatitis, nasal disease, and keratitis [29,30].

Affected cats and dogs may be febrile and show a variety of clinical signs including neurologic abnormalities. Diagnosis is based on finding amoebae in excretions as cysts or trophozoites, or in tissues by cytology or histopathology and genetic characterization by specific PCR assays. Treatment consists of metronidazole for enteric infection and other antiprotozoal and antifungal drugs such as amphotericin B, ketoconazole, and miltefosine for deep organ infection.

Trichomoniasis

Trichomonas spp. are flagellated protozoa that belong to the order Trichomonadida, reproduce by binary fission, and do not produce cysts. Cats and more rarely dogs can be infected with *Tritrichomonas foetus* which is transmitted by the direct fecal–oral route and causes diarrhea [31,32]. *Tritrichomonas foetus* survives in feces and humid environment outside the animal's body for up to a few days. The parasite has been reported in numerous countries and has a worldwide distribution, with infection rates of up to 32% in cat populations from different countries in Europe [32]. Subclinical infection with *T. foetus* is common and there is not a direct relationship between infection and clinical signs. Infection is more common in cats from multicat settings and breeding catteries and clinical signs are more common in young cats under 12 months of age.

Tritrichomonas foetus attaches to the intestinal epithelium and induces a lymphoplamsmacytic and neutrophilic inflammatory response with large bowel diarrhea and frequent passage of soft liquid feces which may contain mucus and fresh blood [33]. Irritation of the anus may be present with swelling and edema. Diagnosis is made by identification of the organism in fresh feces by direct microscopic examination in which typical forward movement directed by the parasite's flagella and undulating membrane can be detected. Stained thin fecal smears may aid in the detection of the parasite with its typical form which is different from the *Giardia* trophozoites (Figure 110.5), when its presence is suspected

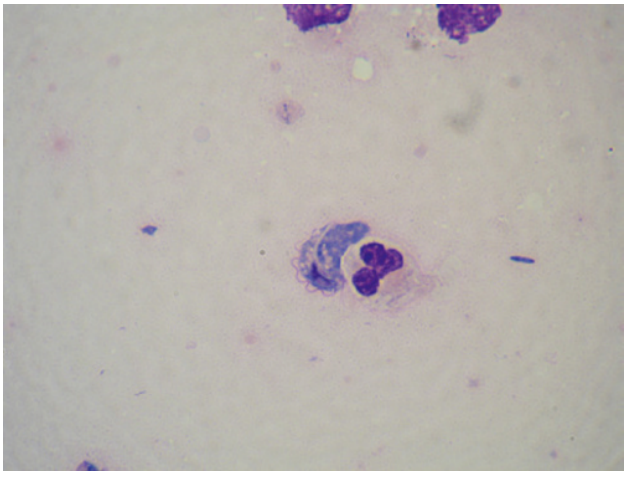

Figure 110.5 *Tritrichomonas foetus* in a stained fecal smear from a naturally infected cat (May Grunwald–Giemsa stain 1000× magnification).

based on wet smear microscopy. PCR is able to diagnose infection with high sensitivity and specificity, and culture in an "in pouch" medium is also used for diagnostic purposes. The drug of choice for treatment of *T. foetus* in cats is ronidazole at 30 mg/kg PO q24h for 14 days. Ronidazole is neurotoxic to cats at higher doses and is also teratogenic and should not be used to treat pregnant or lactating queens or young kittens.

Pneumocystosis

Pneumocystis is a genus of pathogens most closely related to Ascomycetes fungi. Current research has indicated that *Pneumocystis* species appear to be host specific. Five species have been described, including *Pneumocystis jirovecii* which infects humans and *P. carinii* which is a pathogen of rats, although much of the previous scientific literature has related to *P. carinii* as a human pathogen. Dogs may be infected with a different *Pneumocystis* species or strain provisionally termed *P. canis*.

Pneumocystis causes pneumonia in dogs and its transmission is thought to be air-borne in inhaled respiratory aerosol from infected hosts. Young dogs less than 1 year of age of either gender may be infected and Cavalier King Charles spaniels, Shetland sheepdogs and miniature dachshunds are predisposed to disease. Immunoglobulin deficiency and other congenital or acquired states of immune suppression have been reported in infected dogs [34]. Trophozoites and cysts of *Pneumocystis* are found in the lung alveolar spaces where the pathogen and its associated inflammatory response damage the alveolar septa. Dogs with pneumocystosis suffer from respiratory distress, tachypnea, weight loss, tachycardia, and exercise intolerance which progress and worsen over weeks to months. Thoracic radiographs show diffuse interstitial to alveolar patterns of lung disease and fluid collected on bronchoalveolar lavage or lung aspirates may show *Pneumocystis* trophozoites and cysts by cytology. Lung histopathology and PCR are also helpful in confirming infection. *Pneumocystis* does not grow in fungal culture and serologic tests have not provided a reliable diagnosis for canine infection.

The antimicrobial treatment of choice for canine pneumocystosis is trimethoprim-sulfonamide at 15 mg/kg PO q8h for three weeks. Pentamidine isethionate at 4 mg/kg IM q24h for two weeks is also used for pneumocytosis treatment, as well as atovaquone at 15 mg/kg PO q24h for three weeks, and a combination of clindamycin and primaquine (3–13 mg/kg PO q8h for three weeks). Supportive therapy to ease the respiratory distress is necessary in acute pneumocystosis.

Coccidia

Chris Adolph, DVM, MS, Diplomate ACVM (Parasitology)

Zoetis Inc., Tulsa, OK, USA

Cystoisospora spp.

Etiology/Pathophysiology

Within the last few years, canine and feline enteric coccidia belonging to the genus *Isospora* were reorganized and are now recognized by the genus *Cystoisospora*. This designation is now well accepted but not well integrated. The reader should recognize that both terms refer to the same genus.

Coccidia are obligate intracellular parasites classified in the phylum Apicomplexa, and are commonly identified infecting the gastrointestinal tract of dogs and cats. Dogs are the definitive host to four species of *Cystoisospora*: *C. canis*, *C. ohioensis*, *C. burrowsi*, *and C. neorivolta*. The latter three species are generally grouped together as *C. ohioensis* complex. Cats are the definitive host for two species of *Cystoisospora*: *C. felis* and *C. rivolta*. *Cystoisospora* spp. are very species specific; dogs are not infected with cat *Cystoisospora* spp. and cats are not infected with dog *Cystoisospora* spp.

To truly understand the pathophysiology of these organisms, one must first understand the life cycle. The typical Apicomplexa life cycle consists of sexual and asexual reproductive events that occur inside and outside the host. A sporozoite is the infective stage and is the end-product of sporogony, a form of asexual reproduction. For *Cystoisospora* spp., this occurs in the environment outside the host. Sporozoites are contained within a sporulated oocysts. If this environmental sporulated oocyst is ingested by the target host, the sporozoites emerge from the oocyst, or excyst, in the small intestine. It should be noted that *Cystoisospora* spp. have the ability to utilize paratenic hosts as a means of completing the life cycle. If a paratenic host ingests the sporulated oocysts, the sporozoite will invade the extraintestinal soft tissues and encyst. This stage is infective to the final host if the paratenic host is ingested. In the small intestine, the sporozoite excysts from the sporocyst and invades small intestinal cells. The site, location, and number of asexual generation vary with each species of *Cystoisospora*. Once the sporozoite invades the cell wall, it essentially hijacks the host cell and can evade the host immune response. After another round of asexual reproduction by endogeny to produce first-generation schizonts (aka meronts) containing merozoites, the host intestinal cell is ruptured, releasing the merozoites to invade other cells. This process continues for a programmed number of cycles until the last cycle which is the sexual phase known as gametogony. Here, the merozoites differentiate into either a microgametocyte (male) or a macrogametocyte (female). The microgametocyte leaves the cell in search of a macrogametocyte to fertilize. The end-product of the sexual stage is a gametozoite known as an oocyst.

Pathologic changes to the host occur when developing stages (merozoites and gametozoites) emerge and rupture the epithelial cells. This leads to gastrointestinal bacteria colonizing the ruptured enterocyte.

Epidemiology

Transmission of *Cystoisospora* spp. is fecal–oral. Oocysts that are shed are not immediately infective to the next host. The oocyst needs time to sporulate in the environment (eight hours) to be infectious. *Cystoisospora* spp. also infect the definitive host via predation of a paratenic host. When this route is utilized, a paratenic host consumes sporulated oocysts, but asexual and sexual development do not occur. Sporozoites then enter extraintestinal tissue and form monozoic cysts, commonly found in mesenteric lymph nodes. Once a definitive host consumes the paratenic host, the life cycle continues as described previously. Infections are generally self-limiting.

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

The distribution of *Cystoisospora* is worldwide. Due to the fecal–oral route of transmission, cases are associated with crowded and unhygienic environments. In the United States, prevalence of canine *Cystoisospora* spp. has been estimated to be between 3.1% and 4.4% while feline *Cystoisospora* spp. prevalence has been estimated to be between 3.9% and 6.3%.

Signalment

In most surveys, *Cystoisospora* spp. are detected in puppies and kittens less than 6 months of age. There does not appear to be a breed predilection. Patients that are most susceptible to clinical disease include nursing, recently weaned, and immunocompromised dogs and cats.

History and Clinical Signs

Clinical symptoms are more common in puppies and kittens acquired from unsanitary or overcrowded environments. *Cystoisospora* spp. can cause large or small bowel diarrhea, although patients may be asymptomatic despite shedding oocysts. Other clinical symptoms reported include anemia, dehydration, vomiting, anorexia, and weight loss. Physical exam findings of patients with *Cystoisospora* spp. are nonspecific and can include abdominal pain, increased gas or fluid in the gastrointestinal tract, and thickened loops of bowel.

Diagnosis

History, clinical symptoms, and detection of the organism are needed for a definitive diagnosis of coccidiosis. Fecal flotation, centrifugal or passive, can be performed and examined for the presence of characteristic oocysts (Figure 111.1).

It is important to differentiate oocysts of *Cystoisospora* spp. from those of *Eimeria* spp., which are not pathologic to canine and feline patients. Coprophagy of the feces of animals such as cattle, sheep, and chickens may lead to spurious detection of *Eimeria* spp. in canine and feline fecal samples. Both *Eimeria* and *Cystoisospora* are species specific and therefore pathogenic only to their target species.

Therapy

Asymptomatic adult patients demonstrating fecal oocysts may be monitored for development of clinical signs. Patients that meet criteria of history, clinical signs, and detection of the organism are treated symptomatically for diarrhea, and concurrently with antiprotozoal medications such as ponazuril, sulfonamides, or amprolium (Tables 111.1 and 111.2).

Table 111.1 Enteric coccidia of the dog and cat

Organism	Diagnostic stage	Size (μM)
Cystoisospora spp.		
Canine		
C. canis	Oocyst	30 × 38
C. ohioensis	Oocyst	19 × 23
C. neorivolta	Oocyst	11 × 13
C. burrowsi	Oocyst	17 × 20
Feline		
C. felis	Oocyst	30 × 40
C. rivolta	Oocyst	20 × 25

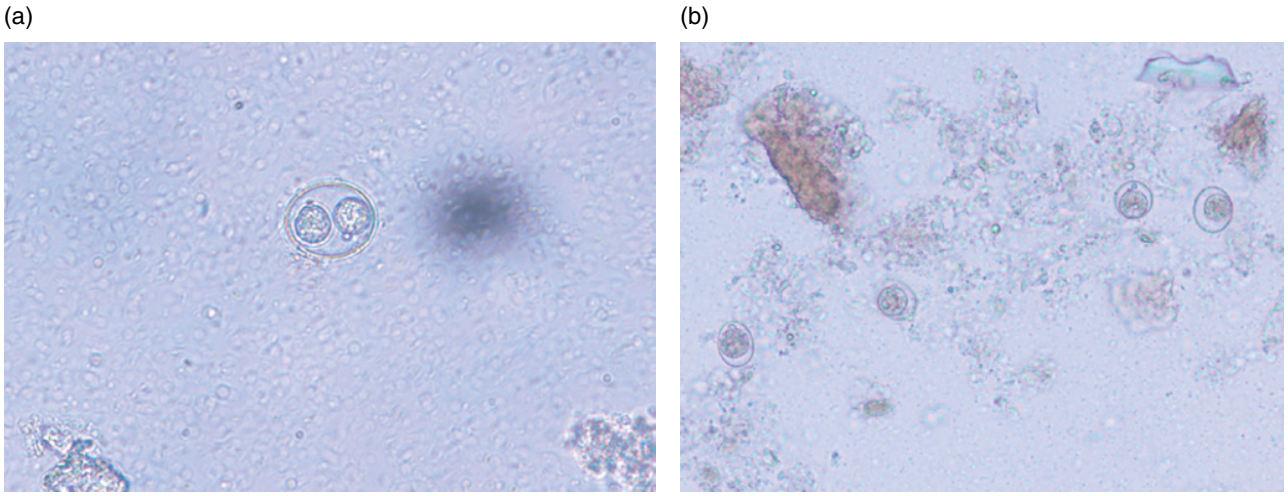

Figure 111.1 (a) Sporulated and (b) unsporulated *Cystoisospora ohioensis*. *Source:* Courtesy of the National Center for Veterinary Parasitology, Oklahoma State University.

Table 111.2 Treatment of enteric coccidiosis in dogs and cats

Antiprotozoal agent	Treatment regimen
Ponazuril[a]	20 mg/kg PO twice 1–7 days apart OR 50 mg/kg PO once
Sulfadimethoxine[b]	50–60 mg/kg PO daily for 5–20 days
Trimethoprim-sulfonamide[c]	15–30 mg/kg PO every 12–24 hours for 5 days
Amprolium[d]	300–400 mg PO daily for 5 days (canine)
	60–100 mg PO daily for 7 days (feline)
Furazolidone	8–20 mg/kg PO every 12–24 hours for 5 days

[a] Ponazuril is coccidiocidal and may be superior to other drugs.
[b] Sulfadimethoxine is the only approved drug for treatment of coccidiosis in the United States.
[c] Trimethoprim-sulfonamide combinations may cause acute hepatic necrosis, keratoconjunctvitis sicca, macrocytic anemia, and type III hypersensitivity reactions.
[d] Amprolium can cause anorexia, depression, diarrhea, and CNS disease due to induction of thiamine deficiency.
PO, by mouth (*per os*).

Symptomatic therapy begins by withholding food initially, followed by small, frequent meals with a bland diet once symptoms diminish. A class of medications commonly utilized to treat coccidiosis are the sulfonamides, which may be potentiated for better efficacy. Sulfadimethoxine is labeled in the US for dogs with bacterial enteritis associated with coccidiosis. Sulfonamides block folic acid synthesis and are effective against the schizont, an asexual stage. Sulfonamides are coccidiostatic, therefore fecal analysis may remain positive for oocysts during the course of therapy. Toxicity with use of sulfonamides has been reported and includes crystalluria, renal toxicity, keratoconjunctivitis sicca, type 3 hypersensitivity disorders, acute hepatic necrosis, and hematopoietic disorders. Dobermans are at increased risk for immune-mediated complications.

Ponazuril, a medication used to treat equine protozoal myeloencephalitis, has recently gained popularity as an off-label treatment for canine and feline coccidiosis. The mechanism of action is incompletely understood. A key improvement over previous treatments is that ponazuril is coccidiocidal rather than coccidiostatic, and fecal flotation can be negative 1–2 days post treatment. Amprolium, another coccidiostat, has also been used for canine and feline coccidiosis. It is a competitive inhibitor of thiamine and is most effective against the first-generation schizont.

Prognosis

Prognosis following proper diagnosis and treatment of canine and feline coccidiosis is good. Patients who recover from *Cystoisospora* spp. infections have species-specific immunity, but remain susceptible to infection with other *Cystoisospora* spp. infections. For example, a puppy that acquires a *C. canis* infection and recovers remains susceptible to infection with *C. ohioensis*. While patients with coccidiosis respond to appropriate therapy, untreated infections can lead to death from dehydration.

Public Health Implications

Due to the species specificity, *Cystoisospora* spp. of dogs and cats are not zoonotic to humans.

Cryptosporidium spp.

Epidemiology/Pathophysiology

There are many species of *Cryptosporidium* that infect a wide range of hosts, including dogs and cats. This genus is considered by some parasitologists to be more closely related to a group of the Apicomplexa known as the gregarines, which infect mostly invertebrates. Recently, gregarine-like stages have been described in multiple *Cryptosporidium* spp. This may lead to a reclassification of this genus in the future, and could possibly explain why most of the medications effective against coccidia are ineffective against *Cryptosporidium* spp.

The major host of *C. canis* is the dog; for *C. felis*, the major host is the cat. Unlike *Cystoisospora* spp., *Cryptosporidium* spp. are not host specific, although dog and cat *Cryptosporidium* spp. tend to favor the major host. This is an important distinction as other species, such as *C. parvum*, can be zoonotic. The life cycle is similar to that of *Cystoisospora*. The oocyst that is infective to the host contains four sporozoites that are not contained within sporocysts. The sporozoite will penetrate the host epithelial cell where trophozoites undergo schizogony to form merozoites. These merozoites will, in turn, invade other epithelial cells and undergo another round of schizogony. This is followed by the sexual phase, or gametogony, where microgametocytes are produced, fuse, and form zygotes. Zygotes can ultimately form either a thick-walled oocyst that is infective (sporulated) when it leaves the host, or a thin-walled oocyst that remains within the host and leads to autoinfection.

Pathologic changes occur when epithelial cells are damaged by emerging stages. Malabsorption ensues, and diarrhea is the primary clinical presentation. The severity of the infection is limited by developing immunity. Infection can be self-limiting if a host has a competent immune system. However, clinical disease may be prolonged in dogs and cats with a compromised immune system.

Epidemiology

Transmission of *Cryptosporidium* spp. is fecal–oral. Oocysts that are shed are immediately infective to the next host. Oocysts are stable in the environment, and high population densities as well as unsanitary conditions favor transmission. Young and immunocompromised animals are considered to be at greater risk. The infective dose is low; very few oocysts are required to produce an infection leading to clinical disease.

The distribution of *Cryptosporidium* spp. in dogs and cats is worldwide. Prevalence of *Cryptosporidium* spp. in dogs and cats varies, but has been estimated at 5%.

Signalment

Most cases of cryptosporidiosis have been reported in dogs and cats with a compromised immune system, those co-infected with other pathogens, or with preexisting conditions of the gastrointestinal tract (inflammatory bowel disease [IBD], lymphoma, feline leukemia virus [FeLV], canine distemper). Gastrointestinal symptoms may be more common in cats than in dogs.

History and Clinical Signs

The majority of canine and feline patients with detectable *Cryptosporidium* spp. oocysts are asymptomatic. When clinical disease is present, small bowel diarrhea, anorexia, and weight loss are common. Water loss secondary to malabsorption can lead to severe fluid imbalance.

Diagnosis

A combination of a direct saline smear and fecal flotation is preferred as the initial step, as oocyst excretion coincides with the onset of clinical signs. However, these techniques have poor sensitivity due to the small size of the oocyst. Fecal smears may be stained to enhance detection. Direct fluorescent antibody, enzyme-linked immunosorbent assay (ELISA), and polymerase chain reaction (PCR) are also available. These detection methods provide greater sensitivity than that observed with other detection methods.

Therapy

Direct treatment of the organism is difficult and the main goal of therapy is supportive. Initiation of highly digestible diets, fiber, and probiotics may be of benefit. Intravenous fluid administration may be needed to treat severe dehydration.

Published data regarding the treatment of cryptosporidiosis are lacking. Treatment protocols at this point are anecdotal and treatment needs to be calibrated to the needs and response of the individual patient. Azithromycin (10 mg/kg PO, SID until resolution), nitazoxanide (25 mg/kg PO, BID for seven days), paromomycin (150 mg/kg PO, SID for at least five days), and tylosin (10–15 mg/kg PO, BID-TID for 14–21 days) have been used. Paromomycin has the potential for nephrotoxicity and should not be used in dehydrated patients.

Prognosis

In an immunocompetent animal, infection with *Cryptosporidium* spp. usually resolves. Conversely, treatment of immunocompromised animals can be very difficult, and extended supportive measures may be necessary.

Public Health Implications

Health professionals should be aware that there have been cases of *Cryptosporidium* spp. transmission from animals to people. In a majority of cases, the pathogen was *C. parvum* and the source of infection was farm animals. However, *C. felis* and *C. canis* have been reported in the feces of some people. With no established treatment protocol for these cases, it is recommended that immunocompromised people avoid contact with animal feces, in particular the feces of strays and young pets (<6 months old) and utilize proper handwashing techniques.

Microspora

Microsporidia typically parasitize invertebrates, but *Encephalitozoon caniculi* can occasionally cause disease in dogs and cats following exposure. The life cycle is direct as environmentally resistant spores are passed in the urine or feces of an infected host and are consumed by a susceptible host. After ingestion and host cell penetration, organisms can be found in many cell types, with kidney and brain being the major organs affected. Transplacental transmission can occur, resulting in weakness, stunted growth, and later development of CNS disease and renal failure. Diagnosis is by detection of stained urine sediment. Serologic testing is also available.

Surgical, Traumatic, and Bite Wound Infections

Laura L. Nelson, DVM, MS, DACVS

College of Veterinary Medicine, North Carolina State University, Raleigh, NC, USA

Surgical and Traumatic Wound Infections

Etiology/Pathophysiology

In its most basic form, a wound is a break in the protective barrier organ that is the skin. Wounds can be created by almost anything, but are usefully described or defined in ways that reflect their degree of bacterial contamination, cause (i.e., bite wound, surgical site infection), and the depth or degree of tissue damage that accompanies them (i.e., superficial vs deep).

All wounds, regardless of cause or conditions present at their creation, can become infected. The likelihood of wound infection is directly related to the number and pathogenicity of bacterial contamination of the wound and inversely related to the overall health of the patient and the wound environment. This relationship can be defined as:

$$\text{Infection risk} = \frac{\#\text{ of bacteria} \times \text{virulence}}{\text{Host resistance}}$$

A threshold number of 10^5 bacteria per gram of tissue has often been quoted for the establishment of infection in a wound. The relationship of contamination to infection is borne out by the significant relationship between wound classification as clean, clean-contaminated, contaminated, and dirty (a proxy for the level of bacterial contamination in wounds) and infection risk in small animals. This number, however, is not absolute, as a wound may become infected after contamination with fewer organisms if the host cannot respond appropriately to bacterial contamination (discussed later) or if the bacteria in the wound possess specific virulence factors. For example, *Staphylococcus aureus* bacteria that do not express compounds anchored to their cell walls that adhere to matrix molecules in the host tissue do not cause invasive infection.

The health of the host and local wound environment are also very important in determining resistance to infection. Although a number of systemic conditions are associated with risk of surgical infection in humans, few of these risks have been investigated in veterinary patients. However, it is likely that patients with significant co-morbidities or extremes of age may be more susceptible. The use of perioperative antibiotics can be viewed as a means of increasing host resistance to infection. Finally, intraoperative management of the patient, including surgical time, surgical technique, use of surgical implants, anesthesia time, and maintenance of normothermia, plays a role in host resistance to infection.

Epidemiology

The bacterial flora of a wound is initially determined by its location (i.e., perineal) and cause (i.e., bite wound), but as time passes, opportunistic nosocomial pathogens such as *Pseudomonas aeruginosa* and *Enterococcus* species become more prevalent. These bacteria often have inherent (*Enterococcus*) and acquired resistance to multiple classes of commonly used antibiotics.

In acute, nonbite wounds, bacterial culture and sensitivity are unlikely to be helpful, as bacteria isolated will reflect wound contamination that may or may not lead to infection. In this circumstance, empiric, broad-spectrum antibiotic treatment based on common flora of the skin is an appropriate first-line therapy. This should take into account the potential for bacterial resistance associated with previous antimicrobial therapy, in which case culture may be warranted.

The presence of biofilms is increasingly recognized as a factor in the pathogenesis of chronic wounds and surgical site infections associated with foreign materials or implants.

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

Biofilms are multispecies aggregates of microbes that manufacture a protective carbohydrate matrix. Within this matrix, they are shielded from their environment, including the immune system and antibiotic therapy. Moreover, bacteria within biofilms assume a sessile rather than planktonic state, which diminishes the likelihood that they will be detected using conventional culture techniques.

Antimicrobial resistance is a growing problem in veterinary and human medicine and is seen in both nosocomial and community-acquired infections. Mechanisms of antimicrobial drug resistance have been well reviewed, and prevention and management of resistant bacterial infections are discussed in Chapter 114.

Signalment

Any animal can develop a surgical site infection or sustain a traumatic wound that becomes infected.

History and Clinical Signs

Surgical site infection is more likely to occur after contaminated surgeries or surgery on contaminated areas (e.g., perineal region), surgeries that involve the implantation of foreign material (orthopedic implants, mesh, bone allografts), and those that involve prolonged anesthesia time. However, any patient undergoing surgery is at risk of surgical site infection. Traumatic wounds that involve significant tissue trauma, that do not receive appropriate early treatment, that are penetrating in nature, or that leave embedded foreign material behind (e.g., pieces of bark) are more likely than superficial lacerations to become infected.

Wound infection is suspected based on the presence of redness, pain, exudate, or swelling of the wound area. In some cases, wound infection is characterized by an apparent delay or interruption of normal healing. Wound infections from surgical or traumatic causes can also be systemically apparent, causing fever, pain, tachycardia, and other signs associated with bacteremia or systemic inflammatory response. Sometimes systemic signs are more prominent than the superficial appearance of the inciting wound, highlighting the need for exploration and debridement of wounds.

Although it seems that wound infection should occur shortly following creation of the wound, it may take days or weeks (even months, in the case of wounds in which implants are placed) before signs of infection become evident. In addition, wound and surgical site infections can occur at various tissue levels, ranging from superficial or incisional infection to deeper or cavitary infection. The depth of infection can play a role in determining the most appropriate course of treatment.

Diagnosis

Box 112.1 defines criteria used in the diagnosis of surgical site infections. Though this scheme was designed to

Box 112.1 Criteria for surgical site infection (SSI) definition

Superficial incisional SSI

Infection occurs within 30 days after operation
and
infection involves only skin or subcutaneous tissue of the incision
and at least one of the following.

1) Purulent drainage, with or without laboratory confirmation, from the superficial incision
2) Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
3) At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat *and* superficial incision is deliberately opened by surgeon, *unless* incision is culture negative
4) Diagnosis of superficial incisional SSI by the surgeon or attending clinician

Suture abscess (minimal inflammation and discharge confined to points of suture penetration) is *not* considered a SSI.

Deep incisional SSI

Infection occurs within 30 days after operation if no implant is left in place or within one year if implant is left in place and infection appears to be related to the operation
and
infection involves deep soft tissues (e.g., fascial and muscle layers) of the incision
and at least one of the following.

1) Purulent drainage from the deep incision but not from the organ/space component of the surgical site
2) A deep incision spontaneously dehisces or is deliberately left open by a surgeon when the patient has at least one of the following signs or symptoms: fever, localized pain, or tenderness, unless site is culture negative
3) An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiographic examination
4) Diagnosis of a deep incisional SSI by a surgeon or attending clinician

Infections that involve both superficial and deep incision sites *and* organ/space SSI that drain through the incision are reported as deep incisional SSI.

Organ/space SSI

Infection occurs within 30 days after the operation if no implant is left in place or within one year if implant is left in place and the infection appears to be related to the operation

and

infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation

and at least one of the following.

1) Purulent drainage from a drain that is placed through a stab wound into the organ/space
2) Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
3) An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4) Diagnosis of an organ/space SSI by a surgeon or attending clinician

Source: Modified from Horan *et al.* (1992).

assist the diagnosis of surgical site infection, it is applicable to the diagnosis of any wound infection.

When an infection is present, clinical signs, particularly pain, lethargy, local swelling, drainage (ranging from serous to purulent to sanguineous in gross appearance), are generally present. Draining tracts can occur in cases of deep traumatic or surgical site infection, particularly if devitalized tissue (e.g., bone sequestrum) or foreign material (e.g., plant material, retained gauze sponge, surgical implant) are present. Draining tracts may occur relatively distant to the inciting foreign material, depending on tissue planes.

A patient suspected of having an infected wound should be thoroughly evaluated with a physical examination and by imaging appropriate to the area of interest if the wound is believed to involve tissue deeper than the skin and subcutis. Patients with traumatic wounds to the trunk should be evaluated with thoracic and abdominal radiographs to evaluate for pneumothorax or pneumoperitoneum, and abdominal or thoracic effusion.

Though many patients with chronic or superficial infections are relatively unaffected, those with significant or deep injuries, uncontrolled infections, continued bacterial contamination, devitalized tissue, and/or abscess formation can show significant systemic illness. Evaluation of these patients should include, in addition to those diagnostics listed earlier, evaluation of a complete blood count, biochemical profile, and urinalysis. Blood and urine cultures may be submitted. Exploration and debridement of infected areas should be performed shortly after initial treatment for sepsis and shock (described elsewhere in this text).

Therapy

Superficial infections that involve only cellulitis without evidence of deeper extension or abscess formation may be managed with oral antibiotic therapy alone. However, antibiotic therapy is not a replacement for exploration and debridement.

Wound management commences after managing more life-threatening concerns, critical diagnostics, and instituting necessary fluid replacement, analgesia, and supportive care. To prevent cross-contamination of the wound and hospital environment, the wound should be covered with a clean dressing and personnel handling the patient and/or wound should wear examination gloves at all times.

Wound Preparation

Under appropriate general anesthesia or heavy sedation, the wounds are packed with damp gauze or clean water-soluble lubricant to prevent further contamination. Hair is clipped widely around the wound area. The most obvious wound openings may represent the "tip of the iceberg," particularly when dealing with deep surgical site infections or bite wounds, so skin must be prepared to allow for extensive exploration and, if indicated, drain placement. Following hair removal, the wound and surrounding tissues are cleaned with an appropriate antiseptic detergent, such as chlorhexidine gluconate.

Exploration and Initial Debridement

The wound should be opened to its full extent to allow for complete exploration. Probing a smaller wound is not sufficient to determine its extent or level of contamination. The wound should be thoroughly assessed for involvement of deeper tissues or cavities (i.e., extension into the abdomen or thorax), necrotic or devitalized tissue, and foreign material. Necrotic, extensively contaminated, or devitalized tissue is judiciously removed using sharp dissection. Because many infected wounds are left open during initial treatment, serial debridement over several days is appropriate for important tissues of uncertain viability, which in some cases can partially or completely recover.

Lavage

Normal saline, a buffered isotonic fluid (i.e., lactated Ringer's solution [LRS]), or, in the case of significantly contaminated or large wounds, clean tap water can be used to copiously lavage the area. Though the hypotonicity of tap water is theoretically cytotoxic to cells in the wound, the clinical effect of this is not significant and may be outweighed by the practical utility of using a large sprayer or shower head to remove gross debris from a large wound area. The use of tap water lavage has not been shown to increase wound infection rates compared to saline in several human studies. Some authors promote intermediate pressure irrigation of 5–8 pounds per square inch, which can be generated by lavaging wounds using a 35 mL syringe and 18 gauge needle or catheter. Commercially available wound lavage units or a sink sprayer (tap water) may also be used. Warmed fluids should be considered to limit hypothermia, particularly in smaller patients, more extensive wounds, or wounds on the trunk.

Bandaging

Infected wounds are best managed as open wounds until healthy, at which time closure or reconstruction may be considered. When wounds communicate with a body cavity, the cavity should be evaluated, lavaged with warm, sterile isotonic solution, and drainage established through the use of a thoracostomy tube or closed-suction abdominal drain. A basic bandage includes the following components.

- *Contact layer*: directly interacts with the wound surface. A number of wound dressings are available and have been extensively reviewed elsewhere. This layer should ideally provide a protected, moist wound environment without macerating the tissue surrounding the wound. Some contact layers have antimicrobial properties or can be used with topical ointments that may provide a useful complement to systemic antibiotic therapy.
- *Secondary layer*: provides protection of wound and absorption of wound drainage.
- *Protective layer*: protects the bandage from dislodgment and environmental contamination.

Bandages should be changed as needed. During the first 1–2 days of wound evaluation (when further sharp debridement may be needed) or with more traditional dressings such as wet-to-dry, the bandage should be changed every 12–24 hours. Bandages should be changed when wound fluid reaches the protective layer of the bandage (also referred to as strikethrough). Some contact dressings such as alginates are intended to be left in place for 3–5 days.

Negative pressure wound therapy (NPWT) has been recently described as an alternative to conventional wound management. A number of NPWT devices are on the market, with increasing expansion into the veterinary field. NPWT can facilitate the development of a healthy granulation tissue bed following initial wound debridement without the need for frequent dressing changes.

Wound Closure

Wound closure is often possible in small animals due to the elasticity and quantity of truncal skin and availability of versatile axial pattern and other skin flaps. Wound closure or reconstruction of an infected wound should not be attempted until the wound is free of debris and necrotic tissue, a healthy wound bed is established, appropriate antimicrobial therapy has been started, the periwound tissues are healthy (not erythematous, macerated, or edematous), and the patient in good health. Many wounds, particularly those on extremities, are difficult to reconstruct or close and may be managed until contraction and epithelialization complete the healing process (second intention healing). Wounds in the perineal region are often best left to heal by second intention because of the difficulty of maintaining bandages in the area. In these cases, owners can be instructed to lavage the wound once or twice daily with tap water with a conventional shower head and apply an antimicrobial cream such as silver sulfadiazine to the area. An e-collar is provided to prevent self-trauma.

Prognosis

The prognosis for wound infections is variable depending on the source, location, and extent of infection (local vs systemic, deep vs superficial). Wound infections are often not amenable to a "quick fix." Owners should be counseled that management of an infected surgical or traumatic wound will likely require serial anesthesia and surgery to debride and potentially to later close the wound. Owners will need to accept that plans to reconstruct or close the wound may be delayed based on the appearance of the wound, and that multiple bandage changes or home wound management may be necessary. In some cases, the consequences of wound infection can negate the benefit associated with a surgery, such as for a total joint replacement. Fortunately, most appropriately managed wound infections can be satisfactorily managed, with patients returning to excellent health and quality of life.

Public Health Implications

Surgical wound infections with antibiotic-resistant bacteria are of significant human and animal health concern.

Bite Wounds

Etiology/Pathophysiology

Although dog and cat bite wounds are managed similarly to other infected or traumatic wounds (see earlier), the frequency and potential severity of bite wounds seen in small animal practice merit particular discussion.

Dogs can bite with significant force, and the orientation of their teeth results in puncture wounds from the canine and crushing or lacerating wounds from the incisor and molar/premolar teeth. Dogs also pull and shake victims following bites, resulting in avulsion of cutaneous vasculature and subcutaneous tissue. Dog bite wounds can be relatively minor lacerations and puncture wounds, or can be associated with extensive, life-threatening injury. Particularly severe are "big dog/little dog" injuries to small dogs or cats in which the victim is lifted and shaken by the aggressor. Although the limbs, head, and neck are common sites, injuries to the thorax and abdomen are relatively common in small-breed dogs. Dog bite wounds can be superficially dramatic, but often the skin wounds are the "tip of the iceberg," with extensive damage and contamination of underlying tissues lying deep to several small puncture wounds.

Due to the presence of contamination and the potential for serious tissue injury, dog bite wounds can lead to the systemic inflammatory response syndrome (SIRS) and septicemia. Without appropriate therapy, patients that survive the initial attack can die of these sequelae. It is important to recognize that a patient that seems relatively stable on initial presentation following a dog attack can rapidly progress to SIRS and septicemia.

Epidemiology

All bite wounds are considered to be contaminated due to the inoculation of the wound with the oral flora of the biter, the skin flora of the victim, and the bacteria or fungi in the environment. The common flora of the canine and feline oral cavity has been reviewed elsewhere, with *Pasteurella multocida* commonly cultured from both species.

Cat bite wounds are more likely to become infected due to the inoculation of oropharyngeal bacteria into deeper tissues. Cat–cat bite wounds are often not diagnosed until an abscess and associated clinical signs develop.

It is important to consider that organisms that cause hematologic disease such as hemotropic mycoplasmas and *Babesia gibsoni* are likely transmitted by bite wounds and follow-up testing may be warranted in some patients.

Signalment

Though any dog or cat can sustain a bite wound, smaller (≤10 kg) male dogs are overrepresented. Studies have identified higher percentages of certain breeds within this number, including Jack Russell terriers, dachshunds, pinschers, Yorkshire terriers, and Maltese dogs.

History and Clinical Signs

Dogs suspected or known to have been in a dog fight, particularly if multiple dogs were involved or if a size disparity was present, should be encouraged to undergo prompt evaluation by a veterinarian.

Diagnosis

The patient should be thoroughly examined, with prompt initial attention paid to cardiovascular and respiratory systems. The clinician should be ready to establish intravenous access and provide respiratory support if necessary through supplemental oxygen, intubation, tracheostomy, or thoracocentesis if indicated. A complete neurologic examination should be performed, particularly if wounds affect the head, neck, back, or extremity. Following initial assessment and stabilization, radiographs of the thorax and abdomen with or without focused assessment with sonography for trauma (FAST) scan for pleural and peritoneal fluid are warranted for wounds over the trunk. However, the absence of apparent free air or other abnormalities on radiographs does not guarantee that damage to the thoracic or abdominal body wall is not present.

Acute bite wounds are not infected, so wound cultures are often not helpful. More chronic wounds should be sampled for aerobic and anaerobic bacterial cultures.

Therapy

Initial stabilization will depend on the condition of the patient and will not be discussed in detail here, but should include the prompt administration of antibiotics. Intravenous administration of a broad-spectrum antibiotic or combination of antibiotics with good activity against skin and oropharygeal flora is warranted. As with infected surgical or traumatic wounds, it is wise to cover the open wound with a clean dressing and to wear gloves during initial assessment to prevent cross-contamination of the wound and hospital environment during assessment and stabilization.

As for infected surgical and traumatic wounds, surgical debridement and the establishment of drainage are important tenets in the successful management of dog bite wounds. The patient is carefully evaluated and the hair liberally clipped in wounded areas. In patients with

thick hair coats, it may not be possible to evaluate for smaller puncture wounds without removing hair along the majority of the neck and trunk. The presence of multiple bites is common and, as mentioned earlier, small puncture wounds can be the only external indication of significant damage to deeper tissues.

After stabilization and anesthesia, the skin is prepared as noted in the general section discussing management of infected wounds. After skin preparation and draping, the wounds should be opened and aseptically explored to determine the extent of tissue damage. Simply probing the cutaneous defects is insufficient for bite wounds. Once each wound area is explored, and debris and devitalized tissue removed, the wound is lavaged with isotonic fluid such as normal saline or LRS. Once opened, wounds can be left open and bandaged or, if minimally extensive, closed with appropriate placement of a drain. The reader is referred to surgical texts for a more detailed description of drain placement.

If there is any doubt about the state of the wound, if the wound is already infected, or if it is particularly severe, the author's preference is to leave wounds open and bandage them for several days. Delayed primary closure or tertiary closure may be pursued when the patient is stable, the wound bed is healthy, and the clinician is sure that no further tissue necrosis will occur.

Prognosis

As for infected traumatic and surgical wounds, the prognosis associated with bite wounds varies with the severity and location of the wound and the general health status of the patient.

Public Health Implications

In a dog or cat that has been or may have been bitten by a wild animal, potential rabies exposure protocols consistent with state regulations should be followed. All draining wounds in cats in particular should be handled with appropriate precautions due to the potential for sporotrichosis and other zoonotic diseases such as tularemia.

Canine Infectious Respiratory Disease Complex

Jonathan Dear, DVM, DACVIM (SAIM)

School of Veterinary Medicine, University of California, Davis, Davis, CA, USA

Canine infectious respiratory disease complex is a multifaceted disease of immunologically naive, immunocompromised, and otherwise healthy dogs. Formerly known as kennel cough or infectious tracheobronchitis, studies show that the syndrome is far more complex than previously imagined, with a multitude of contributory pathogens and risk factors as well as variable outcomes.

Etiology/Pathophysiology

Canine infectious respiratory disease (CIRD) is a complex rather than a single disease in which various pathogens, including viruses, bacteria and mycoplasma, co-infect naive, immunocompromised or previously vaccinated dogs. CIRD usually presents in an acute, self-resolving (uncomplicated) form characterized by a dry, hacking cough with retching and gagging; the syndrome is generally initiated by viral pathogens. Occasionally, in immunocompromised or immunologically naive animals, the pathologic changes induced by viral disease predispose dogs to subsequent infection with opportunistic bacteria and *Mycoplasma*, thereby resulting in more severe (complicated) upper respiratory signs, bronchopneumonia, and death. Susceptibility to the complex is multifactorial and stems from both host and environmental factors. Many pathogens implicated in this complex are ubiquitous, being particularly prevalent in overcrowded housing facilities such as animal shelters, training and boarding facilities. The individual's stress induced by the new environment and exposures to novel pathogens both likely play a role in the development of clinical signs and disease.

Generally, respiratory signs are present for days to weeks and most animals show mild to moderate clinical signs. In most cases, viruses cause initial infection and result in clinical signs within 3–5 days of infection. Viruses that have been identified include canine influenza virus (CIV), canine respiratory coronavirus (CRCoV), canine parainfluenza virus (CPiV), canine adenovirus-2 (CAV-2), canine herpes virus (CHV), and rarely canine distemper virus (CDV). Research suggests that novel viral pathogens (canine reovirus, canine bocavirus, canine pneumovirus, and canine hepacivrus) may also contribute to the disease, but reports remain preliminary.

The tropism of viral agents associated with CIRD varies but mostly includes lymphoid and epithelial tissues throughout the upper and lower respiratory tracts, though notable exceptions are CHV and CDV with pronounced tropism towards monocytic cells. In more severe cases, viral infections cause either a bronchopneumonia or bronchointerstitial pneumonia due to their propensity to infect and damage type I pneumocytes. As the condition progresses, desquamation of the respiratory epithelium and aggregation of inflammatory cells further reduce the lungs' natural defenses, increasing the potential for secondary bacterial colonization and infection. Notably, CRCoV leads to loss of cilia from respiratory epithelium, thereby increasing the severity and duration of clinical signs associated with secondary infections.

While many animals develop only mild, self-limiting disease induced by viral infection, some animals go on to develop progressive clinical signs subsequent to secondary bacterial colonization. Bacteria and *Mycoplasma* which have been implicated in the development of CIRD include *Bordetella bronchiseptica*, *Streptococcus canis*, *Streptococcus equi* subsp. *zooepidemicus*, and *Mycoplasma cynos*.

Bordetella bronchiseptica, once presumed to be the sole player in the development of canine infectious upper airway disease, remains one of the most common pathogens detected and possesses unique mechanisms to evade host immune responses and allow for primary bacterial infection of the airways. Primarily, *B. bronchiseptica* expresses

Companion website: www.wiley.com/go/bruyette/clinical

adhesins along the cell membrane, which facilitate colonization of the ciliated respiratory epithelium. Following adherence, the bacteria release exotoxins that reduce the body's ability to clear the disease and increase its susceptibility to other organisms. *S. equi* subsp. *zooepidemicus* infections, in particular, have been associated with a rapidly progressive and often fatal hemorrhagic pneumonia. Mycoplasmas have long been suspected to be part of the commensal flora of both upper and lower respiratory tracts, though *M. cynos* has been found to be present in significantly greater numbers of affected animals with moderate disease.

Epidemiology

Most of the organisms involved with CIRD are primary pathogens of the respiratory epithelium and thus require aerosol exposure or contact with fomites to facilitate infection. Following exposure, clinical signs generally develop within 3–5 days and the animal may shed virus for up to 8–10 days, though influenza virus can be shed for up to several weeks following infection. The course of disease associated with *S. equi* subsp. *zooepidemicus* seems to be much more rapid, with several case series reporting death within two days of exposure, sometimes without clinical evidence of respiratory disease. Animals in intensive housing with close exposure to other animals are at increased risk for development of clinical signs. Furthermore, prolonged housing in shelters or kennels increases the risk of developing disease and seroconverting.

Signalment

Canine infectious respiratory disease has a propensity for young, immunologically naive animals and immunocompromised patients. No sex or breed predilections have been identified. The greatest known risk factors stem from immune status and environmental history (see later).

History and Clinical Signs

Canine infectious respiratory disease usually presents as a dry, hacking cough often followed by a terminal retch. In particular, paroxysms of cough may be elicited by gentle tracheal palpation. In most cases, the infection is isolated to the upper respiratory tract so most affected dogs lack systemic signs, though mild lethargy and exercise intolerance are sometimes reported.

A history of recent exposure to other animals or housing facilities increases the suspicion of this disease. Animal shelters and rehoming kennels may provide the first exposure to immunologically naive animals, causing outbreak of clinical disease. Intuitively, greater length of exposure increases the risk of developing clinical signs. Additionally, the environmental stresses (i.e., crowded housing and poor nutrition) placed upon the animals may contribute to increased morbidity in these populations.

Most organisms associated with CIRD are found throughout the United States, though CIV seems to have a particularly higher seroprevalence in racing greyhounds and dogs from Florida (H3N8) and the Midwest (H3N2). Certain organisms like CHV are more prone to develop into clinical respiratory disease in patients undergoing immunosuppressive therapy.

Diagnosis

In an ideal world, diagnosis of the diseases associated with CIRD would precede therapy and help guide the use of (or withholding of) antimicrobials. However, even with the best intentions, identification of many of these organisms can be difficult. Furthermore, as many cases of CIRD are mild and self-resolving, diagnosis is often made based on clinical suspicion, taking into consideration the dog's age, environmental history, health, and vaccine status.

In most cases of uncomplicated disease, the physical exam is unremarkable with the exception of an inducible cough. Thoracic auscultation and radiography are generally unrewarding in milder cases. With progressive disease, nonspecific signs of systemic health and respiratory disease may be noted, including oculonasal discharge, pyrexia, adventitious lung sounds, and other indicators of malaise. Ideally, in more severe cases, fluid from a bronchoalveolar lavage (BAL) should be collected using sterile technique and submitted for cytologic analysis, bacterial culture (aerobic and *Mycoplasma* +/- anaerobic) and saved for potential molecular techniques (real-time polymerase chain reaction [PCR]) to detect viral organisms. Recently, the development of PCR panels run on nasal or oropharyngeal swabs has introduced a novel approach to the diagnosis of these diseases. Unfortunately, no published reports validate the sensitivity and specificity of these panels and false positives (due to contamination and/or vaccination) can occur along with false negatives (due to low virus shedding).

Therapy and Prevention

Most cases of CIRD in the otherwise healthy individual are self-limiting and respond well to basic supportive care. Strict environmental containment should be employed to prevent horizontal transmission. Affected

animals should be quarantined beyond complete resolution of clinical signs. Within the veterinary hospital, personal protective equipment (gowns, gloves, shoe covers, and masks) should be used, with care taken to disinfect potential fomites (scales, medical equipment, bowls, and cages). Bactericidal and virucidal disinfectant solutions with rapid action should be used consistently to limit the spread of disease since the pathogens involved with this complex can remain in the environment for weeks to months.

Antimicrobial therapy, when indicated, should be directed by culture of BAL or tracheal wash fluid. In the absence of microbiology results, empiric therapy may be directed to those bacterial pathogens suspected. Tetracycline antibiotics (such as doxycycline 5 mg/kg PO BID for 14–28 days) achieve excellent tissue penetration and are a good choice for *B. bronchiseptica* and *Mycoplasma* infections, but some strains of *S. equi* subsp. *zooepidemicus* have proven antimicrobial resistance to this class of drugs. Alternatives include macrolide antibiotics (azithromycin), potentiated penicillins (amoxicillin/clavulanic acid) or fluoroquinolones (enrofloxacin). Given the potential for disease in young animals, the clinician should consider potential adverse effects of the use of these drugs, including enamel discoloration with tetracyline (less severe with doxycyline) and cartilage development abnormalities with fluoroquinolones. When bronchopneumonia is suspected, routine supportive care including intravenous fluid administration, saline nebulization, and coupage is useful to help expectorate airway secretions.

In refractory cases involving paroxysms of cough and retching, antitussive medications like hydrocodone/homatropine (Hycodan®) or butorphanol (Torbugesic®) can help to relieve clinical signs, though these drugs should not be used in cases of suspected bronchopneumonia as they prevent expectoration of respiratory secretions. The use of antiinflammatory doses of corticosteroids remains controversial.

The most effective strategy for prevention employs strategic immunization and environmental controls to prevent exposure and limit passage of disease. Most owned dogs are immunized (parenterally) against CDV and CAV-2 as part of their core vaccines. Parenteral CAV-2 vaccination is considered a core vaccine due to its ability to cross-protect against CAV-1, but the intranasal vaccine does not provide this protection and is considered noncore but recommended for dogs likely to encounter the virus. Though considered to be noncore, routine vaccination for CPiV and *B. bronchiseptica* is recommended for animals likely to enter facilities where the diseases may be encountered (boarding and grooming facilities, training kennels). A vaccine for CIV (Nobivac® bivalent canine flu H3N8/H3N2) has been licensed in the US and shown to reduce clinical signs and virus shedding, though is still considered noncore. There are no licensed vaccines for CHV, CRCoV, and *S. equi* subsp. *zooepidemicus* at the present time. The reader is advised to consult the most recent AAHA Canine Vaccination Guidelines (2017 at time of publication) for more information regarding vaccine recommendations.

Prognosis

Overall prognosis for otherwise healthy dogs with uncomplicated CIRD is generally good, with most dogs recovering within 7–10 days after receiving only basic supportive care. Dogs with complicated infections (such as with *S. equi* subsp. *zooepidemicus* and *M. cynos*) have a more guarded prognosis. *S. equi* subsp. *zooepidemicus* progresses rapidly following the development of clinical signs and can lead to death due to sepsis, acute respiratory distress syndrome, and multiple organ dysfunction. Disease of the lower respiratory tract in conjunction with *M. cynos* infections seems to yield moderate clinical signs early following exposure, though these seem to lessen within 2–3 weeks.

Public Health Implications

Most pathogens involved in CIRD do not appear to present zoonotic risk, though there remains a possibility of human infection with these diseases. Several reports suggest that both healthy and immunocompromised individuals may be susceptible to *B. bronchiseptica* following administration of modified-live vaccines to companion animals. Given this potential, care should be used when administering all aerosol (intranasal) vaccines; only trained healthcare providers should administer and restrain the animal during this procedure. There have been no confirmed cases of zoonotic transmission of *B. bronchiseptica* from canine to human.

Likewise, though canine respiratory coronavirus has yet to be implicated in the development of respiratory disease in humans, these viruses as a family are known to jump species lines and may have the potential for zoonotic transmission. A notable example is the severe acute respiratory syndrome (SARS), beginning in Asia in 2002 (caused by the SARS-CoV), which is thought to have spread to human patients through wild captive mammals. Further coronavirus outbreaks in the Middle East and Western Europe (2012) continue to demonstrate the infectious and adaptive nature of these viruses that likely originated from animal reservoirs.

Finally, there appears to be some zoonotic risk of transmission of *S. equi* subsp. *zooepidemicus* from canine patients to both healthy and immunocompromised human handlers. Most reported cases of infection in humans develop subsequent to ingestion of contaminated milk and dairy products or contact with infected equine patients. Concurrently, contact with respiratory secretions – either aerosolized or in contact with mucous membranes – appears to be capable of infection causing acute nephritis, meningitis, pneumonia, and death.

Conclusion

Canine infectious respiratory disease is an evolving and multifaceted condition with many implicated pathogens and varied outcomes. Simple cases often respond to nonspecific supportive care while more severe cases may prove lethal even with the most advanced therapy. Prevention, through appropriate sanitation, husbandry and vaccination, remains the most effective way to limit disease transmission and morbidity. The zoonotic implications of many of the organisms associated with the complex deserve further study.

Part 3

Therapeutic Considerations

114

Antimicrobial Therapy in Dogs and Cats

Katrina R. Viviano, DVM, PhD, DACVIM (SAIM), DACVCP

School of Veterinary Medicine, University of Wisconsin, Madison, WI, USA

To optimize antimicrobial therapy, clinicians should have a working knowledge of available antimicrobials and their spectrum of activity. Of equal importance is an understanding of clinically important side-effects, drug–drug interactions, and knowledge of circumstances in which certain antimicrobials should be avoided, or dosage adjustments should be considered to minimize potential adverse effects. This chapter will summarize these important considerations for commonly used antimicrobials in small animal medicine. The common classes of antimicrobials used and the clinically important antimicrobial side-effects/drug–drug interactions in dogs and cats are summarized in Tables 114.1 and 114.2, respectively.

Common Classes of Antimicrobials

Aminoglycosides (AG)

The AG spectrum of activity is primarily limited to gram-negative aerobes, including *Pseudomonas aeruginosa*. *In vivo*, AGs are considered synergistic with beta-lactams. AGs penetrate the bacterial cell envelope in part through an oxygen-dependent active transport mechanism as well as passive diffusion. By co-administering AGs with penicillins, the penicillins interfere with bacterial cell wall synthesis, enhancing the penetration of AGs into the bacterial cell envelope.

The dose-dependent nephrotoxicity of the AGs limits their clinical use. AGs bind the brush border of the proximal renal tubular cells and accumulate in lysosomes through active reabsorption. Through the inhibition of lysosomal phospholipase, phospholipid metabolism is inhibited, resulting in renal tubular cell death. Risk factors for nephrotoxicity include high dosages, multi-dose protocols, long duration of treatment, pre-existing renal dysfunction, dehydration, concurrent use with other nephrotoxic drugs or diuretics, and young or old age.

The active tubular reabsorption of AGs is a saturable process with an increase in nephrotoxicity when lower, more frequent dosing protocols are used. Despite AGs having a short elimination half-life, they demonstrate a post-antibiotic effect and concentration-dependent bacterial killing. Nephrotoxicity correlates with drug trough concentrations and is not observed following a high single dose; but is cumulative and occurs in association with multidose protocols, within 5–7 days after initiating therapy. Once-daily dosing is recommended to minimize nephrotoxicity while maintaining efficacy.

Aminoglycoside nephrotoxicity is reversible if recognized early so close monitoring is recommended. AGs should be avoided in patients with underlying kidney disease. If an alternative antimicrobial with an appropriate spectrum of activity is not available, dose reduction is recommended in azotemic patients. To help prevent nephrotoxicity, all patients should be well hydrated before and during the course of therapy. As mentioned above, once-daily dosing is recommended, and when possible the duration of therapy should be limited to 5–7 days. To detect proximal renal tubular damage, urine should be examined prior to and daily during therapy for the presence of granular casts, proteinuria, and glucosuria. Serum BUN and creatinine levels should also be monitored. Therapy should be discontinued if markers of nephrotoxicity develop.

Aminoglycosides also accumulate in the inner ear, leading to dose-dependent ototoxicity. Auditory toxicity is more common with amikacin, while vestibular toxicity is more common with gentamicin, especially in cats. Also, the use of AG is contraindicated in patients with disease of the neuromuscular junction (e.g., myasthenia gravis) due to inhibition of acetylcholine release and decreased receptor sensitivity leading to neuromuscular blockade.

Table 114.1 Classes of antimicrobials used in small animal veterinary medicine including mechanism of action, spectrum of activity, and common drugs of each class

Drug class	Mechanism of action	Spectrum of activity	Examples*
Aminoglycosides (AG)	Alter protein synthesis – irreversibly bind the 30S ribosome Synergistic with beta-lactams	Gram-negative aerobes (including *Pseudomonas*)	Gentamicin Amikacin Neomycin
Amphenicols	Inhibit protein synthesis – reversibly bind the 50S ribosome subunit	Gram-positive aerobes Gram-negative aerobes Anaerobes *Rickettsia rickettsii* *Mycoplasma* spp. *Chlamydia* spp.	Chloramphenicol
Beta-lactams • Penicillins	Cell wall synthesis inhibitor via binding to penicillin binding protein (PBP) Synergistic with AG	Gram-positive aerobes (including *Enterococcus)* Anaerobes Spirochetes • *Leptospira* spp. • *Borrelia* spp.	Penicillin G Ampicillin/amoxicillin Amoxicillin/clavulanate Ampicillin/sulbactam Ticarcillin Methacillin/oxacillin
Beta-lactams • Cephalosporins	Cell wall synthesis inhibitor via binding to PBP	First generation • Gram-positive aerobes • Gram-negative aerobes (some) • Anaerobes (some) Second generation • Gram-negative aerobes • Gram-positive aerobes • Anaerobes (*Bacteroides*) Third generation • Gram-negative aerobes • *Pseudomonas* spp. (ceftazidime) • Gram-positive aerobes Borrelia Fourth generation • Gram-negative aerobes • Gram-positive aerobes Extended spectrum • Gram-positive aerobes • Gram-negative aerobes (some) • Anaerobes	First generation • Cephalothin • Cefazolin • Cephalexin • Cephadroxil Second generation • Cefoxitin • Cefotetan Third generation • Ceftiofur • Ceftazidime • Cefotaxime • Ceftriaxone • Cefpodoxime proxetil Fourth generation • Cefepime Extended spectrum • Cefovecin
Beta-lactams • Carbapenems	Cell wall synthesis inhibitor via binding the PBP	Gram-positive aerobes Gram-negative aerobes (including *Pseudomonas* spp.) Anaerobes	Imipenem Meropenem
Fluoroquinolones	Inhibit DNA gyrase (topoisomerase II) – target in gram-negative bacteria Inhibit topoisomerase IV – target in gram-positive bacteria	Gram-negative aerobes • Many including *Brucella* Gram-positive aerobes (limited) • *Mycoplasma* • *Chlamydia* • *Mycobacteria* • *Rickettsia rickettsii*	Enrofloxacin Ciprofloxacin Marbofloxacin Pradofloxacin

Table 114.1 (Continued)

Drug class	Mechanism of action	Spectrum of activity	Examples*
Lincosamides	Inhibit protein synthesis – reversibly bind the 50S ribosome subunit	Gram-positive aerobes Anaerobes • *Clostridium perfringens* • *C. tetani* • *Bacteroides* • *Fusobacterium* • *Actinomyces* • *Mycoplasma* spp. Protozoans • *Toxoplasma* • *Neospora*	Clindamycin
Macrolides	Inhibit protein synthesis – reversibly bind the 50S ribosome subunit	Gram-positive aerobes • *Campylobacter jejuni* (erythromycin) • *Mycoplasma* spp. • *Chlamydia* • *Mycobacterium* spp. (azithromycin, clarithromycin)	Erythromycin Azithromycin Clarithromycin Tylosin
Nitroimidazoles	Disrupt bacterial DNA synthesis – under anaerobic conditions converted to a unstable intermediate (nitroso free radical)	Anaerobes • *Bacteroides fragilis* • *Clostridium perfringens* • *Fusobacterium* Protozoans • *Giardia* spp.	Metronidazole
Potentiated sulfonamides	Target bacterial folic acid synthesis at two different steps: 1 Inhibitors of dihydrofolate reductase (trimethoprim, ormetoprim) 2 PABA analog (sulfonamides)	Gram-positive aerobes Gram-negative aerobes • *Nocardia* Protozoans • *Toxoplasma* • *Neospora* Atypical *Mycobacteria*	Trimethoprim/ sulfadiazine Ormetoprin/ sulfadimethoxine Trimethoprim/ sulfamethoxazole
Tetracyclines	Alter protein synthesis via reversibly binding the 30S and 50S ribosome	Gram-positive aerobes • *Staphylococcus* spp. • *Streptococcus* spp. • *Clostridium tetani* • *Nocardia* Gram-negative aerobes (some) • *Bordetella* spp. • *Brucella* Spirochetes • *Leptospira* spp. • *Borrelia* spp. Rickettsial • *E. canis* • *R. rickettsii* • *Anaplasma* spp. • *Wolbachia* *Mycoplasma* spp. *Chlamydia* spp.	Doxycycline Minocycline

* Note that not all organisms listed under "Spectrum of activity" are susceptible to each specific example of antibiotic listed. Please see text and other resources for more comprehensive sensitivity information.

Table 114.2 Clinically important side-effects and drug–drug interactions associated with antimicrobials commonly used in small animal medicine

Antimicrobial	Side-effect	Drug–drug interaction
Aminoglycosides	Nephrotoxicity (dose-dep.) Ototoxicity (dose-dep.) Neuromuscular blockade (inhibition of ACh release)	Synergistic with penicillins
Chloramphenicol	Bone marrow suppression (dose-dep.) Irreversible aplastic anemia (people, idiosyncratic)	Phenobarbital/propofol (dog, CYP 2B inhibition)
Carbapenems	CNS toxicity (imipenem > meropenem) Nephrotoxicity (imipenem)	
Fluoroquinolones	Articular cartilage erosions/blisters (growing animals) Retinal toxicity (cats, dose-dep.)	Antacids/sucralfate (decreased oral absorption) Theophylline (CYP1A inhibition)
Macrolides		Theophylline (CYP3A inhibition, erythromycin, clarithromycin)
Lincosamides	Esophageal structures (cats, clindamycin)	
Metronidazole	Neurotoxicity/cerebellovestibular ataxia	
Potentiated sulfonamides	Idiosyncratic (dogs) • Blood dyscrasias • Hepatoxicity • Polyarthritis • Cutaneous skin eruptions • KCS Dose dependent (dogs) • Nonregenerative anemia • Inhibition of thyroid hormone synthesis	
Tetracyclines	Tooth enamel discoloration (young, tetracyclines, oxytetracycline) Esophageal strictures (cats, doxycycline)	Antacids/sucralfate (decreased oral absorption)

ACh, acetylcholine; CNS, central nervous sysem; KCS, keratoconjunctivitis sicca.

The clinical situation where the risk of the systemic side-effects of nephrotoxicity and ototoxicity may be avoided is the use of orally administered neomycin in the treatment of hepatic encephalopathy. The AGs have poor oral bioavailability. In patients with hepatic encephalopathy, the goal of therapy is to target the ammonia-producing bacteria within the gut. However, if the integrity of the gastrointestinal tract is compromised, systemic absorption and the associated side-effects may theoretically occur.

Amphenicols (e.g., Chloramphenicol)

Chloramphenicol has a wide spectrum of activity against gram-positive and gram-negative organisms. Many anaerobic bacteria are also sensitive to chloramphenicol, including *Clostridium*, *Bacteroides* (*B. fragilis*), and *Fusobacterium* species. Other susceptible bacteria include *Chlamydia* spp., *Mycoplasma* spp., and *Rickettsia rickettsii*.

In dogs and cats, chloramphenicol can result in bone marrow suppression. This side-effect is considered dose-dependent and more likely if patients, especially cats, are treated for an extended duration. In people, the major route of chloramphenicol metabolism and elimination is glucuronidation. This suggests that decreased glucuronidation may contribute to the increased risk of toxicity in cats. In addition, 25% of the dose is reported to be excreted unchanged in the urine of cats compared to most other species, in which elimination is primarily via hepatic metabolism. Therefore, dose reduction should be considered in cats with kidney disease.

In dogs, chloramphenicol is a potent inhibitor of the hepatic microsomal cytochrome P450 enzyme system, specifically the subfamily CYP2B11. Through this CYP inhibition, the metabolism of barbiturates, like phenobarbital, and propofol may be impacted. Dogs concurrently prescribed chloramphenicol and phenobarbital have an increased risk of phenobarbital toxicity and dogs anesthetized with propofol may have prolonged recoveries if they are also being treated with chloramphenicol.

Chloramphenicol is associated with an irreversible aplastic anemia in people that is an idiosyncratic toxicity. Due to this unpredictable toxicity in people,

the use of chloramphenicol in veterinary medicine is limited primarily to patients with cultured bacterial isolates that have maintained their sensitivity to chloramphenicol but are multidrug-resistant organisms (e.g., methicillin-resistant *Staphylococcus pseudintermedius*). When prescribing chloramphenicol, owners need to be educated about the associated risk of exposure and toxicity to themselves and the need to wear gloves whenever the drug is being handled to avoid accidental ingestion or exposure.

Beta-Lactams

Penicillins

The broader spectrum (e.g., amoxicillin, ampicillin) or potentiated penicillins (e.g., amoxicillin/clavulanate and ampicillin/sulbactam) have an increased spectrum of activity against gram-negative organisms, including some of the beta-lactamase-producing bacteria and anaerobes. Ticarcillin has a strong gram-negative spectrum with activity against *Pseudomonas* spp. Methicillin/oxacillin has activity against the beta-lactamase-producing bacteria (e.g., *Staphylococcus* spp.) and is used primarily for susceptibility testing.

Beta-lactams have relatively limited side-effects and are clinically well tolerated. The most common side-effect is gastrointestinal upset, which is most commonly associated with amoxicillin/clavulanate, especially in cats. Hypersensitivity or allergic reactions to the penicillins are not very common in small animal medicine, in comparison to people. The beta-lactams are largely excreted in the urine and in patients with kidney disease, dose reduction may be necessary. However, due to the wide margin of safety of these drugs, dose reduction is often not routinely pursued in patients with mild to moderate azotemia.

Cephalosporins

The cephalosporins have a broad spectrum of activity against gram-positive organisms, with the exception of the *Enterococcus* spp. which are not susceptible. The cephalosporins as a group have some anaerobic activity but relative to the penicillins and potentiated penicillins (e.g., amoxicillin/clavulanate), their anaerobic spectrum is limited. Generally, the gram-negative spectrum of activity increases from the first- to third-generation cephalosporins. However, some of the less frequently dosed third-generation (e.g., cefpodoxime) and extended-generation cephalosporins (e.g., cefovecin) have a bacterial spectrum more consistent with the first-generation cephalosporins, including activity against many gram-positive and some gram-negative organisms but no activity against *Enterococcus* or *Pseudomonas* species.

Cefpodoxime is an oral formulation dosed once a day, and cefovecin an injectable slow-release formulation that delivers antibacterial activity for 14 days. Cefovecin's extended persistence may provide convenient dosing but in the event of an adverse effect, the drug cannot be withdrawn and in the case of treatment failure, continued drug exposure may contribute to antimicrobial resistance. The clinical use of cefovecin should be limited to fractious or noncompliant patients that cannot be medicated daily.

The fourth-generation cephalosporins have both gram-positive and gram-negative activity and their use should be limited to patients with a cultured susceptible gram-negative or gram-positive isolate, patients with susceptible mixed infections, or a serious to life-threatening susceptible multidrug-resistant and/or nosocomial infection(s). The later generation cephalosporins are expensive, require frequent dosing, and in some cases, a constant rate infusion is necessary for effective therapy.

Carbapenems

Carbapenems are considered powerful antibiotics with a very broad spectrum of activity. Therefore, their use should be dictated by the results of bacterial culture and antimicrobial susceptibility testing. The carbapenems are expensive and must be administered parenterally. Side-effects, more common with imipenem than meropenem, include central nervous system (CNS) toxicity and nephrotoxicity. Imipenem is available co-formulated with cilastatin (an inhibitor of imipenem metabolism) which minimizes nephrotoxicity. In the absence of cilastatin, imipenem is converted to a nephrotoxic metabolite in the proximal renal tubule, resulting in necrosis. In many patients, the use of meropenem may be better tolerated as it is more soluble and can delivered in smaller volumes relative to imipenem.

Fluoroquinolones

The spectrum of activity of fluoroquinolones classically targets aerobic gram-negative organisms. Pradofloxacin is a third-generation fluoroquinolone that has recently been approved in the US for the treatment of skin infections in cats. Pradofloxacin has an extended spectrum against many gram-positive organisms and anaerobes in addition to having a good gram-negative spectrum.

Fluoroquinolones are associated with significant side-effects and clinically important drug interactions. Articular cartilage erosions or blister lesions occur in growing animals, especially dogs treated with high doses. Clinical signs of lameness and joint swelling have been reported as early as two days following therapy in

experimental dogs given four times the recommended dose of ofloxacin. The use of fluoroquinolones is generally avoided in young puppies (<8 months), but in an experimental study in young beagles (13–16 weeks old), an oral dose of ciprofloxacin 10 mg/kg/day for 14 days did not induce joint lesions.

A species-specific side-effect of the fluoroquinolones is dose-dependent retinal toxicity in cats. Cats are functionally deficient in the ATP-binding cassette subfamily G member 2 (ABCG2) protein, encoded by the ABCG2 gene. This membrane-associated protein functions at the blood–retinal barrier to limit xenobiotics (e.g., fluoroquinolone) from entering the retina. When fluoroquinolones are administered to cats, the photosensitive fluoroquinolones have access to the retina, leading to retinal degeneration and blindness. All fluoroquinolones have the potential to cause retinal lesions with a modest overdose in cats, although there are differences between the fluoroquinolones. Retinal toxicity has been reported for enrofloxacin at 4-times the label dose and orbifloxacin at 18-times the label dose. In contrast, marbofloxacin and pradofloxacin did not cause retinal lesions when administered at 20-times and 10-times the label dose, respectively. To minimize retinal toxicity in cats, the recommended label dose should not be exceeded, rapid IV infusions and prolonged treatment durations should be avoided, and dose adjustment in patients with underlying kidney disease should be considered.

Two important drug–drug interactions are associated with clinical use of fluoroquinolones. Orally administered fluoroquinolones chelate with di- or tri-valent cations (e.g., calcium, aluminum, or magnesium), resulting in decreased absorption. The co-administration of fluoroquinolones with antacids containing aluminum or magnesium, or sucralfate should be avoided. If co-administration is necessary, separate the administration times by at least two hours (e.g., give the fluoroquinolone at least two hours before any products that contain di- or tri-valent cations). Fluoroquinolones inhibit the hepatic microsomal cytochrome P450 enzyme system, specifically CYP1A2 in people. CYP1A inhibition will decrease the elimination of substrate drugs, like theophylline, resulting in clinical signs of theophylline toxicity (tachycardia, excitability, tremors, or seizures). In clinical practice, it would be best to avoid the concurrent therapy of a fluoroquinolone (e.g., ciprofloxacin) with theophylline. Alternatively, a significant reduction in the theophylline dose can be considered to avoid toxicity.

Lincosamides and Macrolides

The lincosamides and macrolides have a similar spectrum of activity to include most gram-positive organisms. The most common side-effects are gastrointestinal signs, including vomiting and diarrhea after oral administration. Clindamycin capsules have been associated with esophageal strictures in cats. Stricture formation is thought to occur secondary to prolonged esophageal mucosal contact of the capsule if administration is not preceded or followed by food or liquid.

Potential drug interactions associated with some macrolides are their ability to inhibit the metabolism of other drugs which are substrates of the CYP3A subfamily of the microsomal cytochrome P450 enzyme system. Erythromycin and clarithromycin are inhibitors of CYP3A (i.e., CYP3A4 in people) which will inhibit the metabolism of CYP3A substrate drugs (e.g., theophylline), leading to toxicity when prescribed concurrently. Azithromycin is not a cytochrome P450 inhibitor.

Nitroimidazoles (e.g., Metronidazole)

Metronidazole has activity against anaerobes to include *Bacteroides* (*B. fragilis*), *Fusobacterium*, and *Clostridium* species. Other organisms susceptible to metronidazole include *Giardia* and *Trichomonas*. An overdose of metronidazole is associated with neurotoxicity leading to cerebellovestibular ataxia in dog and cats. The mechanism of toxicity is thought to be inhibition of the gamma-aminobutyric acid (GABA) neurotransmitter. At toxic doses, clinical signs include ataxia, nystagmus, and proprioceptive deficits which are reversible once the drug is discontinued. To avoid toxicity in patients with impaired liver function, dose reduction is recommended (e.g., an empirical dose reduction to 7.5 mg/kg twice a day for metronidazole in patients with underlying liver failure or cirrhosis).

Potentiated Sulfonamides

The potentiated sulfonamides provide broad-spectrum activity against gram-positive and gram-negative organisms and some activity against *Coccidia* and *Toxoplasma*. *Pseudomonas aeruginosa* is not susceptible to the potentiated sulfonamides. Many *Staphylococcus* spp., including methicillin-resistant *Staphylococcus pseudintermedius* (MRSP), remain susceptible to the potentiated sulfonamides. The major limitation of the use of potentiated sulfonamides in veterinary medicine, and specifically in dogs, is the risk of an idiosyncratic and/or dose-dependent side-effect.

Sulfonamide-induced side-effects in dogs may be in part due to the dog's inability to metabolize the sulfonamides via acetylation (the major metabolic pathway for sulfonamides in people). The underlying pathophysiology is not well understood but in part involves immune-mediated mechanisms. For example, sulfonamide metabolites may play a role in triggering a T cell-mediated response to haptenated proteins.

Idiosyncratic sulfonamide hypersensitivity reactions in dogs occur at standard doses and have a reported incidence of 0.25%. Many body systems can be affected, including blood dyscrasias (immune-mediated hemolytic anemia, immune-mediated thrombocytopenia and/or neutropenia), acute hepatotoxicity, polyarthropathy (Doberman pinschers are overrepresented or predisposed to developing a sulfonamide-triggered arthropathy), cutaneous skin eruptions, keratoconjunctivitis sicca (KCS), and uveitis. Clinical symptoms occur at least 5–7 days after drug initiation and in many cases resolve with drug withdrawal. The specific clinical signs observed are dependent on the body system(s) affected but often include non-specific systemic signs, most commonly fever. These sulfonamide hypersensitivity reactions are much less common in cats and more likely include mucocutaneous ulceration and ulcerative dermatitis.

Dose-dependent side-effects of the potentiated sulfonamides in dogs include non-regenerative anemia and the inhibition of thyroid hormone synthesis. A normocytic, non-regenerative anemia may arise in dogs treated with high-dose, long-duration therapy (i.e., 30–60 mg/kg/day for eight weeks). The suspected mechanism for this non-regenerative anemia is a secondary folate deficiency arising from the simultaneous inhibition of folate synthesis by trimethoprim (inhibitor of dihydrofolate reductase) and sulfonamide (a folate analog). The degree of anemia tends to be mild to moderate and normocytic. In several species, including dogs, sulfonamides inhibit thyroid peroxidase, the enzyme needed for iodination and thyroid hormone production. Dogs undergoing prolonged therapy with a potentiated sulfonamide may be at risk for clinical hypothyroidism; however, the frequency in dogs appears variable and effects are reversible once the sulfonamide administration is discontinued.

Patients prescribed potentiated sulfonamide therapy should be monitored during therapy for adverse reactions. In addition, owners should be educated as to the clinical signs (decreased appetite, vomiting, diarrhea, lameness, lethargy, ocular changes or discharge, and dark to red urine) associated with an adverse effect to enable early intervention, including drug discontinuation. Ideally, a systemic work-up is indicated in any dog with clinical signs of a sulfonamide hypersensitivity during or following a course of therapy. Indicated diagnostics include a physical exam, ocular exam, complete blood count (CBC), biochemistry profile, urinalysis, and Schirmer test (STT). Prior to prescribing a potentiated sulfonamide to a dog, a baseline physical exam, CBC, biochemistry panel, and STT are recommended to avoid their use in dogs with KCS and to provide a baseline for comparison during and following therapy.

Tetracyclines

As a group, the tetracyclines are considered as relatively broad-spectrum antimicrobials, but the common gram-negative organisms (*E. coli*, *Klebsiella*, *Bacteroides*, *Enterobacter*, *Proteus*, and *Pseudomonas* species) develop resistance to the tetracyclines. In small animal veterinary medicine, doxycycline is the most common tetracycline used in the treatment of some tick-borne diseases, leptospirosis, or respiratory infections associated with *Bordetella bronchiseptica* or *Mycoplasma pneumoniae*.

Minocycline has previously had limited clinical use in veterinary medicine but its use may increase based on the current cost and availability of doxycycline. In people, minocycline is well tolerated, with gastrointestinal signs reported. Anecdotally, the clinical use of oral minocycline in dogs has been associated with more gastrointestinal upset (resulting in drug discontinuation) relative to doxycycline.

Minocycline has a spectrum of activity and pharmacokinetics similar to those of doxycycline. The exceptions are some MRSP isolates that are resistant to tetracycline but remain sensitive to minocycline. A tetracycline induction assay (which may not be available in all microbiology laboratories) is necessary to determine susceptibility of MRSP isolates to minocycline.

Side-effects associated with the tetracyclines may limit their use in some patient populations. Young dogs and cats may experience tooth enamel discoloration following therapy with a tetracycline. Tetracyclines have an affinity for polyvalent cations and are taken up by calcifying tissues (i.e., teeth and bone) as a fluorescent pigment. When tetracyclines are administered during tooth development, the tetracycline pigment is taken up by the enamel and dentin, resulting in permanent discoloration. Doxycycline appears to have a lower risk of tooth discoloration compared to other tetracyclines.

In cats, doxycycline has been associated with the development of esophageal strictures. In people, when capsules are retained in the esophagus, the acidity of doxycycline salts (hyclate or hydrochloride > monohydrate) can cause local esophagitis and ulceration, leading to stricture formation. A similar mechanism of stricture formation has been proposed in cats. Administering a liquid formulation versus capsules of doxycycline to cats is recommended to avoid stricture formation.

Clinically important drug interactions are also associated with orally administered tetracyclines. Tetracyclines administered in association with drugs or vitamins containing di- or tri-valent cations (e.g., calcium, magnesium, iron) result in dramatically lower oral absorption of tetracycline antimicrobials. Common drugs that contain aluminum and/or magnesium should not be co-administered with any of the tetracycline antibiotics,

including bismuth subsalicylate (Pepto-Bismol®), sucralfate, and many antacids. This interaction may be less clinically significant for doxycycline due to its lower affinity for calcium relative to other tetracyclines.

Additional Considerations

To optimize antimicrobial therapy, clinicians should have a working knowledge of the available drugs, including their spectrum of activity, clinically important side-effects, and drug–drug interactions. Prior to writing any antibiotic prescription, consideration of some important questions can help optimize clinical outcomes. Define the need for antimicrobial therapy. Is a bacterial infection suspected or identified? Define the spectrum of activity needed. Where is the site of infection? What is the most likely infecting bacterial pathogen(s)? Are additional diagnostics necessary such as culture and antimicrobial susceptibility testing? Define the patient characteristics which may limit efficacy or increase the risk for an adverse event or drug–drug interaction. Does my patient have underlying kidney or liver disease? What other drugs are being administered to this patient?

Often, in otherwise healthy patients with uncomplicated bacterial infections in which the infecting pathogen(s) are predictable (e.g., canine female lower urinary tract infections), empiric antimicrobial therapy is effective. However, bacterial culture and antimicrobial susceptibility become mandatory for any patient following their first empiric antibiotic therapeutic failure. Other clinical situations in which antimicrobial therapy becomes more complicated include patients with recurrent infections, multidrug-resistant infections, or in immunocompromised patients in which bacterial culture and antimicrobial susceptibility testing are critical to optimize efficacy and minimize further antimicrobial resistance. In cases of chronic recurrent or multidrug-resistant infection, repeating bacterial culture and antimicrobial susceptibility testing during therapy and/or following therapy becomes essential to confirm responsiveness to antimicrobial therapy and/or confirm the resolution of infection. Consensus guidelines for treatment of bacterial infections in dogs and cats are available at the International Society for Companion Animal Infectious Disease website (www.iscaid.org)

Antifungal Therapy

Daniel S. Foy, MS, DVM, DACVIM (SAIM), DACVECC

College of Veterinary Medicine, Midwestern University, Glendale, AZ, USA

Until relatively recently, treatment of systemic mycoses was limited to intravenous amphotericin B and oral ketoconazole. However, in the last two decades, significant progress has been made in the development of first-generation triazole drugs, newer second-generation triazole drugs, and echinocandins.

New antifungal therapies are often constrained by the fact that fungal organisms are eukaryotic, and therefore greater potential exists for host toxicity. For example, traditional antifungal medications that target ergosterol, or its production, can cause toxicity in mammalian cells via inhibition of cholesterol production or damage to cell membranes. Newer therapies are being directed at components unique to fungal organisms, thereby sparing mammalian cells. Although *in vitro* testing frequently finds antifungal drugs to be fungicidal, most appear to be fungistatic *in vivo*, thus the host immune system must eliminate the organisms.

Amphotericin B

Since its discovery in 1956 and increased availability in the early 1960s, amphotericin B has become, and remains, the reference treatment for invasive fungal infections. Amphotericin B is a macrocyclic polyene antibiotic originally extracted from *Streptomyces nodosus*. This drug forms micelles with fungal ergosterol, which creates channels in the fungal membrane, alters cell permeability, and allows leakage of ions and cellular components from the fungal organism. The effectiveness of amphotericin B is due to its greater affinity for ergosterol, the major sterol of fungal cell membranes, relative to cholesterol.

Effective amphotericin B treatment requires intravenous (IV) administration, with the major limiting factor in its use being cumulative nephrotoxicity; however, the only absolute contraindication to use is anaphylaxis. The cause of nephrotoxicity remains incompletely understood, but is potentially related to both direct toxicity to epithelial cell membranes and renal vasoconstriction. In people, serum creatinine is monitored during treatment; a clinically significant increase is considered a new elevation above the normal range, or an increase of greater than 20% from the baseline value.

The inherent nephrotoxicity of the original amphotericin B formulation led to the development of three new formulations: liposomal preparation, lipid complex, and colloidal dispersion with cholesterol sulfate.

Liposomal amphotericin B (lip-amB) achieves higher plasma concentrations than the original formulation; this is thought to be due to decreased uptake by the reticuloendothelial system (RES). Liposomes containing amphotericin B fuse with the fungal cell membrane, leading to fungal cell death. Lip-amB has been evaluated for safety in healthy beagle dogs, and when dosed at 1 mg/kg/day for 29 days, no azotemia was noted, and minimal renal tubular necrosis was seen on histopathology.

Amphotericin B lipid complex (ABLC) is composed of a suspension of amphotericin B complexed with two phospholipids: dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol. ABLC is taken up by the cells of the RES, and subsequently concentrates in the liver, lungs, and spleen. The lipid complexes are likely disrupted by phospholipases at sites of inflammation or infection, leading to the release of amphotericin B. Repeated dosing of up to 5 mg/kg/day in research dogs found ABLC to be 8–10-fold less nephrotoxic, on the basis of renal values and histology, than conventional amphotericin B. Importantly, although mean glomerular filtration rate (GFR) decreased over the course of treatment, only one of 10 dogs that received 8–12 mg/kg ABLC showed a decrease in GFR below the reference range.

The third lipid-incorporated preparation to be developed was amphotericin B colloidal dispersion (ABCD).

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

This formulation is composed of amphotericin B inserted between cholesterol sulfate bilayers, creating a disc-like structure. Similar to ABLC, the RES rapidly takes up ABCD. In one canine study, ABCD led to high concentrations in the bone marrow, liver, and spleen in healthy dogs, while concentrations remained low in the kidneys and lungs.

All three modified amphotericin B preparations have greater hydrophobicity, which likely results in greater delivery to the site of infection, and decreased delivery to the kidneys. All three modifications appear to maintain efficacy relative to conventional amphotericin B, while decreasing nephrotoxicity in humans. Amphotericin B remains an important treatment option in veterinary medicine, as many of the newer drugs available for people are cost-prohibitive in veterinary patients.

Azoles

The azole drugs exert their effect by inhibition of lanosterol 14-alpha demethylase, leading to ergosterol depletion and accumulation of aberrant and potentially toxic sterols in the cell membrane. Azoles are classified as imidazoles or triazoles depending on whether they possess two or three nitrogen molecules within their azole ring. Individual azole drugs are summarized in Table 115.1.

Ketoconazole

Ketoconazole was the first azole released, and is the only imidazole antifungal agent remaining in use for the treatment of systemic mycoses. It is highly lipophilic, and is ~99% plasma protein bound in humans, which impairs distribution to the brain and cerebrospinal fluid. Ketoconazole shows optimal dissolution and absorption at an acidic gastric pH in both humans and dogs, and should not be given with antacids.

In dogs, ketoconazole has been used historically to treat various systemic mycoses, including blastomycosis and histoplasmosis. Although ketoconazole has been successful in treating systemic mycoses, it should be combined with amphotericin B to yield response rates that are comparable to itraconazole alone in dogs with systemic blastomycosis. When dosed at 5–10 mg/kg/day for three weeks, ketoconazole remains an inexpensive and effective treatment for *Malassezia* dermatitis in veterinary patients.

Gastrointestinal upset or decreased appetite account for over half of the adverse events reported in dogs

Table 115.1 Summary of azole antifungal drugs, including formulation, indications, and side-effects

Drug (trade name)	Class and formulation	Indications	Side-effects
Ketoconazole (Nizoral®)	Imidazole (oral, topical)	Topical mycotic infections *Malassezia* dermatitis Third-line treatment for systemic mycoses	GI upset Dose-dependent increases in ALT Potent CYP3A inhibitor Inhibitor of p-glycoprotein Absorption impaired by antacids
Fluconazole (Diflucan®)	First-generation triazole (oral, injectable)	Candidiasis and cryptococcosis Systemic mycoses with ocular or CNS involvement Possibly first-line treatment of blastomycosis	GI upset Dose-dependent increases in ALT Requires dosage reduction in renal failure
Itraconazole (Sporanox®)	First-generation triazole (oral)	First-line for nonlife-threatening systemic mycoses that do not involve CNS	GI upset Dose-dependent increases in ALT CYP3A inhibitor Absorption impaired by antacids
Voriconazole (Vfend®)	Second-generation triazole (oral, injectable)	Invasive aspergillosis Likely efficacious against most systemic mycoses	Visual and neurologic abnormalities CYP3A inhibitor Induces its own metabolism over time in dogs
Posaconazole (Noxafil®)	Second-generation triazole (oral)	Aspergillosis, candidiasis, and cryptococcosis Limited data but likely effective against other systemic mycoses	GI upset Headache Prolongation of QT interval CYP3A inhibitor
Clotrimazole	Imidazole (topical)	Sinonasal aspergillosis *Malassezia* otitis	Poor oral bioavailability
Enilconazole	Imidazole (topical)	Sinonasal aspergillosis	Poor oral bioavailability

treated with ketoconazole, with 7% of dogs exhibiting nausea or vomiting and 5% showing only inappetence; similar signs are seen in treated cats. Hepatotoxicity and cutaneous reactions are much less frequently observed. Hepatotoxicity from ketoconazole typically manifests as mild to moderate increases in alanine aminotransferase (ALT) that are reversible with drug discontinuation.

Ketoconazole is a potent inhibitor of both the P450 enzyme CYP3A and p-glycoprotein, and therefore has many potential drug interactions. For example, ketoconazole leads to increased plasma concentrations of ivermectin and midazolam in dogs, and cyclosporine in dogs and cats. It inhibits the adrenal production of many adrenal steroids such as cortisol and testosterone, and should be avoided in breeding animals.

Fluconazole

Fluconazole is a first-generation triazole drug that was initially released in 1990 for the treatment of candidiasis and cryptococcosis. Its *in vitro* susceptibility profile suggests low potency as an antifungal agent; however, it is relatively water soluble, minimally (~10%) protein bound, and distributes well throughout the body, leading to better efficacy *in vivo*. Fluconazole effectively penetrates the blood–brain barrier, as well as the blood–ocular and blood–prostate barriers, in both people and veterinary patients. Fluconazole absorption is not affected by concurrent use of antacids, and may be a better choice in patients requiring H2 blockers or proton pump inhibitor therapy. Fluconazole also does not require food for optimal absorption. As fluconazole is approximately 70% excreted unchanged in the urine, the dosage should be reduced in patients with compromised renal function.

As in humans, fluconazole has been recommended for veterinary patients with systemic mycoses affecting the central nervous system (CNS) or eyes. Fluconazole has been used successfully in dogs and cats with cryptococcosis and blastomycosis, and the introduction of generic fluconazole has significantly reduced its cost. Moderate, reversible ALT increases have been observed in dogs receiving fluconazole for treatment of blastomycosis. Fluconazole is a teratogen in animals, and should be avoided during pregnancy.

Fluconazole is empirically prescribed at a dosage of 5–10 mg/kg per day in dogs, while cats may receive a dosage of 50 mg per day. Because of its predictable pharmacokinetics, fluconazole does not require therapeutic drug monitoring.

Itraconazole

Itraconazole is another first-generation triazole that was released in 1992, and rapidly became the oral treatment of choice for both histoplasmosis and blastomycosis in humans. Today, itraconazole remains the preferred azole in people for nonlife-threatening systemic mycoses that do not involve the CNS. It is lipophilic and is highly protein bound (>99%). Like ketoconazole, the absorption of itraconazole is diminished in the presence of antacids so it is recommended that itraconazole be administered with food, and that antacids are avoided during itraconazole therapy.

Itraconazole has become the drug of choice for treatment of systemic mycoses in dogs and cats, and is effective for the treatment of blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis. Although itraconazole does not effectively penetrate the blood–brain or blood–ocular barriers, it may achieve adequate levels to treat CNS or ocular infection when there is associated inflammation and compromise of the barriers.

Itraconazole has been dosed at 5–10 mg/kg per day, and may be administered as a single dose or divided into twice-daily dosing. The most common side-effects are gastrointestinal upset and hepatocellular toxicity. Although a loading dose of itraconazole has been suggested when starting therapy, no difference has been found with or without an initial loading dose.

Substitution with generic itraconazole has been shown to reduce plasma itraconazole concentrations to the subtherapeutic range in people, and has led to recrudescence of infection. A recent study in dogs found that neither generic nor compounded itraconazole achieved bioequivalence with branded itraconazole.

As with ketoconazole, itraconazole is an inhibitor of CYP3A and has many potential drug interactions. It has been shown to increase the concentrations of cyclosporine, digoxin, and midazolam in people. Unlike ketoconazole, itraconazole does not appear to be a significant inhibitor of cortisol or testosterone synthesis at clinically relevant doses. Itraconazole is available as an oral capsule and solution.

Newer Triazoles

Voriconazole is a second-generation triazole that is structurally similar to fluconazole. It has become the drug of choice for treatment of invasive aspergillosis in humans. Despite its similarity to fluconazole, voriconazole is poorly water soluble and moderately protein bound.

Hepatotoxicity, skin rash or eruptions, and peripheral neuropathy have been reported. Like ketoconazole and itraconazole, voriconazole is a substrate inhibitor of CYP3A, and can increase plasma concentrations of other drugs in humans. It is also teratogenic in animals and should not be used during pregnancy. In dogs, voriconazole undergoes extensive metabolism; it also induces its own metabolism over time. The *in vitro*

potency of voriconazole against veterinary fungal isolates appears to be favorable when compared to itraconazole. Voriconazole is available as an oral tablet or solution, or as an IV preparation. The use of voriconazole has been reported in cats with unilateral orbital aspergillosis; however, it has also been reported to cause neurologic deficits in cats, including ataxia, hindlimb paralysis, and visual abnormalities.

Posaconazole is a lipophilic second-generation triazole derived from itraconazole. It was approved for use in people for prophylaxis of invasive *Aspergillus* and *Candida* infections and for treatment of oropharyngeal candidiasis. Posaconazole also appears to have efficacy against *Blastomyces*, *Histoplasma*, and *Coccidioides* spp. As with itraconazole, administration of posaconazole with a meal appears to improve bioavailability; however, like fluconazole, alterations in gastric acidity do not appear to affect posaconazole absorption.

The most common adverse effects reported in human patients are headache and gastrointestinal upset; hepatotoxicity and QT interval prolongation are reported but much less common. Although posaconazole appears to have a narrower drug interaction profile, inhibition of CYP3A4 has been demonstrated in humans. Posaconazole is available only in oral formulations.

Topical Azoles

Both clotrimazole and enilconazole are classified as imidazoles within the azole class of drugs; however, both drugs have minimal systemic bioavailability due to a high first-pass effect. These drugs are thus confined to topical use, such as clotrimazole in otic suspensions for the treatment of *Malassezia* otitis in dogs and cats. Both clotrimazole and enilconazole are effective, when instilled into the nasal passages, for treating sinonasal aspergillosis in dogs; clotrimazole has also been reported to be effective in cats with nasal aspergillosis. Although some dogs require multiple treatments, more than 85% of dogs can be cured with up to three treatments.

Echinocandins

Echinocandins are a relatively new class of antifungal medications; the first compound, caspofungin, was approved by the FDA in 2001. Echinocandins inhibit glucan synthase and prevent the synthesis of beta-1,3 glucan, an essential component of the cell wall in certain fungi. In susceptible fungi, the integrity of the cell wall is compromised, leading to cell lysis.

The clinical use of the echinocandins is limited to *Candida* and *Aspergillus* spp. in human patients; *Cryptococcus neoformans* and the zygomycetes are typically resistant. The mycelial forms of *Blastomyces dermatitidis* and *Histoplasma capsulatum* appear to be susceptible to the echinocandins, although the yeast forms are not, due to the predominance of alpha-glucan, which is not a target of echinocandins, in the yeast cell wall. Echinocandins have poor oral bioavailability and are only available in intravenous formulations. The side-effects associated with echinocandins are typically minimal, with fever, gastrointestinal signs, phlebitis, and headache being most commonly reported.

Terbinafine

Terbinafine belongs to the allylamine group of antifungal agents, and is most frequently used in people for the treatment of dermatophytoses and toenail onychomycosis. Its antifungal activity is mediated via noncompetitive inhibition of squalene epoxidase, an enzyme involved in fungal ergosterol synthesis, with more than 4000-fold selectivity for fungal versus mammalian P450 enzymes. Terbinafine is very well absorbed from the gastrointestinal tract and then rapidly diffuses from the bloodstream into the dermis and epidermis. Terbinafine is highly lipophilic, which leads to its high concentration in hair follicles, skin, nail plate, and adipose tissue, with levels in the stratum corneum exceeding those in plasma by a factor of 75 within 12 days of therapy.

Terbinafine has shown high *in vitro* efficacy against many dermatophytes, including *Trichophyton* and *Tinea* spp. It has also been combined with echinocandins or triazoles in a multimodal approach to systemic mycoses in people. Side-effects are generally limited to gastrointestinal upset and, rarely, hepatotoxicity. Terbinafine is currently available in tablet form as well as a topical cream or gel.

In dogs, terbinafine has *in vitro* activity against *Microsporum* and *Trichophyton* isolates, with little evidence of acquired resistance during treatment. Terbinafine appears to be equivalent or superior to ketoconazole for the treatment of *Malassezia* dermatitis in dogs, with a reduction in both yeast counts and pruritus.

Nosocomial and Multidrug-Resistant Infections

Jason W. Stull, VMD, MPVM, PhD, DACVPM[1] *and J. Scott Weese, DVM, DVSc, DACVIM (SAIM)*[2]

[1] *Department of Veterinary Preventive Medicine, Ohio State University, Columbus, OH, USA*
[2] *Ontario Veterinary College, University of Guelph, Guelph, ON, Canada*

Nosocomial infections, typically referred to as "hospital-associated (or healthcare-associated) infections" (HAIs), are infections acquired by patients during hospitalization and are an inherent risk in veterinary medicine. In human hospitals, HAIs are a well-recognized contributor to illness and death, with substantial associated financial costs. Although veterinary data for this field are limited, similar (or even higher) HAI rates have been reported compared to human studies. Between 2003 and 2008, 82% of veterinary teaching hospitals in North America and Europe reported at least one HAI outbreak. Many of these outbreaks required restricted patient admissions or hospital closure.

Animals suffering from HAIs may have an increased hospital stay and suffer permanent health consequences (including death). Some veterinary HA pathogens can be transmitted to staff or pet owners, resulting in human illness. A wide range of pathogens may be involved in HAIs, but most of the focus is on the emerging epidemic of multidrug-resistant bacteria because of dramatic increases in infections, limited antimicrobial options, and potential public health consequences.

Perhaps most important to this topic is the assumption in human medicine that 10–70% of all HAIs are preventable. The proportion of HAIs that are preventable in veterinary medicine is unknown, but likely to be similar. The routine use of simple infection prevention practices can reduce HAIs and related multidrug-resistant organisms (MDROs).

Identification of Hospital-Associated Infections

Early identification of HAIs is critical for effective disease control and prevention. It is not unusual for veterinary HAI outbreaks to go unnoticed because of a lack of centralized data reporting or communication. Key elements of early HAI identification include a hospital-specific surveillance program and routine use of diagnostic culture and susceptibility data to establish practice-specific levels of pathogen prevalence and antimicrobial resistance.

Surveillance programs allow for early recognition of HAI transmission and outbreaks. They also provide "benchmarking" data that can be used to identify changes in disease rates (e.g., understanding the background surgical site infection rate so that any increases can be promptly investigated). These programs can also provide important information for better understanding and responding to other disease occurrences, such as MDROs. The specifics of a surveillance program will be driven by the needs and disease risks of the practice.

There are three main types of surveillance: active, passive, and syndromic. Active surveillance involves collection of data specifically for infection control purposes. This type of surveillance is expensive and time-consuming and, given the small population of susceptible patients and unclear response, not typically justifiable in a veterinary hospital. As the prevalence of MDROs increases in the animal population and more is known about HAIs, active surveillance practices may become useful in some situations. Passive surveillance involves the use of data that are already available. For example, it may be used to monitor surgical site infections by reviewing case records for surgical patients after a procedure or collating susceptibility data from urinary *E. coli* to assess empiric antimicrobial choices. Syndromic surveillance involves detection of identifiable syndromes (e.g., coughing, diarrhea). It is an easy tool for identification of certain high-risk hospitalized cases and can also identify higher-risk patients prior to admission, so that specific infection control practices can be employed.

Common Presentations and Risk Factors for HAIs

In veterinary medicine, urinary tract infections (UTIs), pneumonia, surgical site infections (SSIs), bloodstream infections (BSIs), and gastrointestinal disease (infectious diarrhea) are likely to be the most common presentations for HAIs.

Urinary Tract Infections

Catheter-associated UTIs are one of the more common HAIs in small animal veterinary medicine. Pathogens involved may be either endogenous to the patient, arising from the rectum or perineum, or from the hospital environment or people through contamination of the drainage system or bag. Biofilms (a complex structure of microorganisms and extracellular matrix) can be produced by bacteria on the surface of urinary catheters, resulting in poor antimicrobial penetration, antimicrobial resistance, and treatment failure. Catheter-associated UTIs are best prevented through careful attention to aseptic technique during placement and maintenance of urinary catheters as well as by avoidance of urinary catheterization unless necessary and at least daily reassessment of whether a urinary catheter is still required. Culture of catheters or urine from catheterized patients in the absence of clinical or cytologic evidence of disease is not recommended.

Pneumonia

Hospital-associated pneumonia has been minimally investigated in the veterinary field, in large part because of the limited use of mechanical ventilation (a major contributor in human medicine). Recumbent position, mechanical ventilation, use of endotracheal/nasogastric tubes, and factors that increase aspiration pneumonia (e.g., laryngeal or esophageal disorders and decreased mentation or recumbency) likely increase HAI risk. Recumbent, sedated, or debilitated patients may benefit from having the cranial portion of the body elevated.

Surgical Site Infections

Surgical site infections are an inherent risk of breaching the body's normal barriers and are estimated to occur in approximately 2–7% of veterinary surgical patients. Factors likely to increase SSI risk include longer duration of surgery or anesthesia, inappropriate antimicrobial therapy, greater contamination of the surgical site, endocrine disease, increased number of people in the operating room, and orthopedic surgeries and procedures with an implant. For most SSIs, the source of pathogens is the endogenous flora of the patient. Therefore, the pathogens responsible for SSIs will vary by type of surgery (e.g., gram-negative rods occurring in abdominal surgeries, staphylococci in orthopedic procedures). Methods such as clipping the patient immediately before surgery after induction, following strict aseptic technique, cleaning and care of clipper blades after each use, minimizing personnel flow in the operating room, and prudent use of antimicrobials are important in reducing the likelihood of SSIs.

Bloodstream Infections

In human medicine, most BSIs are associated with intravascular devices, with duration of catheterization being the most important risk factor. Despite this risk, studies have not found a decrease in the incidence of catheter-related (CR) BSIs with prophylactic catheter changes (e.g., every three days). The current recommendation is for catheters to be removed as soon as medically indicated, but for routine changes to be avoided, since a catheter that has remained free of complications for a few days may pose a lower risk than a newly placed catheter. A similar approach is appropriate in veterinary medicine.

Veterinary studies have revealed that jugular and intravenous catheters are frequently contaminated with enteric or environmental pathogens. Factors associated with intravenous catheter contamination in dogs and cats include longer duration of catheter placement and patient immunosuppression. Contamination may occur from the hands of people placing or handling the catheter, the patient's own flora, or the hospital environment. The use of aseptic technique, including appropriate skin preparation, hand hygiene immediately before placement, use of gloves, and minimal contact with the catheter site, is important to reduce CR HAIs. Culture of catheter insertion sites is not recommended since skin bacteria are expected to be present. As HAI outbreaks have been associated with contaminated materials used in skin preparation, all containers holding disinfectant and materials used for skin preparation should be routinely (i.e., daily to weekly) disinfected, sterilized or discarded, rather than continuously refilled.

Infectious Diarrhea

In small animal veterinary facilities, gastrointestinal HAIs may involve a number of pathogens, including *Salmonella* spp. Given the high frequency with which animals may subclinically shed gastrointestinal pathogens, efforts must be aimed at both early identification of animals at increased risk for shedding pathogens linked with HAIs (e.g., recent consumption of raw egg or meat products) and routine use of infection control practices.

Pathogens of Concern

In veterinary medicine, current knowledge of many aspects of the epidemiology of important MDROs and HA pathogens is unclear. Based on reported veterinary HA outbreaks or supposition from the human literature, several important pathogens responsible for HAIs (including MDROs) are identifiable (see later). Pathogens involved in HAIs are often opportunistic and found in healthy animals. The frequency of colonization with each pathogen likely varies with geography, animal species, and veterinary practice (in part influenced by antimicrobial use/pressure). Environmentally stable pathogens have a demonstrated clear "advantage," increasing the chance of transmission. Given the close interaction between veterinary staff and patients, as well as the often poor hand hygiene practices documented in veterinary practices, human commensals with zoonotic potential are important in veterinary HAIs. Finally, increased resistance to antimicrobials is a common feature. The specific resistance profiles and treatment options for common MDR pathogens have recently been summarized.

Staphylococcus spp.

Staphylococcus pseudintermedius and, to a lesser extent, *S. aureus* are frequently the cause of veterinary HAIs. As both are often carried in the nasopharynx, on the skin and in the gastrointestinal tracts of dogs and people (respectively), this is expected given the roles of endogenous bacteria and hands of healthcare workers in HAIs. The emergence of methicillin resistance in these species (MRSP and MRSA) has had profound implications for HAI prevention and control. Methicillin resistance is mediated by the *mecA* gene, which confers resistance to beta-lactam antimicrobials (penicillins, cephalosporins, and carbapenems); isolates are frequently resistant to additional antimicrobial classes.

Methicillin-resistant *Staphylococcus pseudintermedius* (MRSP) has rapidly spread globally in canine populations, often with high levels of antimicrobial resistance, something that is of tremendous concern as *S. pseudintermedius* is the leading opportunistic pathogen in dogs (and to a lesser degree cats). Recent prior hospitalization and beta-lactam antimicrobial administration have been associated with MRSP infections, suggesting nosocomial transmission may be a factor in MRSP disease.

Methicillin-resistant *Staphylococcus aureus* (MRSA) is less of an issue from a veterinary HAI standpoint, although its role as an important human pathogen increases concern for zoonotic transmission. Risk factors for MRSA colonization or infection in companion animals include antimicrobial use, prior hospitalization, ownership by veterinary or human healthcare workers/students, and longer hospitalization (>3 days). A high proportion of veterinarians and staff are colonized with MRSA compared to the general public, likely due to deficiencies in standard infection control and hygiene practices that allow for zoonotic transmission. As such, they may serve as a source for HAIs in their patients if infection control practices are not observed.

Escherichia coli

Escherichia coli is a common component of the commensal gastrointestinal microflora and is an important pathogen. Many community and hospitalized companion animals shed MDR *E. coli* in their feces. Factors associated with dogs shedding or acquiring MDR *E. coli* during hospitalization include duration of hospitalization (>3 days) and treatment with antimicrobials shortly before or while hospitalized. Of particular concern is the ability for some strains of *E. coli* to produce beta-lactamase, notably the extended-spectrum beta-lactamase (ESBL) producers, which provide resistance to a broad range of beta-lactam antimicrobials, including third-generation cephalosporins. Resistance to additional antimicrobial classes is not uncommon. ESBL-producing *E. coli* has been identified as the source of veterinary HAIs, occurring as SSIs and CR UTIs.

Carbapenemase-producing Enterobacteriaceae (or carbapenem-resistant Enterobacteriaceae; CRE) (including *E. coli*), conferring resistance to additional antimicrobial classes, have recently become a significant public health concern. CR *E. coli* have been identified in small animals, with suggested nosocomial transmission. This currently appears to be a rare occurrence, but one that is likely to increase as CREs increase in prevalence in the human population.

Enterococcus spp.

Enterococci are commonly found in the gastrointestinal tract of animals and humans. *E. faecium* and *E. faecalis* are most often involved in HAIs, notably in compromised hosts. Enterococci are inherently resistant to a number of antimicrobial classes, including cephalosporins, some penicillins, fluoroquinolones, clindamycin, and trimethoprim, and may acquire resistance to other antimicrobial classes. Vancomycin-resistant enterococci (VRE) are an increasing concern in human medicine. To date, VRE appear to be rare in companion animals; however, other MDR enterococci are regularly recognized and have been identified in HAIs. Enterococci are often identified as UTIs (including catheter-associated) although infections at other anatomic sites occur

(SSIs, BSIs, pneumonia). The high degree of antimicrobial resistance, ability to propagate for extended periods in small animal hosts as a commensal, and environmental persistence make enterococci particularly challenging when involved in HAIs.

Salmonella spp.

Salmonella has been identified as a source of sporadic illness and hospital-associated outbreaks in small animal hospitals. A notable concern with *Salmonella* HAIs is the occurrence of zoonotic transmission with accompanying human infections. Factors increasing the risk of *Salmonella* shedding in small animals include consumption of raw meat diets and exposure to livestock. As with *E.coli*, ESBL-producing strains are a concern for antimicrobial resistance and have been identified in small animals.

Acinetobacter spp and *Pseudomonas* spp.

As opportunistic pathogens in small animals and able to persist in the environment for extended periods, *Acinetobacter* and *Pseudomonas* are important in veterinary HAIs. Documented HAIs involving *A. baumannii* include intravenous and urinary catheters, surgical drain infections, SSIs, pneumonia, and BSIs. SSIs, including cardiovascular device infections, have been attributed to *P. aeruginosa*. Identification of hospital clusters of *Pseudomonas* infections should prompt investigation of potentially contaminated environmental, equipment (e.g., endoscope) or consumable (e.g., catheter preparation supplies) sources.

Management

Although complete prevention of HAIs and MDROs is our goal, given the nature of medicine, bacterial adaptation, and numerous mechanisms for antimicrobial resistance, it is inevitable they will continue to occur. Methods to manage MDR infections and reduce the risk of HAIs and nosocomial transmission are paramount (Box 116.1).

Efforts should be directed toward prompt identification, appropriate therapy, and infection control practices. Establishing and maintaining an infection control program is vital to integrating these efforts and protecting the health of pets and people.

Therapy

Antimicrobial therapy is an important part of the treatment of many MDROs and HAIs. Although available antimicrobial choices may be limited, the general principles of therapy are the same as for antimicrobial-sensitive pathogens: ensuring the appropriate drug (and dose) is selected based on the patient and infection. As infections caused by MDROs appear clinically identical to those caused by antimicrobial-susceptible bacteria, culture and susceptibility testing are fundamental in this process. Local therapy (e.g., topical therapy, antimicrobial-impregnated materials, intraarticular injection) is often overlooked, and in many cases can provide adequate drug levels for treatment and may be an alternative for drugs that are not an option for systemic therapy. However, the possibility of systemic absorption of locally administered drugs must be considered.

In addition to treating MDROs, it is important to prevent their development. Prudent antimicrobial use will help reduce the risk for HAIs at both the individual patient and hospital population levels. Clinicians should avoid using antimicrobials when a bacterial infection has not been confirmed by culture. Antimicrobials used in the initial treatment of an infection should be selected based on the effectiveness against the most likely organisms causing the infection and penetration into the body site affected. Guidelines are available to assist veterinarians in antimicrobial selection.

Box 116.1 Key methods to manage multidrug-resistant infections and reduce the risk of hospital-associated infections

Reduce the prevalence of MDROs in patients
- Prudent antimicrobial use
- Therapy directed by culture and susceptibility testing
- Withholding therapy (as appropriate) for patients only colonized and not infected
- Discontinue use of higher risk devices (e.g., urinary and intravenous catheters) when no longer medically required
- Infection control practices

Reduce within-hospital exposure
- Hand hygiene
- Environmental cleaning and disinfection
- Personal protective equipment (e.g., gloves, gowns)
- Cohorting patients with similar infectious disease risks
- Isolation of known or suspected infectious cases

Prompt recognition and response
- Culture and susceptibility testing
- HAI surveillance (e.g., passive surveillance for HAIs, reporting of pathogens and syndromes of interest)
- Education of staff and clients

HAI, hospital-associated infection; MDRO, multidrug-resistant organism.

Colonization versus Infection

Following exposure to an opportunistic pathogen, animals may become colonized (pathogen multiplies without tissue invasion/damage), infected (multiplies with tissue damage and often signs of clinical disease), both, or neither. In animals, decolonization therapy for MDROs has not been shown to be effective and unsuccessful attempts result in promotion of further resistance. As such, therapy should be reserved for animals with clinical disease, regardless of the MDRO involved. Animals without clinical signs of disease, assuming they are otherwise immunocompetent and expected to demonstrate clinical signs should infection occur, may be carefully monitored. Staff and clients should be informed of the colonization status of patients, as these patients may nonetheless shed the pathogen, serving as a source for HAIs or zoonotic infections.

Patient Housing

In order to protect other patients and clinic staff, attention to patient housing and animal flow is important in managing patients with MDROs. Patient cohorting entails housing together and maintaining a general flow (e.g., assigning waiting and examination areas) of patients that have similar infectious disease risks, including risk of shedding infectious organisms as well as vulnerability to infection. Additionally, animals infected or suspected to be infected with MDROs should be isolated. The specific protocols will vary with the pathogen, severity of disease, and facility, but should include use of personal protective equipment (PPE), cleaning and disinfection, and restricted personnel access. Materials and equipment used for isolation patients should be dedicated to the patient during its hospital stay, after which they should be cleaned and disinfected.

Hand Hygiene and Contact Precautions

Hand hygiene and use of PPE, such as nonsterile gloves and gowns, are simple techniques that can reduce the risk of HAIs. A number of studies indicate that veterinarians and staff typically do a poor job at performing hand hygiene between patients or using PPE when indicated; improvement in these areas is desperately needed.

Hand hygiene is described as the single most effective and underutilized infection control measure. Use of hand hygiene limits the spread of organisms between patients and between patients and staff. Biocidal soap and water and alcohol-based hand sanitizers (AHS) are most frequently used for this purpose. Individuals should ensure hands have soap or AHS contact for at least 15 seconds, paying attention to fingertips, between fingers, backs of hands and base of the thumbs, as these areas are often missed. Hand hygiene should occur before and after every animal contact and after removing gloves.

Appropriate PPE use reduces the risk of contamination of personal clothing, reduces exposure of skin and mucous membranes of veterinary staff to pathogens, and reduces transmission of pathogens between patients by veterinary personnel. The use of PPE is especially important when handling animals with known or suspected MDROs. This includes the use of a barrier gown (disposable or laboratory coat that is not worn elsewhere) and gloves. As animals with MDROs may be colonized or contaminated at locations distant to the infected site, these clothing precautions should be worn when having contact with any MDRO patient or its housing environment.

Cleaning and Disinfection

Evidence suggests environmental contamination in human hospitals increases the risk for HAIs and interventions that reduce environmental contamination reduce HAIs. This connection is less well established in veterinary medicine, but it is logical to assume that it exists. Examples of fomites that have been identified as reservoirs of HA pathogens include stethoscopes, computer keyboards, thermometers, examination tables, and floors. The role of these items in HAIs is not known but it is prudent to minimize contamination.

Several key steps must be taken to ensure a disinfectant is effective, including ensuring the surface/item is clean and the product is applied at the manufacturer's suggested dilution and contact time (amount of time the disinfectant is in contact with the item before being removed). Disinfectants should be selected based on a number of criteria including the product's spectrum of activity, susceptibility to inactivation by organic matter, and potential pathogens in the environment. Resources are available to guide disinfectant selection (see Chapter 117).

Antimicrobial resistance does not necessarily indicate further resistance to environmental disinfectants, although the consequences for inadequate removal/decontamination are greater. As such, it is prudent to consider the use of a "broad-spectrum" disinfectant (e.g., oxidizing agents), for contact surfaces of patients with HAIs or MDROs.

Zoonotic Concerns

During their careers, many veterinarians report a major animal-related injury resulting in lost work or hospitalization. Although not responsible for the majority of

these injuries, HAIs such as MDROs (e.g., MRSA, *Salmonella*) do occur. Educating staff and clients on zoonotic disease risks and enforcing hospital infection control protocols to reduce these risks will be beneficial to the health of people and patients.

Conclusion

Hospital-associated infections are reported in veterinary medicine and their frequency is likely to increase with the rise in intensive care practices. Prolonged hospitalization and the use of invasive devices and procedures increase the risk of HAIs. All staff members should be educated on the risks and signs associated with HAIs so that cases can be detected early and managed appropriately. A multifaceted approach is necessary to address HAIs and MDROs in small animal veterinary medicine, including prudent antimicrobial use, strengthening surveillance in companion animal species, improving infection control practices, instilling an infection control culture amongst veterinary staff, and improving healthcare worker and public education regarding antimicrobials.

Management of Infectious Disease in Kennels and Multicat Environments: Creating a Culture of Compliance

Frank Bossong, DVM

College of Veterinary Medicine, Western University of Health Sciences, Pomona, CA, USA

Dog kennels and multiple-cat environments exist in various types of venues. Whether a boarding facility, a cattery, dog breeding kennel, animal control shelter or humane society, challenges arise in minimizing and managing infectious disease in environments where multiple individuals co-habit in confined areas. Minimizing the risks, understanding modes of transmission, promoting prevention, taking a structured approach to disinfection, and, most importantly, creating a culture of compliance for established protocols can be helpful in the prevention and control of infectious disease in these settings. Not only will the health of the canine and feline residents be promoted, but such an approach protects the human caretaker from zoonotic disease transmission.

Risks

Some of the major risks for the spread of infectious disease include poor facility design, overcrowding, introduction of new individuals with undetermined health status, untrained/noncompliant staff, and lack of policy, procedures, and/or biologic risk management (BRM) protocols for managing infectious disease.

Overcrowding increases exposure through direct contact between animals and increases stress, which can lead to decreased immunity. Stress can also lead to reactivation of latent infection, which causes increased shedding, and increased infection across the population. The presence of younger individuals and others with naive immune systems (not fully vaccinated) makes the population more susceptible to disease outbreak. The housing of animals according to immune status should be implemented, with the naive individuals (young and/or unvaccinated) housed separately from the adults.

Minimum space requirements should be considered for each facility. The Humane Society of the United States and the Animal Welfare Act have set minimum standards to follow. Dogs in group housing should have a minimum of 4 ×4 feet of floor space per individual. Co-housed cats should have at least 10.8 square feet per cat and an additional 2.5 square feet for cats that are co-housed together. Ventilation is also important, with an optimum exchange rate of air inside a building replaced with fresh outside air 8–15 times per hour. Safe outside housing is ideal in terms of air circulation and has the added benefit of sunlight and ultraviolet light, as they reduce the number of microorganisms and can inactivate viruses, bacteria, fungi, and mycoplasma. The materials in the facility need to be nonporous to allow for proper cleaning and disinfection of surfaces.

Modes of Transmission

Understanding of the modes of transmission is helpful in determining the preventive measures that need to be taken. Aerosol transmission is affected by ventilation and distance between individuals. Oral ingestion of contaminated food/water and oral contact with inanimate objects (fomites) such as toys, cages, bedding, etc. are two of the most common routes of disease transmission. Direct contact or animal-to-animal contact (nose to nose) is also common. Vector transfer of disease via arthropods is another cause for concern. Environmental transmission necessitates proper sanitation protocols.

Prevention

Prevention is paramount to success in the management of infectious disease outbreaks. The staff and supervisors of facilities need to understand and identify the risks and then develop infection control policies and procedures for the facility and education and training protocols for the staff.

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

Upon intake to a facility, animals must be evaluated via physical exam and checking of medical records in order to identify any problem(s) that may be present and develop a preventive health plan for each animal. Staff need to be aware of the clinical signs to look for, which diagnostic tests need to be run (e.g., FeLV/FIV test, SNAP® Parvo Test) and what preventive measures need to be taken (e.g., vaccination protocol followed). If a disease is diagnosed, it is neccessary to follow a protocol on how to treat and where to house ill animals, and how to monitor for additional spread in order to succeed in managing an outbreak.

Numerous pathogens need to be addressed and understanding the agent, mode of excretion, incubation, shedding, and carrier states is key to managing them. The Koret Shelter Medicine website is one valuable resource for providing specific profiles and protocols for addressing diseases (www.sheltermedicine.com).

Along with these management strategies, prevention involves vaccination and diagnostic testing protocols and the use of proper sanitation to prevent transmission. Improving immune status of individuals should be addressed via vaccination, good nutrition, and decreasing stress. Prevention is also accomplished by screening at a designated receiving area and establishing proper isolation and quarantine areas. Staff should understand that with most diseases, isolation of 14 days is a minimal holding time for ill animals. Less than seven days is of little benefit for most infectious diseases.

Vaccination

Vaccination provides an additional safeguard to the health and well-being of cats and dogs. The *2017 American Animal Hospital Association (AAHA) Canine Vaccine Guidelines* and the *2015 World Small Animal Veterinary Association (WSAVA) Guidelines for the Vaccination of Dogs and Cats* provide a comprehensive look at which vaccines are core and noncore, and how protocols may differ between canines seen in general veterinary practice and those in shelter housing (kenneled).

For felines, the *2013 American Association of Feline Practitioners Feline Vaccine Advisory Panel Report* is an excellent resource for the core, noncore, and not recommended feline vaccinations.

Timing can be critical. In shelters, core vaccines should be given as soon as possible and if vaccination status of an incoming animal is unknown, some might argue that it is best to assume that it is unvaccinated. In boarding kennels, proper timing of vaccination (such as *Bordetella bronchiseptica*) well in advance of boarding an individual is warranted. Understanding the role of maternal immunity and how it affects vaccination protocol and proper follow-up of additional boosters in puppies and kittens is crucial for adequate protection of these individuals.

Cleaning and Disinfection

The importance of sanitation is often underestimated and even though immunization for infectious disease is a valuable tool, it is good to remember that one "cannot vaccinate one's way out of an outbreak." If the pathogen load is great enough, a vaccinated animal can still succumb to disease.

It is important to know which disinfectants are the right choices for routine disinfection protocols and what is appropriate when an outbreak occurs. Determine whether broad-spectrum activity or targeting of a specific isolated organism is needed and then choose the appropriate disinfectant, correct concentration, application, and contact time. It is important to know which disinfectants are needed to kill bacteria, enveloped viruses, nonenveloped viruses, fungus/ringworm, parasite eggs, and spores. These are listed from easiest to hardest to kill. Disinfectant failure occurs for a number of reasons. Often, the wrong choice is made for a given pathogen or there is under- or overdilution of the product. Failure to rid a surface of organic material, lack of adequate application, wrong temperature, humidity and especially lack of contact time (no less than 10 minutes with most disinfectants) are additional pitfalls to avoid. The establishment of a "disinfection action plan" includes assessment, cleaning, washing, disinfection, and evaluation. Washing is considered to be the most crucial step in the disinfection process and can result in the removal of 99% of bacteria present in a contaminated area.

Hand washing cannot be overemphasized. Human hands play a major role in the transmission of infectious disease. A "bare below the elbows" policy allows all individuals an easier opportunity to wash the hands, wrists, *and* forearms after contact with animals. Running water and soap should be provided in as many areas of a facility as possible, especially in isolation areas. Understanding the limitations of hand sanitizers is important. These alcohol-based products do not kill nonenveloped viruses like canine parvovirus and panleukopenia and are easily deactivated in the presence of organic material on unclean hands. However, the World Health Organization (WHO) recommends that these alcohol-based products are currently "the only means for rapidly and effectively inactivating a wide array of potentially harmful microorganism on hands." Personal protective equipment (PPE) is also important for staff at animal facilities as clothing is a common fomite. Using gloves, lab jackets or a designated uniform and proper disposal or decontamination of these

items are crucial to preventing the spread of pathogens. This is especially important when handling sick animals or when working in a designated isolation area.

Quaternary compounds are commonly used and some of the brand names are misleading in terms of what organisms they are effective against. The Center for Food Security and Public Health (www.cfsph.iastate.edu) provides charts of both the characteristics and antimicrobial spectrum of various products. These should be routinely used as a reference when decisions about appropriate disinfectant choice are needed. In general, quaternary compounds are *not* effective against canine parvovirus and panleukopenia, both nonenveloped viruses that can have fatal consequences for individuals in kennels and catteries respectively. The hydrogen peroxide-based oxidizing agents are effective against some of these microbes.

Bleach can be very effective but only if proper dilution, length of efficacy after mixing, and proper application protocols are followed. Concentrations greater than 1:32 can be harmful to mucous membranes, thus increasing susceptibility to disease. When cleaning and disinfecting cages, feline patients should be removed from the area when deep cleaning is involved. It is considered a standard of care to remove dogs from kennel runs when they are being sprayed down. Phenolic disinfectants ("Lysol") should not be used in catteries as they are toxic to felines.

Managing Outbreaks

Recognizing an outbreak as early as possible provides the best prevention. Controlling the outbreak requires isolation, proper diagnosis, and treatment. In an outbreak situation, an isolation area can help prevent cross-infection between animals. Separate equipment needs to be stored in this area and the correct PPE and protocols need to be followed by staff. Protective outer equipment should be used when cleaning, and it should be cleaned and changed daily. Disposable shoe covers are used when heavy infection load is suspected and thrown away after use.

Culture of Compliance

One of the biggest risks to proper disease control in kennels and multicat facilities is the lack of an established policy and procedure and the lack of staff compliance with established protocols. Staff need to be aware that their hands and fomites like clothing and equipment may be the biggest risk to the spread of disease in a facility. Outbreaks can be avoided and/or their impact minimized if good protocols exist. However, if there is no compliance from the staff, even the best protocols will be ineffective. Many protocols are ready to follow and the staff has the ability to perform them. Their motivation to do so, on the other hand, may or may not result in compliance.

The idea of establishing an "infection control culture" may be fundamental in providing effective infectious disease control. What people "read, hear, see, and talk about on a regular basis" are what characterize the idea of "culture." The "read" component would be the establishment of a written infection control manual which would be used to train new staff and which existing staff could refer to when needed. The "hear" component comes from supervisors in terms of staff updates about protocol changes and encouraging conversation about the protocol during regular staff meetings. Posters about hand washing and use of hand sanitizers, for example, help as a visual reminder. Additionally, supervisors and senior staff can serve as an example to follow, further supporting the "see" component of the equation. Giving the staff adequate time to perform hand hygiene, proper cleaning and disinfection, changing PPE and other tasks demonstrates the importance that is placed on these practices, and thereby contributes to the infection control culture. The concept of compliance is a critical factor here. As per the *Compendium of Veterinary Precautions*, "a written checklist, which specifies the frequency of cleaning, disinfection procedures, products to be used, and the staff responsible, should be developed for each area of the facility…".

Protection from Zoonotic Pathogens

The emergence of new or evolving pathogens in kennels and catteries will remain a challenge to managing disease. For example, in kennels, *Streptococcus zooepidemicus* is one such pathogen and clinical signs are similar to those of kennel cough. The bacterium is able to spread between dogs as outbreaks at kennels often affect large numbers of animal within a short time. No vaccine exists but good husbandry and isolation of infected individuals are a must. Again, early detection, isolation, and disinfection provide the best management practice and have been found to be fundamental for the control of *S. zooepidemicus* outbreaks. Good hygiene standards will also minimize the risk of transmission of *S. zooepidemicus* to dog handlers.

Conclusion

When following effective protocols for managing infectious disease in kennels and multicat environments, the outcome is not only reduced transmission from animal to animal but also the reduction of potential zoonotic transmission. Again, *S. zooepidemicus* provides an

excellent example. In order to improve control of this disease, it is crucial to raise awareness, to ensure that cases are recognized early. This will allow the implementation of suitable protocols to minimize the spread of infection along with measures to protect staff from zoonotic infection. The National Association of State Public Health Veterinarians has produced the *Compendium of Veterinary Standard Precautions* (www.nasphv.org), which provides a resource for PPE, environmental infection control, and isolation of animals with infectious diseases. Extensive resources are readily available to enhance the management of infectious disease in kennels and multicat environments. With the establishment of an infection control culture as well as a culture of compliance, the spread of infectious disease can be minimized, thus protecting the health of cats and dogs as well as their human caretakers.

Sodium (Na) and water disorders traditionally have been viewed by veterinarians as difficult concepts. An appreciation of the basic physiology underlying these concepts will facilitate their understanding. The objectives of this chapter are to review the pathophysiology of changes in volume and composition of the body fluid compartments associated with hyponatremia and hypernatremia as well as a clinical approach to fluid therapy that takes into account these changes in sodium concentration.

Water Balance Made Easy

Imagine two compartments separated by a semipermeable membrane. Each compartment has the same osmolality (number of solute particles per kilogram of solvent). If solute (without water) is added to compartment #1 without changing the volume of the compartment, the concentration of osmoles in that compartment will increase transiently. The increase in osmolality in compartment #1 will result in movement of water (by osmosis) from compartment #2 to compartment #1 until the osmolality of the two compartments is equalized. The final osmolality will be the same in both compartments, and higher than the initial osmolality.

The same concept will apply if the volume of water or number of sodium ions in body fluids is changed: water will flow from one compartment to the other in order to maintain the same osmolality in both compartments. Thus, there are only four ways to change serum sodium concentration: adding free water, removing free water, adding sodium, or removing sodium.

Hyponatremia is the most common sodium disturbance in small animals. It can result from an excess of free water (e.g., excessive water consumption, intravenous fluid therapy with hypotonic fluids, antidiuretic hormone [ADH] secretion) or from loss of sodium (in excess of water), which is rare because sodium usually is followed by water. Rare examples include salt-losing nephropathy and cerebral salt-wasting syndrome. Hyponatremia usually means that an excessive amount of water is present in body fluids, and the generalization "hyponatremia means too much water" applies in most situations. Treatment of hyponatremia requires understanding and resolution of the primary process. Conversely, the generalization "hypernatremia means not enough water" also is true most of the time. Hypernatremia may arise either as a consequence of loss of free water (i.e., evaporation from the skin or respiratory tract) or hypotonic fluid, or by the addition of sodium (e.g., intravenous fluid therapy with 0.9% saline or hypertonic saline). Treatment of hypernatremia mainly is based on slow volume replacement to avoid detrimental transcellular shifts of water, as will be discussed later.

Sodium and Water Disturbances: A Little Physiology Goes a Long Way

The Darrow–Yannet diagram (Figure 118.1) illustrates the partition of total body water (TBW) into compartments. Although some variation exists due to species, age or sex, it is estimated that:

- total body water is 60% of body weight (BW)
- total body water is divided into two compartments:
  - intracellular fluid (ICF): approximately 2/3 of TBW – 40% of body weight
  - extracellular fluid (ECF): approximately 1/3 of TBW – 20% of body weight
  - ECF is further subdivided into the interstitial compartment (3/4 of ECF) and the intravascular compartment (IV) (1/4 of ECF).

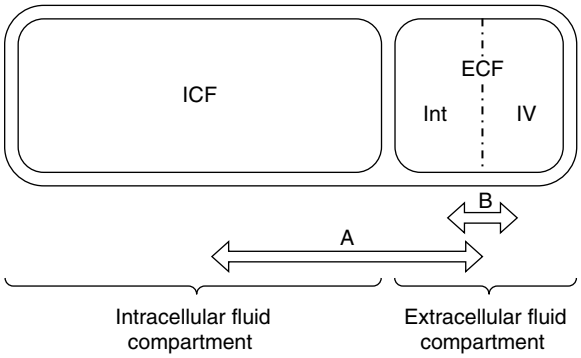

Figure 118.1 Partition of total body water (TBW) into body compartments. See text for details.

To understand changes in serum sodium concentration, it is important to remember that movement of water between ICF and ECF (arrow A on Figure 118.1) depends on osmolality, whereas movement of water within the ECF (arrow B on Figure 118.1) depends on Starling's forces, which will not be reviewed here. An estimation of osmolarity is given by the following equation:

$$\text{Plasma osmolarity}\left(\text{mOsm/L}\right) = 2\left(\text{Na}+\text{K}\right) + \text{BUN}\left(\text{mg/dL}\right)/2.8 + \text{glucose}\left(\text{mg/dL}\right)/18$$

It is noteworthy that osmolality is a function of the number of solute particles and not their molecular weight. If using international units (mmol/L) for BUN or glucose, the dividing factors shown above are not necessary. The dividing factors convert conventional units into international units by dividing the conventional units by molecular weight (i.e., 28 g/mol for urea or 180 g/mol for glucose) and multiplying by 10 to convert deciliters (dL) to liters (L). A very abundant molecule such as albumin (mean plasma concentration of 4.5 g/dL) has a minimal effect on osmolality because its molecular weight is very high (66 000 Da equivalent to a molar mass of 66 000 g/mol), which makes the particle number relatively low. Albumin contributes only approximately 0.75 mOsm/kg to plasma osmolality. By the same token, colloid osmotic pressure refers to the osmolality due to proteins, and contributes approximately 1–2 mOsm/kg. The osmolarity calculated by the equation above and expressed in mOsm/L is always lower than the osmolality measured by freezing point depression osmometry and expressed in mOsm/kg. The so-called osmolal gap is the contribution of osmoles other than sodium, potassium, urea, and glucose and usually is <10 mOsm/kg. If the osmolal gap is increased, it may be due to a large quantity of unmeasured osmoles such as mannitol or ethylene glycol and its metabolites.

Osmoregulation and Volume Regulation

Serum sodium concentration is regulated by changes in water balance, and not by changes in sodium or volume. Similarly, it is important to understand the difference between plasma osmolality and serum sodium concentration, as well as their regulation. Plasma osmolality is regulated by changes in water excretion and intake mediated by ADH secretion and thirst, whereas sodium balance is regulated by changes in sodium excretion via skin, urine, fecal, and respiratory losses. Overall, there is no predictable relationship between serum sodium concentration and ECF volume. However, serum sodium concentration and serum osmolality vary in parallel, except when a large number of *effective osmoles* is present (e.g., glucose). (Effective osmoles are those that do not move across a semipermeable membrane and thus have the potential to initiate water movement by osmosis.)

Serum osmolality is regulated by hypothalamic osmoreceptors that trigger ADH release and stimulate thirst. Antidiuretic hormone secretion in response to changes in osmolality is very sensitive, and a change of just 1% in serum sodium concentration (1–2 mEq/L) will stimulate ADH release. This very sensitive trigger means that a small change, even of 1 mEq/L, in serum sodium concentration can be abnormal for an individual patient despite being within the reference range for a patient population. Antidiuretic hormone secretion increases water reabsorption in the collecting tubules of the kidneys. In addition to hyperosmolality sensed by osmoreceptors, ADH secretion also is triggered by hypovolemia when a decrease in ECF volume is sensed by the baroreceptors (actually stretch receptors) situated in the aortic arch and carotid sinus.

Multiple receptors and effectors are involved in volume regulation. The most pertinent to sodium regulation are the natriuretic peptides and ADH. Natriuretic peptides (e.g. atrial natriuretic peptide [ANP] and brain natriuretic peptide [BNP]) are released by the atria in response to hypervolemia and promote renal sodium excretion. Antidiuretic hormone release has been described above. The renin-angiotensin-aldosterone system (RAAS), although a very potent volume regulator, does not lead to changes in serum sodium concentration. The RAAS endpoint is the release of aldosterone, which triggers isotonic fluid reabsorption in the kidneys in response to hypovolemia. Thus, aldosterone release does not lead to a change in serum sodium concentration. However, some cross-talk occurs between the RAAS and ADH secretion, with angiotensin II triggering ADH release.

Thirst is a commonly overlooked modifier of serum sodium concentration. Thirst is triggered by a variety of factors, including hypovolemia and increased plasma osmolality. Thirst mainly is regulated centrally, with some input from the cerebral cortex which influences nonessential intake (i.e., social drinking in humans), and also by the sensation of a dry mouth. The sensation of thirst is so powerful that normal subjects do not become hypernatremic despite intake of a large amount of sodium as long as they have access to enough water to drink. This is true even in patients with central diabetes insipidus (CDI), which explains the fact that such patients usually are presented with signs of polydipsia and polyuria with normal serum sodium concentration unless they lack access to water (e.g., freezing of the water source or a spilled water bowl).

Hypovolemia triggers both isotonic (via aldosterone) and hypotonic (via ADH) fluid reabsorption. Theoretically, hypotonic fluid reabsorption would generate a hypoosmolar state which would turn off ADH release, in order to maintain plasma osmolality. However, although ADH release due to changes in osmolality is very sensitive, ADH release in response to hypovolemia is very powerful, and restoration of volume will proceed at the expense of osmoregulation (i.e., hyponatremia will ensue). From an evolutionary perspective, it likely was advantageous to survival of the animal to preserve volume over normal osmolality.

Hyponatremia

Causes of Hyponatremia

Hyponatremia is a common electrolyte disorder in critically ill and hospitalized patients. It can be divided into three categories, based on osmolality and volume status (Table 118.1).

Pseudohyponatremia may occur when serum sodium concentration is determined by flame photometry, an obsolete technique by which serum sodium concentration is measured in a defined plasma volume (water and solids such as proteins and lipids). If there is a high concentration of lipids or proteins, the measured serum sodium concentration will be artificially low. This also is true if the serum sodium concentration is measured by indirect potentiometry, which is common in reference laboratories. This does not occur if an ion-selective electrode (i.e., direct potentiometry) is used, which is commonly used in point-of-care instruments.

Most hyponatremic patients fall into the hypovolemic, hypoosmolar category, with the notable exception of patients suffering from diabetes mellitus (see later). Hypovolemia causes reduction of effective circulating volume, triggering ADH secretion and free water retention. Hypovolemia occurs after gastrointestinal losses (i.e., vomiting and diarrhea), renal losses, hypoadrenocorticism, and other causes of hypovolemia.

Patients in congestive heart failure (CHF) or advanced liver failure with ascites also have decreased effective circulating volume although they have excessive total body fluid volume and are hyponatremic. In CHF, decreased "effective stroke volume" secondary, for example, to valvular disease triggers ADH release and thirst, leading to hyponatremia despite hypervolemia. The same is true in the liver failure patient, where portal hypertension leads to ascites and decreased venous return, stimulating ADH release and water retention.

Patients suffering from diabetes mellitus can have normoosmolar hyponatremia. In diabetes mellitus, the hyperosmolality resulting from a high blood glucose concentration induces a shift of water from the ICF compartment to the ECF compartment and results in serum sodium concentration dilution. This is the primary reason why hyponatremia occurs in diabetes mellitus, contrary to the common belief that it is due to a loss of sodium. Actually, osmotic diuresis leads to loss of water in excess of sodium, and potentially to hypernatremia.

Table 118.1 Categories of hyponatremia

Hypoosmolar		
Hypovolemic	**Normovolemic**	**Hypervolemic**
Addison's disease	Syndrome of inappropriate ADH secretion	Acute/chronic renal failure
Salt-losing nephropathy	Hypotonic fluid administration	Nephrotic syndrome
Cerebral salt wasting	Hypothyroidism	Congestive heart failure
Hypovolemic states:	Glucocorticoid insufficiency	Hepatic cirrhosis
Gastrointestinal loss	Psychogenic polydipsia	Accidental ingestion/injection of water
Third space loss	Reset osmostat	
Shock		
Diuretics		
Renal insufficiency		

A correction factor can be applied to correct the serum sodium concentration in diabetic patients. Traditionally, that correction factor has been reported to be 1.6–1.7 mEq/L, such that for each 100 g/dL increase in blood glucose concentration above normal, the serum sodium concentration will decrease by 1.6–1.7 mEq/L. This correction factor has been challenged in human medicine, and the correction factor may be closer to 2.4 mEq/L, and also the association between sodium and glucose concentrations is nonlinear, with a correction factor that can be up to 4.0 mEq/L if blood glucose concentration is above 400 mg/dL. The appropriate correction factor for dogs and cats is unknown.

For example, a patient with a blood glucose concentration of 1100 g/dL and serum sodium concentration between 105 and 125 mEq/L would have a "corrected serum sodium" concentration of 145 mEq/L (i.e., normal) if a correction factor of 2–4 mEq/L is used. This patient therefore is actually not suffering from hyponatremia. Alternatively, the same patient with a measured serum sodium concentration of 135 mEq/L would have a "corrected serum sodium" concentration between 155 and 175 mEq/L. Thus, such a patient actually is suffering from free water loss and should be treated accordingly. Similarly, when monitoring the changes in serum sodium concentration in diabetes mellitus, the "corrected serum sodium" concentration should be used to judge the risk of overly rapid osmotic shifts of water, because these shifts are due to changes in osmolality and should take into account the blood glucose concentration.

The syndrome of inappropriate ADH secretion (SIADH) is a common disorder in critically ill human patients and also has been described in dogs. It is common in neurologic or oncologic patients as well as after major surgery (Table 118.2). The syndrome refers to secretion of ADH that is inappropriate for the physiologic state (i.e., not secondary to hypovolemia or hyperosmolality). It is characterized clinically by normovolemia, low serum sodium concentration, and decreased urine output. The urine osmolality is high and urine sodium concentration is >20 mEq/L, indicating that the patient is not in a sodium-retaining state (i.e., not hypovolemic) and that the ADH secretion is in fact inappropriate (see Table 118.2). The decreased urine output will not respond to fluid administration, which is the first indication for the clinician faced with a patient with decreased urination, and measurements of urine sodium concentration and osmolality are necessary for the diagnosis of SIADH. The usual treatment for SIADH is fluid restriction and treatment of the primary cause, allowing the body to reset its ADH trigger (usually within 24–72 hours). Most criticalists will treat patients with SIADH using a low dosage (e.g., 0.2–0.5 mg/kg) of furosemide.

Clinical Manifestations of Hyponatremia

It is not possible to predict serum sodium concentration based on history and physical examination. Measurement of serum sodium concentration is needed as well as some other clinicopathologic data to rule out pseudohyponatremia. Clinical signs of hyponatremia are nonspecific (e.g., nausea, vomiting), and related to dysfunction of the central nervous system, such as lethargy, disorientation, and diminished reflexes. Most human patients do not manifest clinical signs until serum sodium concentration is below 125 mEq/L, although rapid decrease in serum

Table 118.2 Syndrome of inappropriate ADH secretion summary

Identify appropriate trigger • Postoperative nausea • Pain or stress • Neoplasia (common) • Pulmonary disease • Neurologic disease • Trauma • Drugs (e.g., NSAIDs, narcotics, vincristine)	Diagnosis • Plasma hypoosmolality • Normovolemia[a] (i.e., absence of hypovolemia) • Increased urine specific gravity/osmolality (>100 mOsm/kg) • Urine sodium concentration >20–40 mEq/L indicating absence of an RAAS trigger (i.e., absence of hypovolemia)[b]
Treatment • Stop/decrease fluid therapy • Treat primary trigger • May provide small dose of furosemide	Notes • Low urine output not responsive to fluid therapy • Age is a risk factor in humans • Case reports of SIADH have been published in veterinary medicine

NSAID, nonsteroidal antiinflammatory drug; RAAS, renin-angiotensin-aldosterone system; SIADH, syndrome of inappropriate ADH.
[a] Spot urine sodium concentration can be influenced by administration of steroids or diuretics, osmotic diuresis (e.g., glucosuria, mannitol administration, postobstructive diuresis), chronic kidney disease and bicarbonaturia (e.g., proximal renal tubular acidosis).
[b] A weight gain is common in SIADH (author's personal observation).

sodium concentration can lead to clinical signs such as seizures, coma, respiratory arrest or brainstem herniation.

Consequences of Chronic Hyponatremia

Maintenance of (relatively) constant serum sodium concentration and plasma osmolality is essential for maintenance of cell volume, as explained above. This is especially relevant for brain volume. If hyponatremia develops acutely (i.e., a few hours) due to rapid, massive ingestion of water, for example, an osmotic gradient will develop and water will move rapidly into the brain, increasing brain cell volume and creating severe acute brain edema and eventually death. If a similar degree of hyponatremia develops over several days, the brain cells will release electrolytes (e.g., sodium and potassium) and idiogenic osmoles (also known as osmolytes). Loss of these idiogenic osmoles, such as amino acids (e.g., glutamine, glutamate, taurine), polyols (e.g., myoinositol), and methylamines (e.g., phosphocreatinine) creates an osmotic effect that shifts free water back out of brain cells and slowly allows them to reequilibrate their volume, although it does not completely correct brain hypoosmolality. It takes hours to days for these osmolytes to be effective.

This concept is very important in the correction of hyponatremia. Actually, the major in-hospital deleterious consequence of chronic hyponatremia is mismanagement of the problem. If too rapid, the increase in serum sodium concentration provokes osmotic water movement out of the cells and brain cell shrinkage. Brain shrinkage can cause vascular rupture, leading to cerebral bleeding, and be responsible for acute neurologic signs such as seizures, impaired mental state, and even death. In addition to the immediate changes, overly rapid correction of hyponatremia (as well as rapid hypernatremia) may cause a delayed syndrome, called osmotic demyelination syndrome (ODS) or central pontine demyelination (CPD). This syndrome is characterized by irreversible neurologic damage including ataxia, paresis, dysphagia or coma and has been described in veterinary medicine.

Principles of Management of Hyponatremia

The goal of correction of chronic severe hyponatremia or hypernatremia is to minimize the change in serum sodium concentration to 0.5 mEq/L/h or a maximum of 10–12 mEq/L per day.

Acute hyponatremia can be corrected relatively quickly (1–2 mEq/L/h or more rapidly), if the clinician is certain the change is acute (e.g., acute water or salt intoxication, iatrogenic hypo- or hypernatremia). Furthermore, severe clinical signs (e.g., seizures) due to hyponatremia also can be corrected rapidly, with the goal of increasing serum sodium by 3–7 mEq/L in 1–2 hours and stopping clinical manifestations such as seizures, before resuming a slower rate of sodium correction. The rate of correction of hyponatremia should be decreased as soon as severe clinical signs have resolved (usually when serum sodium concentration is above 125–130 mEq/L).

When presented with a hyponatremic patient, it is very important for the clinician to review causes of hyponatremia, because treating the underlying cause of hyponatremia is the most important part of correcting it. The indiscriminate use of 0.9% NaCl or 3% NaCl is not warranted in all cases of hyponatremia.

History and physical examination, focused on assessment of volume status, are important. Volume status, plasma osmolality, blood glucose concentration, assessment of adrenal function, urine osmolality and urine sodium concentration will help assess the cause of hyponatremia. Urine electrolyte concentrations and urine osmolality are of paramount importance to discriminate between unrecognized low effective circulating volume (i.e., occult hypovolemia) and SIADH (see Table 118.2).

The majority of patients with hyponatremia have an associated depletion of ECF volume (i.e., loss of total body sodium). Such patients require appropriate volume replacement with isotonic fluids. Although 0.9% NaCl can be used, a balanced electrolyte solution (e.g., lactated Ringer's solution, Plasmalyte® 148) is more physiologic than 0.9% NaCl and will avoid the hyperchloremia and mild metabolic acidosis associated with administration of a large volume of 0.9% NaCl. Patients with hypoadrenocorticism should be treated with fluid therapy and mineralocorticosteroid replacement.

Only patients with symptomatic hyponatremia without evidence of hypovolemia should be treated with 0.9% NaCl and diuretics such as furosemide, combined with water restriction. This approach is used primarily in patients with liver failure. The combination of mannitol and furosemide for treatment of symptomatic hyponatremia also has been described. Patients with CHF should be treated with furosemide alone.

Sodium Deficit Calculation

The next step in management of the patient is calculation of the sodium deficit. Most clinicians use the following equation:

$$\text{Sodium deficit} = \text{body weight}\,(\text{in kg}) \times 0.6 \times (\text{normal Na} - \text{patient Na}) \quad \text{Eqn 1}$$

The sodium deficit (in mEq) should be replaced over several hours with a goal of 0.5 mEq/L/h. Sodium

replacement can be accomplished using 0.9% NaCl ([Na]= 154 mEq/L), 3% NaCl ([Na]= 513 mEq/L), 7.5% NaCl ([Na]= 1300 mEq/L) or 23.4% NaCl ([Na]= 4000 mEq/L).

For example, a 10 kg dog has a serum sodium concentration of 100 mEq/L and it is the clinician's goal to increase it to 140 mEq/L over 80 hours at a rate of 0.5 mEq/L per hour. Using Equation 1, we can calculate:

$$\text{Sodium deficit} = 10 \times 0.6 \times (140 - 100)$$

$$\text{Sodium deficit} = 240\,\text{mEq}$$

This 240 mEq of sodium should be replaced over 80 hours or at a rate of 3 mEq/hour. Using 3% NaCl, this corresponds to an infusion rate of 6 mL/h or 19.3 mL/h if 0.9% NaCl is used.

This formula is very basic and necessitates a good understanding of how to replace the sodium deficit. A number of clinicians use the following equation which provides a rate of infusion in mL/h that depends on the sodium goal, the fluid used, and the speed of correction:

$$\text{Rate of infusion}\,(\text{mL/h}) = [0.6 \times \text{body weight}\,(\text{kg}) \times (\text{desired Na} - \text{Na measured}) \times 1000] / (\text{Na content of the fluid}\,[\text{mEq/L}] \times \text{hours})$$

In the example of a 10 kg dog with a sodium deficit of 240 mEq corrected over 80 hours with 3% NaCl, this rate of infusion becomes:

$$\text{Rate of infusion}\,(\text{mL/h}) = (0.6 \times 10 \times 40 \times 1000) / (513 \times 80)$$

$$\text{Rate of infusion}\,(\text{mL/h}) = 240000 / 41040$$

$$\text{Rate of infusion}\,(\text{mL/h}) = 5.85$$

Some clinicians recommend the use of the Adrogué–Madias equation that calculates the change in sodium with the infusion of a liter of a given fluid. This equation can be used for both hyponatremia and hypernatremia:

$$\text{Change in serum Na} = (\text{Na} + \text{K in 1 L of solution} - \text{patient Na}) / (0.6 \times \text{body weight}\,[\text{kg}] + 1)$$

In our case example above (10 kg dog with a serum sodium of 100 mEq/L) using 3% NaCl, this becomes:

$$\text{Change in serum Na} = (513 - 100) / (0.6 \times 10 + 1)$$

$$\text{Change in serum Na} = 413 / 7$$

$$\text{Change in serum Na} = 59\,\text{mEq}$$

One liter of 3% NaCl will increase the patient's serum sodium concentration up to 159 (= 100 + 59) mEq/L. The goal being 140 mEq/L, the clinician will use 678 mL given over 80 hours, or an infusion rate of 8.5 mL/h. Please note that the result is slightly different than that determined by the first two equations.

For asymptomatic patients, complications may arise from the correction of hyponatremia, usually due to overzealous correction of hyponatremia and brain shrinkage. Careful calculation and monitoring of serum sodium concentration (up to every hour) are warranted to avoid such complications. If complications arise, administration of hypotonic fluids is indicated.

Hypernatremia

Hypernatremia reflects a relative excess of sodium compared to water, arising either by loss of water or from addition of salt, the latter being less common (i.e., thirst prevents development of hypernatremia after ingestion of salt as long as the animal has access to drinking water). Loss of water can be a consequence of pure water loss or hypotonic fluid loss (i.e., more water than salt).

Causes of Hypernatremia

Hypernatremia can be classified according to volume status, and in unusual circumstances according to osmolality (Table 118.3).

Hypernatremia typically is associated with water loss in excess of sodium (most common) or a salt gain (occasionally, almost always with concurrent restriction of access to water). For example, although fluid losses in diarrhea can be isosmotic overall, the combined sodium and potassium concentration of diarrhea fluid is lower than that of plasma (typically around 40–100 mEq/L of sodium and potassium combined). Thus, more free water is lost than sodium and the patient becomes hypernatremic, a very common clinical scenario. The same applies for renal losses. Loss of free water by osmotic diuresis or ADH dysregulation also is common. Usually, ADH will be released, thirst will be stimulated, and hypernatremia and hyperosmolality will be corrected.

Clinical Manifestations of Hypernatremia

The clinical signs of hypernatremia usually are vague, and neurologic in nature, including lethargy, confusion, and decreased mentation. Acute hypernatremia (e.g., ingestion of a large amount of salt water or hypertonic saline administration) can lead to seizures and death due to acute brain shrinkage. As stated earlier, if the thirst mechanism is intact and water is readily available, the animal will ingest water and not become hypernatremic. Most patients presented with severe, chronic hypernatremia have a neurologic problem that has either altered

Table 118.3 Causes of hypernatremia

Hyperosmolar			Hypoosmolar[a]
Hypovolemia	**Normovolemia**	**Hypervolemia**	**Hypoproteinemia (hypolipidemia)**
Renal losses Gastrointestinal losses (vomiting or diarrhea) Burns Osmotic diuresis • Diabetes mellitus[b] • Diabetic ketoacidosis[b] • Hyperosmolar nonketotic syndrome[b] • Mannitol infusion • Postobstructive diuresis	Hypodypsia (very rare) Diabetes insipidus (DI) (with decreased water intake) • Central DI • Congenital nephrogenic DI • Acquired nephrogenic DI Fever Decreased access to water	Salt intoxication • Iatrogenic • Sea water ingestion Hypertonic saline infusion Sodium bicarbonate infusion Primary hyperaldosteronism Hyperadrenocorticism	

[a] Pseudohypernatremia may occur when serum sodium concentration is measured by flame photometry, an obsolete technique, or indirect potentiometry, which is common in reference laboratories. These concerns are not relevant if an ion-selective electrode (direct potentiometry) is used to measure serum sodium concentration.
[b] Use corrected sodium concentration (previously discussed).

their thirst mechanism or prevented their ability to obtain and independently drink water. In patients with decreased access to water, intense thirst may be the only clinical sign, and it may subside with chronicity.

Consequences of Chronic Hypernatremia

Similarly (although in the opposite direction) to what happens in chronic hyponatremia, chronic hypernatremia induces increased production of osmolytes, leading to normalization of brain cell volume. This explains why only acute or subacute hypernatremia leads to important clinical signs. Also, clinical signs may arise after acute normalization of serum sodium concentration in patients with chronic hypernatremia, because rapid lowering of the serum sodium concentration may cause brain edema and associated clinical signs. In such cases, administration of hypertonic fluid and mannitol may be warranted.

Principles of Management of Hypernatremia

A thorough history and complete physical examination, including questions about access to water and water consumption, and careful assessment of volume status are the starting points. Ruling out diabetes mellitus is easy and inexpensive. Determination of urine osmolality is important to assess the body's response to ADH. Concentrated urine suggests extrarenal (usually gastrointestinal) water loss, whereas hypoosmolar urine indicates that the kidney is the source of free water loss, usually secondary to diabetes insipidus.

Although usually easily identified, understanding and addressing the underlying cause of hypernatremia are important. Correcting hyperosmolality usually requires slow free water administration. As mentioned earlier, chronic hypernatremia must be corrected slowly to avoid adverse cerebral fluid shifts. The recommended rate for correction of hypernatremia is identical to the correction of hyponatremia, with a maximum rate of 10–12 mEq/L per day, and a goal of 0.5–1 mEq/L per hour. Correction of hypernatremia is achieved by free water replacement.

Water Deficit Calculations

Several equations exist, but the classic water deficit equation is:

$$\text{Water deficit} = 0.6 \times \text{body weight}\,(\text{kg}) \times \left[\left(\text{Plasma Na} / \text{Normal Na}\right) - 1\right]$$

For example, for a 10 kg patient with a normal serum sodium concentration of 145 mEq/L and a current serum sodium concentration of 175 mEq/L:

$$\text{Water deficit} = 0.6 \times 10 \times \left[\left(175/145\right) - 1\right] = 1.2\,\text{L} = 1200\,\text{mL}$$

This formula estimates the amount of free water required to return this patient's serum sodium concentration to normal (i.e., 145 mEq/L). In chronic hypernatremia, the serum sodium concentration should be corrected no more rapidly than 0.5–1 mEq/L/h. The patient described earlier should receive the 1200 mL over 30–60 hours, with a free water fluid rate of of 20–40 mL/h.

As mentioned earlier, the Adrogué–Madias formula that calculates the change in serum sodium concentration with infusion of a liter of a given fluid also can be used:

$$\text{Change in serum sodium concentration} = \left(\text{Na} + \text{K content in 1 L of solution} - \text{Na measured}\right) / \left(0.6 \times \text{body weight [kg]} + 1\right)$$

In the example of a 10 kg dog and using 5% dextrose:

$$\text{Change in serum Na} = \left(0 - 175\right) / \left(0.6 \times 10 + 1\right)$$

$$\text{Change in serum Na} = -175 / 7$$

$$\text{Change in serum Na} = -25$$

This formula indicates that 1 L of 5% dextrose in water will decrease the serum sodium concentration by 25 mEq/L. To decrease it to normal (i.e., 145 mEq/L) from 175 mEq/L, 1.2 L of 5% dextrose in water will be necessary, given over 30–60 hours (at a rate of 0.5–1 mEq/L/h) and thus the infusion rate should be 20–40 mL/h.

The water deficit formula has been challenged for several reasons and may underestimate the true water deficit by as much as 50%. First, it assumes that total body water remains unchanged during hyponatremic states. Also, it does not account for low solute fluid losses (i.e., hypotonic fluids), such as urine and gastrointestinal secretions (i.e., it only accounts for free water loss). Likewise, it does not account for any ongoing hypotonic losses. The Adrogué–Madias equation results in the same volume of free water, and thus also has been challenged. The important clinical implication is that serial monitoring (q4–6h) is necessary to reevaluate serum sodium concentration and serum osmolality, and adjust the fluid infusion rate, which is invariably necessary. Ongoing losses of hypotonic fluid also can persist and make the calculation unpredictable. Some clinicians (personal communication, Dr Steve Haskins) use the quick rule of thumb that "3.7–mL/kg/h of free water will decrease the serum sodium concentration by 1 mEq/L per hour" and reassess the serum sodium concentration after 4–6 hours. For the example above, the animal would have received 37 mL/h.

As mentioned previously, acute changes in serum sodium concentration (e.g., accidental sodium loading in parenteral fluids) can be corrected more rapidly. This is also true for patients with severe clinical signs due to chronic changes in serum sodium concentration, when the serum sodium concentration can be corrected rapidly until clinical signs resolve, before adopting a more chronic approach.

The approach described earlier does not account for any isotonic fluid losses or for the patient's maintenance fluid requirement. If 0.45% NaCl is used (sodium concentration of 77 mEq/L), the rate should be adjusted because only half of this solution represents free water. The patient above should receive 36–71 mL/h, which represents a substantial volume and potentially could worsen brain edema. Thus, the lowest tonicity fluid (and hence volume) is always recommended.

If 5% dextrose in water is contraindicated (e.g., hyperglycemic patients) and only if a central venous catheter is in place, some clinicians have advocated using intravascular sterile water. When administered through a central intravenous catheter, sterile water does not cause clinically relevant intravascular hemolysis.

Shock Resuscitation of the Chronically Hypernatremic Patient

Resuscitation of volume-depleted hypernatremic patients, or those with concomitant isotonic fluid losses, should be done carefully, with the sodium content of the fluid matching the animal's serum sodium concentration within 10 mEq/L to avoid decreasing the serum sodium concentration too rapidly. Consider again the 10 kg dog with a serum sodium concentration of 175 mEq/L, and add the clinical situation of hypovolemic shock.

If lactated Ringer's solution (LRS) is used and the dog requires administration of 1 L of LRS over a one-hour period, we can calculate the impact of 1 L of LRS on the patient's serum sodium concentration. LRS has a sodium concentration of 132 mEq/L, so 75% (i.e., 132/175) of the solution is isotonic to the patient's plasma and 25% is free water. With the administration of 1000 mL of LRS, the patient actually will receive the equivalent of 250 mL of free water, decreasing its serum sodium concentration from 175 to 168 over one hour and possibly leading to cellular swelling, brain edema, seizures, and coma. The use of a fluid isotonic to the patient is necessary for shock resuscitation of a chronically hypernatremic patient. If LRS is used, the addition of 10 mL of 23.4% NaCl (4 mEq/mL of Na) to a liter of LRS will create a balanced electrolyte solution with a sodium concentration of 172 mEq/L (= 132 + 10 × 4) that will be very close to the patient's serum sodium concentration of 175 mEq/L. Once shock is treated, the clinician can focus on the free water deficit. A similar approach also can be used for shock resuscitation of the chronically hyponatremic patient.

Conclusion

A good understanding of sodium and water balance is necessary to appropriately identify and treat chronic and acute changes in serum sodium concentration in small animal patients. The proper approach is always the one of the conscientious clinician: a thorough history and complete physical examination, appropriate diagnostic

tests (including serum sodium concentration and urine electrolyte concentrations if needed), appropriate calculation of sodium (or water) deficit, and careful monitoring of changes in the serum sodium concentration and osmolality in order to avoid deleterious effects of treatment. With these concepts in mind, sodium and water balance becomes both exciting and challenging at the same time.

Disorders of Phosphorus and Magnesium

Phosphorus

Phosphorus is vital for many physiologic roles within the body, including skeletal development and structure, cell metabolism and acting as a urinary and intracellular buffer. Disorders of phosphorus homeostasis are identified with relative frequency in clinical practice and warrant consideration of their underlying etiology, careful monitoring and, in certain circumstances, will require therapeutic intervention.

Phosphorus can be found in the body in two forms: organic and inorganic (orthophosphoric and pyrophosphoric acid). Approximately 85%, of total body phosphorus is found in an organic form as hydroxyapatite ($Ca_{10}(PO_4)_6OH_2$) in bone and as fluorapatite ($Ca_5(PO_4)_3F$) in teeth. Only 14% of total body phosphorus is found intracellularly and 1% within the extracellular fluid (ECF) compartment.

Phosphorus is the principal anion in cells where it is a component of phospholipids and phosphoproteins and incorporated in the structure of nucleic acids and nucleotides. Phospholipids (e.g., phosphatidylcholine, phosphatidylserine) are an important part of the lipid bilayer of cell membranes and are required for platelet aggregation. Phosphorus can also be found in cyclic adenosine monophosphate (cAMP), which is required for intracellular signaling pathways and is incorporated in the high-energy phosphate bonds of adenosine triphosphate (ATP) and guanosine triphosphate (GTP). Within red blood cells, phosphorus is found in 2,3 diphosphoglycerate (2,3 DPG) which is responsible for the release of oxygen from hemoglobin at the tissue level.

Intracellular organic phosphorus can be readily converted to the inorganic form. Rapid translocation between the intracellular fluid and the ECF space can occur, resulting in substantial alteration in ECF concentrations. In the ECF, 70% of plasma phosphorus is in an organic form circulating as phospholipids. The remaining 30% of plasma phosphate exists in an inorganic form where it may be protein bound (10%), complexed to sodium, calcium and magnesium (5%) or circulating free as anions (85%; HPO_4^{2-}, $H_2PO_4^-$).

Regulation of Phosphorus

Homeostasis of calcium and phosphorus is intrinsically linked with many of the hormones recognized in the control of calcium also important in the regulation of phosphorus. Traditionally, it was considered that calcium was tightly regulated and that phosphorus concentrations were maintained in a reciprocal arrangement. However, it is now appreciated that independent regulation of phosphorus is also important.

Phosphorus homeostasis involves three major body organ systems: intestines, bone, and kidneys (Figure 119.1). Plasma phosphorus concentration is the composite effect of dietary phosphorus intake, gastrointestinal absorption, cellular translocation, and renal excretion. In a neutral state of phosphorus balance, daily dietary intake of phosphorus will be countered by renal excretion such that total body phosphorus concentrations vary little.

The main hormones traditionally cited in the regulation of phosphorus are parathyroid hormone (PTH) and calcitriol ($1,25(OH)_2$ cholecalciferol) (Figure 119.2). Recently, further important hormones referred to as phosphotonins have been identified. Phosphotonins, such as fibroblast growth factor 23 (FGF23), play an important role regulating renal handling of phosphorus. In a similar manner to PTH, FGF23 increases renal tubular excretion of phosphorus. However, FGF23 has an opposing action to PTH by inhibiting production of calcitriol and therefore indirectly reducing release of phosphorus from bone and decreasing absorption of phosphorus from the intestinal tract.

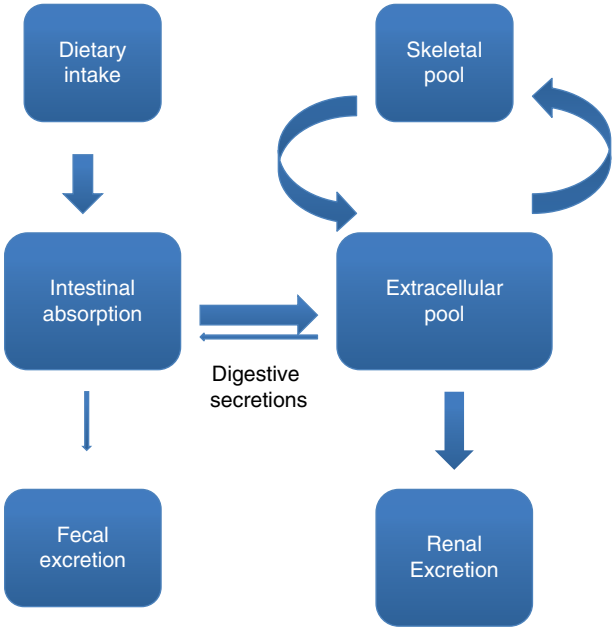

Figure 119.1 Phosphorus homeostasis in the body.

Dietary phosphorus is the main source of phosphorus for the body. Efficient absorption of phosphorus occurs in the small intestine. Phosphorus absorbed from the intestine enters the extracellular pool, with a small quantity excreted back to the intestine within digestive secretions. The skeletal and extracellular phosphorus pools are in a constant state of flux, allowing maintenance of phosphorus concentrations. Excess phosphorus absorbed from dietary intake, in health, is balanced by renal excretion in order to maintain total body phosphorus concentrations.

Regulation of phosphorus is intrinsically linked to the regulation of calcium. However, phosphorus itself has a number of direct regulatory effects.

- Increased phosphorus concentrations, by the law of mass action, result in a relative decline in ionized calcium concentration, driving production of PTH from the parathyroid gland. Phosphorus can also have a direct stimulatory effect on the parathyroid glandm increasing production of PTH.
- PTH acts on the kidney to decrease absorption of phosphate. Given that a driving factor for the production of PTH is a decrease in calcium concentration,

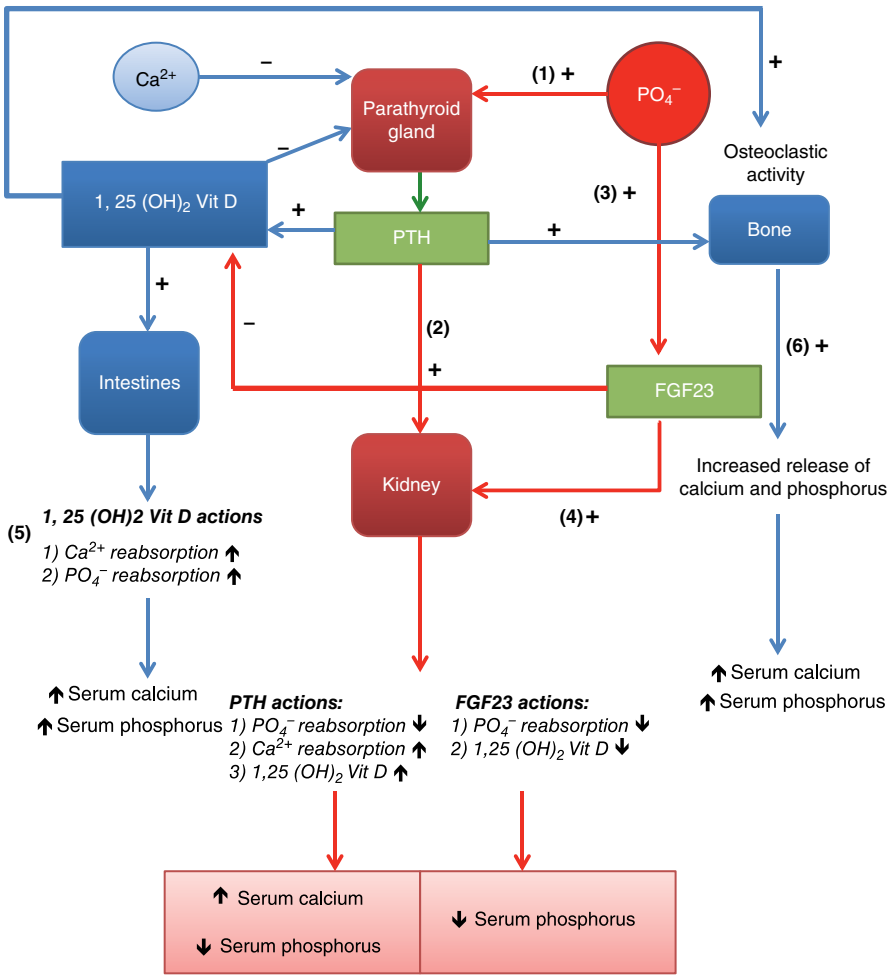

Figure 119.2 Hormonal regulation of phosphorus in health. 1,25 $(OH)_2$ Vit D, calcitriol; Ca^{2+}, calcium; FGF23; fibroblast growth factor 23; PO_4^-, phosphate; PTH, parathyroid hormone.

PTH also increases renal absorption of calcium and stimulates production of calcitriol. The net effect of PTH on the kidney is therefore a reduction in plasma phosphate and an increase in plasma calcium.

- Increased phosphorus concentration also directly stimulates osteocytes to produce the phosphotonin FGF23.
- FGF23 acts on the kidney in a similar manner to PTH, decreasing tubular absorption of phosphorus.
- Calcitriol increases absorption of both calcium and phosphorus from the small intestine. This process is facilitated indirectly by PTH, which increases renal production of calcitriol. FGF23 has an opposing action, inhibiting calcitriol production and therefore decreasing absorption of phosphorus from the intestinal tract.
- Calcitriol and PTH also increase reabsorption of calcium and phosphorus from bone.

Meat, bone, and fish are food sources high in phosphorus and dietary intake is therefore a major source of phosphorus for the body. Typical commercial canine and feline diets have a phosphorus concentration of 0.8–1.6% on a dry matter basis with a calcium to phosphorus ratio of 1.2–2.1. Most organic phosphate is hydrolyzed in the gastrointestinal tract to inorganic phosphate for absorption. Phosphate is absorbed via paracellular pathways in all regions of the small intestine. However, approximately 30% of intestinal absorption is active and occurs in the duodenum, utilizing a sodium-phosphorus co-transporter (NaPi2b). Expression and insertion of the NaPi2b co-transporter are under the control of calcitriol. A decrease in intestinal phosphate or an increase in calcitriol will increase intestinal absorption of phosphate.

Once absorbed, inorganic phosphate within the extracellular pool is exchangeable with the skeletal stores under the influence of both PTH and calcitriol. However, because proportionally only a very small amount of phosphorus is found in the ECF, measurement of plasma phosphorus concentrations does not always provide a good reflection of total body phosphorus.

Inorganic plasma phosphate that is not bound to protein is freely filtered at the glomerulus. Approximately 85% of filtered phosphate is reabsorbed by active transport in the proximal tubule, with a small amount also absorbed in the distal nephron. However, during periods of low dietary intake, efficiency can increase until almost 100% of filtered phosphate is reabsorbed. Active transport occurs via sodium-phosphate co-transporters (NaPi2a and NaPi2c) located in the brush border of proximal tubular cells. Expression of the NaPi2a co-transporter is under the control of PTH, FGF23, and intestinal phosphate absorption (Box 119.1).

Box 119.1 Regulation of phosphate handling by the kidney

In periods of phosphate excess, increase in PTH concentration favors internalization and lysosomal degradation of the NaPi2a co-transporter, thus limiting phosphate reabsorption and increasing phosphate excretion in the urine. Conversely, in periods of hypophosphatemia, decrease in PTH concentrations has a permissive role, favoring insertion and maintenance of the NaPi2a co-transporter in the proximal tubular brush border and increasing phosphate reabsorption. PTH is therefore a phosphaturic hormone promoting excretion of phosphate in the urine.

FGF23, produced by osteocytes in response to increased phosphorus concentration, also acts as a phosphaturic factor. FGF23 in conjunction with its co-factor klotho decreases expression and activity of NaPi2a co-transporter in the proximal tubular cells, thus decreasing tubular reabsorption and increasing renal excretion of phosphorus.

Other factors which can modulate and increase renal tubular phosphate reabsorption include growth hormone, thyroid hormone, insulin, insulin-like growth factor 1 (IGF-1) and 1,25 $(OH)_2$ cholecalciferol. Reabsorption can be reduced by parathyroid hormone-related protein (PTHrP), glucocorticoids, calcitonin, and atrial natriuretic peptide.

Laboratory Assessment of Phosphorus

Circulating inorganic phosphorus (Pi), which can be either free or complexed to calcium, magnesium or sodium, is the component routinely quantified by diagnostic laboratories. Serum phosphate concentrations are slightly higher than plasma phosphate concentrations due to release of phosphate from cells and platelets during the clotting process. Normal phosphate reference intervals will be laboratory dependent but values of approximately 2.5–5.5 mg/dL (0.8–1.8 mmol/L) are reported for dogs and 2.5–6.0 mg/dL (0.8–1.9 mmol/L) for cats.

It is widely recognized that young animals demonstrate elevated plasma phosphorus concentrations. This is likely to be the consequence of increased growth hormone facilitating renal tubular reabsorption of phosphate and also increased concentrations of calcitriol. In puppies up to 8 weeks of age, plasma phosphate concentrations up to 10.8 mg/dL (3.4 mmol/L) can be considered normal. However, an age-related difference in phosphorus concentrations can be present until 1 year of age. This difference is more marked in the dog than the cat.

Phosphate concentrations can be factitiously increased by lipemia, hyperproteinemia, and hemolysis and can be increased postprandially, particularly after a high-protein meal. Patients should therefore ideally be fasted for

8–12 hours prior to measurement. A number of drugs may influence plasma phosphate concentrations either as a desired therapeutic effect (e.g., intestinal phosphate binders) or as a secondary consequence of their administration (e.g., antacids including sucralfate, insulin, and dextrose).

Hypophosphatemia

Hypophosphatemia can be defined as a plasma phosphorus concentration <2.5 mg/dL (0.8 mmol/L) and can occur as a result of three main mechanisms: increased renal excretion, reduced intake or intracellular movement of phosphorus. As only ~1% of total body phosphorus is present in the ECF compartment, transcellular movement can result in marked change in plasma phosphorus concentrations which may not always accurately reflect total body phosphorus.

Clinical Signs

Patients with mild hypophosphatemia can be asymptomatic or show nonspecific signs of weakness, lethargy, and inappetence. However, severe hypophosphatemia can result in more dramatic clinical consequences including anemia, cardiac arrhythmias, depression, coma, seizures, rhabdomyolysis, and respiratory compromise. At plasma phosphorus concentrations <1 mg/dL (0.3 mmol/L), red cell hemolysis becomes a significant clinical concern due to increased fragility and decreased ATP availability.

In total body phosphate depletion, reduction in phospholipid production, loss of cell membrane integrity, decreased cellular enzyme and energy production (ATP), and loss of ion gradients maintained by Na+K+ATPases affect cellular function. This change in cellular function is not restricted to red blood cells and can cause abnormal membrane potentials, resulting in cardiac arrhythmias and neurologic dysfunction. Leukocytes may demonstrate reduced chemotactic, bactericidal, and phagocytic activity, and platelet function may also be impaired. Decreased production of 2,3 DPG can result in decreased release of oxygen from hemoglobin, causing tissue hypoxia. Decreased muscle contractility, particularly affecting the diaphragm, can lead to ventilatory compromise or in extreme hypophosphatemia, disruption of myocytes can result in rhabdomyolysis. Inappetence, nausea, and vomiting may occur as a consequence of ileus.

Conditions associated with hypophosphatemia are outlined in Box 119.2. Mild hypophosphatemia may be identified in patients at diagnosis of diabetes mellitus as a consequence of increased muscle and fat catabolism and diuresis. However, in the diabetic patient and in particular patients with diabetic ketoacidosis, the period of greatest concern with regard to hypophosphatemia is during initiation of therapy. Intravenous fluid therapy, insulin, and bicarbonate administration can all cause intracellular translocation of phosphate. Total body phosphate concentrations may be normal or reduced, but during the acute phase of therapy, severe hypophosphatemia can develop. Plasma phosphate concentrations should be closely monitored during treatment and appropriate intravenous supplementation started in order to prevent secondary consequences of severe hypophosphatemia such as hemolysis.

Box 119.2 Causes of hypophosphatemia

- Increased renal excretion
  - Diabetes mellitus*
  - Primary hyperparathyroidism*
  - Diuretic administration (carbonic anhydrase inhibitors)
  - Renal tubular disorders, e.g., Fanconi syndrome
  - Eclampsia
  - Hyperadrenocorticism
  - Hyperaldosteronism
  - Early stages of hypercalcemia of malignancy
- Decreased phosphorus intake
  - Vomiting and diarrhea
  - Malabsorption, e.g., primary intestinal disease
  - Administration of phosphate binders
  - Vitamin D deficiency (dietary imbalance, rickets)
- Transcellular shifts
  - Insulin administration and treatment of diabetic ketoacidosis*
  - Parenteral glucose administration*
  - Refeeding syndrome/total parenteral nutrition
  - Respiratory alkalosis/hyperventilation
  - Bicarbonate administration
  - Hypothermia
  - Sepsis

* Commonly identified in clinical practice.

Primary hyperparathyroidism (PHPTH) is a relatively uncommon condition in clinical practice. Clinical signs in hyperparathyroidism are often occult and when identified, usually relate to the presence of hypercalcemia or the secondary development of urolithiasis. However, plasma phosphate concentrations within the lower half or below normal reference interval are reported in 30–100% of dogs with PHPTH as a result of PTH-mediated inhibition of renal tubular phosphate reabsorption. Primary hyperparathyroidism is rare in cats and hypophosphatemia is an inconsistent finding.

Hypophosphatemia as a consequence of low dietary intake is uncommon unless there has been a period of prolonged anorexia or dietary deficiency. Rarely,

hypophosphatemia may be identified secondary to hypovitaminosis D (rickets or osteomalacia). Malabsorptive conditions, for example inflammatory bowel disease or exocrine pancreatic insufficiency, or those patients with vomiting and/or diarrhea may have increased intestinal phosphate loss. In such patients, mild hypophosphatemia can be identified but it is uncommon for marked deficiencies to be identified. Oral administration of antacid medications such as sucralfate, or intestinal phosphate binders, can effectively complex dietary phosphate within the intestine. Whilst during periods of hyperphosphatemia this may be the desired effect, inappropriate or overzealous administration can result in hypophosphatemia.

After a sustained period of anorexia, reintroduction of food without adequate phosphorus supplementation and, in particular, introduction of a high-calorie, carbohydrate-dense diet can result in refeeding syndrome. During periods of inadequate nutrition, phosphate may redistribute to the ECF in order to maintain normal plasma phosphate concentrations and hence cell membrane potentials. With refeeding, increased glucose and insulin concentrations potentiate the translocation of phosphate to the intracellular compartment with a resultant decrease in ECF phosphate concentration. Hypophosphatemia in this situation can be extreme and result in hemolysis, rhabdomyolysis, seizures, and neurologic disorders. Refeeding syndrome may be of particular concern for anorexic cats with primary or secondary hepatic lipidosis.

Treatment of Hypophosphatemia

Treatment of hypophosphatemia requires thorough assessment of the patient in order to identify and, where possible, rectify the underlying etiology. For patients where only mild hypophosphatemia is identified and further decrease is unlikely, treatment of the underlying condition, ensuring adequate nutritional intake and continued monitoring, may be sufficient.

However, phosphorus supplementation is recommended for all patients with clinical signs or hematologic abnormalities (e.g., hemolysis) associated with hypophosphatemia. Supplementation should also be considered prophylactically in those patients that are at high risk for developing severe hypophosphatemia, such as patients with diabetic ketoacidosis or those at risk of refeeding syndrome. In these situations, supplementation can be provided intravenously with either sodium phosphate or potassium phosphate as a continuous rate infusion (CRI) at 0.01–0.06 mmol/kg/h.

During intravenous phosphorus supplementation, calcium and phosphorus concentrations should be carefully monitored q6–8h and CRI dose adjusted in order to initially reach low normal phosphate concentrations (>2.0 mg/dL, >0.6 mmol/L) and subsequently to bring phosphate concentrations to the lower end of the normal reference interval. Due to concern regarding precipitation of calcium phosphate, phosphorus-containing fluids should be diluted in saline for administration. Response to supplementation is individual but gradual correction can usually be achieved over a period of hours to days.

Patients should be closely monitored for the development of hypocalcemia, tetany, and hyperphosphatemia. Hyperphosphatemia may be of particular concern during the initial phase of supplementation when pathophysiologic mechanisms that have been activated to ensure maximal phosphate retention and reduction in renal tubular excretion during a period of phosphorus repletion have not yet adapted. In patients receiving phosphorus supplementation, if the calcium:phosphorus product exceeds 60–70 mg^2/dL^2 (4.8–5.6 $mmol^2/L^2$), soft tissue mineralization and renal failure become a concern. In patients with diabetic ketoacidosis where there is evidence of both hypokalemia and hypophosphatemia, supplementation with potassium phosphate may be preferred. In this situation, approximately quarter of potassium supplementation can be administered as potassium phosphate with the remainder as potassium chloride.

Hyperphosphatemia

Hyperphosphatemia can occur as a consequence of three main mechanisms: impaired renal excretion, excessive intestinal absorption, and transcellular shift from tissue/bone to the ECF (Box 119.3).

Clinical signs as a direct consequence of hyperphosphatemia are rarely observed but can relate to relative hypocalcemia, such as weakness, neuromuscular tetany, and seizures. Hyperphosphatemia may also contribute to the risk of soft tissue mineralization if the calcium:phosphorus product exceeds 60–70 mg^2/dL^2 (4.8–5.6 $mmol^2/L^2$).

Impaired renal function, as a consequence of either chronic kidney disease (CKD) or acute kidney injury (AKI), is the most common clinical cause of hyperphosphatemia. Reduction in glomerular filtration rate (GFR) and loss of functioning nephrons result in decreased excretion of phosphorus by the kidney. In the early stages of CKD, initial phosphorus retention is countered by increased production of FGF23, reduction in calcitriol concentrations and, in later stages, increased PTH production. These compensatory mechanisms initially maintain plasma phosphate concentrations within the reference interval by promoting tubular phosphate excretion in remaining nephrons. However, with progressive loss of nephrons and decline in GFR, the compensatory mechanisms are exceeded and hyperphosphatemia ensues.

Box 119.3 Causes of hyperphosphatemia

- Impaired renal excretion
  - Renal*
    - Prerenal causes, e.g., hypoadrenocorticism
    - Renal causes, e.g., chronic kidney disease or acute kidney injury

* Commonly identified in clinical practice.

In both dogs and cats, the prevalence of hyperphosphatemia increases with advancing stages of CKD. A study in cats demonstrated that 20% of cats with compensated CKD, 49% with uremic CKD and 100% with end-stage CKD were hyperphosphatemic. Findings were similar in a group of dogs: 18% with International Renal Interest Society (IRIS) stage 1, 40% stage 2, 92% stage 3, 100% stage 4. In AKI, decline in renal function can occur without sufficient time for adequate compensatory mechanisms to develop. Severe hyperphosphatemia may therefore be identified in AKI and may be proportionally greater for the degree of reduction in GFR than identified with CKD.

Any prerenal or postrenal causes of reduced GFR, for example hypoadrenocorticism or uroabdomen/urinary tract obstruction respectively, which decrease filtration fraction and renal excretion of phosphorus, can result in hyperphosphatemia.

Studies suggest that up to 43% of cats with hyperthyroidism are hyperphosphatemic at diagnosis. In cats that remain nonazotemic, with successful treatment and return of euthyroidism, phosphorus concentrations return to normal. The exact cause of hyperphosphatemia in feline hyperthyroidism has not been fully elucidated. Thyroxine is known to directly increase renal tubular absorption of phosphate. In addition, increased bone isoenzyme alkaline phosphatase and osteocalcin as a marker of osteoblastic activity suggest that altered bone metabolism may contribute. However, in those cats that are revealed to be azotemic after return of euthyroidism, phosphate concentrations do not significantly change and in such patients reduced renal function may also be contributing.

Growth hormone can directly increase renal tubular absorption of phosphate and therefore may theoretically contribute to hyperphosphatemia in acromegaly. However, recent studies evaluating the clinicopathologic abnormaltities in larger cohorts of cats with acromegaly have not confirmed this finding.

In dogs with hypoparathyroidism, reduction in PTH concentration favors insertion of renal tubular NaPi2a co-transporters and therefore reabsorption of phosphorus. Studies suggest that ~30–100% of dogs with hypoparathyroidism demonstrate hyperphosphatemia. Hyperphosphatemia has also been reported in cats with idiopathic hypoparathyroidism although this is a rare condition. However, clinical signs in primary hypoparathyroidism usually relate to marked hypocalcemia rather than any concurrent hyperphosphatemia.

Increased intestinal absorption of phosphorus is an uncommon clinical cause of hyperphosphatemia. Ingestion of excess vitamin D, either in rodenticides containing cholecalciferol or from psoriasis creams containing calcipotriene, can cause increased release of calcium and phosphorus from bone and absorption from the intestinal tract. Absorption of phosphorus from phosphate-containing enemas has been reported to cause hyperphosphatemia in dogs and cats.

Phosphorus is found at high concentrations intracellularly. Any process that results in marked cell destruction has the potential to increase plasma phosphate concentrations. For example, hyperphosphatemia is one of a number of electrolyte abnormalities identified during tumor lysis syndrome (hyperphosphatemia, hypocalcemia, hyperkalemia, hyperuricemia, oliguric AKI). Administration of chemotherapy to a patient with a large tumor burden, that is highly sensitive to the chemotherapeutic agent or radiation dose administered, results in rapid lysis of tumoral cells and release of intracellular phosphorus to the ECF. Acute tumor lysis syndrome has previously been reported in dogs and cats with lymphosarcoma. A similar situation can occur during hemolysis, with release of phosphorus from red blood cells or during rhabdomyolysis, tissue infarction or severe crush

injuries. In rhabdomyolysis, marked myoglobinuria may cause AKI and therefore reduced renal function may also contribute to hyperphosphatemia.

Treatment of Hyperphosphatemia

Similar to the management of hypophosphatemia, the first step in the management of hyperphosphatemia is determining and, when possible, correcting the underlying etiology. Renal excretion of phosphorus should be optimized with correction of any prerenal or postrenal component. Intravenous fluid therapy to correct hypovolemia and/or dehydration and to provide mild expansion of ECF may improve renal excretion of phosphorus. In patients with AKI, dialysis may offer a way to correct electrolyte imbalances including hyperphosphatemia.

However, in those patients with CKD, restricting intestinal absorption of phosphate can control hyperphosphatemia. In early CKD (IRIS stage 2), this can be achieved using a phosphate-restricted diet. However, with advancing CKD, addition of intestinal phosphate binders may be required to achieve phosphate targets, such as aluminum hydroxide, calcium carbonate +/- chitosan, calcium acetate, lanthanum carbonate, and sevelamer hydrochloride. Dietary phosphate restriction is achieved by feeding a low-protein, low-phosphorus diet. Intestinal phosphate binders complex with dietary phosphate, producing an insoluble, nonabsorbable compound, which is excreted in the feces. For maximum efficacy, phosphate binders should therefore be administered with every meal and used in conjunction with phosphate-restricted diets.

Aluminum hydroxide is a commonly used and well-tolerated phosphate binder in canine and feline patients with CKD (30–100 mg/kg/day). Side-effects can include constipation and in human patients with end-stage kidney disease or undergoing hemodialysis, aluminum toxicity and neurotoxicity are reported. Caution is warranted when using calcium-containing phosphate binders, such as calcium carbonate, due to the potential for development of hypercalcemia, an elevated calcium phosphorus product and dystrophic mineralization. Side-effects of calcium-containing phosphate binders can also include nausea and constipation. Sevelamer hydrochloride (30–40 mg/kg PO q8h) is a resin-based phosphate binder that contains neither aluminum nor calcium. Sevelamer binds to the mucosal surface of the intestine, allowing extended periods of phosphate binding. However, its expense, gastrointestinal side-effects, and potential to bind other substances (e.g., vitamins, bile acids and cholesterol) may make it a less desired product. Lanthanum carbonate (dogs 6.25–12.5 mg/kg PO q12h; cats 400–800 mg/cat/day divided according to feeding schedule) is another nonaluminum, noncalcium-based phosphate binder, which is capable of binding phosphate at both low and high pH, being effective therefore in both the stomach and small intestine. Lanthanum undergoes biliary excretion and therefore should not accumulate in patients with compromised renal function.

Interventions to control hyperphosphatemia should be carefully monitored by serial measurement of plasma phosphate concentrations. For patients with CKD, the IRIS provides stage-specific targets for phosphate control. The effect of either introducing a phosphate-restricted diet or phosphate binder or altering dosage of a phosphate binder in patients with CKD can be relatively slow in onset due to whole-body phosphate retention. Assessment of plasma phosphate concentration after ~2–4 weeks is therefore likely to be adequate.

Magnesium

Until recently, magnesium has received relatively little attention in small animal medicine. However, magnesium is known to play a vital part in many cellular functions and the clinical consequences of alteration in magnesium homeostasis are receiving increased recognition in small animal patients, particularly within a critical care setting.

Distribution in the Body

Greater than 99% of the body's magnesium is located intracellularly, with less than 1% found within the ECF. Of the intracellular stores, ~70% is present in bone, ~20% in muscle, and ~10% other soft tissues. Within the ECF, ~55% of magnesium is ionized or free and considered the biologically active component, with a further 20–30% protein bound and 15–20% complexed to anions (e.g., phosphate or bicarbonate). The relatively smaller proportion of protein-bound magnesium in comparison to calcium means that magnesium concentrations are less likely to be influenced by changes in albumin concentration.

Biologic Importance of Magnesium

Magnesium is required in the mitochondria of cells for oxidative phosphorylation and for anaerobic metabolism of glucose. It also plays a role in the synthesis and degradation of DNA, ribosomal binding to RNA, nucleotide synthesis, and production of intracellular messengers such as cAMP.

Magnesium is an important regulator of intracellular calcium cycling in both smooth and cardiac myocytes and is therefore important for cardiac excitability, contraction, and conduction mechanisms. In vascular smooth muscle, intracellular magnesium concentrations

may contribute to peripheral vascular resistance; increased intracellular smooth muscle magnesium concentrations enhance vasorelaxation whilst conversely decreased concentrations facilitate vasoconstriction.

Magnesium is important in neuromuscular transmission and severe magnesium deficiency results in increased neuronal excitability and neuromuscular transmission. The classic neuromuscular clinical signs of hypomagnesemia are more frequently appreciated in large animal internal medicine where severe muscle tetany and seizure are identified in cattle with "grass staggers."

Magnesium is also a vital co-factor for ATP. Given that ATP is the critical energy source for many cellular ion pumps, such as Na+K+ATPase, HCO_3^-ATPase, and Ca^{2+}ATPase, variation in magnesium availability may influence the concentration of intracellular electrolytes such as calcium and potassium.

Regulation of Magnesium

Magnesium homeostasis is incompletely understood but, in a similar manner to calcium and phosphorus, gastrointestinal absorption, renal reabsorption/excretion, and exchange with skeletal stores are important factors in maintaining total body and extracellular magnesium concentrations. Absorption of magnesium in the intestine primarily occurs in the ileum, with further absorption in the jejunum and colon. Intestinal absorption of magnesium is via either a passive paracellular or active transcellular route. Active transport of magnesium in the gut is likely to involve specific magnesium transport proteins, including those from the transient receptor potential (TRP) family such asTRPM6 and TRPM7. Magnesium is freely filtered at the glomerulus but in contrast to other electrolytes, the primary site for reabsorption is the loop of Henle (60–70%), with lesser contributions in the proximal tubule (15%) and distal convoluted tubule (10–15%).

Hormonal regulation of magnesium absorption in the intestine and kidney likely occurs but remains incompletely understood. Parathyroid hormone, calcitonin, glucagon, antidiuretic hormone, aldosterone, and insulin can all increase absorption of magnesium whilst prostaglandin E2, hypokalemia, hypophosphatemia, and acidosis may all reduce magnesium reabsorption.

Laboratory Assessment of Magnesium

Making an assessment of total body hypomagnesemia can be challenging due to the high proportion of magnesium that is present within an intracellular location. Currently there is no consensus with regard to the optimal methodology to assess total body magnesium status.

Quantification of either total or ionized magnesium concentrations can be performed. However, total serum or plasma magnesium concentrations do not correlate well with signs of hypomagnesemia and may not correlate with ionized concentrations. Other factors such as albumin concentrations, sample handling, and acid–base status may influence measured total serum magnesium concentrations. As ionized magnesium equilibrates rapidly across cell membranes, it may be a more representative measure of intracellular magnesium but uncertainty exists as to whether it provides a true reflection of total body magnesium. Quantification of magnesium within red or white blood cells or muscle tissue, and assessment of renal handling of magnesium (e.g., 24-hour urinary excretion or evaluation of magnesium retention) may give further information regarding magnesium status but these methodologies are not routinely available as clinical diagnostic tests.

In those patients where clinical signs are compatible with hypomagnesemia, a low total or ionized magnesium concentration will provide support that clinical signs may be attributable to hypomagnesemia. However, it should be appreciated that intracellular hypomagnesemia can be present with normal serum total or ionized magnesium concentrations.

Hypomagnesemia

A number of clinical causes of hypomagnesemia can be identified (Box 119.4) reflecting increased gastrointestinal loss, reduced intestinal absorption, redistribution between the intracellular and extracellular compartments, or increased renal excretion. The clinical consequences of hypomagnesemia can include electrolyte and neuromuscular abnormalities and cardiac arrhythmias. However, with mild hypomagnesemia, clinical signs can be vague and attributable to general illness.

In human medicine, hypomagnesemia is a commonly reported electrolyte abnormality in critical care populations and is an independent risk factor for mortality. Studies suggest that in veterinary medicine, between 28% and 50% of cats and dogs in a critical care setting also demonstrate hypomagnesemia but information regarding any association with survival, morbidity or mortality is lacking. Other aspects of illness often identified in a critical care setting (e.g., sepsis) or associated treatments (e.g., blood transfusions due to citrate administration, intravenous fluid therapy, insulin administration) may increase a patient's predisposition to develop hypomagnesemia.

Hypomagnesemia has perhaps received most attention for the role it plays in concurrent electrolyte disturbances. Magnesium facilitates potassium leaving the intracellular compartment and enhances renal loss of

Box 119.4 Common clinical conditions associated with hypomagnesemia

- Gastrointestinal loss
  - Anorexia
  - Malabsorption/severe diarrhea
  - Short bowel syndrome
- Renal loss
  - Diabetes mellitus/diabetic ketoacidosis
  - Chronic kidney disease
  - Renal tubular acidosis
  - Drugs: loop diuretics
  - Renal transplantation
- Miscellaneous
  - Eclampsia
  - Redistribution
    - Severe pancreatitis
    - Sepsis
    - Refeeding syndrome
    - Catecholamine excess (pheochromocytoma)
    - Large-volume resuscitation with magnesium-replete fluid

potassium such that hypomagnesemia and hypokalemia occur simultaneously. Clinical signs in this situation usually reflect hypokalemia but potassium deficiency may prove refractory to therapy until magnesium levels have also been corrected. Hypocalcemia has also been reported in conjunction with hypomagnesemia.

In human patients, magnesium deficiency has been reported to contribute to the development and severity of atrial fibrillation, supraventricular tachycardia, and ventricular tachyarrhythmias. Information regarding hypomagnesemia in dogs and cats with cardiac disease is limited and the clinical importance is therefore uncertain. However, certain drugs commonly used in cardiac patients such as digoxin and loop diuretics increase magnesium loss. Patients with cardiac disease that develop hypomagnesemia may be at risk of cardiac arrhythmias, decreased cardiac contractility, and refractory hypokalemia. Consideration could therefore be given to assessment of magnesium concentrations in these situations.

Magnesium deficiency due to reduced dietary intake is unlikely, particularly if commercial diets are being fed, but could occur in patients with prolonged anorexia or severe gastrointestinal disease such as chronic diarrhea, malabsorptive disease, and short bowel syndrome. Hypomagnesemia has previously been reported in dogs with protein-losing enteropathy (PLE) and as a component of refeeding syndrome when increased cellular demand occurs in addition to chronic depletion secondary to prior anorexia.

Hypomagnesemia has also been reported in association with a number of endocrine conditions, for example, in cats with hyperthyroidism, diabetes mellitus, and diabetic ketoacidosis. However, the clinical significance of these associations is still uncertain and a study evaluating magnesium concentrations in dogs with diabetes mellitus did not find an association.

Hypomanesemia may be identified in lactating bitches although is rarely clinically significant in the healthy bitch. The prevalence of hypomagnesemia in bitches with eclampsia has been reported to be 44%.

Treatment of Hypomagnesemia

Magnesium supplementation should be considered when a patient's clinical signs are attributable to hypomagnesemia. Supplementation may also be indicated in those patients with refractory hypokalemia or hypocalcemia despite appropriate potassium and calcium supplementation respectively.

Intravenous magnesium supplementation is usually provided as magnesium sulfate or magnesium chloride. Typical dosages reported are 0.03–0.04 mEq/kg/h administered as a CRI diluted in 5% dextrose or 0.9% saline. Magnesium salt concentrations >20% should not be administered and magnesium salt solutions are not compatible with calcium- or bicarbonate-containing fluids. Careful monitoring should be performed during administration to avoid inadvertent overdosage and supplementation continued until low normal concentrations have been achieved and maintenance magnesium requirements can be provided via the patient's daily dietary intake. Caution should be exercised when providing magnesium supplementation, particularly in those patients with reduced renal function where risk of development of hypermagnesemia is increased. The value of chronic supplementation is uncertain in veterinary medicine but oral supplementation with magnesium oxide (1–2 mEq/kg/day) has been reported.

Reports of magnesium supplementation in the veterinary literature have also included patients with tetanus where supplemental magnesium may aid in reducing muscle spasm and sedative requirements, and in patients with cardiac arrhythmias where hypomagnesmia is deemed contributory.

Hypermagnesemia

The kidney excretes excess magnesium. Hypermagnesemia may occur with any marked reduction in GFR. It is rare for dogs and cats to demonstrate clinical signs associated with mild to moderate hypermagnesemia. Clinical signs reported with severe hypermagnesemia can include depression, weakness, lethargy, flaccid paralysis, and decreased reflexes. Hypotension may be

documented secondary to decreased total peripheral resistance. Bradycardia may be identified associated with prolongation of the QRS complex and an increased P-Q interval. Untreated, severe hypermagnesemia will result in ventricular fibrillation, asystole, and death.

Iatrogenic hypermagnesemia has been reported in human medicine in children associated with excessive use of magnesium-containing laxative agents and antacids. In veterinary medicine, iatrogenic hypermagnesemia has been reported in a dog and a cat due to oversupplementation. These patients demonstrated magnesium concentrations 7–9 times the normal reference interval and clinical signs including hypotension and bradycardia. This emphasizes the need for careful dose calculation and monitoring during magnesium supplementation. Increased magnesium concentrations have also been reported in dogs with hypoadrenocorticism and after surgery/anaesthesia although these changes were not clinically significant.

Treatment of hypermagnesemia depends on severity and should involve discontinuation of any supplementation being provided. Saline diuresis and administration of loop diuretics may increase magnesium renal excretion. In an acute situation with arrhythmias secondary to hypermagnesemia, calcium gluconate should be administered (50–150 mg/kg) as a bolus over 20–30 minutes to reverse cardiac toxicity. In human medicine, in certain clinical situations, dialysis may also be used for correction of hypermagnesemia.

Acute Kidney Injury

Adam E. Eatroff, DVM, DACVIM (SAIM)

ACCESS Specialty Animal Hospitals, Culver City, CA, USA

Etiology/Pathophysiology

Acute kidney injury (AKI) has classically been categorized into hemodynamic (prerenal), renal parenchymal (intrinsic), and postrenal etiologies. Hemodynamic causes include decreases in renal perfusion and/or excessive vasoconstriction, and are characterized as rapidly reversible if the inciting cause is eliminated shortly after occurrence. It is questionable whether hemodynamic changes resulting in azotemia represent true renal injury or an appropriate physiologic attempt to conserve fluid volume as a response to a reduced effective circulating blood volume. Neurohumoral responses to reductions in effective circulating volume result in a reduction in renal blood flow and, thus, glomerular filtration rate (GFR) as a means of conserving fluid volume. Regardless of whether the hemodynamic changes represent pathology or physiology, it is generally accepted that prolonged ischemia can contribute to renal parenchymal injury.

Intrinsic causes of AKI include infectious diseases, toxins, and systemic diseases with renal manifestations. Removal of the inciting cause of parenchymal injury is often the only means of directly addressing this type of insult. Postrenal AKI is due to obstruction or diversion of urine flow, including urethral obstruction, bilateral ureteral obstruction or unilateral obstruction with a nonfunctional contralateral kidney, or rupture of any portion of the urinary tract. Restoration of urine flow may rapidly reduce the concentrations of circulating uremic toxins. However, prolonged obstruction of urine flow may lead to renal parenchymal injury.

During the diagnostic evaluation for AKI, it is important to recognize that (1) the classic etiologies of AKI frequently produce insults that encompass more than one of the hemodynamic, intrinsic, or postrenal processes and (2) an etiologic cause of AKI is frequently not identified. Table 120.1 provides an extensive, but not exhaustive, list of etiologies for canine and feline AKI.

The pathophysiologic process of AKI is often multifactorial, with overlapping ischemic, inflammatory, toxic, and septic components. Classically, the clinical course of AKI proceeds through four phases. These phases are defined by experimental models of ischemic acute kidney injury and may not be representative of the multifactorial nature of the disease.

The *initiation* phase is characterized by the first stages of renal injury. Intervention at this phase may prevent progression to more severe injury, but injury at this stage occurs on a subcellular level and may not be biochemically evident. During the *extension* phase, cellular injury progresses to cell death. At this stage, biochemical derangements and clinical manifestations of disease manifest. During the *maintenance* phase, both cell death and regeneration occur simultaneously, and the potential for and length of recovery from this phase may be determined by the balance between these processes. Removal of the initiating cause at this stage does not alter the existing damage, but may allow for the balance to shift in favor of parenchymal regeneration. The *recovery* phase is characterized by improvement in GFR and tubular function; this final phase may last weeks to months.

Epidemiology

The epidemiology of AKI has not been thoroughly characterized in veterinary medicine. The difficulty in establishing the population characteristics of this disease is primarily related to the lack of a standard definition for AKI and the wide spectrum of disease (ranging from clinically undetectable, subcellular damage to fulminant, excretory failure). Table 120.1 List of etiologies for canine and feline acute kidney injury

Nephrotoxins

Antimicrobial agents
Aminoglycosides
Aztreonam
Carbapenems
Cephalosporins
Penicillins
Polymyxins
Quinolones
Rifampin
Sulfonamides
Tetracyclines
Vancomycin

Antifungal agents
Amphotericin B

Antineoplastic drugs
Cisplatin and carboplatin
Doxorubicin
Methotrexate

Antiviral agents
Aciclovir
Foscarnet

Antiprotozoal agents
Dapsone
Pentamidine
Sulfadiazine
Thiacetarsamide
Trimethoprim-sulfamethoxazole

Immunosuppressive drugs
Azathioprine
Calcineurin inhibitors (e.g., ciclosporin, tacrlimus)
Interleukin-2

Miscellaneous therapeutic agents
Acetaminophen
Allopurinol
Angiotensin enzyme converting inhibitors
Antidepressants
Apomorphine
Cimetidine
Deferoxamine
Dextran-40
Diuretics
epsilon-Aminocaproic acid
EDTA
Lipid-lowering drugs
Lithium
Methoxyflurane
Nonsteroidal antiinflammatory drugs
Penicillamine
Phosphorus-containing urinary acidifiers
Streptokinase
Tricyclic antidepressants
Vitamin D analogs

Endogenous compounds
Hemoglobin
Myoglobin (e.g., trauma/rhabdomyolysis)

Heavy metals
Antimony
Arsenic
Bismuth salts
Cadmium
Chromium
Copper
Gold
Lead
Mercury
Nickel
Silver
Thallium
Uranium

Organic compounds
Carbon tetrachloride and other chlorinated hydrocarbons
Chloroform
Ethylene glycol
Herbicides
Pesticides
Solvents

Miscellaneous nontherapeutic agents
Bee venom
Diphosphonate
Calcium antagonists
Gallium nitrate
Grapes or raisins
Illicit drugs
Lilies
Mushrooms
Radiocontrast agents
Snake venom
Sodium fluoride
Superphosphate fertilizer
Vitamin D-containing rodenticides, "Jerky treats"

Nonnephrotoxic insults

Decreased cardiac output/ischemia
Volume depletion
Congestive heart failure
Arrhythmias
Cardiac arrest
Cardiac tamponade
Fluid overload
Deep anesthesia/extensive surgery
Renal vessel thrombosis
Hyperviscosity – polycythemia
Hepatorenal syndrome

Infectious
Bacterial/fungal
Pyelonephritis
Leptospirosis
Borreliosis
Feline infectious peritonitis
Babesiosis
Leishmaniasis
Bacterial endocarditis

Immune-mediated inflammatory
Acute glomerulonephritis
Systemic lupus erythematosus
Renal transplant rejection
Vasculitis
Systemic inflammatory response syndrome
Sepsis
Disseminated intravascular coagulation

Obstructive
Ureteral obstruction
Urethral obstruction

Miscellaneous
Lymphoma
Blood transfusion reactions
Heatstroke/hyperthermia
Malignant hypertension
Neoplasia
Hypercalcemia

existed in human medicine, but has largely been overcome by the development of standardized classification schemes. The most widely accepted schemes are the Risk Injury Failure End Stage Kidney Disease (RIFLE) scheme, the Acute Kidney Injury Network (AKIN), and the Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guideline for Acute Kidney Injury. Both sets of criteria appear to perform equally well when both sensitivity for detection of AKI and predictive ability of adverse outcomes are evaluated and, therefore, these schemes have become accepted within the human nephrology community as the standard means of defining AKI for epidemiologic characterization.

There is considerable difficulty, however, with application of these criteria to veterinary AKI because both RIFLE and AKIN schemes primarily rely on relative changes in serum or plasma creatinine concentrations. In contrast to human medicine, in which most cases of AKI are hospital acquired and as such, relative changes in serum or plasma creatinine concentrations are more easily measured, most cases of veterinary AKI currently recognized are community acquired, and a baseline serum or plasma creatinine concentration is not available. Additional criteria for identification and staging of AKI exist within these schemes, but these criteria also have limitations (e.g., lack of baseline value for GFR and practical considerations of indwelling urinary collection system for monitoring of urine output). Nonetheless, recently published retrospective data collected from hospitalized dogs, utilizing a scheme similar to AKIN (Table 120.2), suggest that an association between small changes in plasma creatinine concentration (≥0.3 mg/dL) and mortality may exist.

Due to the limitations associated with defining and staging AKI based on relative changes in serum or plasma creatinine, Cowgill recently proposed a veterinary staging scheme based primarily on absolute serum or plasma creatinine concentrations (Table 120.3). This proposed scheme is being validated in a prospective study that is currently under way.

Table 120.2 Veterinary Acute Kidney Injury (VAKI) staging scheme for dogs

VAKI stage	Criteria
Stage 0	Creatinine increase <150% from baseline
Stage 1	Creatinine increase of 150–199% from baseline OR Creatinine increase of 0.3 mg/dL from baseline
Stage 2	Creatinine increase of 200–299% from baseline
Stage 3	Creatinine increase of ≥300% from baseline OR An absolute creatinine value of >4.0 mg/dL

Table 120.3 International Renal Interest Society grading scheme for acute kidney injury (AKI) (dogs and cats)

Grade	Creatinine	Clinical description
Grade I	<1.6	**Nonazotemic AKI** – Documented AKI: historical, clinical, laboratory, or imaging evidence of acute kidney injury, clinical oliguria/anuria, volume responsiveness[a] and/or – Progressive *nonazotemic* increase in serum creatinine ≥0.3 mg/dL (≥26.4 µmol/L) within 48 hours – Measured oliguria (<1 mL/kg/h) or anuria over 6 hours
Grade II	1.6–2.5	**Mild AKI** – Documented AKI and static or progressive azotemia – Progressive azotemic increase in serum creatinine ≥0.3 mg/dL (≥26.4 µmol/L) within 48 hours, or volume responsiveness[b] – Measured oliguria (<1 mL/kg/h) or anuria over 6 hours
Grade III	2.6–5.0	**Moderate to severe AKI** – Documented AKI and increasing severities of azotemia and functional failure
Grade IV	5.0–10.0	
Grade V	>10.0	

[a] Volume responsive is an increase in urine production to >1 mL/kg/h over 6 hours and/or decrease in serum creatinine to baseline over 48 hours.
[b] Each grade of acute kidney injury is further substaged on the basis of current urine production as oliguric (O) or nonoliguric (NO) and on the requirement for renal replacement therapy (RRT).

Signalment

To date, there are no studies that document an age, sex, or breed predisposition for acute kidney injury. Within certain etiologies, however, predispositions based on signalment may exist. For example, epidemiologic studies have shown an increased risk for positive *Leptospira* serology in male dogs and herding dogs, hounds, working dogs, and mixed breed dogs. German shepherds, in particular, appear to be overrepresented for leptospirosis manifesting clinical signs. Risk factors for AKI based on signalment and etiology may be more readily identified once a standard definition/classification scheme for AKI has been established.

History and Clinical Signs

Common historical findings include lethargy, vomiting, diarrhea, and anorexia, but these signs are nonspecific and may be the result of a variety of extrarenal diseases. Oliguria, anuria, or polyuria may be reported. When a patient is polyuric, compensatory polydipsia may be present, or water intake may be reduced due to anorexia.

When patients are severely affected, reports of seizures, syncope, and dyspnea may overshadow more classic presenting signs associated with AKI.

Physical examination yields few findings specific to AKI, aside from enlarged, painful kidneys. Renomegaly and renal angina are inconsistently present, however, and for some cases in which underlying chronic kidney disease is present, the kidneys are small. Dehydration is a common finding at the time of initial presentation. However, inaccurate assessment of hydration status by physical examination parameters is common, and many euhydrated and overhydrated patients are erroneously categorized as dehydrated. Other findings may include halitosis, oral ulceration, tongue tip necrosis, scleral injection, bradycardia, cutaneous bruising, peripheral edema, and melena/diarrhea. These findings may be secondary to uremia or associated with the primary disease process resulting in AKI (e.g., disseminated intravascular coagulation [DIC], vasculitis). Hypothermia is a frequent finding and, in the absence of circulatory shock, is typically associated with alteration of the hypothalamic thermoregulatory set point. Normothermia or hyperthermia may be suggestive of an infectious, inflammatory, or immune-mediated etiology.

Diagnosis

Acute kidney injury is typically diagnosed on the basis of a combination of history, physical examination findings, and the results of laboratory and imaging tests. For some patients that present with azotemia and clinical signs associated with uremia, discrimination between AKI, chronic kidney disease, or an acute kidney injury superimposed on chronic kidney disease may be difficult. For many cases in which the chronicity of disease is not readily apparent, previous laboratory work is not available for establishment of baseline renal function and imaging discloses no renal abnormalities. Therefore, subtle findings in the clinical history, physical examination, and laboratory work may prove vital in determining chronicity, which has a large influence on the appropriate diagnostic, therapeutic, and prognostic algorithms.

Laboratory Tests

The complete blood count may show hemoconcentration or anemia secondary to gastrointestinal (GI) blood loss, hemolysis, or hemodilution. The platelet count may be normal or low, although platelet count alone should not be used to determine functionality of primary hemostasis, as uremia and various infectious diseases (e.g., leptospirosis) induce a thrombocytopathy. An infectious or immune-mediated etiology should be suspected when severe leukocytosis is present.

The serum/plasma biochemistry panel may show changes specific to renal dysfunction (e.g., azotemia and hyperphosphatemia) or changes associated with multisystemic disease. The severity of azotemia depends on the etiology and duration of AKI. The ratio of blood urea nitrogen to creatinine can be high from GI bleeding or dehydration, or it can be low in early stages of AKI. The degree of hyperphosphatemia typically mirrors that of hypercreatinemia with a few exceptions (e.g., acute ethylene glycol intoxication, juvenile growing animal, refeeding syndrome). Ionized calcium concentrations are normal or low (provided that hypercalcemia is not a cause of AKI). Ethylene glycol intoxication causes a profound ionized hypocalcemia, due to both severe hyperphosphatemia and chelation of calcium by oxalate.

The anion gap is usually high secondary to retained organic and inorganic acids, but can be normal early in the course of disease, or if hypoalbuminemia is present. A high anion gap without (or prior to) the presence of azotemia is supportive of intoxication in cases of suspected ethylene glycol exposure. The anion gap is calculated by the formula:

$$\text{Anion gap} = \left(Na^+ + K^+\right) - \left(HCO_3^- + Cl^-\right)$$

where Na^+ = sodium, K^+ = potassium, HCO_3^- = bicarbonate, and Cl^- = chloride. The normal anion gap is approximately 12–26 mEq/L, with the average anion gap being 5 mEq/L higher in cats than dogs.

Urinalysis can provide information regarding the etiology and severity of AKI. Care must be taken, however, to examine urine shortly after collection to avoid artifactual changes in biochemical and cellular composition. The urine specific gravity is frequently isosthenuric (1.007–1.015) in cases of intrinsic failure. A urine dipstick may reveal any combination of glucosuria (without hyperglycemia), proteinuria, bilirubinuria, and hemoglobinuria, depending on the underlying etiology. Glucosuria is frequently present in cases of leptospirosis and AKI associated with jerky treat ingestion. Proteinuria is frequently present, but qualitative (dipstick) and quantitative (protein:creatinine ratio) severity can vary within a specific etiology. The urine pH is usually acidic, unless there is a concurrent bacterial urinary tract infection. Careful microscopic assessment of urine sediment may disclose dysmorphic red blood cells (suggestive of glomerular disease), pyuria (suggestive of nephritis), or casts (most frequently granular, but red and white blood cell casts are uncommonly observed). In human medicine, eosinouria has historically been associated with acute interstitial nephritis (secondary to a drug reaction). However, more recent publications have shown that this finding lacks the satisfactory test characteristics to make it useful in the identification of this specific etiology. Calcium oxalate crystals if present in large numbers are supportive of

ethylene glycol intoxication, although a few oxalate crystals may be present in the urine of healthy patients (crystalluria is a common *in vitro* artifact that is secondary to prolonged storage of urine prior to analysis). An in-house variation of a Romanowsky stain is frequently useful for detailed assessment of red and white blood cell morphology, as well as for the identification of bacteria. A bacterial urine culture is important to confirm the presence of a urinary tract infection and to guide antimicrobial therapy.

Imaging

Survey abdominal radiographs may show a normal renal silhouette or renomegaly, but hydronephrosis cannot be detected by radiography. Nephroliths or ureteroliths may be apparent, provided they are above the limit of detection. Although radiography and ultrasonography are typically complementary (ureteral calculi that may be obscured by gas or ingesta during ultrasonography frequently can be detected by radiography), ultrasonography typically provides more information.

Abdominal ultrasonography usually shows normal or enlarged kidneys with normal parenchymal architecture. Perirenal fluid is commonly seen with a variety of etiologies. It is important to note, however, that many (especially geriatric) patients with AKI may have underlying chronic kidney disease, which may manifest as ultrasonographic changes such as decreased corticomedullary definition, cysts, infarcts, small size, and irregular renal contour. The presence of ultrasonographic changes consistent with chronic kidney disease does not preclude the possibility of an acute injury superimposed on chronic kidney disease. Likewise, normal ultrasonographic renal architecture does not rule out the possibility of chronic kidney disease.

Oxalate crystal deposition in the kidneys increases the echogenicity with ethylene glycol intoxication, making the renal cortices and, to a lesser extent, the medulla hyperechoic. Obstruction is characterized by renal pelvic dilation or hydronephrosis. Historically, pyelonephritis has been associated with renal pelvic dilation. However, this ultrasonographic sign is associated with a variety of other lesions and is not pathognomonic for renal infection. An intravenous pyelogram can aid in the identification of pelvic, ureteral, and cystic disease processes, especially obstructive renal lesions that are not readily apparent with survey radiography or ultrasound. In addition, it can provide information regarding renal function in the contralateral kidney (i.e., if uptake of radiocontrast is not detectable in the renal parenchyma or collecting system, the likelihood of a substantial GFR in that kidney is low). If the GFR in an obstructed kidney is below a certain threshold, an intravenous pyelogram will result in inadequate study quality due to poor uptake of contrast. Antegrade pyelography may be a better choice for ureteroliths, as this technique does not rely on an adequate GFR for proper distribution of contrast material. Computed tomography or magnetic resonance imaging can add information about renal architecture and better characterize obstruction, but are infrequently utilized.

Other Diagnostic Modalities

Measurement of GFR (e.g., iohexol clearance, endogenous creatinine clearance, scintigraphy) can be expensive and some techniques are not readily available. These studies have limited applicability in the initial treatment of AKI, as the degree of impairment in GFR is almost always detectable by surrogate markers, such as serum or plasma creatinine concentration. Typically, following a diagnosis of AKI with serum or plasma creatinine and urea concentrations, no additional tests are useful in confirming that renal impairment is present or further characterizing the degree of impairment.

Leptospira serology detects antibodies produced in response to organism or vaccine exposure. There are multiple limitations to the application of this test. While there is considerable cross-reactivity among different *Leptospira* serovars, most available assays test a maximum of seven serovars and, due to the large number (>250) of potentially pathogenic serovars, this limitation may lead to false-negative test results. Titers may also be negative within the first 7–10 days of illness; a fourfold rise after 2–4 weeks is used to confirm exposure when initial titers are negative. A single titer of 1:800 or greater, with appropriate clinical signs and in the absence of recent vaccination, is also suggestive of *Leptospira* spp. exposure. However, there is a high degree of discordance in interpretation of leptospirosis among different commercial laboratories, potentially affecting interpretation of borderline results. A strong clinical suspicion for leptospirosis must be present with titers in excess of 1:800 for serovar Autumnalis, as titers often increase parallel to vaccinal serovars and with other diseases. While the microscopic agglutination test remains the gold standard for leptospira serology, new antibody detection kits are now commercially available that allow more rapid and inexpensive detection of circulating antibodies. These newer assays do not disinguish serovars.

Polymerase chain reaction assays for both blood and urine have been developed for rapid, early diagnosis in dogs, but data on their clinical utility are lacking.

Serologic tests for other infectious diseases known to cause AKI, such as Rocky Mountain spotted fever (*Rickettsia rickettsii*), *Ehrlichia canis*, Lyme disease (*Borrelia burgdorferi*), *Babesia* spp., or *Leishmania* spp., may be useful in certain areas or when there are other consistent clinical or pathologic signs, although a positive titer does not prove causality of AKI.

Cytology of tissue acquired by fine needle aspirates has limited utility in cases of AKI, but can aid in detection of an infiltrative etiology. Cytology for the diagnosis of renal lymphosarcoma may produce false-negative results. Therefore, for cases in which lymphosarcoma is suspected, histopathologic assessment of tissue may be necessary to rule out this etiology. Diagnosis of amyloidosis and feline infectious peritonitis requires special cytologic techniques (e.g., Congo red staining or coronavirus immunocytochemistry, respectively), and these diagnostic techniques have not been rigorously assessed. The risk of bleeding secondary to fine needle aspiration of the kidneys is low but possible, especially when platelet dysfunction is present.

Histopathologic samples can be obtained by percutaneous, ultrasonographically guided needle biopsy, laparoscopy, or surgical wedge biopsy. Histopathology may confirm a suspected etiology (e.g., ethylene glycol intoxication, renal lymphosarcoma) or it may disclose nonspecific findings. When AKI cannot be clinically distinguished from end-stage chronic kidney disease, histopathology (particularly Masson's trichrome stain) can aid in assessment of the severity of fibrosis and provide insight into the potential for renal recovery. The risk of significant hemorrhage secondary to renal biopsy is high when uremia is severe and platelet dysfunction is present.

Ethylene glycol intoxication is an emergency situation requiring immediate, specific therapy, which makes accurate and timely diagnosis crucial. Commercially available in-house test kits are available.

Therapy

Treatment of AKI is primarily aimed at addressing the underlying cause (if it can be identified and treated) and supportive measures to minimize the clinical sequelae of uremia. This section provides treatment recommendations for cases of severe AKI, in which severe uremic manifestations and abnormalities of acid–base, electrolyte, and fluid balance dominate the clinical picture. Specific doses for many of the drugs discussed are listed

Table 120.4 Indications, doses, adverse effects, and comments for drugs frequently used in cases of acute kidney injury

Drug	Indication	Dose	Adverse effects	Comments
Furosemide	Fluid overload, oliguria/anuria, hyperkalemia	2–5 mg/kg IV bolus, may be repeated up 3–5 times; 0.5–1 mg/kg/h CRI if urine production increased following bolus	Ototoxicity; volume depletion (unlikely if patient is monitored)	Results are frequently not satisfactory in cases of severe AKI, but adverse effects minimal so use in anuric AKI
Regular insulin	Hyperkalemia	0.5 units/kg IV or IM, may be repeated q4–6h provided hypoglycemia is avoided	Hypoglycemia	Hypokalemic effect modest and transient; IV dextrose must be administered concurrent with and following insulin administration
Dextrose	Hyperkalemia; avoidance of hypoglycemia following insulin administration	IV bolus of 2 g/unit of insulin administered; bolus followed by CRI (dextrose concentration and administration rate are dependent on serial blood glucose concentrations, patient's fluid status, and accessibility of central line)	Hyperglycemia, hyperosmolarity, hyponatremia, phlebitis with high dextrose concentrations	Dextrose should be diluted to avoid phlebitis; frequent changes in dextrose CRI often necessary based on serial blood glucose measurements
Calcium gluconate (10%)	Hyperkalemia; symptomatic hypocalcemia	0.5–1.5 mL/kg of 10% solution or 50–150 mg/kg IV slowly, to effect, while monitoring ECG, may be repeated	Worsening bradycardia and ECG changes; hypercalcemia; soft tissue mineralization	ECG should be monitored during administration; will not affect extracellular potassium concentration; effective in rapidly normalizing ECG, but results transient; administration of large volumes may contribute to soft tissue mineralization
Sodium bicarbonate	Severe acidemia	1/4 to 1/3 of the base deficit over 30–60 min followed by an additional 1/4 over the next 4–6 hours; additional dosing based on serial blood gas analyses	Paradoxic central nervous system acidosis; hypernatremia; fluid overload; hypochloremia; may cause or exacerbate hypokalemia if patient is polyuric; may exacerbate hypocalcemia	Requires close monitoring of blood gases and electrolytes for effective treatment and avoidance of adverse effects

CRI, continuous rate infusion; ECG, electrocardiogram; IM, intramuscular; IV, intravenous.

in Table 120.4. While renal replacement therapy (dialysis) is referenced, it is discussed in greater detail in Chapter 126.

Fluid Therapy

To ensure adequate tissue perfusion, extracellular fluid deficits should be corrected with a balanced polyionic solution. Ultimately, the type of fluid administered must be guided by monitoring of serum or plasma concentration of electrolytes because the degree of solute and free water balance varies widely in patients with AKI. Colloidal support may also be considered to reduce the total amount of fluid administered, if oliguria or anuria is suspected, although no benefit over crystalloid therapy has been documented in human or veterinary medicine. Goal-directed therapy to restore surrogate markers of perfusion (e.g., blood pressure, venous lactate concentration, venous oxygen saturation) should be employed with endpoints set to be reached within 24 hours. If oliguria or anuria persists despite achievement of normal surrogate markers of perfusion, additional fluid administration is more likely to result in fluid overload than urine production. Avoidance of fluid overload (typically defined as fluid accumulation >10% of baseline body weight) is essential, as there is ample evidence documenting the association between fluid overload and worse clinical outcomes.

Maintenance fluid administration (both volume and composition) should be guided by the volume and composition of urine produced, as well as ongoing sensible losses (vomitus, diarrhea, and yield from gastric suction) and insensible loss (respiration, formed stool). Urine volume can be determined by a variety of methods, including:

- indwelling urinary catheter and closed collection system
- collection of naturally voided urine
- metabolic cage
- weighing cage bedding and litter pans (1 mL of urine = 1 g)
- using body weight prior to and immediately following urination.

Urine production can be categorized as anuria (none to negligible amount), oliguria (<0.5 mL/kg/h), or polyuria (>2 mL/kg/h). Insensible losses can be estimated between 12 and 29 mL/kg/day and are dependent on a variety of factors, such as species, patient activity, and body temperature. Careful attention must be given to serial changes in the patient's body weight, as peracute fluctuations in weight are most likely due to changes in fluid balance rather than changes in lean muscle or fat content.

Once the patient's fluid deficit has been corrected, care must be taken to maintain a neutral fluid balance, as well as normal surrogate markers of perfusion. Consideration of the fluid load with enteral and parenteral nutrition and medication, as well as intravenous catheter flushes, is essential to avoidance of fluid overload, and the fluid volume administered with these treatments should be incorporated into the fluid plan. High-maintenance fluid rates have been historically advocated for cases of AKI based on the rationale that high-volume fluid administration beyond that which is necessary to restore normal volume status will improve GFR. However, there is no evidence supporting this claim and, in the author's experience, this practice is often futile in restoring GFR and frequently results in fluid overload.

Maintenance fluid therapy for an anuric, euhydrated patient should consist of replacement of insensible losses only. Frequently, this fluid requirement is achieved in excess by administration of medications, nutrition, and catheter flushes alone and the administration of these treatments may promote fluid overload. If the patient is diagnosed with fluid overload, all fluid therapy should be withheld. Fluid overload with concurrent oliguria or anuria is a clear indication for dialysis.

Monitoring fluid status is an ongoing process that must be repeated frequently. Efforts should be made to adhere to objective monitoring parameters (e.g., body weight, venous lactate concentration, urine production) of fluid status because subjective parameters, (e.g., skin turgor, saliva production) are inaccurate and often affected by variables other than hydration status. Body weight should be measured at least twice daily to assess for trends in fluid accumulation or deficit. Central venous pressure measurement has traditionally been recommended as a surrogate marker of cardiac preload, and thus fluid status. However, a thorough understanding of the limitations of this technique is necessary for appropriate interpretation, as the correlation between central venous pressure and clinical manifestations of fluid overload is increasingly recognized as flawed.

Diuretics

The use of diuretics in the treatment of AKI is a controversial topic in both human and veterinary medicine. Many of the benefits of the most commonly used diuretics in veterinary AKI, furosemide and mannitol, have only been theorized or demonstrated in experimental models of AKI. In fact, there is little or no clinical evidence in human or veterinary medicine that diuretics improve outcome in established AKI. It has been postulated that the ability to respond to diuretics is a marker of less severe renal injury associated with a better prognosis. However, an increase in urine output after diuretic administration does not necessarily coincide with an increase in uremic solute excretion and, therefore, does not preclude the need for dialysis if severe uremia or acid–base and electrolyte abnormalities persist.

In veterinary medicine, because dialysis is not readily available, diuretic administration plays a large role in volume management. Conversion from an oliguric or anuric state to normal urine production or polyuria may enhance the clinician's ability to prevent or manage fluid overload and thus allow administration of necessary parenteral medications and nutrition that would otherwise contribute to fluid overload. No class of diuretics has been proven to be superior to another. However, the use of loop diuretics predominates in both human and veterinary AKI due to the relatively high efficacy and safety margin of these drugs, compared to the osmotic diuretics. For this reason, the author does not recommend the use of mannitol as a diuretic for AKI.

Acid–Base Balance

Metabolic acidosis is a frequent complication in AKI of varying severities, and is due to the damaged nephron's inability to excrete hydrogen ions and reabsorb bicarbonate ions, as well as lactic acidosis secondary to compromised tissue perfusion (i.e., either volume deficit or excess). Once perfusion has been restored, provision of supplemental alkali, usually in the form of parenteral sodium bicarbonate, should be considered if severe acidemia (pH <7.2, bicarbonate <12 mmol) persists. The bicarbonate dosage can be calculated from the formula:

$$0.3 \times \text{body weight}\ (\text{kg}) \times \text{base deficit} = \text{bicarbonate}\ (\text{mEq/L})$$

where the base deficit = 24 mEq/L – (patient bicarbonate concentration). One-fourth to one-third of the dose should be given intravenously as a slow bolus, and an additional one-fourth over the next 4–6 hours. Subsequent doses should be based on serial venous blood gas analyses.

Bicarbonate administration to a hypoventilating patient can further increase the partial pressure of carbon dioxide and can lead to paradoxical central nervous system (CNS) acidosis. This phenomenon is due to the ability of carbon dioxide to diffuse across the blood–brain barrier, while the charged bicarbonate molecule diffuses across this barrier less readily. An additional drawback to parenteral sodium bicarbonate administration is that most formulations have high osmolality (e.g., 8.4% solution = 1 mEq/mL = 2000 mosm/L). Therefore, this solution must be diluted prior to administration, and the total volume administered must be factored into the fluid therapy plan. Provision of bicarbonate during dialysis is as effective in restoring extracellular acid–base status as sodium bicarbonate infusion, and has the added advantage of avoiding the fluid load necessary with the latter treatment. While there is no evidence in the form of randomized controlled trials supporting supplementation of alkali in human AKI, it is recommended in veterinary AKI when dialysis is not available.

Electrolyte Balance

Hyperkalemia can be an immediately life-threatening complication of AKI and is secondary to a decline in renal excretory function. Excitable cells become refractory to repolarization, thus resulting in decreased conduction of both cardiac and neuromuscular tissue. Typical electrocardiographic changes include bradycardia, tall T-waves, shortened QT intervals, wide QRS complexes, and small, wide, or absent P-waves. Severe hyperkalemia can lead to sine waves, ventricular fibrillation, or standstill. There are a variety of pharmacologic treatments available for emergent hyperkalemia, but these therapies act to translocate potassium to the intracellular space or increase the resting membrane potential to allow repolarization of excitable cells, rather than enhance excretion of potassium. The efficacy of these treatments is typically modest and transient. Only provision of dialysis or restoration of native renal excretory function can significantly reduce the potassium burden in fulminant AKI.

Expansion of the extracellular space with a nonpotassium-containing fluid (e.g., 0.9% sodium chloride) may be sufficient to at least partially correct hyperkalemia. This maneuver should be implemented in cases of suspected volume depletion, but should be used with caution or not at all if a patient is anuric or has volume overload.

Administration of regular insulin is a common pharmacologic treatment for hyperkalemia. Insulin upregulates synthesis of subunits of the Na+/K+ATPase pump, recruits the pump to the plasma cell membrane, and activates those pumps already located in the plasma membrane to stimulate intracellular translocation of potassium. The potassium-lowering effect of regular insulin may be observed within 20 minutes, but the effect is typically modest (decline of 1–2 mmol/L) and transient (redosing is frequently necessary within 4–6 hours). A potentially catastrophic adverse effect associated with regular insulin administration is hypoglycemia, so dextrose must be administered concurrently with regular insulin. If fluid overload is not present, the administration of a continuous rate infusion of dextrose, following the initial bolus, is recommended. Frequent assessment of blood glucose concentrations is imperative, as dextrose is metabolized more rapidly than insulin, and redosing of dextrose is often required.

Calcium salts are frequently administered intravenously to increase the threshold potential of polarized

cells, thus allowing depolarization at high extracellular potassium concentrations. The membrane-stabilizing effects of calcium salts are rapid and dramatic but the beneficial effects are even more transient than those of regular insulin. Readministration is typically necessary within 1–4 hours. The patient should be monitored with an electrocardiogram during administration to identify worsening bradycardia, a shortened QT interval, a widened T-wave, or alterations in the ST amplitude. If any of these changes are recognized, the calcium infusion should be discontinued. Calcium gluconate is favored over calcium chloride, due to the severe extravasation injuries that can occur with calcium chloride administration. It should be noted, however, that calcium gluconate can also cause extravasation injuries (albeit less severe), so care must be taken to ensure intravenous catheter patency prior to administration.

Lastly, theoretical concerns regarding promotion of calcium-phosphorus/phosphate precipitation and soft tissue mineralization exist with repeated administration of calcium salts.

Alternative treatments for hyperkalemia exist, but each has limitations in efficacy and side-effects, compared with provision of dialysis. These treatments include beta-2 agonist drugs, polystyrene sodium sulfonate, sodium bicarbonate, and loop diuretics.

While ionized hypocalcemia occurs frequently in AKI, clinical signs (e.g., tetany) associated with this problem are rare. When manifestations of hypocalcemia do occur, the minimum dose of supplemental calcium that controls clinical signs should be used to minimize precipitation with phosphorus. As with the treatment of hyperkalemia, the electrocardiogram should be monitored closely during infusion.

Additional electrolyte abnormalities may be present or develop during the course of disease, the most common of which are hyponatremia and hyperphosphatemia. Hyponatremia may be the result of gastrointestinal or urinary losses, with or without the contribution of decreased excretion of free water. Hyponatremia, if severe (<120 mmol/L), may result in neurologic sequelae. Hyperphosphatemia contributes to acidosis and renal secondary hyperparathyroidism. However, the use of phosphate-binding drugs has not been shown to improve outcome in human or veterinary cases of AKI. Furthermore, administration of aluminum hydroxide (the most commonly used phosphate-binding drug in veterinary medicine) may result in acute aluminum intoxication, which manifests as encephalopathy, a condition which may not be readily recognizable in a patient severely affected with AKI. Therefore, aluminum-containing phosphate-binding drugs should be used with caution in cases of AKI.

Nutritional Support

Nutritional support is an important component of supportive care for AKI. Enteral feeding is the preferred method of nutrient delivery, but is often limited by vomiting and ileus. For those patients that are not vomiting, esophageal, gastric, and jejunal feeding devices can be used. If vomiting cannot be controlled, partial or total parenteral nutrition should be considered. In patients which are anuric or oliguric, the volume and osmolality of nutritional product, whether administered enterally or parenterally, must be taken into consideration and may constitute a relative contraindication unless there is a method of excess fluid and solute removal (e.g., dialysis).

The optimal dietary composition for veterinary AKI patients has not been determined. The author is unaware of any particular diet that is appropriate in all scenarios of AKI. Rather, each individual patient should be evaluated for the following factors, as each may influence the choice of diet to be fed: degree of uremia, availability of dialysis, volume status and volume of urine produced, electrolyte balance, and availability of assisted feeding (e.g., esophagostomy or gastrostomy tube). Patients with severe uremia may benefit from a protein-restricted diet because a reduced protein content may decrease the endogenous production of uremic toxins. However, a negative protein balance may hinder renal repair/recovery. Patients treated with dialysis may actually require more protein than patients with extrarenal disease, due to loss of amino acids in dialysate. Patients with feeding tubes that are prone to volume overload should be fed the most calorically dense diet that will pass through the tube to minimize the amount of fluid administered. Some commercially available recovery diets have caloric contents of approximately 2 kcal/mL and easily pass through most 14 Fr red rubber catheters or feeding tubes. These diets typically have a high protein and potassium content, the latter of which may be problematic in hyperkalemic patients. There are multiple appropriate, commercially available diets from which to select, depending on the individual patient's clinical status.

However, a common misconception among veterinary personnel is that commercial renal diets, formulated and marketed for patients with chronic kidney disease, are also appropriate for patients with AKI. While these diets have reduced protein content, which may be desirable in certain situations, they require dilution and blending with water, which reduces their caloric density and increases the amount of fluid that must be administered with each feeding. Furthermore, these diets have a low sodium content, which is reduced even further when they are diluted with water. Many

patients with AKI are hyponatremic due to gastrointestinal and renal losses, so administration of large volumes of hypotonic enteral fluid in the form of a diluted renal diet may exacerbate hyponatremia and cause severe neurologic sequelae. Lastly, many feline commercial renal diets have a high potassium content which, as with recovery diets, can be problematic for hyperkalemic patients. For these reasons, the author typically refrains from administration of renal diets to tube-fed patients with AKI. Consideration is given to transition to a renal diet once renal recovery is presumed to be complete and it has been confidently established that the patient has residual chronic kidney disease.

Renal Replacement Therapy/Dialysis

Renal replacement therapy (referred to as dialysis) is discussed (in the context of AKI, as well as other disease states) in Chapter 126. Dialysis is the most efficient means of managing uremic, acid–base, electrolyte, and fluid-related sequelae of AKI. In fulminant cases, available pharmacologic therapies are, at best, incompletely effective at reversing the aforementioned complications, and their effects are transient. The cost and limited availability of dialysis, however, make it impractical for many owners and veterinarians.

Additional Treatment Considerations

Antiemetic therapy is recommended for all patients with severe AKI, regardless of whether they are vomiting. Metoclopramide is frequently used for this purpose, but reduced clearance associated with compromised renal function, and resultant adverse effects (primarily neurologic) must be considered. Furthermore, metoclopramide was found to be inferior to the 5-HT3 antagonist ondansetron in prevention of vomiting and nausea in uremic human patients.

The use of antisecretory drugs (e.g., H2 receptor antagonists, proton pump inhibitors) has historically been recommended for patients with AKI. Although uremic gastritis and stress-related mucosal disease are concerns in human AKI patients, gastric acid output and intragastric pH are not compatible with a hypersecretory state. Nonetheless, due to the high incidence of hemorrhage from the gastrointestinal tract in human AKI patients (presumably related to a combination of uremic injury and stress-related mucosal disease) and its association with mortality, antisecretory drugs should be considered in high-risk patients. A recent metaanalysis showed superiority of proton pump inhibitors versus H2 receptor antagonists in the prevention of stress-related mucosal bleeding. These results, in combination with the potential for accumulation of H2 receptor antagonists in patients with diminished renal function, favor the use of proton pump inhibitors. Sucralfate is frequently used for gastroprotection, but human data show that even short-term administration of this drug to patients with AKI can result in toxic aluminum concentrations.

Some human physicians advocate the use of diltiazem in the treatment of posttransplant AKI and the prevention of AKI following cardiovascular surgery, and there are data describing its use in dogs with AKI secondary to leptospirosis. While results of the canine study suggested a favorable trend with the use of diltiazem, evidence is insufficient to recommend its routine use.

Dopamine is a pharmacologic treatment for AKI that has fallen into and out of favor with both human and veterinary nephrologists. Stimulation of intrarenal dopamine receptors (DA-1, DA-2) results in vasodilation and natriuresis and diuresis, which have historically been regarded as favorable events in AKI. However, it is unclear whether reduced renal blood flow is a significant contributor to the initiation and maintenance of AKI. Furthermore, at higher doses, dopamine has inotropic and chronotropic cardiac effects that result in increased cardiac output, which may not be desirable if cardiac output is otherwise sufficient. Because of the difficulty in selecting appropriate dosing strategies for individual patients that target the desired receptors, dopamine is not currently recommended for the treatment of AKI. The use of fenoldopam, a selective DA-1 agonist, may favor activation of intrarenal dopamine receptors over adrenergic receptors, which may result in more desirable outcomes. However, there is currently insufficient evidence to recommend the routine use of fenoldopam for its vasodilatory and natriuretic effects.

Prognosis

The approximate mortality rate for AKI in cats and dogs is 50%; this figure is unchanged when assessing cats and dogs treated with intermittent hemodialysis. If it is acknowledged that patients treated with dialysis are more likely to have a greater severity of renal dysfunction and more complications associated with AKI, it can be deduced that dialysis offers a survival benefit in these cases. In those that survive, approximately 50% recover normal renal function.

Certain subsets of patients have better prognoses. Dogs with leptospirosis have survival rates approaching 80–90%. Patients with polyuria typically have a better outcome than those with oliguria or anuria. Azotemic AKI caused by ethylene glycol intoxication, however, has a poor prognosis, with approximately 80% of dogs requiring dialysis for the remainder of their lives.

Glomerular Disease

Shelly L. Vaden, DVM, PhD, DACVIM (SAIM)

College of Veterinary Medicine, North Carolina State University, Raleigh, NC, USA

Etiology/Pathophysiology

Glomerular disease is a leading cause of renal disease in dogs but appears to be less common in cats. Accordingly, most of the content of this chapter is in reference to dogs.

Historically, glomerular diseases have been classified as being either primary or secondary. Primary glomerular diseases arise in the kidney and secondary diseases occur when the glomeruli are injured as part of a systemic disorder. Secondary glomerular injury is generally the result of damage that is either sustained following immune complex deposition (e.g., membranous glomerulonephritis, membranoproliferative glomerulonephritis, proliferative glomerulonephritis) or due to systemic factors affecting the glomeruli (e.g., amyloidosis, focal segmental glomerulosclerosis, minimal change disease).

Recently, an alternative approach to classification has been suggested in veterinary medicine where, on the basis of renal biopsy evaluation, three broad categories of disease are used: amyloidosis, immune complex-mediated glomerulonephritis (ICGN), and non-ICGN. This system should greatly facilitate the clinical management of dogs and cats with glomerular disease by separating out those that might benefit the most from a thorough search for a systemic disorder and therapy with immunosuppressive drugs. In a study of renal biopsies from 501 dogs with glomerular disease, 48% had ICGN and 15% had amyloidosis, leaving 37% with a variety of non-ICGN.

Because of the strong association between glomerular injury and immune complex deposition or systemic inflammation, glomerular diseases are often linked to systemic disease processes – specifically neoplastic, infectious, or noninfectious inflammatory (NIN) disorders. Published studies have suggested that approximately 50% of dogs with glomerular disease have an identifiable NIN. The categorization of biopsies from the previously mentioned 501 dogs suggests that as many as 63% of dogs with glomerular disease have undergone renal damage secondary to a disorder occurring elsewhere in the body. A NIN disorder may not be obvious at first presentation because it is either resolved or occult. Because occult NIN disorders may become overt months after initial presentation for proteinuria, continued observation and scrutiny of the dog and cat with glomerular disease are necessary.

Familial glomerulopathies have been reported in several breeds of dogs and can cross most of the before mentioned categories (Table 121.1).

Hereditary nephritis is the result of defective collagen synthesis and has been reported in bull terriers, English cocker spaniels, Dalmatians, Samoyed, and mixed breed dogs. An inherited podocytopathy is the cause of familial protein-losing nephropathy of soft-coated wheaten terriers. Shar-peis develop familial renal amyloidosis following episodes of recurrent fever and swollen joints. The etiopathogenesis of many of the remaining disorders is unknown.

Signalment

Glomerular diseases can develop at any age but may be more common in middle-aged to older dogs. The reported average from 876 dogs in six different studies was 7.4 years of age. In general, male and female dogs are nearly equally represented among dogs with glomerular disease. The average age and gender predilection seen with specific glomerular diseases will vary somewhat from the overall averages.

Any breed can be affected by glomerular disease. However, Labrador retrievers, golden retrievers, and Yorkshire terriers may be predisposed based on reported higher incidence of glomerular disease in these breeds; however, it is also possible that this increased representation reflects the popularity of these breeds. Amyloidosis may be overrepresented in Chinese shar-peis and English bulldogs.

Table 121.1 Select breeds of dogs with familial glomerulopathies

Breed	Glomerular disease(s)
Beagle	Amyloidosis, primary glomerulopathy
Bernese mountain dog	Mesangiocapillary glomerulonephritis
Bull mastiff	Glomerulosclerosis
Bull terrier	Hereditary nephritis
Dalmatian	Hereditary nephritis
Doberman pinscher	Glomerulosclerosis, cystic glomerular atrophy
English cocker spaniel	Hereditary nephritis
English foxhound	Amyloidosis
Greyhound	Glomerular vasculopathy and necrosis
Newfoundland	Glomerulosclerosis
Pembroke Welsh corgi	Glomerulosclerosis, cystic glomerular atrophy
Rottweiler	Atrophic glomerulopathy
Samoyed	Hereditary nephritis
Shar-pei	Amyloidosis
Soft-coated wheaten terrier	Podocytopathy

History and Clinical Signs

Dogs and cats with glomerular disease can present with a variety of clinical signs, determined by the severity of proteinuria or renal disease and the presence or absence of any systemic disorders. They may be asymptomatic, have nonspecific signs (e.g., anorexia, weight loss, lethargy) or have signs of more advanced renal disease (e.g., polyuria, polydipsia, vomiting, diarrhea, halitosis). Animals with severe urinary protein loss may develop nephrotic syndrome and have evidence of fluid retention (e.g., abdominal enlargement consistent with ascites, peripheral edema). Animals also may develop clinical signs from thromboembolism (e.g., dyspnea, loss of limb function), or hypertension (e.g., acute blindness, or recent onset of neurologic signs or cardiac murmur). When glomerular disease is suspected, the history should include questions about the environment, possible exposure to infectious diseases as well as relevant drug or dietary exposure.

Complete physical examinations should be performed on dogs and cats with suspected glomerular disease, including body condition score, retinal and rectal examinations. Physical examination is often unremarkable. Poor body condition or poor hair coat may be nonspecific evidence of systemic disease. Animals with advanced renal disease may have oral ulcerations, pale mucous membranes, or dehydration. Subcutaneous edema or ascites, or both, are sometimes noted and consistent with nephrotic syndrome. Occasionally, there is physical evidence of thromboembolic disease, such as dyspnea or a decreased or absent peripheral pulse. Evidence of a predisposing inflammatory, infectious, or neoplastic process may be detected during the physical examination. The kidneys of affected animals are variable in size. Animals with chronic kidney disease often have small, firm, irregularly shaped kidneys, whereas those with less severe or long-standing disease often have normal-sized or, occasionally, enlarged kidneys.

Diagnosis

When proteinuria is detected, there are three key elements that need to be assessed: localization, persistence, and magnitude. Although proteinuria is the hallmark of glomerular disease, it can also occur secondary to prerenal, postrenal or renal tubular causes. The magnitude of proteinuria is generally assessed via the urine protein:creatinine ratio (UPC). Persistent renal proteinuria that is of high magnitude (i.e., UPC >2) is most likely of glomerular origin; however, there is no range of numbers that is diagnostic for any one renal disease and the overlap in expected ranges is too broad to be clinically reliable. In fact, glomerular lesions have been seen in dogs without proteinuria. Urine albumin can also be used to assess proteinuria. Microalbuminuria may develop before the UPC is increased. It therefore seems reasonable to conclude that a dog or cat with persistent microalbuminuria of increasing magnitude should be assessed as having an injurious process to the glomerular filtration barrier and may eventually develop overt proteinuria.

Once glomerular disease is suspected, a comprehensive diagnostic evaluation is recommended for all dogs and cats which includes urinalysis, serial UPC measurements, completed blood count, biochemical profile, and blood pressure measurement. Urine culture is warranted if there is pyuria, hematuria, bacteriuria, dilute urine (e.g., urine specific gravity <1.025) or concurrent diseases which might predispose the patient to urinary tract infection (e.g., hyperadrenocorticism). Animals with potential exposure to infectious diseases should undergo the appropriate testing. Any concominant extrarenal disease should be evaluated further (e.g., aspriation cytology of cutaneous masses, appropriate testing for hyperadrenocorticism). If proteinuria is of high magnitude (i.e., UPC >3.5), associated with hypoalbuminemia, azotemia, or hypertension, or progressive or nonresponsive to treatment, additional diagnostics including but not limited to abdominal ultrasound, thoracic radiographs, more extensive evaluation for infectious

diseases, and assessment of the coagulation system are indicated.

The results of this comprehensive evaluation will vary considerably in affected animals. Hypoproteinemia due to hypoalbuminemia develops in many dogs and cats with glomerular disease but is more likely in animals with heavy proteinuria. Azotemia, hyperphosphatemia, and metabolic acidosis, consistent with renal failure, may be present in animals with severe disease, although as many as 50% of affected animals will be nonazotemic. Nonregenerative anemia, secondary to renal failure or a systemic disease, is observed in many affected animals.

Other hematologic abnormalities also may reflect concurrent and possibly underlying systemic diseases. Thrombocytosis and hyperfibrinogenemia are common findings in dogs with glomerular disease. The nephrotic syndrome of hypoalbuminemia, proteinuria, hypercholesterolemia, and edema, although pathognomonic for glomerular disease, will only be present in a small proportion of dogs with glomerular disease (i.e., 10–15%). Because fluid retention can sometimes be cavitary, thoracic radiographs and abdominal ultrasound can be used to help detect edema. However, incomplete nephrotic syndrome (i.e., without edema or ascites) occurs in about half of affected dogs. The nephritic syndrome is a term that has primarily been used in people to describe a set of signs that develop secondary to renal inflammation, generally acute, that extends into the glomeruli. In people, this syndrome is characterized by hematuria and red blood cell (RBC) casts with one or more of the following: subnephrotic proteinuria, edema, hypertension, azotemia, oliguria. Although the nephritic syndrome has not been fully characterized in dogs, perhaps because of the probable low prevalence of acute glomerulonephritides in dogs, it is possible that dogs with acute inflammatory glomerular diseases (e.g., Lyme nephritis) may present with a nephritic-like syndrome. Isosthenuria is a variable finding in dogs and cats with glomerular disease and as many as 40% of affected dogs with glomerular disease will maintain renal concentrating ability, achieving urine specific gravities in excess of 1.035.

The finding of concurrent renal azotemia, concentrated urine, and proteinuria is indicative of glomerular disease. Cylindruria is common in dogs with glomerular disease; casts are most often hyaline but can be granular, waxy, or fatty. When affected animals are imaged, the kidneys may appear normal or small and irregular; some animals may have abnormally enlarged kidneys. Increased echogenicity of the cortex and loss of corticomedullary distinction may also be noted during abdominal ultrasound. The renal pelvis may be mildly dilated if polyuria is present or if fluids are being administered.

Renal biopsy should be considered under certain circumstances: proteinuria is of high magnitude (UPC >3.5, with or without concurrent hypoalbuminemia), progressive, or unresponsive to standard therapy; immunosuppressive therapy is being considered; medical contraindications to biopsy are not present; the renal biopsy can be collected, prepared and interpreted by experienced personnel; and, the sample can be submitted for evaluation using standard light microscopy but also electron microscopy and immunofluorescence. Medical contraindications to biopsy include advanced chronic kidney disease (i.e., IRIS stage 4), coagulopathy, cystic disease, hydronephrosis, pyelonephritis, perirenal abscess, uncontrolled hypertension, severe anemia, and pregnancy.

Electron microscopy is essential if a renal biopsy is to be evaluated and was required to confirm or rule out ICGN in 27.4% and 23.1% of biopsies, respectively, from one study. Light microscopy alone was 94% sensitive and 77% specific in identifying ICGN when specimens were evaluated by highly experienced nephropathologists; it is unlikely that pathologists without nephropathology training would achieve these same results.

Therapy

Standard Therapy

Standard therapy is the foundation for the care that should given to all dogs with glomerular disease, regardless of the inciting cause, and includes inhibition of the renin-angiotensin-aldosterone system (RAAS), and management of dietary intake, hypercoagulability, systemic hypertension, and body fluid volume (Box 121.1).

Evidence suggests that UPC >1.0 is associated with negative patient outcomes and when the UPC is reduced to <0.5, the outcome is improved. Therefore, it is recommended that standard therapies be considered when the UPC is persistently >0.5. However, standard therapy rarely leads to complete resolution of the renal lesions.

Inhibition of RAAS

Hemodynamic forces influence the transglomerular movement of proteins. The RAAS can be therapeutically targeted to alter renal hemodynamics, leading to a reduction in proteinuria. Decreased efferent glomerular arteriolar resistance leads to decreased glomerular transcapillary hydraulic pressure, which ideally leads to a reduction in proteinuria. Other proposed mechanisms include reduced loss of glomerular heparan sulfate, decreased size of the glomerular capillary endothelial pores, improved lipoprotein metabolism, slowed glomerular mesangial growth and proliferation, and inhibition of bradykinin degradation.

Box 121.1 Management of glomerular disease in dogs

Inhibition of renin-angiotensin-aldosterone system
Angiotensin-converting enzyme inhibitors (e.g., enalapril, benazapril)
Angiotensin receptor blockers (e.g., telmisartan)
Aldosterone receptor blockers (e.g., spironolactone)

Modified dietary intake
Increased n-3 polyunsaturated fatty acids
Modified protein content
Reduced sodium chloride

Antithrombotic therapy
Aspirin
Clopidogrel

Antihypertensive therapy
Angiotensin-converting enzyme inhibitors (e.g., enalapril, benazapril)
Angiotensin receptor blockers (e.g., telmisartan)
Calcium channel blocker (i.e., amlodipine)

Manage body fluid volume
Careful fluid therapy when fluid deficit present
Diuretics for fluid excesses that are contributing to respiratory distress

Immunosuppressive therapy for immune complex-mediated glomerulonephritis

Angiotensin-converting enzyme inhibitors (ACEi; e.g., enalapril, benazapril), angiotensin receptor blockers (ARB; e.g., telmisartan), and aldosterone receptor blockers (e.g., spironolactone) are the agents that target RAAS.

For most dogs with glomerular-range proteinuria, an ACEi is the initial agent used. Typically, an ACEi is given once daily initially, but more than half of the dogs will eventually need twice-daily administration and perhaps additional dosage escalations. Although worsening azotemia is a concern regarding the use of ACEi, severe worsening (i.e., >30% increase from baseline) due to ACEi administration alone seems uncommon and dogs that are dehydrated may be at highest risk. Less is known about the use of an ARB in dogs with glomerular disease although they have been extensively studied in people. The ARB that has historically been used in dogs with glomerular disease is losartan, although it has not always been effective. Recently, telmisartan has been shown to be very effective in some dogs and may prove useful as the initial line of therapy. Telmisartan has a more profound effect on lowering blood pressure than ACEis and should be used carefully in dogs that have low basal blood pressures (e.g., systolic <140 mmHg).

Because neither an ACEi nor an ARB as a single agent provides complete blockade of the RAAS, there may be an added benefit to combined therapy; however, this approach should be used with caution as it has been associated with a higher risk of kidney failure and death in people. Serum aldosterone increases over time (i.e., aldosterone escape) in people treated even with maximal dosages of ACEi and ARB; prolonged hyperaldosteronism may have adverse effects on the heart, systemic blood vessels, and glomeruli. People with hyperaldosteronism may have a greater reduction in proteinuria when an aldosterone receptor antagonist is added to their therapy. Spironolactone has been used most commonly in dogs; however, there are few data that support the efficacy of this drug in dogs in the management of glomerular disease. Spironolactone should only be effective if serum aldosterone concentrations are increased. This drug could be tried in animals that have high serum aldosterone concentrations and persistent proteinuria in spite of treatment with an ACEi, ARB or both, with the understanding that its efficacy in reducing proteinuria has not been established.

All dogs that are being treated for glomerular disease via RAAS inhibition should be monitored at least quarterly by a minimum of UPC, urinalysis, systemic arterial blood pressure and serum albumin, creatinine and potassium concentrations. The UPC, serum creatinine, serum potassium, and blood pressure should be evaluated 1–2 weeks after an ACEi or ARB has been added or altered. The desired therapeutic effect is a reduction in proteinuria without a severe worsening of renal function (i.e., >30% increase in serum creatinine), a critical increase in serum potassium or the unlikely development of hypotension. Changes in the magnitude of urine protein are most accurately measured by assessing trends in the UPC over time. Day-to-day variations in the UPC occur in most dogs with glomerular proteinuria, with greater variation occurring in dogs with UPC >4. Consideration should be given to either averaging 2–3 serial UPC or measuring a UPC in urine that has been pooled from 2–3 collections. The target for reduction is a UPC of <0.5 without inappropriate worsening of renal function; however, when that is not possible, a partial response with a reduction in the UPC of 50% or more is the alternative target.

Dogs with serum potassium concentrations of >6 mEq/L should be monitored closely and therapy should be modified when serum potassium concentrations are >6.5 mEq/L. Before modifying treatment, pseudohyperkalemia, due to the high potassium content of some blood cells which may occur in dogs with glomerular disease, should be eliminated as a cause by measuring the potassium concentration in lithium heparin plasma. True hyperkalemia can be managed by reducing the ACEi or ARB drug dosage, discontinuing spironolactone administration, or by feeding

diets that are reduced in potassium or administering an intestinal potassium binder (e.g., kayexelate). If the target reduction in UPC is not achieved and the dog does not have the before mentioned adverse effects, the dosages may be increased every 4–6 weeks.

Modified Dietary Intake

Modification of dietary intake has a central role in the management of all dogs with kidney disease and has been associated with delaying spontaneous progression of kidney disease and reducing the magnitude of proteinuria. It is well known that fat content of a diet can affect renal outcome. Most commercially available renal diets are modified with respect to polyunsaturated fatty acids (PUFA) content with the goal of slowing progression and reducing proteinuria. The consensus recommendation is that dogs with glomerular disease should be fed a diet with a reduced n-6:n-3 PUFA ratio of approximately 5:1. It is unknown if there is any additional benefit of supplementing n-3 PUFA when this ratio is already being provided via the diet. If supplementation is chosen, care should also be taken to provide adequate antioxidants (e.g., vitamin E). Dogs with glomerular disease should be fed modified protein diets because this has been shown to reduce proteinuria and slow progression.

Lastly, the sodium chloride content should be reduced in diets fed to dogs with glomerular disease. Salt restriction may enhance the beneficial effects of agents used to inhibit RAAS and help reduce fluid retention.

Antithrombotic Therapy

Hypercoagulability is a complication of protein-losing glomerular diseases and thromboembolism can occur in as many as 25% of dogs with glomerular disease. The pathogenesis of hypercoagulability in glomerular disease is complex and incompletely understood. Urinary loss of antithrombin has long been given as the explanation but in reality, the pathogenesis is more complex than this and probably includes vascular stasis as well as increased platelet aggregation, plasma procoagulant factors, and fibrinogen concentrations. Unfortunately, serum albumin concentrations, antithrombin activity, and UPC cannot be used in isolation to predict hypercoagulability in individual patients. It follows then that it remains unclear when to implement thromboprophylaxis. Consensus recommendations call for the daily administration of low-dose aspirin (1–5 mg/kg/day) in dogs with protein-losing glomerular diseases. Clopidogrel may be an effective alternative.

Antihypertensive Therapy

All dogs with glomerular disease should undergo repeat evaluation for systemic hypertension. This evaluation should not only include measurement of systemic blood pressure but also assessing the patient for target organ damage, evaluating for conditions that may contribute to hypertension and determining if any concurrent conditions that may complicate antihypertensive therapy are present. Personal preference and experience should dictate how the blood pressure is measured; however, the substaging by arterial blood pressure system that has been proposed by the International Renal Interest Society (IRIS) should be used to guide therapy (Table 121.2).

Antihypertensive therapy should be initiated when the blood pressure exceeds 160 mmHg systolic or 100 mmHg diastolic (i.e., AP2 or above). The goal of therapy is to reduce the blood pressure to less than 150 mmHg systolic or 96 mmHg diastolic (i.e., AP0). Lowering the blood pressure is not an emergency unless there is severe ocular or central nervous system target organ damage. In most cases, blood pressure reduction can be achieved gradually over a period of several weeks. Effective treatment of hypertension should lead to a concomitant reduction in the magnitude of proteinuria in dogs with glomerular disease. Feeding a salt-restricted diet alone will not lower the blood pressure into the target range but it may enhance the antihypertensive effects of the inhibitors of RAAS, generally ACEi. However, ACEi are generally only associated with a 10–15% reduction in blood pressure. This reduction may be all that is needed for dogs that are only moderately hypertensive (i.e., AP2). Dogs that are severely hypertensive (i.e., AP3) should have a calcium channel blocker (i.e., amlodipine) added to their RAAS inhibition therapy. Alternatively, telmisartan can be used as a single agent to manage hypertension and proteinuria.

The consensus recommendation is that dogs with IRIS chronic kidney disease stages 1 or 2 should have blood pressure evaluated 3–14 days after any change in antihypertensive therapy whereas those in stages 3 or 4 should

Table 121.2 International Renal Interest Society substaging by arterial blood pressure

Systolic blood pressure	Substage
<150 mmHg	Normotensive, Minimal Risk
150–159 mmHg	Borderline hypertensive, Mild Risk
160–179 mmHg	Hypertensive, Moderate Risk
>180 mmHg	Severely hypertensive, Severe Risk
No evidence of end-organ damage	nc (no complications)
Evidence of end-organ damage	c (complications)
Blood pressure not measured	RND (risks not determined)

be evaluated 3–5 days after making any change. Dogs that have hypertensive emergencies should be evaluated daily. The purpose of these evaluations is not only to assess effectiveness of the antihypertensive therapy but also to evaluate for exacerbation of azotemia. Dosages should be reduced if the serum creatinine has increased more than 30% from baseline or if the blood pressure is reduced to less than 120–mmHg systolic or 60–mmHg diastolic. Once target blood pressure is achieved, the dogs should be evaluated at 1–4-month intervals, depending upon the stability and severity of the renal disease.

Body Fluid Volume

Dogs with glomerular disease may have fluid excesses, deficits or maldistribution, which may need to be corrected if the dog has decompensated or is being prepared for anesthesia. Correcting body fluid imbalances in dogs that are hypoalbuminemic from glomerular disease is a very difficult therapeutic challenge. Fluid therapy can exacerbate edema and hypertension and diuretics can exacerbate azotemia or uremia. As such, those who have experience and expertise in critical care are the best people to deliver these therapies to dogs with glomerular disease.

Fluid therapy should be given only when needed to help control clinical signs or provide support to those dogs that have inadequate fluid intake. Both colloids and crystalloid can be used. However, the decision to use colloids should not be based on the presence of hypoalbuminemia or decreased colloidal oncotic pressure alone. Colloids should be considered when crystalloids have failed to bring about the desired result. The fluid status of affected dogs should be assessed before and during fluid therapy on the basis of serial body weight and other physical examination findings (e.g., skin turgor, appearance of mucous membranes, capillary refill time, pulse rate and quality, arterial blood pressure). When the serum albumin decreases below 2 g/dL in people, the plasma oncotic pressure is sufficiently reduced to allow for transudation of fluid from the vascular compartment into the interstitial space. Dogs may be more resistant to the formation of edema, which does not generally occur until the serum albumin concentration is below 1.5 g/dL. Plasma volume may be reduced at this point, making the use of diuretics in the management of edema relatively ineffective and also dangerous because of the increased risk of acute kidney injury and vascular stasis leading to thromboembolism.

Diuretics should be avoided unless needed to control respiratory distress. When needed, furosemide is the drug of choice for pulmonary edema but spironolactone may be best for pleural or abdominal effusion. Provision of adequate exercise also may help reduce the formation of edema or ascites.

Immunosuppressive Therapy

Immunosuppressive therapy should be considered in dogs that have severe, persistent or progressive glomerular disease and ICGN documented via appropriate evaluation of a renal biopsy specimen. However, there are many practical and medical reasons why a biopsy might not be performed. In addition, financial limitations may prevent biopsy. The end-result is that sometimes veterinarians must decide about the use of immunosuppressive therapy in dogs with glomerular disease without a pathologic diagnosis. In these situations, immunosuppressive therapy should not be administered if there is any doubt that the proteinuria is of glomerular origin, administration of the specific drug is medically contraindicated, or there is a high index of suspicion that the dog has a non-immune-mediated familial disease or amyloidosis.

Immunosuppressive drugs should be considered without a pathologic diagnosis when standard therapy has been implemented but the azotemia is progressive or the serum creatinine is >3.0 mg/dL or serum albumin is <2.0 g/dL. Because ICGN is the disease process in approximately 50% of dogs with glomerular disease, using immunosuppressive agents in these dogs without a renal pathologic diagnosis has a 50:50 chance of being appropriate. The risks associated with such therapy need to be clearly communicated to the pet owners.

Even with biopsy-proven ICGN, the profession does not have data regarding the expected outcomes of the various possible protocols. Therefore, specific drug recommendations are difficult to formulate. The immunosuppressive protocol should probably vary based on the severity of clinical signs and the rate of progression of the glomerular disease. More aggressive protocols that use rapidly active agents are probably best for dogs with severe and rapidly progressive disease. The rapidity with which the drug becomes active is of less concern in dogs with more slowly progressive disease. Drugs that could be considered are glucocorticoids, mycophenolate, cyclosporine, cyclophosphamide, chlorambucil and azathioprine. Likewise, combined therapy of mycophenolate and prednisolone, cyclophosphamide and prednisolone or chlorambucil and azathioprine could be considered. There is only weak evidence that supports worse outcomes when dogs with glomerulonephritis are managed with glucocorticoids and more evidence is needed before the use of these drugs is discarded. However, it is clear that glucocorticoids will increase proteinuria; UPC monitoring is best performed in samples collected on days when glucocorticoids are not administered in patients receiving alternate-day therapy. Glucocorticoids should also be used with caution in dogs that are receiving concurrent aspirin therapy.

Patients receiving immunosuppressive drugs should be monitored for drug-specific adverse effects as well as

a therapeutic response. Dogs should be thoroughly evaluated 1–2 weeks after starting therapy and every two weeks after for the first 4–6 weeks of treatment, then every four weeks for the next three months and then quarterly until disease resolution.

A therapeutic response is viewed as a reduction in the magnitude of proteinuria with improvement or stabilization of renal function and increases in serum albumin concentration. A reduction in proteinuria is as described earlier (see Inhibition of RAAS). Improvement or stabilization in renal function is defined as a sustained reduction in serum creatinine to less than 1.4 mg/dL (complete response) or by >25% of baseline (partial response). A meaningful increase in serum albumin is defined as a sustained increase to >2.5 mg/dL (complete response) or either to 2.0–2.5 mg/dL or by >50% of baseline (partial response). Secondary goals include improved blood pressure regulation, resolution of edema, and stabilization of body weight. If there are no unacceptable adverse drug effects, treatment should be continued for 8–12 weeks before changing the regimen or discontinuing treatment. Those demonstrating a partial or complete response should have therapy continued for at least 12–16 weeks. If partial or complete responses are not evident by the end of 8–12 weeks, the immunosuppressive protocol should be changed or discontinued. If there is no response by 3–4 months, all immunosuppressive therapy should be discontinued following appropriate drug tapering.

Prognosis

The prognosis for dogs and cats with glomerular disease is variable and probably based on a combination of factors. The prognosis is expected to differ with the various diseases. Although progressive disease can be expected to occur in a large percentage of animals with glomerular disease, spontaneous remission and response to specific therapy can also be expected. Furthermore, disease progression can be slow enough for the animals to lead relatively normal lives, especially when the diagnosis is established early in the disease process. In humans, azotemia, severe proteinuria, systemic hypertension, and marked tubulointerstitial lesions at presentation are the most significant predictors of an unfavorable outcome in most forms of glomerular disease. In dogs, the presence of nephrotic syndrome or azotemia is a negative prognostic indicator. Median survival time for dogs with nephrotic syndrome was only 12.5 days versus 104.5 days for dogs without nephrotic syndrome. When only nonazotemic dogs were considered, (i.e., serum creatinine <1.5 g/dL), the median survival for those with nephrotic syndrome was 51 days versus 605 days for those without nephrotic syndrome.

Urethral Obstruction

Etiology/Pathophysiology

There are a number of potential etiologies for urethral obstruction (UO), with important differences between dogs and cats. For dogs, the most common cause is urolithiasis, with neoplasia, prostatic disease, trauma, and stricture as additional considerations. Calcium oxalate and struvite stones occur most commonly in dogs, followed by ammonium biurate and cystine stones. Urethral strictures develop secondary to chronic urethritis, trauma during prior urethral catheterization, damage to the urethral epithelium from urolith passage, urethral tear or avulsion secondary to trauma, or as a result of exuberant healing following surgical urethral incision. Transitional cell carcinoma of the bladder trigone and prostatic carcinoma are the urothelial neoplasms most commonly associated with urethral obstruction.

For feline UO, urolithiaisis (predominantly calcium oxalate) represents a smaller proportion of cases, with the presence of a urethral plug and/or functional obstruction from urethral spasm/edema recognized more commonly. In any of these circumstances, it is thought that the presence of feline idiopathic cystitis (FIC), and associated inflammation of the lower urinary tract, may set the stage for obstruction. Much less commonly, though for reasons similar to those seen in dogs, cats may have obstruction caused by neoplasia or urethral stricture.

Regardless of underlying cause, complete obstruction of the urethra results in a similar pathologic progression. Urine will accumulate within the urethra and urinary bladder until those tissues can no longer distend. Once this occurs, intraluminal pressure builds, resulting in mucosal injury. The intraluminal pressure is then transmitted up the ureters to the kidney and Bowman's capsule with subsequent reduction of glomerular filtration. As a result, there will be accumulation of normal excretory products such as blood urea nitrogen, creatinine, phosphorus, potassium, and hydrogen ion within approximately 24–48 hours. These then combine to create the expected clinical course associated with UO.

Uremia can have a number of effects including depression, nausea, vomiting, and anorexia. The resulting decreased intake and ongoing losses can cause the patient to become dehydrated. Retention of organic and inorganic acids can result in severe metabolic acidosis with severe implications. Normal protein and enzyme function can be pH dependent, as well as responsiveness to catecholamines and the ability to maintain cardiovascular homoestasis. Finally, the development of severe hyperkalemia contributes significantly to the life-threatening nature of this disease process. Hyperkalemia affects electrical conduction and ultimately leads to bradycardia, atrial standstill, and eventually cardiac arrest (particularly at potassium levels above 9 or 10 mEq/L). As a result of this combination of factors, without intervention complete urethral obstruction will lead to significant illness within 24–48 hours, and mortality within 3–5 days.

Epidemiology and Signalment

Given their long and narrow urethra (compared to females), males are much more likely to develop UO. Among cats, there do not appear to be specific breed predispositions for UO in general, though Himalayan and Persian cats may have an increased risk of urolithiasis. There is some evidence to suggest indoor-only cats, and cats fed an exclusively dry food diet, may have an increased risk of UO.

Dogs that have a predisposition for stone formation have a greater risk for developing UO. This includes older castrated males and small-breed dogs (bichon frise,

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

Pomeranian, shih tzu, etc.) at risk for calcium oxalate stones. Because of their strong association with urinary tract infection (UTI), female dogs are much more likely to have struvite urolithiasis. Dalmatians and breeds predisposed to portosystemic shunts (e.g., Yorkshire terriers) should be considered for the potential of urate stones. Lower urinary tract neoplasia is reported to have a higher prevalence in Scottish terriers, Shetland sheepdogs, wire-haired fox terriers, and West Highland white terrier.

History and Clinical Signs

Feline UO typically involves demonstration of lower urinary tract signs: vocalizing and straining unproductively in the litter box. Cats with FIC may present similarly, which could serve to complicate the diagnosis based on these signs alone. Signs of systemic illness (vomiting, lethargy, anorexia, changes in mentation) in conjunction with lower urinary tract signs should point more strongly to UO than FIC. Owners may not be aware of lower urinary tract signs when litter boxes are kept in isolated areas, or the cat is indoor-outdoor. These patients will present for their systemic signs, and so UO might not be considered as quickly. Along those lines, UO should be considered as a differential for any sick male cat that presents.

Dogs may present for signs consistent with lower urinary tract disease leading to obstruction, including frequent trips outside, stranguria/dysuria, and pollakiuria. Once obstruction occurs, owners might report unproductive attempts to urinate, abdominal distension, and abdominal discomfort.

Clinical signs will depend on duration of obstruction and degree of systemic impact by the time of presentation. A firm, distended urinary bladder will be the most prominent feature for patients early in the disease process. In dogs, it may be possible to palpate the presence of a stone in the pelvic urethra, or prostatomegaly, when performing a rectal exam. If the obstruction has been present for greater than 24 hours, the patient may display signs of systemic illness. Systemic signs include dehydration, dull mentation, bradycardia, and hypothermia. Hyperkalemia should be considered for any ill patient that presents with bradycardia as the normal stress response to hospital presentation is tachycardia (though patients with a primary conduction disturbance or cats with septic or cardiogenic shock can also demonstrate bradycardia). For cats with UO, the combination of bradycardia (HR <140) and hypothermia (T <96.6 °F) strongly suggests a serum potassium level greater than 8 mEq/L.

Diagnosis

Diagnosis of UO is largely based on history, clinical signs, and physical exam. However, further diagnostics are helpful to assess the systemic compromise of the patient as well as to determine the underlying cause of obstruction.

Point-of-care diagnostics are especially important in the initial stages of assessing the sick obstructed patient. This should include packed cell volume and total protein, as well as assessment of electrolyte, acid–base status, and/or kidney values (if available). Expected abnormalities include azotemia, hyperkalemia, and metabolic acidosis. An ECG should be placed to evaluate the effects of hyperkalemia on electrical conduction in the heart, even if the patient is not demonstrating bradycardia. Progressive changes that can be seen associated with hyperkalemia include prolonged P-Q interval, diminished to absent P-waves, widened QRS and tall, tented T-waves (Figure 122.1). Eventually, ECG changes can progress to atrial standstill, ventricular fibrillation or asystole. In cats, it is important to note that wide complex tachycardia, rather than the expected bradycardia, has been reported in the setting of severe hyperkalemia.

Once stabilized, more complete systemic bloodwork (complete blood count, biochemical profile) should be performed if clinically indicated. Urinalysis is typically performed in dogs with UO to assess urine pH, presence of crystalluria, and evidence for UTI. As cats are much less likely to have a UTI, and the clinical importance of crystalluria is unclear, the diagnostic value of urinalysis is questionable. Similarly, given evidence that the incidence of UTI at the time of presentation is very low in cats, urine culture should not be performed. However, dogs with UO are much more likely to have concurrent UTI and a culture is more likely indicated.

Diagnostic imaging of some form should be performed in any patient with UO. Typically, abdominal radiographs are a first step to assess for the presence of cystic and/or urethral calculi. Calcium oxalate and struvite stones are radiopaque and should be evident on radiographs. However, ammonium biurate and cystine may be radiolucent and so an apparent absence of stones does not rule out urolithiasis. The entire lower urinary tract should be included (Figure 122.2), and the patient positioned to help minimize superimposition of the pelvis or hindlimbs (Figure 122.3). Common sites where stones lodge include the base of the os penis for dogs and

the distal tip of the urethra in cats. Cats may also have mineralized mucous plugs evident on abdominal radiographs (Figure 122.4).

Male dogs should be assessed for prostatomegaly and/or the presence of prostatic mineralization. Loss of abdominal detail may suggest uroabdomen secondary to bladder leakage/rupture. In some cases, it may be useful to perform a positive or negative contrast cystourethrogram, especially if radiolucent stones, stricture or urethral tear are suspected. Abdominal ultrasound may also be of benefit in patients with radiolucent stones, prostatic disease, or lower urinary tract neoplasia.

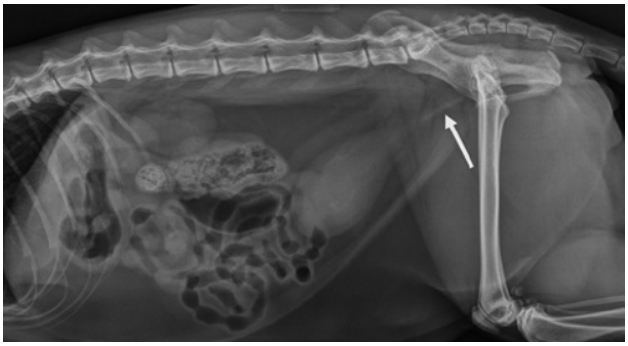

Figure 122.4 Lateral abdominal radiographic projection of a cat depicting the presence of a linear opacity within the proximal urethra, likely representing a mineralized urethral plug (*arrow*).

Therapy

Intravenous catheter placement and fluid therapy should be initiated immediately in the "sick" UO patient. This will serve to begin rehydration/volume repletion, as well as have a dilutional effect on the serum potassium level. There is some debate as to the optimal fluid to use. Traditionally, 0.9% NaCl has been considered the fluid of choice because it has a greater dilutional effect on potassium. However, 0.9% NaCl is an acidifying solution which could exacerbate metabolic acidosis. Conversely, balanced electrolyte solutions are alkalinizing but contain small amounts of potassium (4–5 mEq/L) and therefore may have less of a dilutional effect. It has been demonstrated that between 0.9% NaCl and a balanced electrolyte solution (Normosol R®) there were no differences in outcome (survival, length of stay) or in reduction of serum potassium levels, though acid–base abnormalities corrected more rapidly in the Normosol R group. If cardiovascular collapse is present, it may be necessary to

administer crystalloid "shock doses" (80–90 mL/kg dog, 40–60 mL/kg cat) in bolus fractions (1/4 to 1/3 shock dose over 15–30 minutes, repeated as necessary) to rapidly restore vascular volume. If resuscitation is not necessary, fluid rate should be based on replacement of dehydration added to the maintenance fluid requirement. If time does not allow more accurate determination of fluid rate, it is reasonable to start at a rate of 10 mL/kg in the initial stages and then reassess. Care must also be taken with the amount of fluids given, especially in cats, as a recent study has shown that cats with UO are at risk for volume overload.

While urinary catheter placement and IV fluids will be important in addressing the underlying cause, there is a significant delay for glomerular filtration rate (GFR) to resume and for potassium excretion to occur. Calcium gluconate is the most immediate way to offset the effects of hyperkalemia on electric conduction, though this medication does not decrease the potassium itself. In addition, medications that promote intracellular shift of potassium include regular insulin, dextrose, terbutaline, and/or sodium bicarbonate (see Table 122.1 for dosing recommendations).

Generally, if it was deemed necessary to give calcium gluconate, then one or more of these medications should also be given. It should be noted that dextrose should always be given with insulin to prevent the development of hypoglycemia.

There is also consideration of cystocentesis as part of initial management. On the one hand, it may allow for more immediate relief of bladder pressure compared to urinary catheter placement (particularly for those with limited experience in deobstructing). In addition, relatively less sedation is typically needed to perform cystocentesis. Cystocentesis can allow an uncontaminated urine sample to be obtained for urinalysis and/or urine culture. Finally, it is speculated that decreasing intraluminal pressure may make for easier passage of a urinary catheter. The major counterargument against the use of cystocentesis is related to the concern for bladder tear or rupture. While this is a known potential side-effect whenever cystocentesis is performed, it is believed by some that a distended and friable bladder present with UO is associated with increased risk. There is evidence to suggest that development of clinically significant abdominal effusion, as shown by abdominal ultrasound or radiographs, occurs very uncommonly after cystocentesis in cats with UO and that this procedure can be safely performed. Similar information regarding cystocentesis in dogs with UO is currently unavailable.

Urethral catheterization

Urinary catheter placement is an important step in the management of UO. In this process, every effort should be made to minimize the risk of urethral trauma and optimize the likelihood of successful catheterization. Along these lines, UO patients should receive appropriate sedation and pain medication, with consideration of coccygeal epidural and/or general anesthesia. In addition to impacts on patient comfort and standard of care, inadequate analgesia and sedation may be associated with urethral spasm and urethral injury. If the patient is still reactive to effort (vocalizing, moving), additional medications should be given; alternatively, general anesthesia should be performed.

For cats, the perineal region should be clipped, prepped, and draped in order to minimize risk of contamination. An open-ended semi-rigid catheter (polypropylene or

Table 122.1 Emergency dosing for severe hyperkalemia. All medications given intravenously (IV)

Medication	Dose (IV)	Rate	Indications
Isotonic crystalloid	10–15 mL/kg (c) 20–30 mL/kg (d) 5–10 mL/kg/h	15–30 minutes, repeat if needed Constant rate infusion	Shock Replacement fluid rate
Calcium gluconate	50–150 mg/kg	Over 5 minutes while monitoring ECG	Severe ECG changes Bradycardia
Regular insulin	1 unit (c) 0.1 U/kg (d)	IV bolus	If Ca gluconate given Potassium >8 mEq/L
Dextrose	0.5 g/kg 2.5–5% in fluids	Admin over 3–5 min Constant rate infusion	If Ca gluconate given If insulin given Potassium >8 mEq/L
Terbutaline	0.01 mg/kg	IV bolus	If Ca gluconate given Potassium >8 mEq/L
Sodium bicarb	1 mEq/kg	Admin over 3–5 min	Potassium >10 mEq/L

c, cat; d, dog; ECG, electrocardiogram.

polytetrafluoroethylene) can be used to initially relieve the obstruction. Given the very rigid nature of polypropylene catheters, care should be taken not to use too much force in advancing. For comfort, as well as associated inflammation and irritation, these catheters should also not be left in place. With regard to optimal catheter size, there is some evidence to suggest that use of a 3.5 Fr urinary catheter may be associated with less risk of immediate reobstruction compared to 5 Fr. However, another study failed to show this association.

When passing the catheter, aggressive flushing (rather than force) should be utilized to dilate the urethra and retropulse/break down any physical component of the obstruction. For the flush solution, adding sterile lubricant to sterile saline and mixing across a three-way stopcock (in a ratio of 10:1) may help to decrease urethral injury by allowing lubricant to be deposited throughout catheter placement (rather than just lubricating the end of the catheter). Another helpful technique is to pull the prepuce dorsal and caudally after the catheter is introduced into the penile urethra (Figure 122.5). Elevating the natural downward angle of the urethra as it passes out of the pelvic canal may facilitate catheter placement.

Once the initial catheter is in place, the urinary bladder can be emptied and flushed. A sterile closed collection system should be connected to allow for urine production to be quantified, and decrease risk of ascending infection.

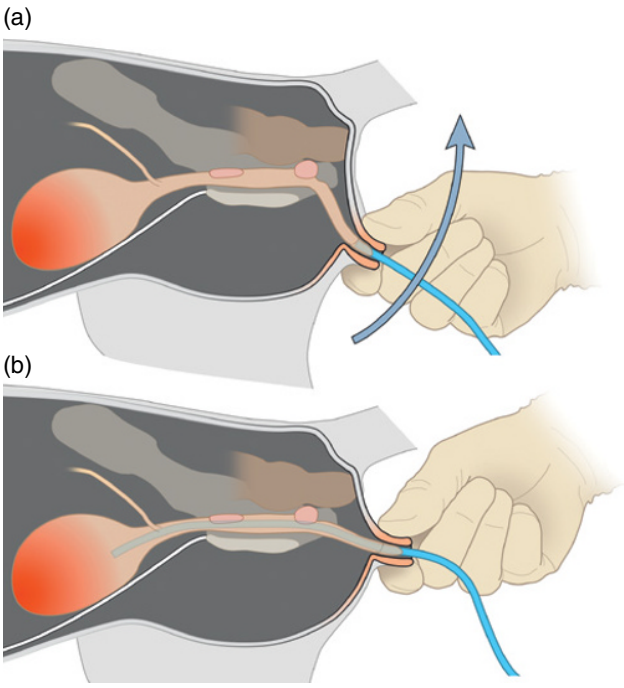

Figure 122.5 Once the catheter is seeded in the distal urethral, the prepuce is pulled dorsal and caudal to straighten the urethra and facilitate passage.

For catheterization and deobstruction in dogs, general anesthesia can be especially important to ensure optimal urethral relaxation. The prepuce or vulva should be cleaned and flushed to decrease risk of contamination. A red rubber or Foley catheter is typically used, though in some circumstances a more rigid catheter may be needed (with potential increased risk of urethral trauma). Similar to the process described for cats, hydropulsion with lubricated saline should be the primary means of retropulsing any physical obstruction. In male dogs, it is helpful to pinch the urethral orifice to prevent antegrade movement of flush solution. An additional useful trick (in either male or female dogs) is to have an assistant rectally apply pressure to the pelvic urethral during hydropulsion. This allows a build-up of pressure which, when released, can help dislodge a luminal obstruction.

If urethral catheterization fails due to urethral trauma, rupture, or persistent partial obstruction, antegrade urethral access can provide a means to deobstruct the patient and facilitate catheterization (Figure 122.6).

Briefly, percutaneous access into the bladder is achieved with an 18 gauge over-the-needle catheter by palpation or ultrasound guidance. Through the catheter, a hydrophilic wire is directed toward the bladder trigone and out the urethra. As the tear or trauma is usually created from a retrograde direction, the wire finds the true urethral lumen easily and often can be directly advanced out the penile urethra. Once wire access is achieved in this manner, the open-ended urinary catheter is advanced over the wire into the bladder lumen. The access catheter and wire are then removed and the urethral catheter sutured in placed and cared for routinely. Ideally, this procedure is performed under fluoroscopic guidance to visualize the path of the wire and appropriate positioning of the catheter.

Postobstructive Care

One major facet of postobstructive care is careful monitoring of urine output and maintaining fluid balance. Some patients may experience a postobstructive diuresis which can lead to significant quantities of urine production. Proposed mechanisms for this diuresis include accumulation of osmotically active substances in the blood, pressure necrosis, medullary washout and/or antidiuretic hormone resistance. Likely owing to these mechanisms, it has been demonstrated that up to 50% of cats may have increased urine production after deobstruction. However, in some circumstances it is unclear whether the initial rates of fluids administered may have also been contributing to increased urine production. Similar data are not available for dogs.

Given the potential to produce significant quantities of urine (>5–10 mL/kg/h), it is very important to keep up with urinary losses to prevent dehydration and hypov-

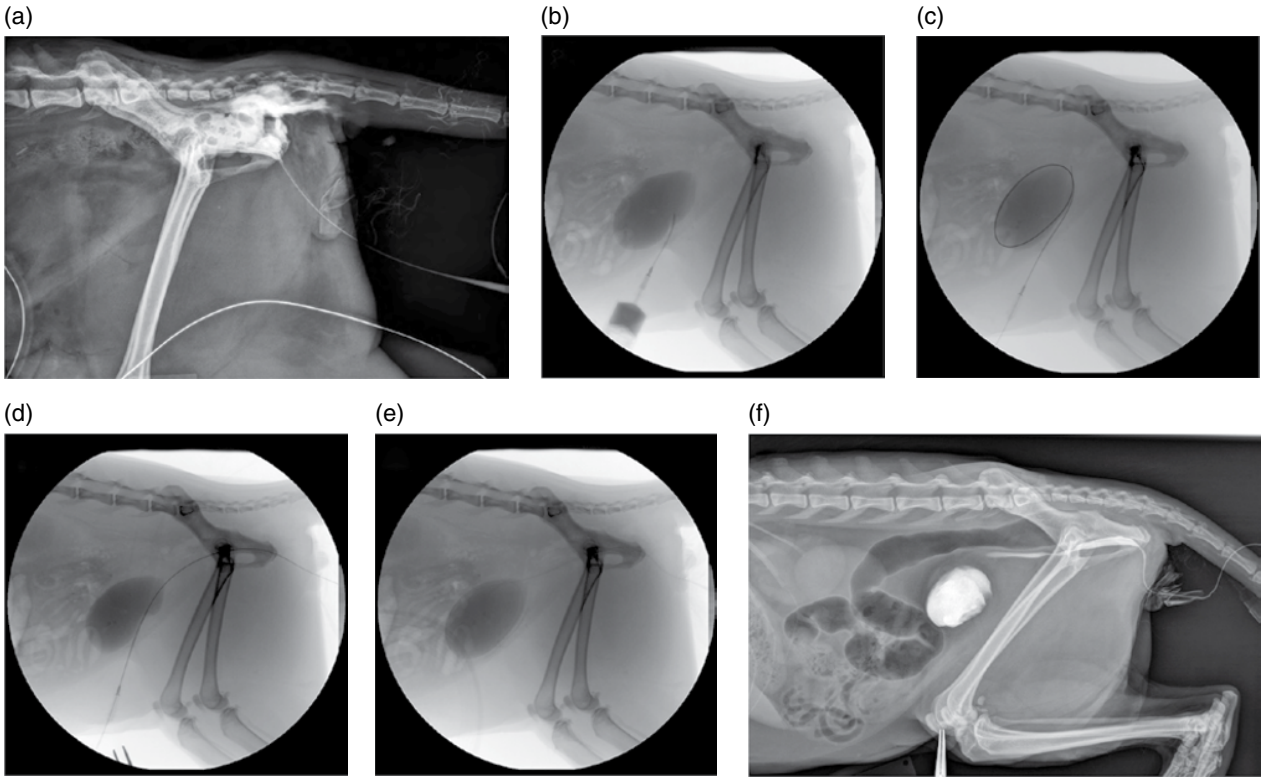

Figure 122.6 Radiographic images of antegrade urethral catheterization for urethral tear in a cat. (a) The initial retrograde urethrogram showing severe contrast extravasation throughout the pelvic canal consistent with urethral rupture during attempted urethral catheterization. (b) Percutaneous access to the bladder has been obtained with an 18-gauge over-the-needle catheter and iodinated contrast has been delivered to highlight the urinary bladder. (c) A hydrophilic guidewire is then advanced through the catheter and into the urinary bladder. (d) The wire is manipulated under fluoroscopic guidance and advanced antegrade out the urethra. As the tear was made during retrograde catheterization, the soft wire will follow the normal urethral lumen and pass out the penile urethra. (e) Once the wire is exteriorized, an open-ended urinary catheter can be advanced over the wire and will follow the true urethral lumen. Once the urinary catheter is within the bladder, the wire and bladder catheter are removed. (f) After seven days of in-dwelling urethral catheterization, a repeat urethrogram shows the urethral tear has healed and the urinary catheter is removed.

olemia. This can be achieved by at least matching the fluid rate to hourly urine production (even though the resultant rate could be very high). In the postobstructive period there is also the potential concern for inadequate urine production (<1 mL/kg/h). Major concerns in this setting would be obstruction of the collection system, dehydration, or oliguria from acute kidney injury.

The obstructive process and urethral catheter placement are painful and stressful, and could add to postobstructive morbidity. As such, provision of adequate analgesia and sedation is also important for managing these patients. For cats, buprenorphine (0.01–0.02 mg/kg q8h) generally provides sufficient pain control. If buprenorphine is not sufficient, a fentanyl continuous rate infusion (CRI) (2–4 µg/kg/h) or intermittent methadone (0.2–0.3 mg/kg q6h) is recommended. Because of the potential to cause excitability and hyperthermia, hydromorphone is typically avoided. For dogs, fentanyl or methadone (similar doses as cats) or hydromorphone (0.05–0.1 mg/kg) typically provide adequate analgesia. Acepromazine (0.05 mg/kg IV/IM/SC or 0.5 mg/kg PO) can provide adequate sedation to decrease stress and agitation, so long as the patient is stable. Given the potential functional nature of feline UO, the alpha-antagonist effects of acepromazine might promote urethral relaxation and decrease risk of reobstruction once the urinary catheter is removed.

Another important consideration is whether UO patients should be placed on antibiotics after catheter placement. This may be done with concern for existing UTI, or for introducing a UTI secondary to catheter placement. For cats, it has traditionally been accepted that the incidence of bacterial infection in lower urinary tract disease is very low. There is also evidence that prophylactic antibiotics do not prevent development of catheter-associated UTI. Therefore, antibiotic therapy is not recommended for UO in cats while the urinary catheter is in place unless bacteriuria and pyuria are documented. Dogs with evidence of UTI (based on urine cytology or positive culture) should be placed onto appropriate antibiotics.

Electrolytes and renal values should be monitored every 12–24 hours (or more frequently depending on patient severity at presentation) and should rapidly correct to normal. If there has not been a significant reduction in renal values within 24 hours, complications (such as uroabdomen) may have occurred. Given the potential for potassium wasting secondary to diuresis in the postobstructive period, supplementation may be needed, even for patients that initially presented with life-threatening hyperkalemia.

Further Therapeutic Considerations

For cats with UO not secondary to urolithiasis, medical management is typically sufficient. The urinary catheter should remain in place until bloodwork abnormalities, gross urine changes (major debris, clots or plugs), and postobstructive diuresis have resolved in order to help minimize the risk of immediate reobstruction. Performing a urine culture and susceptibility after catheter removal (sample obtained by cystocentesis) is recommended to determine if a UTI has been introduced. Observation for 12–24 hours after catheter removal will help to ensure effective spontaneous urination prior to discharge. In order to improve comfort and potentially decrease risk of reobstruction, continued analgesia and sedation after discharge may be helpful. While buprenorphine was previously recommended for oral administration in cats, its bioavailability has been called into question and it may not be effective. Instead, gabapentin (10 mg/kg) has potential as an oral analgesic, and could be given in conjunction with continued administration of acepromazine (0.5 mg/kg) for 5–7 days. As an alpha-1 antagonist and urethral relaxant, prazosin (0.25–0.5 mg per cat q12h) has also been suggested to decrease urethral spasm. However, a recent study failed to show an impact of prazosin administration on the overall risk of reobstruction. Antibiotics should only be dispensed based on results of urine culture taken after catheter removal.

Other recommendations which may help to decrease the risk of reobstruction include increasing water intake by switching to wet food, flavoring the water, or using a running-water bowl. In order to decrease stress, and thereby potentially reduce risk of reobstruction, environmental enrichment may be of benefit.

Urethral obstruction caused by urolithiasis often requires surgical intervention for stone removal. In most circumstances, successful catheterization is associated with retrohydropulsion of stones into the urinary bladder, which can be removed by subsequent cystotomy. If catheterization and deobstruction was not successful, it may be necessary to perform a urethrotomy, but this can be associated with significant risk of urethral stricture. For more distally lodged stones, penile amputation and perineal or scrotal urethrostomy may be preferred. Minimally invasive techniques for stone removal, including laser lithotripsy, percutaneous cystolithotomy, and cystoscopic-guided stone basket retrieval, are available in some centers. Stones should always be submitted for analysis to determine composition, with subsequent dietary management to decrease risk of recurrence.

Historically, dogs that presented with complete UO secondary to neoplasia were euthanized, managed by indwelling urinary catheters until NSAIDs (piroxicam), chemotherapy or radiation therapy alleviated the obstruction, or underwent urinary diversion procedures that are invasive and associated with moderate to severe rates of morbidity. In the last decade, intraluminal stenting for malignant urethral obstruction has been employed with increasing frequency as a mechanism to palliate the disease and restore urethral patency (Figure 122.7).

In the largest series to date on urethral stent implantation, involving 42 dogs, the obstruction was relieved in 41 dogs and median survival was reported as 78 days, with some dogs living for over a year after stent implantation. The most common complication associated with the procedure was urinary incontinence, graded as severe in approximately 25% of the dogs. While placement of a urethral stent for urothelial malignancy provides a minimally invasive option for animals with complete urethral obstruction, it is solely a palliative procedure and further tumor growth and/or spread should be expected unless additional chemotherapy or radiation therapy is pursued.

Surgical therapy is often advised for patients with urethral stricture if the animal is stranguric or oliguric and can result in an excellent outcome if the stricture is in the penile urethra and either a perineal urethrostomy (feline) or scrotal urethrostomy (canine) can be performed. Treatment of urethral strictures is complicated when they occur within the pelvic urethra as this will require surgical exposure to the pelvic canal and resection of the stricture. Additionally, surgical resection and anastomosis to remove a urethral stricture may induce development of a stricture at the anastomotic site as the tissues heal. Options in these cases include urinary diversion procedures such as a cystostomy tube, which are associated with a high rate of complications, balloon dilation of the stricture, or placement of an intraluminal stent. Urethral stenting for the palliation of urethral strictures has been reported with good to excellent results in both the dog and cat (Figure 122.8).

While effective in many cases, there is a risk of urinary incontinence with stent implantation that is higher in female dogs and in animals with greater amounts of urethral coverage (e.g., longer stents). Anecdotally, strictures have been observed to grow through the interstices of bare-metal stents. Consequently, covered stents may

(a) The contrast urethrogram prior to stent implantation with a focal stricture in the urethra (*arrow*). (b) One day post stent implantation with improved urethral lumen diameter; the dog was continent and urinating normally upon stenting.

be considered to avoid this potential development, albeit with a possible increased stent infection rate, in the authors' experience.

Alternative Management Protocols for Feline UO

Unfortunately, the ability to provide the optimal treatment course (close monitoring, IV and urinary catheterization) may be limited by owner financial constraints. Predicated on the notion that there is a component of functional obstruction (urethral edema and spasm), it has been demonstrated that pharmacologic manipulation (buprenorphine and acepromazine +/- dexmedetomidine), a low-stress environment, and intermittent cystocentesis can result in spontaneous urination without the need for catheterization. This approach was successful in achieving spontaneous urination in approximately 75% of cats in one study. However, while a reasonable alternative to euthanasia, this protocol cannot be recommended in lieu of traditional management (which carries a reported success rate of 91–94%) as no direct comparison between the two has been made. Further, severely debilitated cats in need of emergency stabilization, based on significant physical exam/metabolic derangements, should be excluded from this protocol.

In some cases, financial limitations might preclude the ability to hospitalize for treatment. Under those circumstances, it may be necessary to offer euthanasia, especially for severely affected patients (hypothermia, bradycardia, lateral recumbency, etc.). For those patients presenting in the earlier stages of obstruction that are not yet significantly ill, it may be possible to provide care on an outpatient basis, though this should be reserved as a last resort. One option would be to provide sedation and analgesia (acepromazine and buprenorphine) and bladder decompression through either passage of a urinary catheter or cystocentesis. Catheterization would offer the benefit of removing any physical obstruction within the urethra but could also result in damage or irritation to the urethral and an increased risk of reobstruction. Cystocentesis would likely be less expensive to perform and less injurious to the urethra, but might only provide temporary relief if a significant physical obstruction is present.

In either approach, the patient would be discharged in the hopes that continued analgesia and sedation will allow for spontaneous urination to occur. Aside from anecdotal reports and clinical experience, there is no evidence to support the merits of either of these approaches, nor is there information regarding the likelihood of success or recurrence. The client would have to be well informed of the potential for treatment failure, and follow-up phone calls to determine response would be strongly recommended.

Prognosis

Depending on the underlying cause, there is an approximately 15–40% incidence of recurrence with feline UO. With repeated obstructive episodes, it may be necessary to consider perineal urethrostomy (PU). This procedure will decrease risk of UO, though will not impact underlying FIC if present. In addition, patients with a PU may be at increased risk for UTI.

Prognosis for UO in dogs is even more dependent on the underlying cause. Obstruction secondary to urolithiasis is generally very good with successful catheterization and stone removal, though there is potential for recurrence. Proper dietary management to decrease stone formation may help decrease this risk. Prognosis for bladder/urethral/prostatic neoplasia is guarded, with palliative efforts (chemotherapy, radiation, urethral stenting) only providing temporary relief. Reported median survival for dogs with urothelial malignancy varies from days to nearly one year after diagnosis, depending on the severity of disease and the treatment pursued.

Ureteral Obstruction

Etiology/Pathophysiology

Ureteral obstruction in small animals results from urolithiasis, stricture, blood clots, congenital anomalies (ureteropelvic junction stenosis), neoplasia, external compression, severe ureteritis, or as a functional consequence of urethral obstruction. In nearly all cats and most dogs, urolithiasis is identified as the underlying cause. A rare cause of ureteral stricture is the presence of a circumcaval ureter, reported in four of 10 cats with strictures in one series and also reported in case reports of dogs. The consequences of ureteral obstruction vary depending on several factors: whether one or both kidneys are affected, the acuity versus chronicity of the disease, whether the obstruction is partial or complete, and the presence of any complicating co-morbidities, such as infection.

Ureteral obstruction may be complete or partial, depending on whether any urine is able to flow beyond the site of obstruction. The degree of obstruction dictates the severity of any rise in hydrostatic pressure exerted upstream of the obstruction – to the proximal ureter, renal pelvis, and renal parenchyma. The effect of this increased pressure on the proximal ureter and renal pelvis is passive dilation of these structures, which can become profound (Figure 122.9).

Similar to UO, the increased pressure upstream of a ureteral obstruction is transmitted from the renal pelvis to the renal parenchyma, specifically to the nephron and

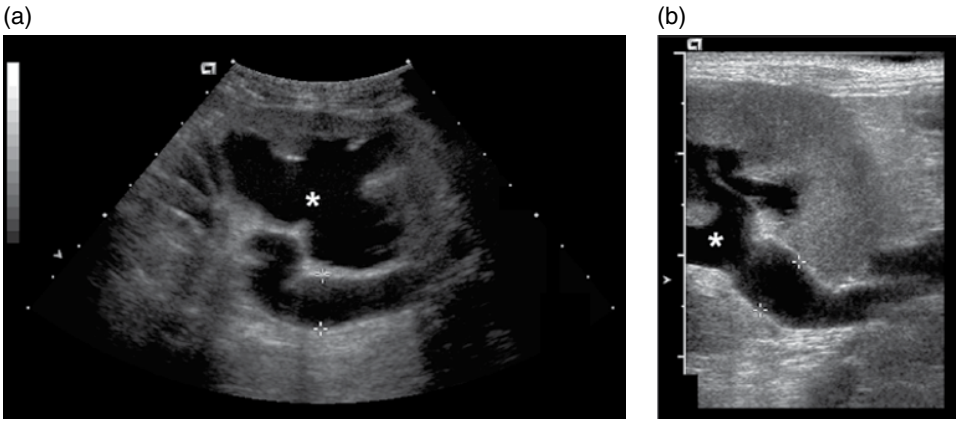

Figure 122.9 Ultrasound images of ureteral obstruction in a dog (a) and cat (b). In both images, moderate to severe dilation of the renal pelvis (*) and proximal ureter (between the +) can be appreciated. The dog suffered from transitional cell carcinoma of the bladder and the cat from ureterolithiasis.

Bowman's space, resulting in impairment or even cessation of glomerular filtration. With experimental acute ureteral obstruction, renal blood flow initially increases, but gradually declines as ureteral hydrostatic pressure rises and the obstruction is not alleviated. Permanent damage to the kidney occurs within days to weeks after ureteral obstruction though if the obstruction can be alleviated rapidly, there may be no permanent effect on renal function. Experimental studies in dogs suggest the obstructed kidney will recover only a fraction of its initial, normal GFR after weeks of complete obstruction even if the obstruction is completely alleviated at that time. In the setting of bilateral ureteral obstruction, the effect on GFR is even more dramatic. This implies that diagnosis of ureteral obstruction is an urgent problem that requires rapid deobstruction to preserve renal function, particularly as animals with ureteral obstruction often are older and likely have a degree of renal compromise prior to the development of the obstruction.

Epidemiology and Signalment

Large-scale epidemiologic studies of ureteral obstruction in veterinary medicine are lacking. As described above, the cause in most feline cases appears related to ureterolithiasis while the cause in dogs is often related to ureterolithiasis or urothelial malignancy. The epidemiology of urolithiasis (both upper and lower urinary tract) in small animals suggests that from the 1980s to the early 2000s, there was an increasing frequency of this condition in both dogs and cats, concurrent with an increased proportion of calcium oxalate calculi compared to struvite. This trend for increasing calcium oxalate calculi in cats appears even more dramatic when only upper urinary tract stones are considered. In dogs with ureterolithiasis, struvite and calcium oxalate calculi seem to be found in a comparable proportion.

Breed predilections are observed in dogs with upper urinary tract calculi, with miniature schnauzers, Lhasa apsos, shih tzus, and Yorkshire terriers affected with greater frequency than other breeds. No consistent breed differences have been reported in cats specific to ureterolithiasis. There are breeds of dog that are recognized to have a greater incidence of urothelial malignancy than others. Specifically, the Scottish terrier, Shetland sheepdog, beagle, wire-haired fox terrier, and West Highland white terrier are reported to have an increased risk.

The effect of gender on prevalence of ureterolithiasis is unclear. It has been suggested that male cats are more frequently affected by urolithiasis in general than females, though reports evaluating solely ureteral stones suggest a higher proportion of female cats. In dogs with ureterolithiasis, there are fewer cases reported, but a female majority was also observed. Female dogs have been recognized as having a higher prevalence of urothelial neoplasia compared to males; additionally, castrated dogs of both sexes are at higher risk for transitional cell carcinoma compared to sexually intact dogs.

History and Clinical Signs

The signs of ureteral obstruction are often nonspecific, with vomiting, lethargy, and inappetence commonly reported. Abnormalities in urination, such as pollakiuria, hematuria, or stranguria, can also be seen, which may be related to concurrent lower urinary tract uroliths, lower urinary tract infection, or ureteral irritation. Weight loss may be reported if the animal has a chronic course of disease with compromised renal function. Increased urination and thirst may also be observed, associated with renal dysfunction if present.

Diagnosis

Abdominal pain may be the only finding associated with unilateral ureteral obstruction, as the animal's renal function from the contralateral kidney should be sufficient to maintain renal values in a normal range. Abdominal discomfort appears to be a more easily recognized sign in the dog than the cat. On physical examination, a poor body condition may be observed if the obstruction has been chronic and renal dysfunction is long-standing. It is relatively common to observe cats with marked discrepancy in renal size on abdominal palpation, the so-called "big kidney, little kidney" syndrome. This is theorized to occur secondary to prior chronic obstruction of the little kidney, which led to a reduction in glomerular filtration and renal blood flow, progressive nephron loss, renal fibrosis, and compensatory hypertrophy of the unobstructed big kidney.

Diagnostic testing involves arterial blood pressure measurement, serum biochemical analyses to investigate the degree of renal dysfunction and concurrent disease, a complete blood count to screen for anemia or leukocytosis, urinalysis and urine culture, and imaging. Abdominal radiographs are advised to look for evidence of urolithiasis as most, at least in the cat, are calcium oxalate and therefore radiopaque. However, radiography is imperfect as small stones may be missed or findings interpreted as stones may not be within the urinary tract. The presence of calculi in the kidneys, bladder, or urethra as well as the relative size of each kidney can also be investigated with survey radiographs. For dogs with urothelial neoplasia, an increased soft tissue opacity may be observed at the bladder trigone or prostate. Confirmation of ureteral obstruction, however, typically requires ultrasound (see Figure 122.9). Ultrasound should be utilized to quantify the magnitude of renal pelvic and ureteral dilation, the presence, number, and location of uroliths throughout the urinary tract, the existence of a stricture or area of ureteral thickening, the location of a trigonal or other extramural lesion compressing the ureter, an assessment of renal blood flow, and the presence of any free abdominal fluid.

Therapy

Treatment is directed at providing the animal comfort and alleviating the obstruction. Analgesia should be given due to the pain associated with ureteral obstruction, related to stretch of the ureteral wall and renal capsule resulting in activation of mechanoreceptors. Medical therapy should be initiated as soon as a diagnosis of ureteral obstruction is made as it will be necessary to help stabilize the animal and may aid in alleviating the obstruction in a small proportion of cases. However, medical therapy is typically insufficient to cure most ureteral obstructions, as the physical barrier (stone, tumor, stricture) must be addressed.

Upper urinary tract calculi are typically calcium oxalate, particularly in the cat, and dietary dissolution will therefore not be effective in most cases. Furthermore, there is insufficient time to allow dissolution to take place in the setting of a complete ureteral obstruction in which rapid nephron loss is occurring. In the patient with ureterolithiasis, intravenous fluid therapy should be initiated as the animal is often dehydrated and an increase in urine flow may help to move the calculus into the bladder.

Ureteral relaxation and reduced ureterospasm can be achieved by administration of an alpha-receptor antagonist such as prazosin (0.25–0.5 mg per cat q12h) or the smooth muscle relaxant amitriptyline (1 mg/kg PO q24h). There are additional medications with greater urinary selectivity now available on the human market, such as tamsulosin, though there is only anecdotal evidence of their use in animals. An additional strategy to facilitate movement of ureteroliths is a mannitol infusion (0.25-0.5 g/kg over 20 min, followed by CRI at 1 mg/kg/min) to promote an osmotic diuresis. Mannitol should be given with caution in these animals, however, as hypervolemia can develop – particularly in cats or dogs with bilateral ureteral obstruction. In the dog, broad-spectrum antibiotics should be initiated as canine upper urinary tract calculi are more likely to be infected than in cats, which are typically sterile.

While medical therapy should be initiated once a diagnosis of ureteral obstruction is made, it must be recognized that medical therapy is effective in only a small portion (reported as less than 15%) of cats with obstructive ureteroliths. Medical therapy should be attempted for no more than 12–48 hours in animals with ureteral obstruction secondary to urolithiasis, depending on the stability of the patient, with serial monitoring to evaluate for progressive renal decline or movement of the stone. If medical therapy is unsuccessful, or in the setting of ureteral obstruction secondary to urothelial malignancy that will not respond rapidly to medical therapy, intervention by surgery or minimally invasive therapy is advised.

Currently, noninvasive therapy for ureteral obstruction secondary to urolithiasis involves the use of extracorporeal shock wave lithotripsy. This treatment modality employs high-energy shock waves directed through the body and focused at the site to pulverize the urolith into sufficiently small particles that can be safely passed out of the body. This is the standard of care in the treatment of human upper urinary tract calculi, but has not gained wide use in veterinary medicine. Few veterinarians employ this therapy in cats as the small size of the feline

ureter makes even small stone fragments problematic and even in dogs there is risk of ureteral obstruction after shock wave therapy of nephroliths. The likelihood of ureteral obstruction following shock wave therapy can be limited if a ureteral stent is implanted at the time of the shock wave treatment. Extracorporeal shock wave lithotripsy is a consideration for dogs and appears well tolerated, though transient hematuria or shock wave-induced pancreatitis may occur.

In dogs, surgical ureterotomy for an obstructive urolith is typically associated with a favorable outcome in the hands of an experienced surgeon. In cats, however, major complications were reported in a significant number of the cases, with a mortality rate of 18% in the largest series from a highly experienced center. In light of these figures, alternatives to surgical ureterolith removal have been developed in recent years, including ureteral stenting (Figure 122.10) and subcutaneous ureteral bypass (Figure 122.11).

An indwelling ureteral stent is composed of a flexible polymeric compound that has a loop at each end, which help maintain the stent's position throughout the ureter, with one loop in the renal pelvis and the other in the bladder. Ureteral stents may be placed endoscopically, though this is most feasible in female dogs where a rigid cystoscope and a comparatively larger urethra facilitate the procedure. For cats, the stents are typically placed via an open abdominal procedure with fluoroscopic guidance. The stent may be placed antegrade through the renal parenchyma after needle access into the renal pelvis, or retrograde through a cystotomy incision and visualization of the ureterovesicular orifices. Reports of ureteral stents in both dogs and cats suggest successful implantation in greater than 95% of cases with low complication or reintervention rates. The cat shown in Figure 122.10 presented with a BUN of 280 mg/dL (reference interval, 13–30 mg/dL) and a creatinine of 20.5 mg/gL (reference interval, 0.9–2.1 mg/dL) and complete

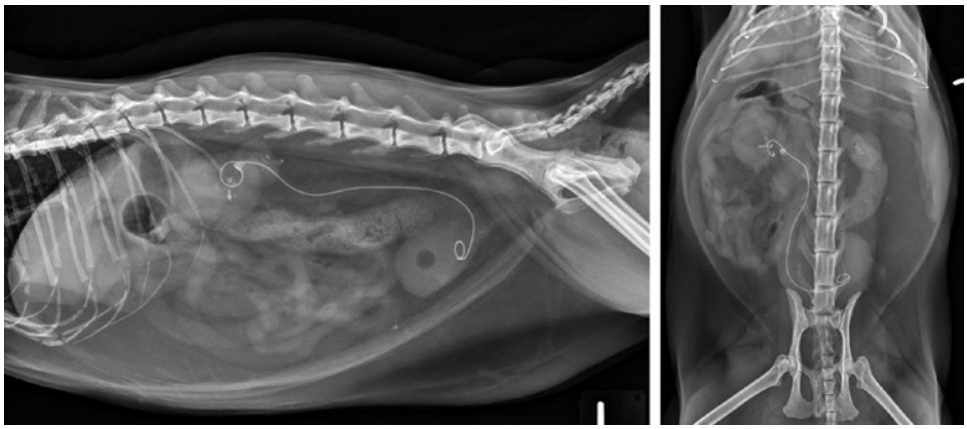

Figure 122.10 Radiographic images from a cat with complete right ureteral obstruction secondary to a circumcaval ureter and ureterolithiasis. A double-pigtail ureteral stent has been implanted in the obstructed right ureter to restore urine flow. Note that the left kidney is severely shrunken and small.

Figure 122.11 Radiographic images from a cat with a subcutaneous ureteral bypass system. The system includes a nephrostomy tube and a cystostomy tube connected to a dual-lumen vascular port that is sutured to the body wall under the ventral skin.

right ureteral obstruction. In addition, it had a severely shrunken left kidney, which was likely nonfunctional. After placement of the right ureteral stent, the cat was discharged four days later with a BUN of 16 mg/dL and a creatinine of 1.4 mg/dL.

In the authors' experience, ureteral stents in cats provide acute resolution of the obstruction but have a moderate risk for ureteral irritation and pollakiuria that can be challenging to manage. Studies suggest one-third of cats with a ureteral stent will have dysuria either transiently or permanently and that 19% of feline ureteral stents will become obstructed. There is also an increased risk of ascending urinary infection with a stent in place. In human medicine, ureteral stents are left in place for only 3–4 months in most cases to avoid stent encrustation and calcification. However, stents have been left indwelling in cats for greater than five years that were seemingly well tolerated (see Figure 122.10). In dogs, ureteral stents for benign ureteral obstructions are well tolerated, can be placed cystoscopically, and are often removed once the obstructive stone has passed, avoiding long-term risk for stent dysfunction. The presence of a ureteral stent induces passive ureteral dilation which may allow a previously obstructive urolith to pass, after which the stent can be removed via an outpatient cystoscopic procedure. Currently, the authors monitor animals with ureteral stents every 3–4 months by imaging and urine culture. If stent malfunction develops, evidenced by recurrent infection, pollakiuria, obstruction, abdominal pain, or stent migration/fracture, then the stent is removed via cystoscopy or cystotomy.

To avoid eventual dysuria and potential complications of a ureteral stent in cats, or for those animals in which a stent cannot be placed, subcutaneous ureteral bypass devices are commercially available. Subcutaneous ureteral bypass employs a nephrostomy tube and a cystostomy tube, which are connected to a dual-lumen vascular port that is attached under the skin to the ventral body wall. This port allows the system to be flushed at regular intervals to avoid obstruction and facilitates urine sampling (see Figure 122.11). At many centers, subcutaneous ureteral bypass devices are now the treatment of choice for obstructive urolithiasis in cats but are rarely implanted in dogs where conventional surgery or temporary ureteral stenting are often effective. Long-term complications of ureteral bypass devices include infection and biofilm formation, encrustation and obstruction, and rarely signs of dysuria. The rate of complications appears lower in cats with a subcutaneous ureteral bypass device than was observed with ureteral stents but routine surveillance (imaging, system flushing, urine culture) is still required.

For animals with ureteral obstruction secondary to urothelial malignancy, ureteral stenting is advised to deobstruct the kidney and restore urine flow. In the dog, this is done via percutaneous transabdominal access to the dilated renal pelvis with a small needle, through which a wire is advanced under fluoroscopic guidance to the site of obstruction (Figure 122.12).

The wire is manipulated through the obstruction, into the bladder, and out the urethra. The stent is then advanced over this wire and into place within the renal pelvis proximally and the bladder distally and urine now flows through the stent lumen, bypassing the neoplastic obstruction. A small series of 12 cases found that percutaneous stent implantation for trigonal urothelial carcinoma was feasible in all dogs and the stents remained patent for the remainder of the animals' lives, which ranged from 0.25 to 11 months.

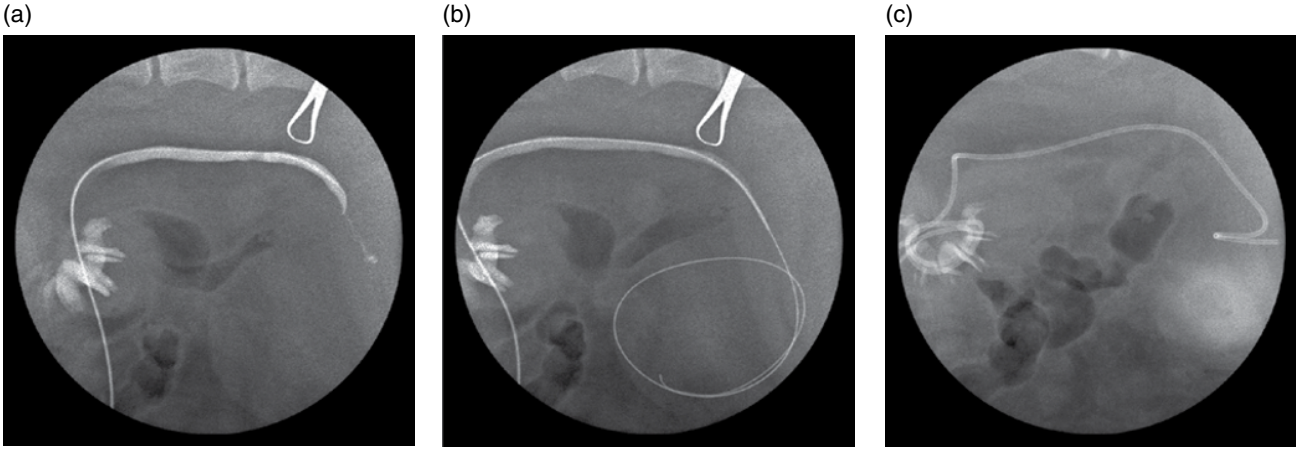

Figure 122.12 Fluoroscopic images from an 8-year-old Labrador retriever with urothelial neoplasia causing ureteral obstruction. (a) Direct puncture of the renal pelvis was obtained and a wire was advanced down the dilated ureter to the site of obstruction at the ureterovesicular junction. (b) With manipulation, the wire is advanced across the obstruction and into the bladder. (c) The stent has been positioned throughout the length of the ureter with one pigtail in the renal pelvis and one in the bladder, allowing restoration of urine flow past the malignant obstruction.

Prognosis

The prognosis for ureteral obstruction is fair, dependent on the chronicity of the obstruction, the ability of the veterinarian to alleviate the obstruction, and the underlying disease process. If the obstruction has been in place for some time, a return to normal renal function after ureteral patency is restored is unlikely. In the setting of urolithiasis, recurrence of stones and progression of intrinsic renal dysfunction are common, but typically manageable. In dogs with urothelial malignancy, the prognosis by the time they have developed ureteral obstruction is typically poor. However, ureteral decompression in this disease can allow an improved quality of life and give the patient additional time until conventional therapy (e.g., chemotherapy) has an impact.

Overview

Definition

Urine is a complex solution that contains multiple crystal components. The ionic elements of crystals in urine are referred to as crystalloids, which can be organic or inorganic. Uroliths are organized assemblages of crystalloids, combined with a small amount of organic matrix, located within the urinary tract.

Urolith Formation

Formation of urinary calculi (uroliths) has been hypothesized to occur through multiple mechanisms or processes. Three of the more common of these theories are:

- *the precipitation-crystallization theory*: supersaturation of urine with crystalloids is followed by growth of calculi
- *the matrix-nucleation theory*: an abnormal substance in the urine is responsible for calculi development
- *the crystallization-inhibition theory*: the absence of a critical inhibitor (or the presence of a promoter) of crystal formation is the primary factor in calculi development.

All three of the above theories (individually or in combination) likely contribute to development of individual uroliths.

Urine is commonly supersaturated with crystalloids, and this is a prerequisite for urolith formation (Figure 123.1). Supersaturation of urine with crystalloids depends on urine crystal volume, renal crystal excretion, urine concentration, urine pH, and the presence of urolith promoters or lack of inhibitors. Following establishment of these supersaturation criteria, and dependent on numerous patient-related factors, urine crystals may begin to aggregate into a nucleus. The crystal nucleus, commonly referred to as the nidus, can then develop into a urolith, aka the "stone."

Additional theories regarding urolith development have been postulated. One of these, homogenous nucleation, refers to the spontaneous precipitation of crystals from a pure solution. This process is considered uncommon in urine, and urine crystal formation is believed to occur through heterogenous nucleation. This theory is similar to the matrix-nucleation theory, whereby another substance (e.g., bacteria, inflammatory cells or debris) acts as a nidus for crystal precipitation. Once again, after the crystal nidus has formed, it may develop into a urolith dependent on the following: degree and duration of urine supersaturation, and sufficient time for the nidus to remain in the urinary tract without being flushed out.

Factors that predispose to urine stasis also play an important role in urolithiasis formation. Consequently, factors that induce frequent and regular voiding of urine may be protective and aid in prevention of urolith development and progression.

History and Physical Examination

History

Dogs and cats with uroliths may present for a variety of animal owner concerns. Most commonly, dogs and cats present with lower urinary tract signs (i.e., pollakiuria, hematuria, stranguria) related to the irritating presence of uroliths in the bladder or urethra. In patients with upper urinary tract uroliths (i.e., nephroliths, ureteroliths), signs

of systemic disease may be noted (e.g., vomiting, lethargy, anorexia, polyuria-polydipsia secondary to uremia, etc.), which can range in severity, as related to secondary infection or complete urethral obstruction. Other patients may have subclinical disease, that is, no signs, and either upper or lower urinary tract uroliths are discovered incidentally, for example via radiographs, ultrasound, etc.

Physical Examination Findings

Physical examination is frequently normal but dependent on stone type and, more importantly, location, abnormalities associated with either the lower or upper urinary tract can occur and are detailed below. Systemic signs (i.e., fever, dehydration, etc.) can be found in patients with secondary infections or obstructive disease.

Lower Urinary Tract Urolith Physical Exam Findings

Palpation of urinary calculi can be challenging, particularly in overweight or tense patients. If the bladder is empty and there are multiple stones, a crepitant sensation may be noted on bladder palpation. Urethral stones can sometimes be palpated rectally or via palpation of the perineum or penile urethra. A large firm bladder may be suggestive of urethral obstruction. However, in the case of uroabdomen, the bladder may be empty (not palpable), and the patient may have a tense and painful abdomen.

Upper Urinary Tract Urolith Physical Exam Findings

The patient may be subclinical. An enlarged kidney may be palpated with hydronephrosis associated with ureteral obstruction in dogs and cats; however, most cats have chronically small kidneys, even with obstruction. Unilateral renal or ureteral obstruction should not result in clinical signs related to uremia, unless there is contralateral kidney disease.

Systemic disease signs, such as fever, weight loss or dehydration, associated with uremia may be present dependent on functionality of the renal parenchyma and the presence of infection. Flank pain may be present with ureteral obstruction or infection.

Patient Signalment Related to Specific Stone Types

In dogs and cats, signalment (breed, sex, age) and geographic region can provide clues to urolith composition (Tables 123.1, 123.2).

Oxalate Urolithiasis

Calcium oxalate uroliths are usually composed of 100% calcium oxalate, although some also contain varying amounts of calcium phosphate. Additionally, concurrent infection can change the composition of the stone, for example calcium oxalate nidus encased in struvite shell. Two crystalline forms of calcium oxalate uroliths can occur: calcium oxalate monohydrate (whewellite) and calcium oxalate dihydrate (weddellite). Calcium oxalate monohydrate is more frequent in canine uroliths than calcium oxalate dihydrate.

The surface characteristics of oxalate uroliths can vary widely; uroliths may be smooth, mulberry shaped or have sharp projections (Figure 123.2; see also Figure 123.1).

Epidemiology and Risk Factors

Calcium oxalate uroliths represented 48.1% (49.5% including mixed stones) of all canine and feline uroliths submitted to the Canadian Veterinary Urolith Centre (CVUC) from 2009 to 2014 (see Table 123.2). Most upper urinary tract uroliths in cats (98%) and half of those found in dogs are composed of calcium oxalate.

Although calcium oxalate stones are not considered infection induced, they may be associated with secondary urinary tract infections (UTI). This is because the presence of the uroliths is believed to affect the patient's local immune defenses. In one study, 52% of female dogs and 31% of male dogs with calcium oxalate urolithiasis were found to have concurrent bacteria present, that is, positive urine or urolith cultures. However, other studies have not supported an association between calcium uroliths and UTI.

Risk factors for calcium oxalate uroliths in dogs include sex, and they occur more commonly in male than female dogs. Additionally, neutered male dogs have an increased risk of calcium oxalate uroliths compared with intact males. Obese dogs are more likely to form calcium oxalate uroliths, which is similar to cats and humans.

Table 123.1 Summary of the signalment of cats and dogs with each type of stone

	Dogs			Cats		
	Breed	**Sex**	**Age**	**Breed**	**Sex**	**Age**
Cystine	English bulldog, Newfoundland, dachshund, Irish terrier, basset hound, bullmastiff, Rottweiler,mastiff, Australian cattle dog, Australian shepherd, Chihuahua, Basenji, Scottish deerhound, Staffordshire terrier, pitbull terrier, Welsh corgi, miniature pinscher, silky terrier, bichon frise, Yorkshire terrier, Dalmatian, borzoi, Shetland sheepdog, Doberman, border collie	Male dogs much more commonly than females (except in Newfoundlands)	Young to middle-aged dogs (3–8 years), exception in Newfoundlands	Very rare in cats	Males equal to female	Any age, average 3–5 years or older
Oxalate	Any breed but increased risk in miniature schnauzer, bichon frise, Lhasa apso, Yorkshire terrier, miniature poodle, shih tzu, and other small breed dogs. The predisposition for smaller breeds may be related to their lower urine volume, fewer numbers of micturitions, and likely increased mineral concentrations compared with larger breeds	Male dogs more commonly than females; exception miniature schnauzer	No age predilection (generally older than those with struvite calculi)	Persian and Himalayan cats	Male neutered cats more commonly than females	>7 but <10 years
Purine	Black Russian terriers, shih tzus, miniature schnauzers, Yorkshire terriers, Dalmatians, English bulldogs	Pure urates are more common in males than females	Variable (in Dalmatians, any age but often 1–4 years; other breeds 3–6 years)	Siamese, Birman, Egyptian Mau (male)	No sex predisposition in cats	Mean age 6.3 ± 0.17 years; portosystemic vascular shunts (PSS) are more common in cats <1–5 years
Silicate	German shepherds, Old English sheepdog, miniature schnauzer, shih tzu, Lhasa apso, Yorkshire terrier, Pekingese, Labrador retriever, golden retriever, cocker spaniel, English bulldog, bichon frise, Rottweiler, and mixed breeds	Male dogs much more commonly than females	Middle-aged dogs	Does not appear to be a breed predisposition	Does not appear to be a gender predisposition	Does not appear to be an age predisposition
Struvite	Any breed Increased risk in miniature schnauzer, bichon frise, shih tzu, Lhasa apso, Yorkshire terrier, miniature poodle (and other small-breed dogs). The predisposition for smaller breeds may be related to their lower urine volume, fewer numbers of micturitions, and likely increased urine mineral concentrations compared with larger breeds	Female dogs more commonly than males	No age predilection (middle-aged but generally younger than those with oxalate calculi). Calculi that occur in dogs younger than 1 year are frequently composed of struvite	Any breed Himalayan Persian, domestic cats	No sex predilection, may be slightly more common in females >2 years	No age predisposition but typically >6 years

Table 123.2 Urolith composition for feline and canine samples submitted to the Canadian Veterinary Urolith Centre (Guelph, Ontario, Canada; 2009–2012)

Major composition	Canine n (%)	Feline n (%)	Total n (%)
Ammonium urate	619 (2.9)	257 (4.7)	876 (3.3)
Brushite	60 (0.3)	2 (0.04)	62 (0.2)
Calcium oxalate	10 043 (47.4)	2778 (50.7)	12 821 (48.1)
Calcium phos apatite	221 (1.0)	69 (1.3)	290 (1.1)
Calcium phos carbonate	240 (1.1)	11 (0.2)	251 (0.9)
Cystine	134 (0.6)	6 (0.1)	140 (0.5)
Silica	181 (0.9)	7 (0.1)	188 (0.7)
Sodium urate	21 (0.1)	1 (0.01)	22 (0.08)
Struvite	7226 (34.1)	2238 (40.9)	9464 (35.5)
Uric acid	5 (0.02)	0	5 (0.02)
Xanthine	5 (0.02)	5 (0.09)	10 (0.04)
X-oxalate/Ca phosphate	237 (1.1)	28 (0.5)	265 (1.0)
X-oxalate/silica	63 (0.3)	1 (0.02)	64 (0.2)

Etiopathogenesis

Hypercalciuria and Hyperoxaluria

Excessive urinary excretion of calcium (hypercalciuria) or oxalate (hyperoxaluria) results in increased risk of calcium oxalate urolith formation. Lulich *et al*. reported that 6/6 miniature schnauzers with calcium oxalate urolithiasis had hypercalciuria. Similarly, urinary concentration of oxalate is an important factor in calcium oxalate crystallization and urolithiasis. This is because increases in urine oxalate concentration have a greater effect on urinary saturation of calcium oxalate than equivalent increases in urinary calcium concentration on a molar basis.

Urinary oxalate is derived mainly from endogenous production in the liver (metabolism of ascorbic acid, glyoxylate, and glycine) with lesser amounts from dietary intake of oxalate. Enteric (large intestine) colonization of *Oxalobacter formigenes*, an anaerobe which exclusively relies on oxalate metabolism for energy, is correlated with absence of hyperoxaluria or calcium oxalate (CaOx) urolithiasis in humans and laboratory animals. It has recently been demonstrated that the absence of enteric colonization of *O. formigenes* is a risk factor for CaOx urolithiasis in dogs.

Water Type

In humans, the mineral content of water may play a role in calcium oxalate urolith formation. It is also thought that increased sodium content can increase water intake and offset its calciuretic effect. Increased water sodium, calcium, or the absence of trace minerals such as zinc, which chelates calcium, may increase the risk of calcium oxalate urolithiasis. However, in cats, the source of water (bottle, municipal, etc.) did not appear to affect the risk of calcium oxalate urolithiasis. A similar study has not been conducted in dogs.

Modifiers of Calcium Oxalate Crystal Formation

In humans, urine normally contains several natural inhibitors of urolith formation and growth. Inhibitors can be either organic or inorganic substances in urine that reduce crystal formation, aggregation, or growth. A defect or deficiency in these inhibitors may contribute to urolith formation. Inhibitors of calcium oxalate include citrate, magnesium, pyrophosphate, glycosaminoglycans, nephrocalcin, and Tamm–Horsfall mucoprotein. Although little is known about these inhibitors in dogs, it is suspected they may play a similar role as in humans.

Concurrent Medical Conditions

Hyperadrenocorticism is associated with calcium oxalate urolithiasis in humans and dogs. In humans, glucocorticoid excess leads to hypercalciuria secondary to increased mobilization of calcium from bone. Glucocorticoid-

induced decreases in tubular resorption of calcium, chronic metabolic acidosis, and decrease in urinary excretion of citrate may also occur. Similar glucocorticoid-associated mechanisms are believed to occur in dogs.

A recent study in humans demonstrated an association between calcium oxalate stones and hypertriglyceridemia. The predisposition of miniature schnauzers for idiopathic hyperlipidemia may one day be found to explain why this breed is at high risk of calcium oxalate stones.

Struvite Urolithiasis

Epidemiology

Struvite uroliths are typically composed of 100% magnesium ammonium phosphate hexahydrate. Struvite stones may also contain varying amounts of calcium phosphate (termed *calcium apatite*) or calcium carbonate phosphate (termed *carbonate apatite)*. These uroliths are commonly referred to as "infection stones" or "urease stones" because, in dogs, they are primarily due to the presence of urease-producing bacteria. Struvite stones are often multifaceted or pyramidal in appearance, especially when multiple urocystoliths are present, because the adjacent surfaces are smooth and flattened. If solitary, struvite may have sharp spiculated projections (Figure 123.3). Struvite uroliths represented 35.5% (43.6% including mixed stones) of all canine and feline uroliths submitted to CVUC from 2009 to 2012 (see Table 123.2). More recently, struvite urolith submissions have increased and have exceeded the calcium oxalate urolith submissions for small animals (2018 Minnesota Urolith Center [MUC] Global Data generated by Minnesota Urolith Center, February 2019).

Figure 123.3 Bladder struvite uroliths retrieved from a 10-year-old female spayed golden retriever. *Source:* Courtesy of Andrew Moore, Canadian Veterinary Urolith Centre.

Struvites are most commonly located in the lower urinary tract (LUT) (95%). Risk factors appear related to sex and associated higher bacterial infection risk, as they are more frequent in female dogs (71–85% of struvite submitted to urolith centers) than male dogs (15–29%). Certain breeds are predisposed to struvite uroliths (see Table 123.1).

Etiopathogenesis

The majority of canine struvite uroliths are due to urinary tract infection, most commonly related to bacterial infection with urease-producing organisms. However, sterile struvite urolithiasis has been reported in related cocker spaniels. In dogs, *Staphylococcus pseudintermedius* is cited as the most common urease-producing bacterium associated with struvite uroliths. Other less common urease-producing organisms include *Pseudomonas* spp., *Klebsiella* spp., *Proteus*, and *Corynebacterium urealyticum*. Urease-producing mycoplasmas (termed ureaplasma) such as *Ureaplasma urealyticium* may also cause struvite urolithiasis.

Infection-based struvite uroliths form when urease cleaves urea to form ammonia and bicarbonate. The available ammonium then combines with magnesium and phosphate, normally present in urine, to form magnesium ammonium phosphate hexahydrate (struvite) crystals. Bicarbonate increases the urine pH (i.e., urine becomes more basic), which then decreases the solubility of struvite crystals. Ammonium also damages the urothelial glycosaminoglycan layer by acting as an irritant. This allows struvite crystals and bacteria to adhere to the urothelium and may promote production of an organic matrix for the crystal–matrix interaction, leading to stone formation. Unlike in cats, where sterile struvite urolithiasis may occur solely because of excess mineral intake in the diet, infection with a urease-producing bacterium is associated with struvite urolithiasis in most dogs.

Infection-induced struvite uroliths may contain viable bacteria trapped in the interstices of the stone layers. Bacteria have been cultured from the core of struvite uroliths that have been stored in formalin for years. Dissolution or fragmentation of struvite uroliths may release viable bacteria into the urinary tract and this may cause reinfection unless appropriate antimicrobials and duration of therapy are provided. If the bacteria isolated from the urine and the urolith differ, a change in antimicrobial is only necessary if poor clinical response is observed. If a nonurease-producing bacterium is isolated and subclinical bacteriuria is suspected, an antimicrobial

is rarely indicated. If a urease-producing bacterium is isolated, antibiotic therapy should be continued as long as struvite uroliths are present. If therapy duration is insufficient, UTIs will not resolve or a relapse of infection will likely occur.

Purine Urolithiasis

Epidemiology

Naturally occurring purine uroliths consist of uric acid (and its various salts) and xanthine. Xanthine and uric acid are successive biodegradation products in the metabolism of purines (Figure 123.4). Purine uroliths may be pure (100%) in composition, or less commonly, may contain varying amounts of other minerals. The term "urate" includes uric acid, ammonium urate, and the other salts of uric acid, mostly sodium acid urate, sodium calcium urate, and ammonium calcium urate. Ammonium urate accounts for 86% of urate uroliths.

Urate uroliths are typically small, round, smooth stones that are greenish-brown in color (Figure 123.5). There are often multiple urate uroliths present. Cross-sections of urate uroliths reveal a concentric appearance. Xanthine uroliths are typically similar in size and shape to urate uroliths but are usually yellow to brown (Figure 123.6).

Purine uroliths accounted for 6.4% of canine uroliths analyzed at the MUC between 1981 and 2007, making it the third most common type of canine urolith in this region. In Canada, purine uroliths represented 3.44% of canine and feline uroliths submitted to the CVUC between 2009 and 2012 (see Table 123.2). The majority of urate (97%) and xanthine (94%) uroliths that are submitted for analysis have been removed from the LUT. However, considering the difficulty in removing uroliths from the upper urinary tract (UUT), nephroliths and ureteroliths may be underrepresented in submission frequency.

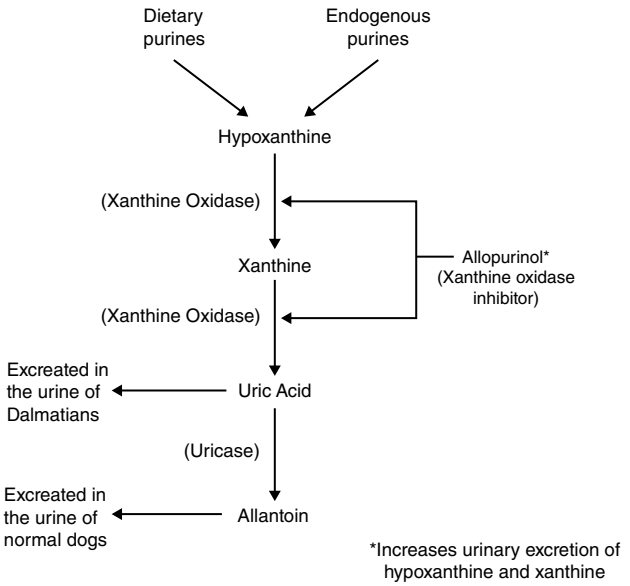

Figure 123.4 Normal canine purine degradation pathway.

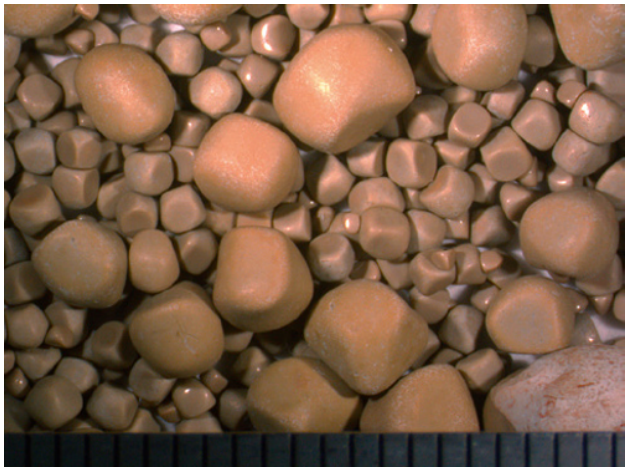

Figure 123.5 Urate stones retrieved from a 12-year-old male neutered Dalmatian dog. *Source:* Courtesy of Andrew Moore, Canadian Veterinary Urolith Centre.

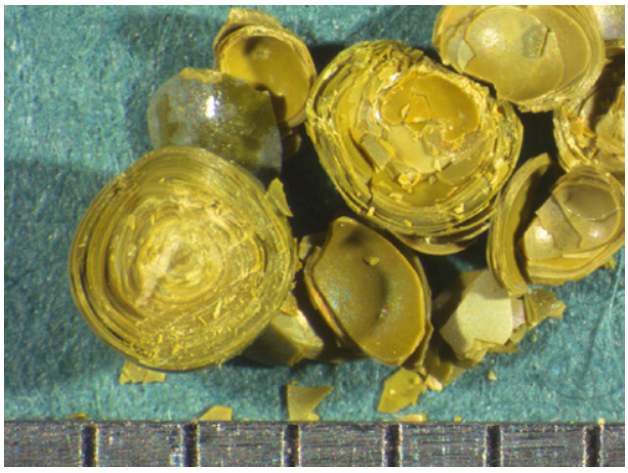

Figure 123.6 Xanthine stone retrieved from a 2-year-old male neutered Dalmatian. *Source:* Courtesy of Andrew Moore, Canadian Veterinary Urolith Centre.

Risk factors for purine uroliths (and types of these) include species, breed, age, and sex. Ammonium urate is the most common (approx. 95%) naturally occurring purine urolith in cats. Xanthine uroliths are uncommon specimens submitted to the CVUC, having been diagnosed in only five cats and five dogs (0.02% of uroliths in cats and 0.09% of uroliths submitted in dogs) from 2009 to 2012 (see Table 123.2). Uroliths composed of hypoxanthine have not been recognized in cats.

Urate stones may be found in dogs of any age but are most frequently retrieved from young to middle-aged dogs (see Table 123.1). Pure urate uroliths occur more

often in males than in females. Female dogs may spontaneously void urate uroliths without being detected. In dogs, urate uroliths are most commonly retrieved from Dalmatians (61% of ammonium urate and 91% of sodium and calcium urate uroliths). In cats, the typical patient with urate uroliths is a pure-bred neutered cat, 4–7 years old, with uroliths in the bladder or urethra. The Siamese breed seems to be overrepresented, along with the Egyptian Mau and Birman breeds. Cat breeds that had lower odds for urate urolith submission than mixed breeds included Abyssinian, American shorthair, Himalayan, Manx, and Persian. There is no sex predisposition in cats.

Naturally occurring xanthine uroliths are rare and are frequently retrieved from dogs that have been treated with allopurinol.

Etiopathogenesis in Dogs

The purine metabolites, uric acid and xanthine, have much lower solubility than that of allantoin. Consequently, if urine is oversaturated with these substances, uroliths can form. A high dietary intake of purines and purine precursors, along with acidic urine, aids in urolith formation. Infection with urease-producing bacteria may also promote formation of urate uroliths by increasing ammonium ion concentration from the breakdown of urea (see Figure 123.6).

Dalmatian Dogs

Dalmatian dogs are predisposed to the development of urate uroliths because of their reduced transport of uric acid into hepatocytes. This results in decreased conversion of uric acid to allantoin, a subsequent moderate increase in serum uric acid concentration (hyperuricemia), and then hyperuricosuria. The inheritance of hyperuricosuria in Dalmatians is via a simple autosomal recessive gene. The missense mutation in the SLC2A9 gene that encodes for a urate transporter is responsible for this defect, and all Dalmatians are homozygous. Despite excretion of relatively large quantities of uric acid, not all Dalmatians form urate uroliths. It is estimated that 25% of male Dalmatians will have urolithiasis and it is suspected that other risk factors play a role in dogs who become urate stone formers.

Non-Dalmatian Dogs

Dogs other than Dalmatians accounted for approximately 30–60% of urate uroliths submitted for analysis. Similar to Dalmatians, urolith-forming bulldogs and black Russian terriers have been shown to be homozygous for a mutation in SLC2A9. However, the reasons for development of urate uroliths in these non-Dalmatian breeds is unknown and does not appear associated with hepatic dysfunction.

Hepatic Dysfunction

Hepatic dysfunction is associated with a reduced ability to convert ammonia to urea and uric acid to allantoin. Therefore, dogs suffering from hepatic dysfunction may develop hyperammonuria and hyperuricuria, which may result in urate urolith formation. The incidence of urate urolithiasis appears to be higher in dogs with portal vascular anomalies than with other causes of hepatic dysfunction.

Xanthine

Xanthine is an important mediator in purine metabolism; the drug allopurinol binds rapidly to (and inhibits the action of) xanthine oxidase, thereby decreasing conversion of hypoxanthine to xanthine and xanthine to uric acid. The result is a reduction of serum and urine concentrations of uric acid, with an increase in serum and urine concentrations of xanthine. As such, most xanthine uroliths in dogs form secondary to therapy with allopurinol via this mechanism. This is particularly true when a diet high in purines (meat based) is fed to these at-risk dogs.

Naturally occurring xanthinuria has been reported in Cavalier King Charles spaniels and dachshunds, and is thought to reflect an inborn error of xanthine oxidase activity.

Etiopathogenesis of Urate Urolithiasis in Cats

The pathophysiology of urate urolith formation in cats is unknown. Ammonium urate uroliths have been recovered from cats with portovascular anomalies. Such congenital anomalies can be found in male and female cats and are typically are detected when cats are <12 months of age. As Siamese cats are overrepresented among those with portosystemic shunts, it is recommended to evaluate them for underlying liver pathology when this breed is presented with calculi. However, most cats with urate stones do not have portovascular anomalies, and risk factors for urate lithogenesis in cats are thought to include an increase in renal excretion and urine concentration of uric acid, the potential presence of promoters, or the absence of inhibitors of urate urolith formation.

Xanthine urolithiasis is considered rare in cats, and only five cats have been reported with spontaneous xanthine urolithiasis and hyperxanthinuria in the last 20 years.

Calcium Phosphate Urolithiasis

Calcium phosphate uroliths are commonly called apatite uroliths. Most pure calcium phosphate uroliths in dogs are composed of hydroxyapatite. Brushite (calcium hydrogen phosphate dehydrate) stones are less common and whitlockite (calcium orthophosphate) uroliths are rare.

Epidemiology and Risk Factors

Pure calcium phosphate uroliths are rare in dogs, comprising only 0.3–0.6% of uroliths submitted to the MUC per year and 2% of uroliths submitted to the CVUC (see Table 123.2). Most calcium phosphate uroliths are mixed in composition and are predominantly (≥70%) struvite or calcium oxalate. Mixed stones are very common in cats and dogs.

Risk factors for these uroliths vary based on stone content and sex, as pure hydroxyapatite uroliths occur slightly more in male dogs (52%) than female dogs (48%) whereas with brushite uroliths, male dogs (75%) are more commonly affected than female dogs (24%).

Etiopathogenesis

Several factors may influence urine calcium phosphate saturation including urine concentration of calcium and phosphate, urine pH, and the presence or absence of inhibitors of calcium phosphate crystal formation. Alkaline urine pH decreases the solubility of hydroxyapatite and likely contributes to calcium phosphate uroliths. Excessive urinary excretion of calcium (hypercalciuria) and phosphate (hyperphosphaturia) may also induce calcium phosphate urolith formation.

Co-morbidities such as primary hyperparathyroidism and hypercalcemia may influence stone formation, and up to 30–40% of dogs with primary hyperparathyroidism present with calcium-containing uroliths. However, hypercalcemic cats are more likely to have calcium oxalate rather than calcium phosphate uroliths.

It has been reported that some dogs with urinary tract hemorrhage can develop blood clots mineralized with calcium phosphate. These stones are not considered true calcium phosphate uroliths as they do not contain the same matrix proteins or ultrastructure as typical calcium phosphate uroliths.

Cystine Urolithiasis

Dogs that develop cystine uroliths excrete an increased amount of cystine (and to a variable extent other amino acids) in their urine, a condition called cystinuria. Cystine is composed of two cysteine amino acid molecules linked by a disulfide bond. Urine solubility of cystine is low, and dogs with cystinuria are predisposed to urolith formation.

Canine cystine uroliths are typically pure, but a few contain struvite, urate, silicate, oxalate or calcium apatite. Typically, urolith appearance is smooth, oval and light yellow to reddish-brown. The size of cystine uroliths varies, but small and multiple stones are common. The cystine uroliths submitted to urolith centers have usually been retrieved from the LUT.

Epidemiology

Geographic location of the dog or cat plays a large role in the prevalence of cystine urolithiasis. In the USA, urolith prevalence has been reported as 1–2%. This is in contrast to parts of Europe where cystine urolithiasis has been reported as 8% in Sweden and 26% in central Spain. In Canada, cystine uroliths submitted to the CVUC represented 0.6% and 0.1% of all canine and feline stones, respectively, between 2009 and 2012 (see Table 123.2).

Risk factors for cystine urolithiasis in dogs include age, breed, and sex. Most affected dogs are males (98%), although the disease is not genetically sex linked, and young to middle-aged (3–8 years). The exception to these risk factors is the Newfoundland breed, where these stones occur in both genders and often at a younger age. Newfoundland dogs also appear to have an increased incidence of cystine nephroliths.

Breed predisposition has varied widely over the last 15 years and urolith risk may depend on the dog's geographic location. Unfortunately, most studies do not compare breed distribution to the national registry for dog breeds, nor are dog health insurance numbers, which have provided the information for these studies, common everywhere. Bull mastiff, Scottish deerhound, English bulldog, Newfoundland, Chihuahua and dachshund are the most common breeds affected in North America, while terrier breeds (Yorkshire, Jack Russell, and West Highland white) are the most affected in the UK.

Etiopathogenesis

In normal dogs, cystine is freely filtered at the glomerulus and then actively reabsorbed in the proximal tubules. Cystinuria is a limited hereditary renal transport disorder involving cystine and the dibasic amino acids ornithine, lysine, and arginine, collectively known as COLA. Instead of the normal >99% reabsorption in the proximal renal tubules, these amino acids are lost in the urine; however, only cystine causes a problem. In cystinuric patients, the carrier proteins responsible for reabsorption are defective. The type of amino acids lost and their quantity vary depending on the case. The low solubility of cystine in acidic urine predisposes to the formation of cystine crystals and uroliths in the urinary tract.

Cystinuria in humans and dogs is classified into several distinct types depending on age of onset, severity, sex, inheritance, and mutant gene. In dogs, type I-a cystinuria is an autosomal recessive disease caused by a SLC3A1 gene mutation common in the Newfoundland, Landseer, and Labrador retriever breeds.

A nonsense mutation in exon 2 of the SLC3A1 (amino acid – aa-transport) gene has been identified as a molecular basis of the defect but the underlying genetic

defect(s) in most cystinuric breeds of dogs have yet to be identified. More recently, Labrador retrievers were found to have a different mutation in the same gene, encoding for a renal basic amino acid transporter. DNA-based genetic tests are available to detect abnormal cystine excretion for some breeds of dogs.

Type II cystinuria is an autosomal dominant disease that has been reported in Australian cattle dogs, border collies (type II-a) and miniature pinscher (type II-b). In the latter, the mutation affects the SLC7A9 gene and encodes for intramembrane transporter protein.

The molecular basis for androgen-dependent type (type III) cystinuria is unknown. Type III cystinuria regroups several breeds of dogs such as the English bulldog, English mastiff, French bulldog. Type III cystinuria is typically detected later in life, is less severe clinically, and appears to involve only males. Castration seems to lower cystine excretion, therefore the mode of inheritance is unclear. No gene mutation has been identified as the cause of type III cystinuria.

Etiopathogenesis of cystine in cats is not well characterized, but one study recently reported an SLC3A1 mutation causing cystinuria in a cat as well as three different SLC7A9 gene variants in four cats.

Resources for cystinuria testing (urine nitroprusside/genetic testing) can be found at PennGen Laboratories: http://research.vet.upenn.edu/penngen

Silicate Urolithiasis

Epidemiology

Silica (silicon dioxide) uroliths are infrequently diagnosed. They account for 0.9% of specimens submitted to the MUC and 0.7% of specimens submitted to the CVUC between 2009 and 2012 (see Table 123.2). Silica-containing nephroliths are rarely submitted to urolith centers, but have been reported in native Kenyan dogs.

Some silica uroliths are pure, while others are composed of different layers, with oxalate and struvite being the most commonly associated minerals. Most silica uroliths have a "jackstone" appearance; however, an outer layer (coating) of another mineral type may mask this configuration. Typically, multiple silica uroliths present and cross-section of the urolith usually reveals laminations.

The majority of dogs with silica uroliths are male, with a mean age of 7.2 +/- 3.1 years (range 1–17 years).

Etiopathogenesis

Silica uroliths are thought to form due to individual animal increase in consumption of this mineral. Animal protein contains very low concentrations of silica and consumed dietary sources are likely plant origin, such as direct ingestion of soil or ingestion of contaminated crops. Plant sources implicated in silicate urolithiasis include rice and soybean hulls and corn gluten feed. Silicates may be high in certain home-made diets and in some groundwater from aquifers. In certain regions, soil may contain high concentrations of silicate so consumption of dirt and grass (pica) should be discouraged.

Experimentally, beagle dogs consuming large quantities of antacids containing magnesium trisilicate were predisposed to silica uroliths. Homeopathic, other medications and vitamin-mineral supplements may contain silica, for example silica is used in anticaking materials added to tablets.

Other Types of Urolithiasis

In dogs, mixed composition uroliths comprised 2.3% of uroliths submitted to the MUC, with an additional 8.8% of uroliths being described as compound. Compound uroliths are likely to form when factors initially promoting precipitation of one type of mineral are replaced by factors promoting precipitation of a different mineral. This can make compound uroliths poorly responsive to medical management due to the need to treat each mineral type separately for dissolution or prevention.

The list below includes uncommon types of uroliths submitted to major urolith centers.

- *Suture induced*: some stones can be induced by residual or retained suture material. Uroliths typically have a piece of suture contained within the stone, or have a hole where the suture was located (Figures 123.7 and 123.8).
- *Dried solidified blood calculi*: calculi composed solely of dried solidified blood have been removed from the urinary tract of cats.

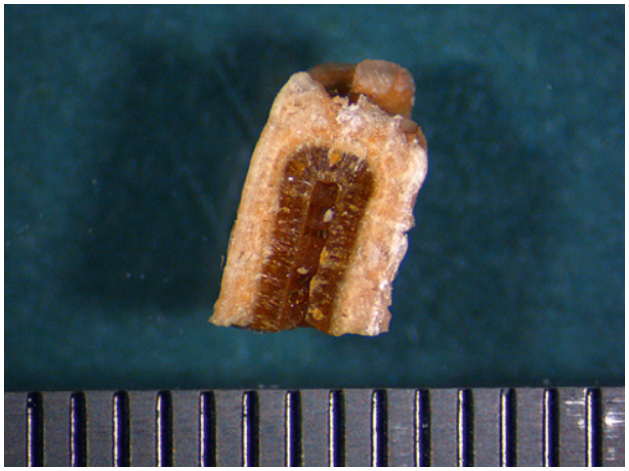

Figure 123.8 Suture-induced stone (60% struvite, 40% calcium phosphate) removed from a 4-year-old female spayed miniature schnauzer. *Source:* Courtesy of Andrew Moore, Canadian Veterinary Urolith Centre.

- *Potassium magnesium pyrophosphate*: the etiology of these uroliths is not definitively known, and it is theorized that formation is related to a type of temporary or permanent enzymatic dysfunction causing pyrophosphate supersaturation of the urine.
- *Melamine and/or cyanuric acid-induced uroliths*: after a devastating occurrence of diet-related renal failure in dogs and cats, melamine urolithiasis or crystalluria was noted in affected patients (Figure 123.9).
- *Drug and drug metabolite uroliths*: these are most commonly related to the use of the sulfonamides or allopurinol and there are reports of fluoroquinolone (ciprofloxacin), primadone, and tetracycline uroliths. Factors predisposing to precipitation of drugs in urine include reduced volume of highly concentrated urine, urine stasis, high rate of urinary excretion of drugs that are poorly soluble in urine, and/or prolonged treatment with high doses of potentially lithogenic drugs.

Urolith Diagnosis

Urinalysis

Urine Sediment

Urolithiasis typically induces inflammatory urine sediment, such as pyuria (presence of white blood cells), hematuria (red blood cells), and proteinuria. Bacteria may also be present if there is a primary or secondary UTI, (i.e., infection induced by urolith-associated trauma).

Urine pH

The urine pH of dogs and cats depends on many factors and can be affected by method of measurement. A study in dogs found that urine dipstick tended to overestimate pH, in some cases yielding an alkaline result for a sample that had a mildly acidic urine as determined by the reference method. As such, if accurate measurement of urine pH is important, a pH meter should be used. Relatively inexpensive hand-held instruments are commercially available.

Certain minerals are more soluble in acidic or alkaline pH. For these reasons, some minerals tend to precipitate and form stones in acidic (e.g., cystine, purine, calcium oxalate) or in alkaline pH (e.g., struvite, calcium carbonate, and calcium phosphate stones). At present, research indicates conflicting results regarding the role urine pH plays in the formation of calcium oxalate stones.

Crystals

Crystals may indicate the presence of uroliths or be normal, that is, no urolith. As such, specific therapy for crystalluria is not indicated unless a urolith is documented through imaging, the patient has a history of urolithiasis or urethral plugs (cats), and/or specific crystal types are noted.

In order to correctly identify crystalluria, urine should be analyzed within one hour of collection. This is advised because both calcium oxalate and struvite crystals can form *in vitro* if there is a delay prior to analysis or due to refrigeration. Crystal types that are not normally present in the urine, and demand attention regardless of urolith presence, include cystine, xanthine, and urate (excluding Dalmatians).

Urine Culture

Urine culture and susceptibility should be performed in all patients with urolithiasis in order to detect infections and start appropriate antibiotic treatment if necessary,

that is, there are concurrent clinical signs of infection. Urinary tract infections can be the primary cause of urolith formation (e.g., struvite uroliths in dogs), or they can be secondary to urolith-induced irritation of the urinary tract. If the urine culture is negative despite a high suspicion of UTI in a patient (i.e., a dog with struvite stones), culture of the bladder wall and stone nidus, at the time of stone removal, is strongly advised in order to accurately direct any needed antimicrobial therapy.

Bloodwork

Complete blood count (CBC) is usually normal in patients with urolithiasis. A left shift may (or may not) be present with pyelonephritis or pyonephrosis. A serum biochemistry may show evidence of liver dysfunction in a dog with hepatic vascular abnormalities (portosystemic shunt [PSS]), microvascular dysplasia (portal hypoplasia), or severe hepatic disease. The lab changes can include increased alanine aminotransferase (ALT) and alkaline phosphatase (ALP), and with hepatic dysfunction there can be low albumin, urea, and glucose.

Bile acid (pre- and postprandial) measurement is strongly recommended if a young dog or cat presents with bladder stones and clinical signs compatible with PSS (i.e., signs of hepatoencephalopathy, polyuria/polydipsia [PU/PD], poor growth) or increased liver enzymes. Dogs with portovascular abnormalities are more likely to have urate uroliths than those with other types of hepatic dysfunction. Middle-aged, small-breed dogs with a portovascular anomaly and good portal perfusion can have normal chemistry panels with urate stones, making bile acid testing indicated.

In cases of ureteral calculi resulting in urinary tract obstruction, blood urea nitrogen (BUN) and creatinine may or may not be increased. This will depend on the laterality (unilateral or bilateral obstruction) and underlying intrinsic renal damage due to the calculi. Azotemia will not be present if the contralateral (nonobstructed) kidney is normal. Most cats (88%) with unilateral ureteral calculi are azotemic (>90%), indicating the presence of intrinsic renal disease in the contralateral kidney.

Stone Analysis

A common pitfall for clinicians dealing with urolithiasis in small animals is attempting to guess the type of stone(s) noted on imaging based on signalment of the patient, diet, urine pH, urine culture results, and radiographic density of the stone. For this reason (and if possible), it is always recommended to submit uroliths for mineral analysis. It is important to note that even if there is recurrence of urolithiasis in the same patient, the urolith type may be different from the prior episode. An example of this is a calcium oxalate stone forming in an at-risk breed of dog after an incidence of struvite urolithiasis due to bacterial infection.

Stone Layers

When a urolith is analyzed, it is named according to the constituents making up the majority of the "stone" (Figure 123.10). These layers consist of the following.

- *Nidus* (center of the urolith): this may or may not be composed of crystalline material and/or a foreign body, such as suture material.
- *Stone*: the stone may or may not be composed of the same minerals as the nidus.
- *Shell*: the layer(s) that surround the stone. The shell is the outermost complete layer on the urolith.
- *Surface crystals*: these may or may not be present on the outermost surface of the urolith. They do not completely encase the urolith (incomplete layer).

Ideally, all four layers of the urolith should be analyzed separately and their respective mineral amounts listed. Only quantitative analysis ensures that all urolith layers are examined and provides an estimate of the mineral content of each visible layer. This is important since confusion over urolith content and therapy and prevention can occur when only the outer layer is analyzed. This type of confusion can also occur when using the qualitative

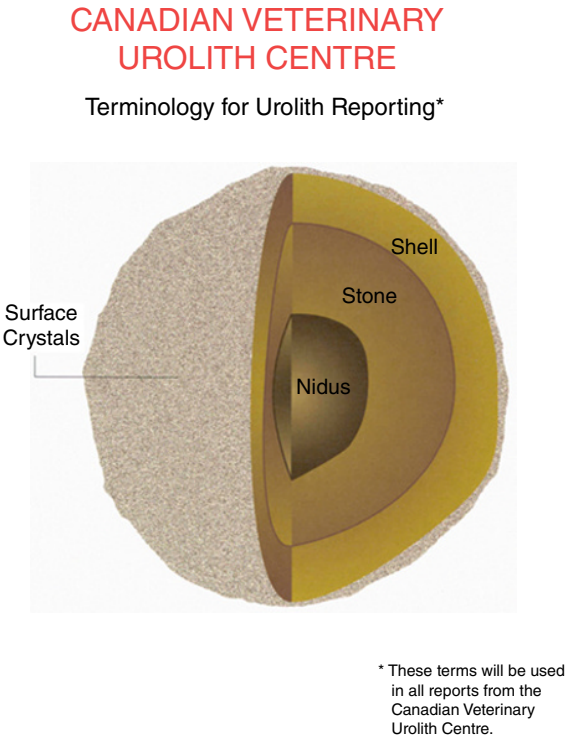

Figure 123.10 Stone layers description. *Source:* Courtesy of Andrew Moore, Canadian Veterinary Urolith Centre.

test for urolith analyses, where the entire urolith is crushed and then analyzed. An example of why this is important would be with a primary metabolic stones (i.e., urate) which may have a large (or several) outer covering (s) of struvite. If only the outer layer was assessed or if the urolith was crushed and then analyzed, then ongoing diagnostics and therapy would be misdirected, at the struvite rather than the urate portion.

Stone Characterization

Uroliths are defined based on their mineral composition as noted earlier. The following terms are used to identify type.

- *Pure urolith*: when 70% or more of the urolith is composed of one type of crystalloid, it is named for that crystal type. In dogs and cats, most stones have one major crystal component.
- *Mixed urolith*: when less than 70% of the urolith is composed of one mineral, it is called a mixed urolith. This means that the urolith does not contain one predominant mineral type but is a combination of two or more types.
- *Compound urolith*: this is a urolith in which each layer is composed of a different mineral. Uroliths that have formed around foreign material in the urinary tract are often classified as compound. Suture material, urinary catheter, metal pellets, plant material, hair strands, and other foreign objects (ex. porcupine quill) have all been reported to be a part of uroliths of various mineral types.

Specific Tests to Detect Cystinuric Dogs

On average, dogs with type I cystinuria have a several-fold higher urinary COLA excretion than non-type I cystinuric male dogs. A simple urinary screening test to determine if a dog is cystinuric is available through the Metabolic Screening Laboratory, Section of Medical Genetics, at the University of Pennsylvania (http://research.vet.upenn.edu/penngen). This test can detect any type I cystinuric animal, but not necessarily all dogs with non-type I cystinuria. High-performance liquid chromatography can be further used to determine the amount of cystine and other amino acids in urine. However, this form of quantitative amino acid analysis is currently restricted to a few laboratories (PennGen and LaboKlin) and is relatively expensive. Based on studies, dogs with either cystine levels of >200 µmol/g creatinine or COLA values of >700 µmol/g creatinine are considered cystinuric. Moreover, for Newfoundlands and Labrador retrievers, a breed-specific mutation test is available that detects not only cystinuric dogs but also asymptomatic carriers. Finally, in mastiffs, a preliminary linked marker test to identify dogs at risk for early stone formation is being evaluated.

Imaging of the Urinary Tract

Radiography

Most uroliths are radiopaque on survey abdominal radiographs. Radiopaque uroliths include calcium phosphate, calcium oxalate, struvite and silicate (Figures 123.11 and 123.12). Survey radiography is suitable for identification of these radiopaque uroliths, provided they are greater than approximately 2–3 mm in diameter. However, urate, cystine, and xanthine uroliths are generally characterized as radiolucent or only slightly radiopaque on survey radiographs. The failure rate for detection of uroliths by survey radiography was 2–27% dependent on urolith size and composition.

Clinicians may try to guess the chemical composition of a urolith based on the density, shape, and number of uroliths on radiographs. One aid for this type of "guesstimate" is the pneumonic POCUS, which is used by clinicians to remember the order of the stones that are most radiodense to radiolucent: calcium phosphate, calcium oxalate, struvite, silicate, cystine, and urate calculi.

Contrast-enhanced radiographic procedures or ultrasound are needed to identify uroliths composed of compounds similar to the radiographic density of soft tissue. Double-contrast cystography has been associated with high sensitivity and low false-negative detection rates (Figure 123.13). Small uroliths are detected more reliably by double-contrast cystography or ultrasonography. However, ultrasound is superior to double-contrast cystogram in experienced hands and for very small stones and sand.

Ultrasonography

Ultrasonography is a cost-effective tool in the diagnosis of urolithiasis but it may overlook some important aspects of the stones that can help the clinician predict the nature of the uroliths, such as surface contour and shape. One limitation of ultrasound is that it often overestimates urolith size, so radiographs should be used for determining size when possible. Ultrasound is also less reliable than radiography for predicting the number of stones and their location. Finally, ultrasound only provides evaluation of the most proximal portion of the urethra and therefore cannot replace radiography.

Ultrasonographic examination can detect radiopaque and radiolucent uroliths. One study compared survey and contrast radiographs, pneumocystography, double-contrast cystography, and ultrasound using a 7.5 MHz transducer, and found that ultrasonography may be more sensitive than survey and contrast cystography for detection of urocystoliths, with false-negative rates of 6%.

Ultrasonography allows simultaneous evaluation of the upper urinary tract for nephroliths and ureteroliths. Therefore, radiography combined with ultrasonography are preferred over contrast radiography alone. Ultrasound can detect upper urinary tract obstruction that is characterized by renal pelvis dilation >13 mm. However, pelvis dilation can be iatrogenic (diuresis) or secondary to different diseases such as chronic kidney disease or pyelonephritis. Although a renal pelvis >13 mm may indicate ureteral obstruction, the absence of dilated renal pelvis does not rule out an upper urinary tract obstruction. The combination of proximal ureteral dilation and normal kidney pelvis diameter can be associated with ureteral obstruction in cats. In a recent study, 25% of cats with confirmed ureteral obstruction had a renal pelvis <13 mm but a proximal ureteral dilation. In 25% of cats with ureteral obstruction, ureteropyelography is necessary to determine the cause of the obstruction.

Computed Tomography

Determination of urolith composition using computed tomographic (CT) peak attenuation measurement has been described *in vitro*. In humans, this technique is preferentially used in order to detect uroliths and also to predict their composition. CT may be more specific for ureteral calculi than either radiography and/or ultrasonography in cats.

Educated Guess

Determining the type of urolith based on imaging studies alone is very risky. This type of "guesstimate" of urolith composition based on the radiolucency of a stone and its shape can lead the clinician to misdiagnosis (Figure 123.14). In certain scenarios the chemical composition of uroliths may be predicted based on patient signalment, in combination with the results of urinalysis, urine culture, and radiographs. However, it must be understood that this technique can lead to error and is not advised as the best method of urolith identification. In situations where uroliths are not available for analysis or are pending analysis, the guesstimate may need to be used; however, communication to clients that errors may be made with this technique and verification of stone type (when practical and possible) are ideal. Unfortunately, this verification cannot be made until stone analysis occurs. For example, the clinician can make an educated guess as to the likelihood that a given stone is composed of struvite based on finding a urease-positive

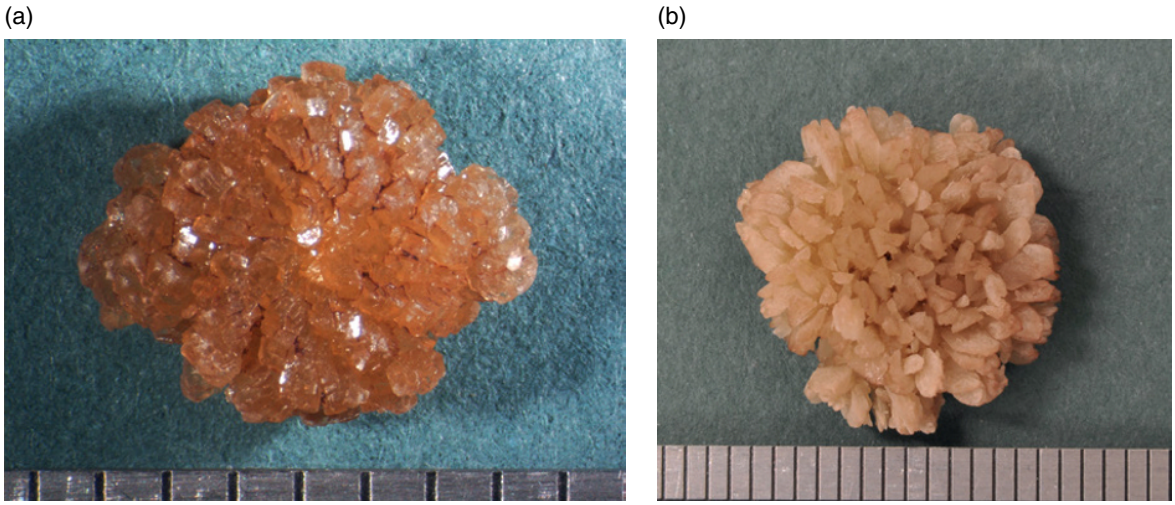

Figure 123.14 (a) Cystine stone in a 3-year-old male pug. (b) Struvite urolith in a 4-year-old female Chihuahua mixed dog. These two look the same, but they are not the same type. *Source:* Courtesy of Andrew Moore, Canadian Veterinary Urolith Centre.

UTI (usually *Staphylococcus* spp.), alkaline urine, struvite crystalluria, and radiodense calculus in a high-risk breed (ex. female bichon frise). Certain breeds are also predisposed to a specific type of urolith which makes guesstimating a bit less risky, for example Dalmatians (see Table 123.1).

As mentioned, there are multiple "traps" or pitfalls to avoid when guesstimating the chemical composition of a urolith. Areas where errors can occur include urine pH, urinalysis and crystalluria, urine culture results, and radiographic density of the stone. Urine pH can be influenced by meals and time of day. First morning preprandial urine is typically the most acidic and concentrated sample of the day. After eating, the pH will become more alkaline, often referred to as the "alkaline tide." Urine pH is also affected by stress and hyperventilation, leading to respiratory alkalosis and consequent urine alkalinization, for example a stressed dog panting in clinic. Additionally, an acidic pH does not rule out the presence of struvite stones. One example of this would be a compound urolith made of a struvite core surrounded by an oxalate shell. The pH may also be alkaline if there is concurrent infection with urease-producing bacteria, while the predominant urolith type may be unrelated to infection, for example a calcium oxalate stone and concurrent *Staphylococcus* spp. infection.

Similarly to urine pH pitfalls, crystalluria is not a consistent feature of the urinalysis in dogs and cats with uroliths. For example, in one study of 30 cats with struvite urocystoliths, struvite crystals were only detected in 17 patients. Additionally, dogs and cats may have a small number of struvite or calcium oxalate crystals, but other types of crystals do not typically form *in vitro*.

Medical Management of Lower Urinary Tract Stones

It is ideal to identify urolith type prior to initiation of dissolution protocols, and if uroliths are small enough, voiding or catheter retrieval may be possible and allow for this. Unfortunately, stone composition identification is rarely possible prior to the need to make therapy decisions, and best "guesstimate" strategies are warranted in most cases. As such, it is imperative to perform diagnostic studies (urinalysis, urine culture, radiography) to evaluate urolith size and location and to provide the most information to guide therapy as available.

Attempts to medically dissolve uroliths are not always the least expensive method of management, nor is medical dissolution an option for all stone types, such as calcium oxalate. For other urolith types (e.g., struvite), the cost of diet and antimicrobial therapy along with the cost of the recheck appointments and imaging should be discussed thoroughly when considering medical dissolution. Similarly, animal owner communication to ensure compliance is essential in order for medical dissolution strategies to be successful.

Rationale for Medical Dissolution

Medical dissolution of amenable urolith types consists of reducing the concentration of the calculogenic material in the urine and increasing its solubility.

Regardless of urolith type, increasing water intake through diet and via increased water consumption will assist in dilution of urine crystalloids and help prevent ongoing crystal formation. This may also aid in flushing existing stones from the bladder in female dogs. The aim

of water increase strategies is to obtain a urine specific gravity of <1.020.

Indications for (and Limitations of) Medical Urolith Dissolution

Urolith Type

Struvite, urate, and cystine stones in dogs may be amenable to medical dissolution; however, the uroliths must be located in undersaturated urine for this to occur. This requires intervention with diet and urine dilution strategies, along with appropriate therapy of concurrent bacterial infections. Dissolution success is much lower for urate and cystine stones than struvite, and in cats, only struvite uroliths are responsive to medical dissolution. In cats, low-protein diet and allopurinol has been reported as effective in urate stone dissolution; however, until further studies looking into safety and efficacy of this treatment are performed, mechanical removal of bladder or urethral urate uroliths is advised. Mechanical urolith removal is recommended for bladder or urethral cystine stones in cats, in part because 2-MPG (Thiola®, tiopronin) is toxic in cats, and is only effective about 60% of the time in dogs.

Urolith Location

Medical dissolution for specific stone types can be successful, but is more efficient when uroliths are located in an area where they are in constant contact with urine, such as the bladder. Suspected struvite nephroliths or ureteroliths should be medically dissolved unless they are too large to be effectively bathed in urine.

If uroliths are obstructive, relief of obstruction with a minimally invasive approach and rapid control of infection should preserve kidney function.

Obstructive ureteroliths cannot be dissolved by medical or dietary protocols unless a ureteral stent is placed concurrently. Urethroliths are typically not amenable to dissolution, although they may be flushed into the bladder by retrograde hydropulsion and then dissolution can be attempted.

Calcium oxalate uroliths are not amenable to medical dissolution regardless of location, and must be removed from the urinary tract mechanically. In cats, because more than 90% of feline upper urinary tract stones are composed of calcium oxalate, dissolution should not be attempted with obstructive nephroliths or ureteroliths. Silica uroliths are also thought to be unresponsive to medical dissolution.

Size and Number of Uroliths

The size and number of the stones will influence rapidity of dissolution but do not dictate the likelihood of therapy success in stones that are amenable to dissolution. Since the rapidity of dissolution is related to the size and surface area of the urolith being exposed to urine, one large urolith will take longer to dissolve than multiple small uroliths. An analogy for this is that one large ice cube will dissolve more slowly than an equal volume of crushed ice. The rate of dissolution is influenced by the surface area of the urolith exposed ("bathed") in undersaturated urine.

Presence of Obstruction

Medical dissolution is contraindicated in patients with obstruction of the urinary tract. Relieving urinary tract obstruction in those cases is mandatory in order to avoid consequences such as postrenal azotemia, irreversible renal damage, bladder rupture, and death.

Risk of Obstruction in Males

Medical dissolution of urocystoliths in male dogs is associated with a risk of urethral obstruction once the urocystoliths are small enough to pass into the urethra. The risks and clinical signs of urethral obstruction should be explained to the owner if medical dissolution is elected in male dogs, and regular monitoring of urination is recommended. Medical dissolution should only be tried in male dogs after clear owner communication and assurance of owner compliance and ability to observe and act on clinical evidence of obstruction.

Infection-Induced Urolith

If the urease-producing bacterium is isolated from urolith culture, appropriate antibiotic therapy based on urine culture and susceptibility must be administered during the entire urolith dissolution period. Otherwise, the persistence of infection with a urease-producing organism will confound dissolution of the stones. Despite diet change, concurrent urinary tract infection will maintain alkaline urine and promote urolith formation and growth.

Dietary Factors

Limitations of medical dissolution are inherent to the diet and medical therapy needed for the given urolith; for example, an acidifying diet with low protein and caloric content should not be fed to a pregnant or lactating bitch. Similarly, thoughtful consideration of nutritional growth requirements in young dogs and kittens needs to occur when a diet lower in purines (protein) is indicated for medical urolith dissolution (e.g., urate uroliths). Similarly, a diet with a high salt or fat content should be avoided in a patient with congestive heart failure or pancreatitis, respectively, as these patients may require varying levels of sodium or fat restriction for their concurrent medical condition.

Protocol for Medical Management and Prevention of Individual Urolith Types

Calcium Oxalate Uroliths

Dissolution of Calcium Oxalate Uroliths

At present, calcium oxalate stones cannot be dissolved through medical (nutritional) means in dogs and cats. As such, removal or bypass of these uroliths by different interventional methods is recommended. As upper urinary tract stones in cats are predominantly composed of calcium oxalate (>98%), medical dissolution is also not recommended in these patients.

Follow-Up and Prevention of Calcium Oxalate Uroliths

Dietary therapy has been recommended to help prevent recurrence of calcium oxalate stones. Nutritional strategies to aid prevention of calcium oxalate stones in cats or dogs primarily focus on increasing water intake via feeding canned or wet food or by adding water to dry food. These techniques help to increase dilution of urine and flush crystals from the urinary tract, and one study showed that feeding canned food to a group of dogs decreased their risk of calcium oxalate compared to feeding a dry diet.

Medical management that is believed to prevent recurrence of calcium oxalate urolithiasis includes the following factors.

- Increased water content of food (>75% water: high moisture).
- Avoidance of dietary urinary acidification (pH <6.25 cats and <6.6. dogs).
- Correction of underlying hypercalcemia. In cats with recurrent CaOx stones and idiopathic hypercalcemia, there may be a benefit to feeding a high-fiber diet in association with potassium citrate therapy.
- Dietary sodium increase. Controversial at this time. Feeding high-sodium diets (3.5 g/1000 kcal) is not a substitute for increased dietary moisture, as had been previously thought, and any benefit of dietary increase in salt is believed to be short-lived.
- Management with potassium citrate in cats and dogs with persistence of acidic urine, and consideration of thiazide diuretics if recurrence despite other interventions.
- Dietary protein restriction. At present, the recommendation to restrict dietary protein in these patients is controversial and it is very difficult to reduce dietary protein without concurrent dietary phosphorus reduction. Unfortunately, lower phosphorus has been associated with a higher risk of calcium oxalate uroliths. This is due to low diet phosphorus leading to increased intestinal absorption of calcium and increased calcitriol production, which then leads to further calcium gastrointestinal absorption and calciuresis.
- Avoidance of calcium-containing supplements in at-risk patients.
- Reduction in foods rich in oxalate precursors. Examples of these include chocolate, nuts, beans, sweet potatoes, wheatgerm, spinach, rhubarb. For a complete list of the oxalate content in foods, please visit the Oxalosis and Hyperoxaluria Foundation website: www.ohf.org.

In dogs, the diets recommended to achieve the above goals are those that have undergone specific urinary testing (i.e., CORI, RSS, Activity Product Ratio) to reduce risk of calcium oxalate formation. Examples of these diets include Hill's c/d, Purina St/Ox, and Royal Canin S/O. Unfortunately, the ideal diet to prevent calcium oxalate urolith recurrence remains unknown.

Despite diet modification, recurrence in animals with CaOx is high: 33% at two years in cats and up to 57% at three years in dogs. If calcium oxalate uroliths recur despite dietary therapy, the use of medications such as thiazide diuretics or potassium citrate may benefit specific patients.

Potassium citrate supplementation has been shown to reduce recurrence of calcium oxalate uroliths in humans. In veterinary patients, there are conflicting opinions on the utility of potassium citrate for prevention of calcium oxalate urolithiasis. In normal dogs, potassium citrate supplementation did not significantly increase the mean citrate excretion, although in three miniature schnauzers supplementation did increase urinary citrate excretion and lower relative calcium oxalate supersaturation. In another study, potassium citrate did not increase mean urinary citrate concentration but did cause a dose-dependent increase in urine pH. If calcium oxalate crystalluria is persistent or calcium oxalate uroliths recur, potassium citrate is commonly recommended to achieve a urine pH of 6.5–7.0 using a dose of 150 mg/kg PO q24h. The serum potassium should be initially monitored monthly during potassium citrate supplementation and the dose reduced if hyperkalemia occurs.

Thiazide diuretics are proven to reduce the recurrence of calcium oxalate urolithiasis in humans by reducing urinary calcium excretion. However, there are conflicting results for dogs, and in normal dogs, administration of chlorothiazide did not reduce urinary calcium excretion. In contrast, administration of hydrochlorothiazide decreased urinary calcium excretion and urine calcium concentration in dogs with calcium oxalate urolithiasis. Reduction in urinary calcium was greatest in dogs with the highest pretreatment urine calcium concentrations when combined with using Hill's Prescription Diet u/d. As thiazide diuretics contribute to urine acidification, concomitant administration of potassium citrate may be recommended. Hydrochlorothiazide (2 mg/kg PO q12h)

should be considered in dogs that have persistent calcium oxalate crystalluria or recurrence of calcium oxalate urolithiasis despite dietary therapy. This drug can cause severe gastrointestinal (GI) side-effects.

Decreased serum vitamin B6 concentrations were detected in a small number of oxalate stone-forming dogs compared to nonstone formers. Based on this study, supplementation of vitamin B6 (2–4 mg/kg PO q24–48h) could be considered in repeat stone formers. Vitamin C is converted to oxalate, so vitamin C supplementation may contribute to hyperoxaluria and increased risk of calcium oxalate urolithiasis. Vitamin D supplementation increases intestinal absorption of calcium, thereby promoting hypercalciuria and increased risk of calcium oxalate urolithiasis.

Dietary recommendations for prevention of calcium oxalate uroliths in cats are thought to be similar to those in dogs, although higher salt levels are sometimes used to aid increased urination. In addition, one two-year study in cats showed no significant difference between two diets that differed in calcium and magnesium contents and in urinary pH potential. Primary hyperoxaluria can occur in cats. Examples of diets that have undergone urinary testing for reduction of calcium oxalate include Hill's c/d Multicare (canned and dry), Purina UR St/Ox (canned and dry), and Royal Canin S/O (canned, chunks and gravy, and dry).

Struvite Uroliths

Dissolution of Struvite Uroliths in Dogs

Struvite uroliths in dogs are almost always due to infection with a urease-producing organism, and as such medical dissolution of struvite depends on the careful elimination of infection together with specific dietary therapy.

The calculolytic diets most commonly advised for struvite stone dissolution in dogs are the Prescription Diet Canine s/d (Hill's Pet Products, Topeka, Kansas) and Royal Canin S/O. Of these two, the Prescription Diet Canine s/d has been used successfully to induce dissolution of struvite calculi in dogs. The Royal Canin diet was effective for struvite dissolution in an *ex vivo* setting.

When using the Hill's s/d diet, laboratory changes in the patient will occur that can also be used to monitor owner compliance. The diet is low in phosphorus and protein which reduces urea, phosphorus, and serum albumin. Mild increases in serum alkaline phosphatase may also be present. These changes are not expected with Royal Canin S/O. Both diets promote undersaturation of the urine with ions necessary for the formation of struvite uroliths and, thus, promote dissolution of existing struvite calculi. Both diets also contain a high NaCl content in order to induce diuresis and dilution of urine. Concurrent antibiotic therapy is recommended to eradicate UTI throughout the diet treatment and is likely the most important facet of medical dissolution of struvite uroliths. The average time of dissolution of canine infection-induced struvite urocystoliths on the Hill's s/d diet was approximately 2–3 months in dogs. This diet should not be continued beyond this time as it is not meant to be a long-term diet.

Feeding small meals throughout the day rather than one or two large meals may prevent postprandial alkaline tide and is associated with more acidic urine production and less struvite crystalluria.

The use of urinary acidifiers has been suggested in dogs because struvite and hydroxyapatite are most soluble in acidic urine (pH 6.0–6.5). In most dogs with infection-induced struvite uroliths, eradication of the UTI with dietary modification will return urine pH to the acidic range. Use of urine acidifiers in these cases is not indicated.

Most clinical symptoms of lower urinary tract inflammation resolve after the first 10 days of antibiotic and diet therapy. However, antibiotic and diet therapy should be continued for one month beyond radiographic evidence of urolith dissolution or one month beyond stone removal. Although feeding a dissolution diet is advised, struvite uroliths have been managed with effective control of the underlying UTI alone.

Prevention and Follow-Up of Struvite Uroliths in Dogs

Examination of urine pH, specific gravity, sediment, and culture is recommended at 5–7 days after starting therapy, and then every four weeks until the stones are dissolved (Table 123.3). Once dissolution (based on radiographic evidence) or removal is accomplished, a urine culture should be obtained at four and eight weeks later, with cessation of antibiotic and dietary therapy four weeks after resolution. Urine culture and radiographs should then be repeated every three months for one year and then every six months thereafter. The goal is to maintain the average urine pH 6–6.5, the average urine specific gravity <1.020, the sediment free of significant crystalluria, and the dog free of bacterial infection.

In dogs with a history of urinary tract infections, proactive and routine urine culture and susceptibility is recommended. This is particularly important if co-morbid situations arise (e.g., hyperadrenocorticism, renal disease) that may predispose to the development of a urinary tract infection.

The need for specific ongoing dietary therapy for prevention of struvite uroliths in dogs is unknown. Since the majority of dogs have infection-induced struvite uroliths, it is likely that effective control and prevention of infection alone would be sufficient to prevent recurrence. However, dietary therapy to lower urine concentration (canned food or addition of water) or minimize

Table 123.3 Compound urolith recurrence prevention strategies. The strategy for prevention of compound uroliths is typically directed at the nidus of the urolith; however, dependent on the proportion of the concurrent mineral layers/types, preventive measures may need to be instituted for more than one mineral type. Further consultation is advised for these complex stones. As with all uroliths, increased water intake should be promoted to decrease the resulting concentration of calculogenic material in urine

Type of compound urolith		
Inner layer –nidus	**Outer layer**	**Prevention strategies**
Calcium oxalate	Magnesium ammonium phosphate (struvite)	Infection is very common with urolith-induced trauma of the LUT, so treat the infection with appropriate antibiotics and direct nutritional therapy at the calcium oxalate
Calcium oxalate	Calcium phosphate	Calcium phosphate is commonly found – patient-related and nutritional control strategies are directed at the calcium oxalate
Calcium oxalate	Silica	Control strategies are directed at the calcium oxalate
Magnesium ammonium phosphate (struvite)	Calcium phosphate	Calcium phosphate is commonly found – patient-related and nutritional control strategies are directed at the struvite
Magnesium ammonium phosphate (struvite)	Ammonium urate	Patient-related and nutritional control strategies are directed at control of urease-producing micro organisms, and/or assessment of liver function. Control is typically directed at the struvite portion of the stone and/or concurrent liver disease if present
Purine/urate salts	Magnesium ammonium phosphate (struvite)	Infection is very common with urolith-induced trauma of the LUT, so treat the infection with appropriate antibiotics and direct nutritional therapy at the purine/urate. Liver assessment may be indicated in these patients
Purine/urate salts	Calcium oxalate	Control strategies are directed at the purine/urate. Liver assessment may be indicated in these patients
Purine/urate salts	Calcium phosphate	Calcium phosphate is commonly found – control strategies are directed at the purine/urate. Liver assessment may be indicated in these patients
Hollow cylindrical central area	Calcium oxalate	Selection and use of appropriate suture material for the urinary tract. Attempt to minimize suture material in the lumen of the urinary tract, thus eliminating a potential nidus for crystal formation

LUT, lower urinary tract.

urolith burden may aid in prevention of urine stasis and crystal aggregation (to "help flush" the urinary tract). Diets proposed for prevention in dogs include Hill's c/d, Royal Canin S/O, and Purina St/Ox UR. If the struvite stones are sterile, which is very rare in dogs, acidifying the urine pH is necessary. This can be achieved with calculolytic dietary therapy or urine acidifiers alone. Antibiotic therapy is not required.

Medical Management of Struvite Uroliths in Cats

Struvite uroliths in cats are typically sterile. Since struvite is more soluble in acidic urine, any factors that may contribute to urine alkalinization should be assessed (e.g., vegetable protein diet, familial history, obesity/inactivity leading to urine stasis). Although struvite stones in cats are generally sterile, lower urinary tract infection can occur and predispose to alkaline urine. Urinary tract infections are more common in cats <1 year and >10 years, as well as in those with compromised host defenses (e.g., diabetes mellitus, perineal urethrostomy, renal disease, urinary tract neoplasia, upper urinary tract stone disease, etc.). A thorough urine assessment and culture should not be omitted in at-risk patients. Upper urinary tract stones in cats are almost never struvite.

The calculolytic diets most commonly advised for struvite stone dissolution in cats are Hill's s/d and Royal Canin S/O. Hill's Feline s/d diet has been used successfully to dissolve stones in cats with struvite urolithiasis. The average time for dissolution of sterile struvite cystoliths in cats fed this diet was about 30 days. Dissolution of feline infection-induced struvite stones, which are uncommon, took 60–90 days. Urinary acidifiers are not useful or advised in cats fed Hill's c/d, s/d, or soft-moist diets because these foods are already acidifying. Dissolution of feline struvite stones in cats eating Royal Canin Urinary SO (canned and dry) occurred in a median of 18 days (range, 10–55 days) in 31 of 39 cats.

Prevention and Follow-Up of Struvite Uroliths in Cats

Radiographs are recommended after stone removal or dissolution to ensure all uroliths have been eradicated.

After this time, examination of urine pH, specific gravity, and sediment is recommended at two weeks, four weeks and then every three months for one year. The aim is to maintain the average urine pH <6.5, the urine specific gravity <1.030 and the sediment free of significant crystalluria. If the cat remains free of clinical signs and free of significant crystalluria and uroliths, rechecks may be decreased to twice yearly.

For cats with infection-induced struvite uroliths, follow-up urine culture and sensitivity is recommended one week after the end of the antibiotics. Further assessment is recommended in cats that have repeat urinary tract infections and struvite crystalluria.

Examples of diets recommended for use in struvite prevention due to their known efficacy in reducing magnesium and phosphorus levels and urinary acidification properties include Hill's c/d Multicare (canned and dry), Purina UR St/Ox (canned and dry), and Royal Canin S/O (canned, chunks and gravy, and dry). Many of the lifestage diets from Hill's, Purina, and Royal Canin are also aimed at concurrent struvite urolith prevention. It is particularly important in cats that therapy is directed at reduction of urine concentration, and thus a high-moisture diet is advised.

Ammonium Urate Uroliths

Dissolution of Ammonium Urate Uroliths in Dogs

Medical dissolution of urate can be achieved, although it may not always be in the patient's best interest, such as urinary tract obstruction.

Dissolution of urate is only indicated in patients with an underlying defect in purine metabolism and not in cases of liver dysfunction. Nutritional therapy for urate dissolution is achieved with a combination of the following.

- *Urine alkalinization*: alkaline urine contains low amounts of ammonia, which subsequently reduces ammonium urate. Feeding a low-protein (purine) diet and/or with potassium citrate supplementation produces alkaline urine.
- *Increase in urine volume*: a canned diet (or addition of water to the diet) is preferred for this reason. A low-protein diet also decreases the concentration of urine by "wash-out" of the medullary concentration gradient (via low urea). The goal is a urine specific gravity of <1.020.
- *Decreasing the excretion of ammonium ions*: feeding a diet low in protein-purines decreases urea production and consequently ammonium and its ions.
- *Decreasing the excretion of uric acid*: feeding a diet low in purines and their precursors will aid in this. The purine content of proteins varies (e.g., it is high in organ meats and fish), and by using selected protein sources (plant, egg white), severe protein restriction is not mandatory to achieve a low urinary urate level.
- The desired urine pH for urate dissolution is approximately 7.0. Targeting a higher urine pH (>7.5) could be detrimental because it could favor the formation of calcium phosphate urolith. Potassium citrate (50–150 mg/kg q12h) may be needed to alkalinize the urine if diet alone is not enough to sustain an average urine pH of approximately 6.8–7.0. Obtaining both a fasting and postprandial (2–6 hours after a meal) urinary pH will allow for consistent and accurate medical titration of potassium citrate. The patient should be monitored for hyperkalemia when higher doses of potassium citrate are used.

Hill's Prescription Diet canine canned u/d (the most purine-restricted diet currently commercially available) and allopurinol (30 mg/kg/day, divided q8–24h) has been recommended for medical dissolution of urate stones. This diet is very low in protein-purine and contains potassium citrate and calcium carbonate for urinary alkalinization. In a clinical study of 25 dogs with ammonium urate uroliths fed this diet and treated with allopurinol, complete urolith dissolution occurred in nine dogs (36%), partial dissolution in eight (32%), and no dissolution in eight (32%). The mean time for urate urolith dissolution was 3.5 months. Similar results were reported when this diet was used for dissolution of sodium urate uroliths. Owners must be fully compliant (i.e., no other food or treats should be given) if this option is selected. Careful patient monitoring is necessary as these uroliths are prone to migrating into the urethra where lower urinary tract obstruction can occur. However, Hill's u/d is contraindicated in dogs prone to pancreatitis or hyperlipidemia due to its high fat content.

Allopurinol is a specific enzyme inhibitor that causes partial blockage of the purine degradation pathway above the level of uric acid (see Figure 123.6). Allopurinol inhibits the enzyme xanthine oxidase. As a result, hypoxanthine, xanthine, and urate are all excreted in the urine. Each of these purine metabolites has a different urinary solubility; hypoxanthine is very soluble, whereas xanthine and urate are only poorly soluble. Allopurinol will reduce the oxidation of xanthine to urate. Consequently, xanthine concentration in the urine increases.

The dose of allopurinol recommended is variable (5–30 mg/kg/day, divided q8–24h). It has a dose-dependent half-life of 2.5–3 hours in dogs. For dissolution of ammonium urate stones, the higher dose is recommended (15 mg/kg q12h). Allopurinol and its metabolites are excreted via the kidney, therefore the dose should be reduced in patients with renal failure. In addition, any medications the dog is receiving need to be carefully assessed. For example, allopurinol can inhibit

metabolism of azathioprine, and can reduce metabolism of anticoagulants, theophylline or aminophylline. Ciclosporin (Atopica®) increases uric acid levels in urine and should not be used in dogs with urate urolithasis.

There is a risk of xanthine stone formation with allopurinol use. Careful monitoring for the presence of xanthine is strongly advised in all patients on allopurinol, as it is likely to occur in patients treated with allopurinol while fed a nonpurine-restricted diet. This may also occur in patients treated for leishmaniosis with allopurinol. Clinicians may be able to dissolve xanthine uroliths by discontinuing allopurinol and starting a low-purine diet. Alternatively, a preliminary study evaluating a low-purine, moderate-protein diet evaluated the reduction of xanthine calculi in dogs on allopurinol for long-term support of leishmaniasis therapy and appears to be promising. Control of concurrent urinary tract infection with appropriate antibiotics based on culture and sensitivity is also essential for both dissolution and prevention of urate uroliths.

Follow-Up and Prevention of Ammonium Urate Uroliths in Dogs

A low-purine diet is advised (Hill's Prescription Diet u/d or Royal Canin UC Low Purine). Diets that contain lean meat and glandular organs are high in purines, thus avoidance of meat-based protein (diet or treats) is recommended. Acceptable treats include carrots, apple slices, and air-popped popcorn. Urine alkalinization to decrease the production of ammonia and ammonium ions by the kidneys is also recommended. The goal of urinary alkalinization is to keep the urine pH around 6.8–7.0.

Allopurinol is only recommended for urate prevention if urate crystals persist despite dilute and alkaline urine. If urate crystals persist despite these interventions, the lowest dose of allopurinol that prevents crystals is advised, to avoid risk of xanthine stones.

For all urolith types, increasing water consumption decreases supersaturation of urine with crystals through dilution. Ideally, a urine specific gravity <1.020 in the morning is desired. Dry food may be soaked with water (aka "swim the kibbles") or canned food may be fed to help increase water consumption. Multiple water bowls, small feedings, and ice cubes are all potential ways to encourage drinking. Control of urinary tract infections with appropriate antibiotics (based on culture and sensitivity results) is essential in prevention.

The risk of recurrence is high for metabolic uroliths. Owner compliance is essential to reduce risk, and awareness of the genetic (breed) predisposition must be encouraged.

The recommended follow-up for these patients is examination of urine pH, specific gravity and sediment at two weeks, four weeks, and then every three months (see Table 123.3). Double-contrast cystography or ultrasonography should be performed every two months. If the dog remains urolith free, free of clinical signs, and significant crystalluria, rechecks may be decreased to every 2–4 months for the first postoperative year, and then twice yearly.

If the urate uroliths are secondary to a PSS, correction of the portal vascular anomaly is expected to resolve hyperuricuria and hyperammonuria followed by dissolution of ammonium urate uroliths. The frequency of successful dissolution post attenuation of the shunt has not been reported. Similarly, there is no study evaluating the success rate of a low-protein diet alone to dissolve urate stones in dogs with a PSS. Stones can and should be removed during correction of the PSS. Nephroliths typically dissolve after PSS attenuation, so they do not need to be removed unless problematic (obstruction).

Prevention of Ammonium Urate Uroliths in Cats

Similar to dogs, the features of a balanced diet designed to prevent recurrence of ammonium urate and uric acid urolithiasis in cats are high moisture, low purine (low-protein or vegetable-based protein), and the ability to produce a urine pH of 6.8–7.0. For example, Hill's Prescription Diet k/d (wet) would be recommended. Anecdotally, a commercially available hydrolyzed soy protein diet has been fed to cats to provide an adequate protein intake in a low purine form.

Calcium Phosphate Uroliths

Calcium phosphate uroliths are frequently multiple small uroliths, and their removal by surgical or nonsurgical methods is recommended to avoid urethral obstruction. Dissolution of calcium phosphate has been reported following parathyroidectomy for treatment of hyperparathyroidism in dogs.

Prevention of stone recurrence includes identification and therapy of any underlying disorder that causes an elevated calcium or phosphorus level or alkaline urine pH. Examples of these include primary hyperparathyroidism, disorders that predispose to hypercalciuria (hypercalcemia, excess vitamin D, systemic acidosis, excess dietary calcium), disorders that predispose to hyperphosphaturia (excess dietary phosphorus), and decreased urine volume.

Dietary manipulation that increases moisture and subsequent polyuria (e.g., canned formula or moderate sodium supplementation), and also provides the targeted calcium and calcium:phosphorus ratio is also recommended to prevent recurrence. A diet that avoids excessive acidification (to prevent calcium oxalate risk) or excessive alkalinization of urine is desired. The features of a diet designed to prevent recurrence of calcium

phosphate urolithiasis in cats are thought to be similar to those in dogs.

Cystine Uroliths

Cystine Uroliths in Dogs

Medical dissolution of cystine in dogs consists of reducing cystine concentration in the urine and increasing its solubility. As with all uroliths, increasing urine volume is beneficial for dilution of crystalloids. The solubility of cystine can be increased by making the urine pH alkaline (approximately 7.0–7.5), either by feeding a specific diet or by treatment with potassium citrate.

Features of a diet thought to help recurrence of cystine are:

- urine dilution
- low protein/purine levels (low protein or vegetable protein)
- alkalinize urine – target pH of 6.8–7.0
- limit sodium intake
- taurine and carnitine supplementation.

Hill's Prescription Diet Canine u/d and Royal Canin UC Low Purine have been recommended because they alkalinize the urine and reduce urine concentration. They are also markedly protein restricted (low in sulfur-containing amino acids), which decreases cystine excretion by 20–25% via reduction of cystine precursors.

Some dogs with cystinuria have increased renal excretion of carnitine, and low-protein diets increase the risk of carnitine deficiency and associated dilated cardiomyopathy in cystinuric dogs. As such, carnitine supplementation may be indicated. In addition, cystine is a precursor for taurine synthesis, and taurine supplementation may be warranted in these patients.

Dissolution of cystine urolithiasis has been reported by treating patients with a thiol-containing drug without feeding a protein-restricted diet. Thiol-containing drugs react with cystine, resulting in its conversion to a more soluble compound by a disulfide exchange reaction. Thiol-containing drugs include D-penicillamine and 2-mercaptopropionylglycine (2-MPG) (tiopronin, Thiola®, Mission Pharmaceuticals). Although both drugs are effective, metal chelation and gastrointestinal side-effects of D-penicillamine make it a less desirable choice. 2-MPG, at a dosage of 15–20 mg/kg of body weight divided and given orally twice daily, is the treatment of choice, in combination with dietary modifications for dissolution and prevention of cystine calculi. Use of this protocol resulted in dissolution of 60% of uroliths in one study within 1–3 months and was effective in 18/18 dogs in another. This drug has been reported to be associated with side-effects in dogs such as aggression, myopathy, anemia, proteinuria, thrombocytopenia, elevations of liver enzymes, and dermatologic changes.

Prevention of Cystine Uroliths

Diets used for dissolution of cystine uroliths are appropriate for cystine urolith prevention. Thiol-containing drugs have been used to prevent recurrence of cystine uroliths in dogs, at doses similar to those used for dissolution. Older dogs are less likely to form cystine uroliths and it may be possible to stop or taper therapies as patients mature. The risk of recurrence of these uroliths is high because cystinuria is an inherited defect in some affected dogs. Giger *et al*. observed that castration of mastiffs, Kromfohrlanders, and Irish terriers with non-type I cystinuria drastically diminished the excretion of cystine and dibasic amino acids. Maintaining a negative cyanide-nitroprusside test may be used to monitor and adjust therapy. In the subset of dogs with androgen-dependent cystinuria, castration can resolve cystinuria. If cystinuria decreases two months after castration compared to baseline measurement (before castration), the patient is less likely to have recurrence of cystine uroliths. If cystinuria persists four months after castration, it was probably not androgen dependent. Nitroprusside test and cystine crystalluria are less reliable tests than urine cystine measurement to detect persistent risk of cystine uroliths formation.

Silica Uroliths in Cats and Dogs

Effective dissolution protocols have not been reported for silicate stones in small animals. The risk of silica urolith recurrence is not well documented. In one study of silica uroliths, 12% of dogs had a previous episode of urolithiasis, but in most cases it was not known whether the previous urolith was also composed of silica.

To reduce the risk of silica stone recurrence, it is recommended to change the diet to one in which the vegetable content is limited. The recommendation is to avoid diets containing soybean hulls and corn gluten feed, and to avoid the ingestion of soil. As with all uroliths, increased water intake should be promoted to decrease the resulting concentration of calculogenic material in urine.

Mixed and Compound Uroliths

The management of compound uroliths is challenging because they consist of layers containing different mineral

compositions. Theoretically, the objective of compound urolith dissolution is to design a protocol to dissolve the outer layer of the urolith first, and then change the protocol to address each successive outer layer. Serial reevaluation of the size of the compound urolith by an appropriate imaging technique is recommended. Once the urolith does not decrease in size, medical therapy may be adjusted to attempt dissolution of suspected minerals in the inner layers. An alternative to the above consists of dissolving the outer layer of the urolith to reduce its size, followed by removing the remaining smaller portion by voiding urohydropropulsion. Neither of these techniques is usually possible in practice given the inability to predict each layer of the compound urolith and then adjust medical therapy as each layer dissolves. As such, mechanical removal is recommended for the majority of compound stones.

Compound uroliths may also contain layers that are not amenable to dissolution (i.e., calcium oxalate). For example, dissolution of an outer layer (i.e., struvite) may lead to a smaller size of urolith, which will then not dissolve any further as the underlying layer is calcium oxalate. This may increase the risk of urinary tract obstruction in male dogs. For this reason, most compound uroliths are removed either surgically or using a minimally invasive method (see later). Following removal of the compound urolith, the specific management strategy is aimed at prevention of the inner layer (nidus) of the compound urolith (i.e., the first layer to form).

Suture-associated stones have become more common. In one study they accounted for 0.6% of all canine uroliths and 9.4% of recurrent uroliths from 1999 to 2006. Suture-induced stones were more likely to be compound uroliths and often had a calcium phosphate nidus. Suture material that dissolves rapidly (like poliglecaprone versus polydioxonone) is recommended, in case bladder mucosal penetration occurs during closure.

Removal of Lower Urinary Tract Uroliths

Lower urinary tract calculi should be removed if they are not amenable to medical dissolution and if they are causing, or may cause, clinical signs, urinary tract obstruction, inflammation, or recurrent infection.

Surgical Removal

In small animals, surgical removal of uroliths by cystotomy or urethrotomy was the traditional standard of care for many years. However, urethral surgeries may result in permanent alterations of the anatomy and function of the urethra. For this reason, urethral surgeries are now discouraged and minimally invasive management of urethral stones has become the standard of care (see later).

Calculi remained in the bladder after cystotomy in up to 20% of dogs and cats. When removing cystic calculi, the urethra should be catheterized and flushed to ensure that it is free of calculi. Postoperative radiographs of the entire urethra are indicated as well to ensure that all calculi have been removed. A 2008 study reported that 9.4% of recurrent stones in dogs were suture induced. Luminal penetration is common in thin-walled bladders, but this is not believed to be associated with formation of calculus if absorbable monofilament suture is used.

Complications of cystotomy include a high recurrence rate of calculi, the need for serial surgeries that can lead to suture-induced stones, strictures, adhesions, bleeding, uroabdomen, pain, and other life-threatening complications.

Nonsurgical Treatment Options

In humans, minimally invasive treatment options have mostly replaced traditional surgical stone removal. In 2002, open surgical removal of uroliths was described in only 0.3–4% of human patients. In small animals, minimally invasive treatment options are now considered the standard of care to manage lower urinary tract stones. They consist of voiding urohydropropulsion (VUH), intracorporeal lithotripsy, extracorporeal shock wave lithotripsy (ESWL), cystoscopic stone basket retrieval, percutaneous cystolithotomy (PCCL), and laparoscopic-assisted cystotomy.

All minimally invasive stone retrieval procedures should ideally be performed after a negative urine culture has been documented, or the patient has been placed on an appropriate antibiotic for at least 24 hours.

Voiding Urohydropulsion

Voiding Urohydropulsion consists of removing small bladder calculi by inducing voiding while the dog or cat is positioned vertically or laterally (Figure 123.15). This procedure was first described by Lulich *et al.* and can be successfully performed in dogs and female cats but not in male cats as their narrow urethra may become obstructed by the stones.

Stone size is the most important criterion in deciding if VUH is an appropriate treatment option. Stones smaller than 3–4 mm can typically be voided respectively by small and small-medium female dogs. In female ultra-small breeds (such as Pomeranian, Chihuahua), careful evaluation of the size of the urethra in relation to stone is indicated. We recommend passing an 8 Fr urinary catheter before doing a VUH while the dog is under anesthesia and choosing an alternative stone removal method if

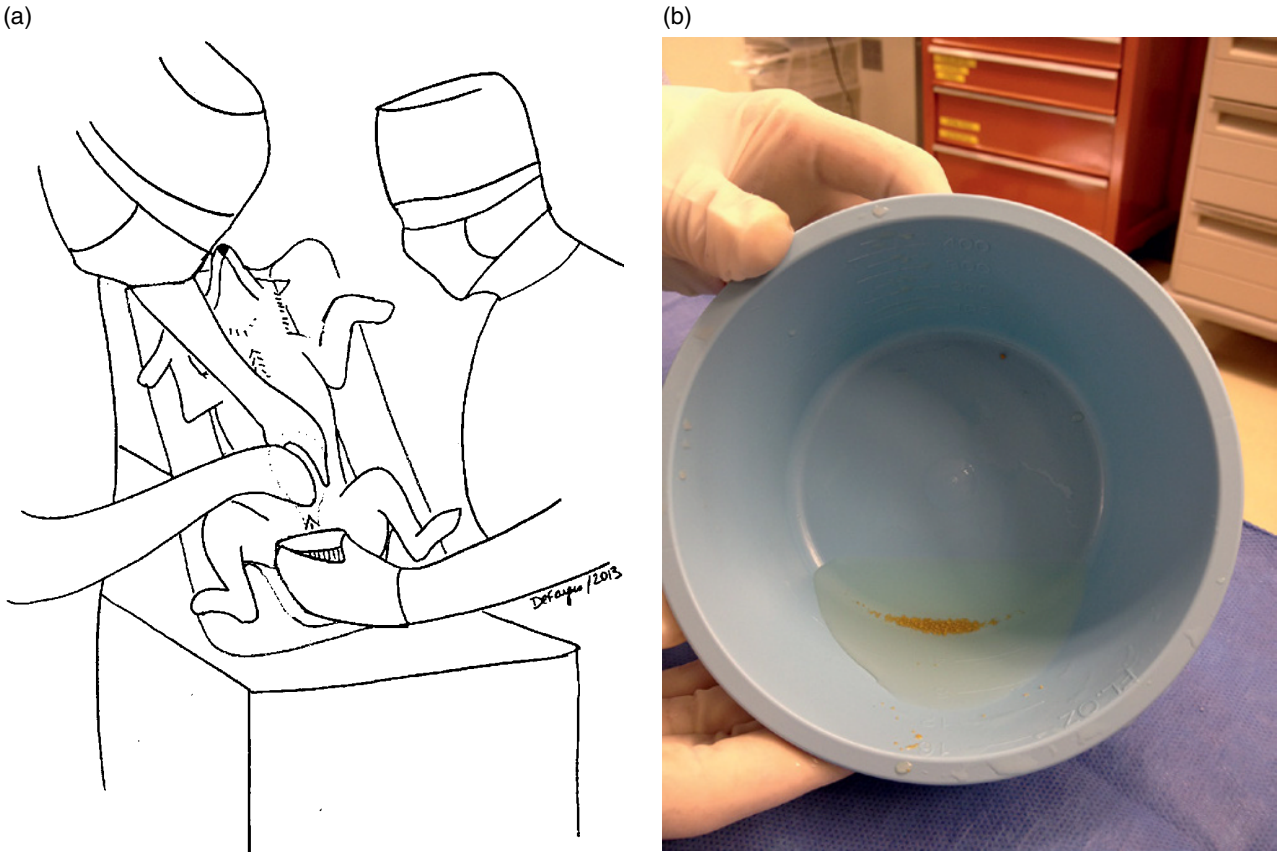

Figure 123.15 (a) Vertical positioning of a female dog to perform voiding urohydropulsion. (b) Container with cystic calculi removed by voiding urohydropulsion.

the urethra is smaller than 8 Fr. Stones smaller than 3 mm can be voided by male dogs weighing 10–25 kg. In male dogs weighing 5–10 kg, stones smaller than 2–3 mm may be voided. The clinician needs to try to catheterize the urethra first to evaluate its size. A catheter that is 3 Fr is equivalent to 1 mm, so that if an 8 Fr urinary catheter can be passed through the urethra, a 3 mm stone can be voided.

For VUH, the patient is placed under general anesthesia. The urethra is catheterized and the bladder is distended with warm sterile saline. The capacity of the bladder is typically 10–15 mL/kg. Once the bladder is fully distended, the patient is positioned vertically and then the urinary catheter is removed (see Figure 123.15a). The bladder is agitated so that gravity causes the stones to fall into the trigone. With strong, steady bladder expression while pulling the bladder cranially to straighten the urethra, the intravesicular pressure will maintain a strong urine stream as small fragments of stone material are voided into a container (see Figure 123.15b). General anesthesia is mandatory for this procedure, as the bladder can rupture if the patient does not have a relaxed, unobstructed urethra. The procedure is repeated until no calculi or stone fragments are passed for two expressions. Radiography, with or without positive or negative contrast (depending on the lucency of the stones), or cystoscopy, can be performed after the procedure to confirm complete urolith removal. VUH can also be used to obtain a few small stones for analysis to determine whether medical dissolution is an option for the remaining stones. Empiric antibiotics should be given during the procedure and for 3–5 days afterward. Broad-spectrum antibiotics such as amoxicillin or cephalexin are usually prescribed. To minimize discomfort during urination, NSAIDs or opioids are administered for 1–4 days as needed and based on clinical signs.

Extracorporeal Shock Wave Lithotripsy (Box 123.1)

Extracorporeal shock wave lithotripsy uses an external unit guided by fluoroscopic visualization to create shock waves that pass through the soft tissue of the patient. It is typically used for the fragmentation of upper urinary tract calculi from a renal pelvis or ureter, which are then left to pass spontaneously through the ureter, bladder, and urethra. It has also been used to fragment bladder stones in some dogs. However, the movement of stones within the bladder during treatment limits the repeated

Box 123.1 Candidates for extracorporeal shock wave lithotripsy

Nephroliths (dogs)

Indications
- Hydronephrosis
- Recurrent infection
- Pain
- Worsening chronic renal failure

Stone size
- <10 mm: ESWL alone
- >10–25 mm: ESWL with ureteral stent or PCNL
- >25 mm: consider PCNL

Ureteroliths (dogs and cats)

Indications
- Ureteral obstruction
- Pain
- Recurrent infection

Patient characteristics
- Dogs with ureteroliths; cats with distal ureteroliths
- Normal coagulation status
- Not pregnant
- No evidence of concurrent pancreatitis
- Appropriate antibiotic therapy for >48 hours before ESWL

Source: Reproduced with permission from Defarges A, Berent AC, Dunn M. New alternatives for minimally invasive management of uroliths: nephroliths. *Compend Contin Educ Vet* 2013; **35**(2): E3.
ESWL, extracorporeal shockwave lithotripsy; PCNL, percutaneous nephrolithotomy.

shock wave effect and may result in larger than desired fragments. After ESWL for bladder stones, VUH or cystoscopic stone basket retrieval is required for stone fragment removal. Typically, intracorporeal methods are preferred for optimal fragmentation and immediate removal of cystoliths.

Intracorporeal Lithotripsy

Electrohydraulic lithotripsy (EHL) and laser (Ho:YAG: holmium:yttrium, aluminum, garnet) lithotripsy were developed in the 1970s to fragment bladder uroliths in humans, with success rates reported to exceed 90%. Both types of intracorporeal lithotripsy have been described in veterinary patients. To date, the Ho:YAG laser is the most commonly used device for intracorporeal lithotripsy in veterinary and human medicine.

During laser lithotripsy, the patient is placed under general anesthesia as for routine cystoscopy. Once the urolith is visualized with the cystoscope, a small-diameter flexible quartz laser fiber (200, 365, or 550 µm) is guided through the working channel. The tip of the fiber is placed in direct contact with the surface of the urolith at a 90° angle, and pulsed laser energy is transmitted from the energized crystal to the urolith via the fiber (Figure 123.16). The stone is fragmented by a thermal drilling process, in which the pulse of energy traveling through the fiber creates a microscopic vapor bubble on the surface of the calculus. The closer the fiber tip is to the target, the larger the effect, having its greatest effect in contact mode. The energy is absorbed in <0.5 mm of fluid, making it safe to fragment uroliths in tight locations, such as within the urethra, ureter, renal pelvis, or urinary bladder, with limited risk of adjacent urothelial damage.

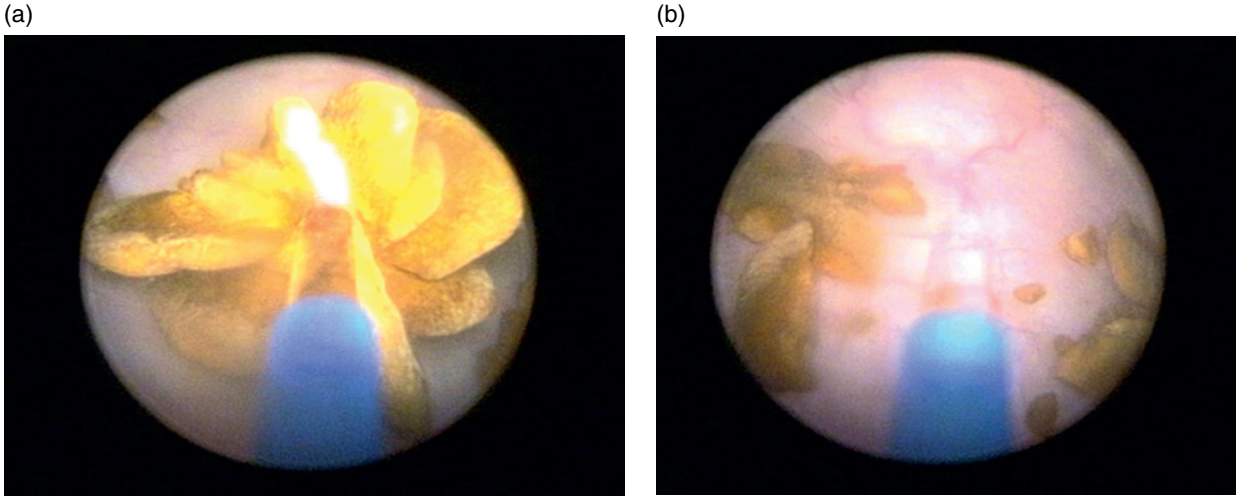

Figure 123.16 Visualization of bladder stones (oxalate) before (a) and after (b) fragmentation with the Ho:YAG laser in a female dog.

Stones are typically fragmented until the pieces are small enough to be voided using VUH or manually extracted from the bladder using a stone retrieval basket. This technology is considered the standard of care in human medicine and is currently being utilized for lower urinary tract stones in many veterinary hospitals in North America.

The Ho:YAG laser has been reported to be effective on all stone types. Adams *et al*. reported that laser lithotripsy resulted in complete fragmentation of all uroliths in 100% of females (28/28 dogs) and 86.7% of males (39/45 dogs). In the literature, complete urolith removal is typically achieved in 100% of dogs with urethroliths, 83–96% of female dogs with cystoliths, and 68–81% of male dogs with cystoliths. In the Adams *et al*. study, the complication rate reported with laser lithotripsy was 17.9% in female dogs and 13.3% in male dogs. Complications were typically minor and shortterm, including urethral swelling, edema, and mild hematuria, which were medically managed. Shortterm complications were most commonly related to urethral mucosal swelling from serial passage of the cystoscope in female dogs and resolved with the placement of an indwelling urinary catheter for 12–24 hours. Short-term complications were reported in 5/28 (17.9%) of female dogs and 6/45 (13.3%) male dogs in this study. In comparison, Thierman-Mankin *et al*. reported short-term complications in 37–50% of 144 dogs using traditional surgical cystotomy.

In another canine study in which laser lithotripsy was retrospectively compared with traditional cystotomy, both methods were considered equally effective. Complete urolith removal rate was not significantly different between dogs in the cystotomy group (86%) and those in the lithotripsy group (89%). There were no significant differences in complications evaluated between the groups and patients undergoing lithotripsy were discharged from the hospital 12 hours earlier than those having a cystotomy. Adams *et al*. reported that of 73 dogs with uroliths treated by laser lithotripsy, only 19% (14/73) had stone recurrence after approximately 12–24 months of follow-up, which is less than that previously reported with cystotomy (42%).

The greatest challenge of both laser and EHL lithotripsy is the removal of small stone fragments from the bladder following fragmentation, which can take extended periods of time and result in urethral trauma/edema during repetitive endoscope passage. Grant *et al*. identified female sex as a positive predictor of success (complete stone removal). They reported that smaller body weight, large urolith burden, and increasing urolith size significantly increased the time required to perform laser lithotripsy. This has made the use of other procedures, like PCCL, appealing for smaller dogs and cats with a large bladder stone burden, regardless of size or sex.

Cystoscopic-Guided Basket Removal

Another option for stones that are too large for VUH but small enough to fit through the urethra with gentle traction is stone basket retrieval. A variety of stone baskets are available from several manufacturers. Basket retrieval is usually performed under cystoscopic guidance, although fluoroscopy can also be used. Typically, the size of the stone is the limiting factor. Basket retrieval can be considered in female dogs with stones <4–5 mm, male dogs with stones <3 mm, and female cats with stones <3 mm.

Percutaneous Cystolithotomy (PCCL)

This minimally invasive approach has been reported in 27 dogs and cats with excellent complete stone removal rates (96%), short procedure times (40–75 min), and similar hospitalization times as those seen with transurethral lithotripsy, regardless of patient sex, size, stone number, or species. This procedure can be an alternative in animals in which transurethral lithotripsy is a challenge (small male dogs, male dogs with a large stone burden, male and female cats, rabbits, guinea pigs, etc.) or if lithotripsy is unavailable.

For this procedure, a single small incision (approximately 1–1.5 cm) is made into the abdominal cavity just over the apex of the urinary bladder. Once the bladder is palpated digitally, stay sutures are used to hold the bladder up to the incision while a laparoscopic screw-tip cannula or port is inserted into the bladder at the apex. Surgical aspiration is usually used while fluid is flushed into the bladder with a urethral catheter, as the best visualization is achieved with a saline-filled bladder. The bladder is typically not fully exteriorized (Figure 123.17a,b). A small, rigid cystoscope is inserted through this port into the bladder, and stones are identified and removed with a stone retrieval basket through the working channel of the cystoscope (Figure 123.17c–e). If the stones are very small, they can be flushed out of the port in a retrograde manner with a urinary catheter in the urethra flushing fluid into the bladder while a suction device is placed into the port suctioning out the fluid and small fragments. If the stones are larger than the port, they can either be fragmented by lithotripsy or manipulated through the small incision with the stone basket. It is very rare that lithotripsy is needed concurrently. After all calculi are removed from the bladder, the entire urethra is examined with a rigid cystoscope (female dogs) or a flexible ureteroscope (male dogs) to ensure that all fragments have been removed and the small incision is sutured closed. A basket

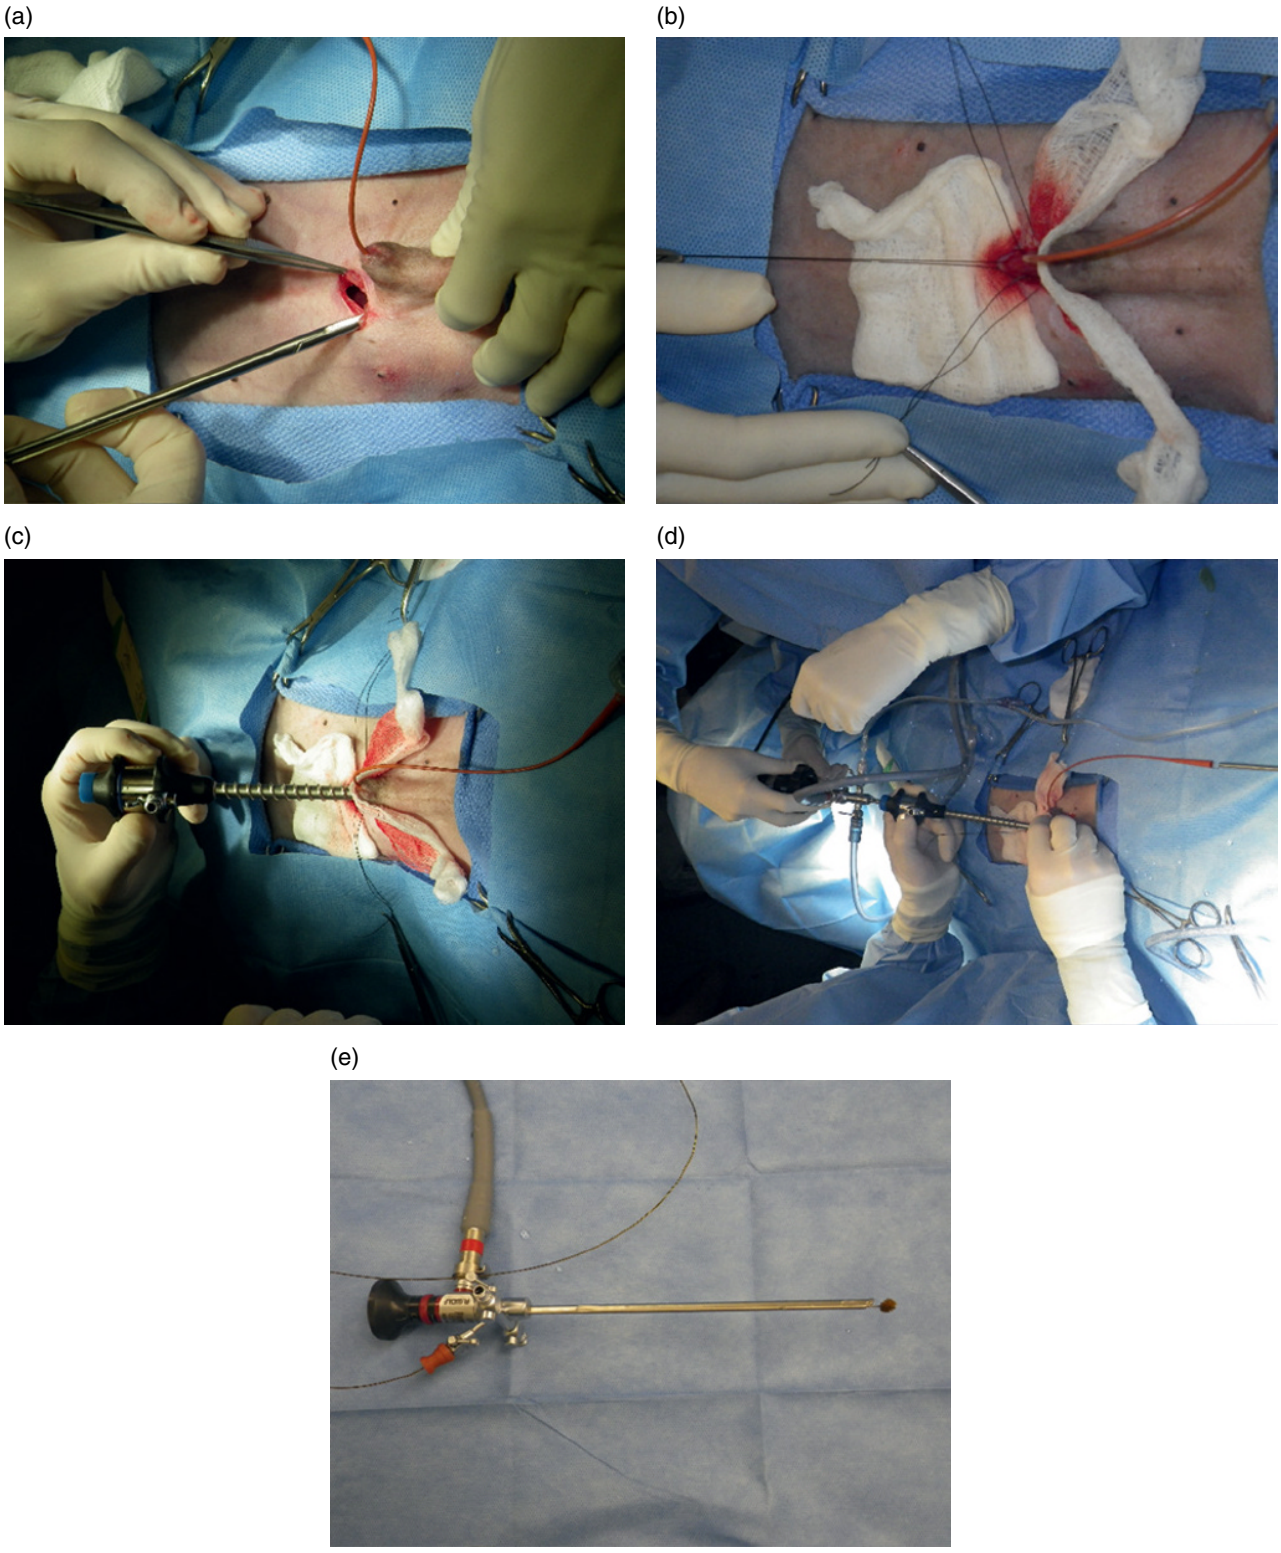

Figure 123.17 Percutaneous cystolithotomy performed in a male dog. (a) A single small incision is made into the abdominal cavity just over the apex of the urinary bladder. (b) Once the bladder is palpated digitally, stay sutures are used to hold the bladder up to the incision. (c) A laparoscopic screw-tip cannula is inserted into the bladder at the apex. (d) A small rigid cystoscope is inserted through this port into the bladder. (e) Stones are identified and removed.

retrieval device can be used to remove any remaining urethral calculi through the working channel of the endoscope.

In patients with embedded urethral stones, laser lithotripsy can be performed. Percutaneous cystotomy can also be used to aid in gaining access to the ureters for diagnostic or therapeutic purposes and for resection of bladder polyps or diagnostic evaluation of the bladder and proximal urethra in dogs that are too small for retrograde cystoscopy.

Laparoscopic-Assisted Cystoscopy

Laparoscopic-assisted cystoscopy is performed via a mini laparotomy. In this technique, the abdomen is insufflated with carbon dioxide and the bladder is isolated. Another trocar is inserted into the abdomen at the level of the bladder apex, and the bladder is exteriorized at this access point using a laparoscopic Babcock forceps. The incision is enlarged, creating a mini laparotomy, to pull the urinary bladder. A small cystotomy is performed and the bladder wall is sutured to the skin of this small abdominal incision. A rigid cystoscope is then inserted into the bladder for calculus retrieval. The use of a basket passed through the working channel or a grasping forceps next to the cystoscope aids in removal of the stones. The cystotomy incision is closed routinely. This procedure makes it difficult to maintain bladder distension for the best visibility.

Laparoscopic-assisted cystoscopy can circumvent some of the limitations associated with laser lithotripsy, but it does require creating a pneumoperitoneum, making the alternative PCCL very appealing.

Removal of Upper Urinary Tract Uroliths

The incidence of nephroliths and ureteroliths in cats has increased as much as 50-fold since the early 1980s. Calcium oxalate is the most common (>98%) type of stone found in the upper tract of cats, followed by calcium phosphate, in the form of apatite, or urate. Approximately 30–60% of ureteroliths in dogs are composed of calcium oxalate.

Indications for Upper Urinary Tract Urolith Removal

Nephroliths

Many canine and feline nephroliths remain static in size and clinically silent for years. Some controversy exists as to whether nonobstructive kidney stones worsen underlying kidney disease. Most recent studies in human and cats show that the presence of nephroliths (vs no nephroliths) seems to worsen renal disease and outcome. For this reason, removal of nephroliths in people is encouraged. In small animals, because of the challenges associated with removal of nephroliths and the lack of evidence that nephroliths are a cause of renal disease progression rather than a marker for more aggressive renal disease, it is not yet recommended to remove nephroliths that are not complicated. Nephrolith removal is not indicated unless uroliths are increasing in size and compressing the renal parenchyma, causing recurrent infections despite appropriate duration of medical management, or if the patient has a partial or complete ureteropelvic junction (UPJ) obstruction resulting in hydronephrosis, renal parenchymal loss, worsening renal function, chronic hematuria, or pain.

Ureteroliths

If one or more ureteroliths are obstructing urine flow, causing hydroureter and/or hydronephrosis, or are associated with discomfort, hemorrhage, or concurrent pyelonephritis, management for medical stone passage or interventional urinary diversion is indicated immediately, regardless of stone composition, as time is critical. The presence of a hydroureter without renal pelvic dilation greater than 5 mm is sufficient to suspect ureteral obstruction. If the ureteral obstruction is complete, decompression of the renal pelvis becomes urgent to preserve the function of the ipsilateral kidney. The longer the ureter remains obstructed, the more significant and irreversible the damage. In one study, after seven days of obstruction, the GFR was permanently diminished by 35% after relief of the obstruction, and recovery took five weeks to occur. When the obstruction lasted for 14 days, the GFR was permanently diminished by 54%, with recovery taking four months to occur. These studies were performed in dogs without preexisting renal or ureteral disease, so a worse outcome might be expected in feline and canine patients with chronic obstructions, previous and/or exhausted renal hypertrophy compensation, and preexisting renal insufficiency. These data suggest that aggressive and timely intervention is necessary when a ureteral obstruction is diagnosed and that the "watch and wait method" should be avoided whenever possible.

Medical Management

Medical management of upper urinary tract stones includes dissolution (nephroliths), aggressive diuresis, or intermittent hemodialysis (IHD).

More than 50% of dogs with ureteral obstructions have been reported to have urinary tract infection. For that reason, any patient with ureteral obstruction should have a urine culture performed and should be given the

appropriate antimicrobials. For dissolution to occur, the uroliths must be surrounded by undersaturated urine to allow them to go back into solution. For these reasons, urocystoliths and nephroliths are amenable to dissolution but ureteroliths and urethroliths are not. Dissolution of struvite nephroliths has been reported in six dogs that had bacterial pyelonephritis and impaired urine-concentrating ability. An average of 184 days of treatment (range, 67–300 days) with a calculolytic diet (Hill's Prescription Diet Canine s/d) and antibiotic therapy was required for radiographic dissolution of the stones in these dogs. In the author's experience (AB), ureteroliths should be dissolved within 2–6 weeks and nephroliths should be decreased in size (<75 % initial size) by three months. It can take up to nine months to dissolve large nephroliths. Increasing the number of walks per day should be encouraged to improve stone elimination.

Aggressive diuresis has been effective at helping move ureteroliths down into the bladder and in resolving azotemia in 8–14% of cats with ureteroliths. This limited success rate of diuresis may be explained by the high percentage of ureteral obstruction secondary to stricture in cats.

Surgical management was effective in 101 cases, but has a high postoperative complication rate (31% in cats and ~35% in dogs) and perioperative mortality rate (18% in cats and 25% in dogs). Medical management should be considered prior to surgical intervention; however, more aggressive management should be considered if the patient fails to improve with medical management alone for 48 hours, or if the patient is anuric/oliguria, hyperkalemic, overhydrated or if there is progressive renal pelvic dilation.

In the authors' experience, aggressive diuresis in cats appears to be more effective for small stones (<1–2 mm) in the distal third of the ureter compared to larger stones, or those in the proximal ureter. Aggressive diuresis consists of aggressive IV fluid therapy while monitoring central venous pressure, body weight, electrolyte concentrations, and hydration status. One recommended fluid therapy protocol includes administering 0.45% saline mixed with 2.5% dextrose at a maintenance rate (e.g., 50–60 mL/kg/d). Additionally, a replacement fluid such as Plasma-Lyte® (Abbott Animal Health) or lactated Ringer's solution (avoiding saline, if possible, to reduce sodium load) is administered to correct dehydration and promote diuresis (e.g., 45–75 mL/kg/d). The maximum combined fluid rate should not exceed 120 mL/kg/day. In patients without cardiac compromise, mannitol is administered as a bolus at 0.25–0.5 g/kg over 20–30 minutes followed by a constant rate infusion of 1 mg/kg/min for 24 hours. If, after 24 hours, there is no evidence of improvement based on imaging and serial bloodwork, the mannitol infusion is discontinued. Other medical alternatives include amitriptyline, alpha-adrenergic antagonist therapy (prazosin or tamsulosin), or glucagon therapy.

Intermittent hemodialysis has been reported to resolve acute kidney injury secondary to obstructive ureteroliths. Thirteen cats did not have any surgical intervention and eight of these 13 survived 365 days or longer past discharge; all of these cats had a degree of renal recovery sufficient for discontinuation of IHD prior to hospital discharge.

If medical management fails or the patient is unstable (e.g., hyperkalemic, overhydrated, oligo-/anuric, developing progressive hydronephrosis), or if IHD is not available at the institution, immediate renal decompression should be considered. If minimally invasive urolith extraction or bypass is not possible, then the two best options are to (1) place a nephrostomy tube or (2) initiate IHD or continuous renal replacement therapy (CRRT), for stabilization. Immediate renal pelvis decompression is recommended over hemodialysis or CRRT if the patient is stable enough to undergo anesthesia and the operator is comfortable with the procedure. Renal pelvis decompression halts the damage being done by the increased hydrostatic backpressure, whereas hemodialysis stabilizes a patient while the ureteral obstruction persists, resulting in ongoing renal injury. A short delay in treatment in a stable patient is preferred over immediate treatment by an inexperienced operator, as the complication rates with any of the decompression procedures are high if experience is limited. Partial obstructions allow a longer window of opportunity for treatment without such dramatic renal damage as seen with complete obstructions, allowing time to arrange referral to a facility with experience in these procedures. Over 75% of obstructed feline patients have a partial ureteral obstruction based on ureteropyelography.

Many patients with ureteral obstruction have concurrent urinary tract infections (75% of dogs and 10–30% of cats) so broad-spectrum antimicrobial therapy is recommended for all patients, and a urine culture and sensitivity should be part of the work-up.

Surgical Removal of Upper Urinary Tract Uroliths

Nephroliths

In small animals, traditional intervention for treatment of nephrolithiasis involves a nephrotomy, pyelotomy, or salvage ureteronephrectomy. Complications can be severe and life-threatening after a nephrotomy, including hemorrhage, decreased renal function, ureteral obstruction by remaining nephrolith fragment passage, and urinary leakage into the abdomen from the renal incision.

In a study of normal cats, the GFR of the ipsilateral kidney decreased by 10%–20% after a nephrotomy. This was clinically insignificant in normal cats but in a clinical patient with maximally hypertrophied nephrons due to prior nephrolith-induced damage, the significance could be dramatic. Therefore, feline patients with an already compromised GFR from chronic stone disease may develop a clinically significant decline in renal function after nephrotomy. Since over 30% of adult cats eventually develop chronic kidney disease associated with a 75% decline of renal function, a 10–20% further decline in GFR from a nephrotomy may be poorly tolerated. Hence, nephrotomy should be avoided when possible in all cats, especially those with existing renal disease. In dogs undergoing traditional surgery for nephrolithiasis, there was a very high complication rate (23%) following the procedure, as well as remaining fragments in more than 40%. In addition, 67% of dogs undergoing nephrectomy developed renal azotemia.

Typically, unless the stone results in a ureteral obstruction or severe perisitent hematuria, is the cause of chronic UTIs, or is so large that it is overtaking the renal parenchyma, nephroliths remain clinically silent for the life of the dog or cat and removal is currently not being recommended. The 2016 ACVIM consensus statement on the management of urinary tract stone disease recommends management of upper urinary uroliths by minimally invasive techniques rather than standard surgery when possible.

Ureteroliths

Traditional surgical intervention to address ureteroliths includes ureterotomy, neoureterocystostomy, ureteronephrectomy, or renal transplantation. Kyles *et al*. reported procedure-associated complication and mortality rates of >30% and 18–38%, respectively, in more than 150 cats that underwent at least one of these procedures. These cases were seen at two universities where microsurgical expertise was available and a renal transplant program existed. The morbidity and mortality rates may be higher in environments where operating microscopes and microsurgical experience and expertise are not available.

Many of the complications associated with surgery are due to site edema, recurrence of stones that then pass from the renal pelvis to the surgery site, stricture formation, persistent obstructions, missed ureteroliths, and ureterotomy-associated or nephrostomy tube-associated urine leakage. In the Kyles *et al*. study, patients that underwent a ureterotomy for treatment of a ureteral obstruction (the most commonly performed procedure in practice) had a perioperative mortality rate of 25%. Uroabdomen occurred in 15% of cats in which a ureteroneocystotomy was performed.

When ureterotomy or ureteroneocystotomy is unsuccessful, a ureteronephrectomy may be required, which is not ideal due to the high risk of subsequent stone-induced obstruction of the contralateral kidney and the majority of cats being azotemic at the time of diagnosis with a unilateral ureteral obstruction. Chronic kidney disease is common in cats when a ureteral obstruction is diagnosed, with 75–97% of cats with a unilateral obstruction reported to be azotemic. For this reason, removing a kidney for a diseased ureter should never be encouraged.

Another major concern is that in one study, 40% of cats developed a second ureteral obstruction over a 1–2-year follow-up, and of these cats, 62% had evidence of nephrolithiasis documented at the time of the first surgery. Unfortunately, removing a nephrolith in a cat is challenging and potentially harmful, and it is impossible to predict whether a nephrolith will become an obstructive ureterolith, so nephrotomy should not be encouraged.

Results after ureterotomy, pyelotomy, and/or ureteronephrectomy have been reported in 16 dogs. The mortality rate (death related to azotemia or to clinical signs related to the urinary system) in this study was 25% (4/16 dogs). Of the 12 dogs that were followed, 17% required an additional surgery within four months for ureteral stricture or recurrent ureteroliths. Most dogs (88%) had urinary tract infections at diagnosis, and 50% had concurrent nephrolithiasis. Ten (62.5%) dogs presented to the hospital with elevated blood urea nitrogen and/or creatinine concentrations and 50% remained elevated after successful surgery. Postoperatively, two dogs had worsening azotemia.

Minimally Invasive Management of Nephroliths and Ureteroliths

In humans, minimally invasive procedures are the treatment of choice for nephrolithiasis and ureteroliths due to the high complication rates and morbidity associated with traditional surgery (Table 123.4). These procedures include ESWL for nephroliths <1–2 cm and endoscopic nephrolithotomy (percutaneous nephrolithotomy [PCNL] or surgically assisted endoscopic nephrolithotomy [SENL]) for nephroliths >1–2 cm. Open surgery and laparoscopy are typically only considered after other less invasive options have failed or been deemed inappropriate.

Over the last 10 years, evidence-based data support that minimally invasive treatment of upper urinary tract uroliths in dogs and cats is associated with a lower morbidity and mortality rate compared to surgical procedures. Selection of the most kidney-sparing procedure should always be a priority to treat upper urinary tract uroliths in small animals.

Table 123.4 Considerations for various interventional procedures in patients with partial or complete ureteral obstruction[a]

Procedure	Cats	Dogs
Medical management (aggressive diuresis)	• Indicated within 48 h of ureteral obstruction • Contraindicated if patient is unstable (hyperkalemic, excessively overhydrated, becoming oliguric, or has cardiac disease)	• Indicated within 48 h of ureteral obstruction • Contraindicated if patient is unstable (hyperkalemic, excessively overhydrated, becoming oliguric, or has cardiac disease)
Nephrostomy tube	• Indicated for urgent decompression of the renal pelvis if ESWL and ureteral stenting not available • Renal pelvis must be >10 mm • Surgically placed; percutaneous placement not recommended because of increased risk of uroabdomen due to mobility of feline kidneys	• Indicated for urgent decompression of the renal pelvis if ESWL and ureteral stenting not available • Renal pelvis must be >10 mm • Percutaneously placed
ESWL	• Indicated for ureteroliths <3 mm • Add ureteral stent if ureterolith is between 3 and 5 mm or obstruction is present	• Indicated for ureteroliths <5 mm • Add ureteral stent if ureterolith is >5 mm or obstruction is present
Ureteral stents	• Indicated for obstructive ureteroliths (any degree of hydroureter and hydronephrosis) • Placed antegrade via nephrostomy access • Placed retrograde via cystoscopy or ureterotomy	• Indicated for any obstructive ureterolith • Placed retrograde (cystotomy or cystoscopy) or antegrade (percutaneous or surgical nephrostomy access)
Ureteroscopy	Not performed because of small patient size	• Indicated for dogs >18 kg • Ureteral stents placed when complete obstruction
SUB	• Current preferred method for ureteral obstruction in cats • Indicated for ureteral strictures or very proximal ureteral obstructions • Indicated for ureteral stent reactions	• Indicated for ureteral stent reactions or intolerance or recurrence of occlusion
Ureterotomy or ureteral reimplantation	If deemed appropriate by attending surgeon	If deemed appropriate by attending surgeon

[a] Immediate treatment of partial ureteral obstruction is typically recommended.

ESWL, extracorporeal shock wave lithotripsy; SUB, subcutaneous ureteral bypass.

Extracorporeal Shock Wave Lithotripsy

Extracorporeal shock wave lithotripsy is used to fragment uroliths fixed in one location. It has been successfully used to fragment nephroliths and ureteroliths in dogs and ureteroliths in cats. The patient is placed under general anesthesia to permit positioning and provide analgesia. Fluoroscopy is used to position the ESWL unit to target the urolith. If compromised renal function is of concern, or if bilateral ESWL is to be performed concurrently, limiting treatment to a maximum of 2000–2500 shock waves per kidney is recommended. For uroliths in the distal ureter or urinary bladder, higher doses are possible because the kidney is not within the treatment focal zone and collateral damage to surrounding tissues seems to be minimal.

Extracorporeal shock wave lithotripsy is most commonly recommended for the treatment of nephroliths and ureteroliths in dogs, rather than cats, for two reasons. First, the feline ureter does not routinely accommodate nephrolith fragment passage. Therefore, a nonobstructive nephrolith could become an obstructive ureterolith after ESWL. Post ESWL, nephrolith fragments are typically ≥1 mm in diameter, and the typical unstented feline ureter is 0.3–0.4 mm in diameter. Second, there is some concern that feline kidneys are more sensitive than canine kidneys to shock waves and could experience bleeding.

Extracorporeal shock wave lithotripsy treatment was reported to be successful in approximately 85% of dogs with calcium-containing nephroliths and ureteroliths. Successful fragmentation of renal stones was achieved in 90% of dogs, but some dogs required multiple treatments. Overall, 30% of dogs required more than one ESWL treatment for adequate fragmentation of nephroliths when lithotripsy was used; when an older model dry unit (Modulith SL-20) was used, up to 50% of dogs required more than one treatment. Success rates approach ~85% with one treatment when ureteral stenting is concurrently performed. In one study of five cats with ureterolithiasis treated by ESWL (wet unit),

only one cat had complete resolution of the ureterolith, and partial fragmentation occurred in two other cats; however, these fragments were still too large to pass down the ureter. In the authors' (AB) experience, success in stone fragmentation and passage was seen in two of an additional five cats, suggesting an approximate 30% passage rate overall (3/10). However, larger studies are needed to confirm these results and this procedure is not currently recommended in cats by the authors.

Extracorporeal shock wave lithotripsy is believed to be safe and well tolerated by canine kidneys. In a series of 140 dogs with nephroliths or ureteroliths treated by ESWL, the most common complication was ureteral obstruction by stone fragments, which occurred in approximately 10% of dogs. With the advocacy of ureteral stent placement for larger nephroliths (>10–20 mm) before ESWL, this risk has declined. In dogs, it has been shown that the renal changes observed after ESWL typically result in minimal decreases in GFR and renal blood flow during the first 24 hours of treatment, and both return to baseline within one week. Extrarenal complications with ESWL include abdominal pain, diarrhea, and pancreatic injury (i.e., increased enzymes levels not associated with clinical signs). Shock wave-induced dysrhythmias have been described in a few human patients (<8%).

Hospitalization typically ranges from eight to 24 hours to monitor for the passage of urolith fragments and to allow postprocedure analgesia and diuresis with intravenous fluid therapy. Stone fragments may be voided 1–2 days after the procedure and collected in a strainer or cheesecloth to be analyzed. Animals with ureteral stents often require shorter hospital stays, as the concern for post-ESWL ureteral obstruction is diminished. Patients are discharged with instructions for monitoring urination and urine appearance, lethargy, abdominal pain, or vomiting. Follow-up radiography and ultrasonography are typically recommended one day after treatment, then in 2–4 weeks, and then every month thereafter until all stones are passed. If fragments that have passed into the urinary bladder are not voided within 1–2 months after ESWL, VUH or cystoscopic stone basketing is recommended. If stone fragments remain in the kidney or ureter after 2–3 months, repeat ESWL is suggested as long as there is no concurrent ureteral obstruction. A second treatment is required in 15–35% of cases to achieve effective fragmentation if the remaining fragments appear too large to safely pass through the ureter. In cases of ureteral obstruction, placement of a ureteral stent would be recommended.

Ureteral Stents

The use of ureteral stents in dogs and cats has been investigated for the last 14 years as a less invasive alternative to traditional surgery. Placement of a double-pigtail ureteral stent (Figure 123.18), via either minimally invasive techniques (endoscopy and fluoroscopy in most dogs) or surgically assisted (nephrostomy access in most cats), can circumvent many of the perioperative complications of surgery (e.g., leakage, stricture, reobstruction)

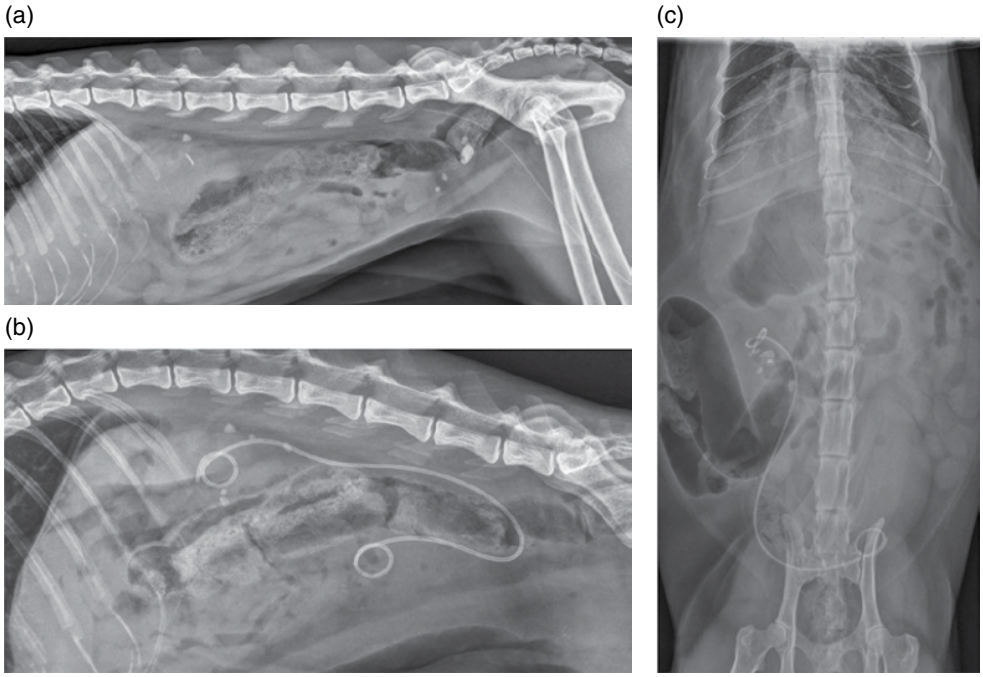

Figure 123.18 Preoperative lateral (a), postoperative lateral (b) and ventrodorsal (c) radiographs following ureteral stent placement in a cat.

and quickly stabilize the patient. Typical ureteral stent sizes are 2.5 Fr for cats and 3.7 or 4.7 Fr for dogs. Ureteral stents have many benefits:

- immediate decompression of the renal pelvis
- passive ureteral dilation for urine and stone passage
- prevention of strictures and leakage associated with surgical or nonsurgical procedures
- prevention of a ureteral obstruction after ESWL
- can be easily removed.

In cases of obstructive pyonephrosis, endoscopic ureteral and renal pelvic catheterization can lavage the renal pelvis and ureter of infected debris and a ureteral stent can then be placed to maintain ureteral patency. All of these benefits have been clearly documented in human medicine and, more recently, in veterinary medicine.

Ureteral stenting in dogs and cats performed by an experienced operator is associated with a lower morbidity and mortality rate (<2% and 7%, respectively) than traditional surgery. Surgical placement with fluoroscopic guidance has a procedural success rate of more than 95% in cats and 100% in dogs; with endoscopic and fluoroscopic guidance, the success rate is 20% in cats and over 90% in dogs. There are relatively few major long- or short-term complications (Table 123.5), and the stents are typically left in place long term. In the authors' (AB) experience to date, the longest duration of stent patency in a feline ureter is more than seven years and in dogs more than 10 years.

The risks of stent placement need to be understood, and owners must be educated on these risks before considering this option (see Table 123.5). The greatest risks are associated with device placement, as the stent can be very difficult to place in some feline patients, and appropriate training and experience with the procedure are critical to its success. Risks seen months to years after stent placement are typically not life threatening, and are relatively easy to address on an outpatient basis

Table 123.5 Immediate, short-term, and long-term complications of various minimally invasive procedures to manage ureteroliths in dogs and cats

	Complications			
Procedure	**Operative**	**Postoperative (<1 week)**	**Short-term (1 week–1 month)**	**Long-term (>1 month)**
Feline ureteral stent	Ureteral perforation with guidewire (little clinical consequence) Leakage if concurrent ureterotomy needed Eversion of ureteral mucosa during stent passage Ureteral tear during stent passage	Fluid overload during postobstructive diuresis (<5%) Failure of creatinine to improve (<5%) MORTALITY (<8%) typically due to nonurinary causes (pancreatitis or congestive heart failure)	Dysuria (self-limiting 7–14 days) Inappetence (temporary)	Dysuria (38%) nearly all respond to prednisolone and/or prazosin UTI (30%; 34% pre-op) Reobstruction (19%) – Stricture recurrence (54%) – Adhesions around ureter (23%) Obstructive pyelonephritis (8%) Chronic hematuria (18%) Stent migration (6%) Ureteral reflux (1%)
Canine ureteral stent	Endoscopic failure (~3%) Ureteral perforation (<1%) Leakage (<1%) Ureteral tear (<1%)	MORTALITY (<1%)	Dysuria (<1%)	Proliferative tissue at ureterovesicular junction (25%) UTIs (~10%; >60% pre-op) Migration (<5%) Occlusion (<5%) Dysuria (<3%)
SUB	Renal pelvis penetration by guidewire (<5%) Kinking of catheters (~5%) Inability to place SUB device (<1%)	Leakage (5%) Fluid overload (<5%) Failure of creatinine to improve (<5%) Blockage of system (3%) (blood clot, purulent material, device failure) MORTALITY 5.6%	Dysuria (<2%) Inappetence (temporary)	UTI (15%; 35% pre-op) Blockage of system (9%) (stones 8%, purulent material 1%) Dysuria (<2%)

SUB, subcutaneous ureteral bypass; UTI, urinary tract infection.

and include reocclusion, migration, or dysuria. In dogs, ureteral stents have replaced standard surgery to decompress upper urinary tract obstruction. Long-term complications include urinary tract infection (26%), occlusion of the stent (9%), ureteritis (5%), stent migration (5%), encrustation (2%), and hematuria (7%). More than three-quarters of the patients were able to clear the infections if present before ureteral stent placement. In cats, ureteral stent placement can be challenging and is associated with a 38% rate of long-term dysuria (responsive to steroid therapy). Since subcutaneous ureteral bypass has been associated with lower complication rates (see later) than ureteral stenting in cats, it is now considered the treatment of choice to relieve upper urinary tract obstruction in cats in the authors' practices.

Endoscopic Nephrolithotomy

In humans, PCNL is typically performed for large or embedded nephroliths (>15–20 mm). In small animals, PCNL/SENL is considered if ESWL fails or is not available, cystine stones (which are resistant to EWSL) are present, or the stone is >15–20 mm (depending on patient size).

Typically, a combination of ultrasonographic, endoscopic, and fluoroscopic guidance is used for both PCNL and SENL. PCNL has been performed in 11 dogs and one cat to date. The smallest patient to date having a PCNL/SENL was 5 lbs (2.3 kg), making patient size less of an issue than other alternatives.

Typically, for PCNL, a renal access needle is used to access the renal pelvis through the greater curvature of the kidney under ultrasonographic guidance. Subsequently, a nephroscope is inserted through a sheath and into the renal pelvis to visualize the stone. If the latter is small enough, a stone retrieval basket is used to remove the stone. If the stone is larger than the sheath, intracorporeal lithotripsy (ultrasonic, pneumonic, electrohydraulic, or Ho:YAG laser) is used to fragment it. Once the stone fragments are small enough to fit through the sheath, they are removed and a locking-loop nephrostomy tube (5 or 6 Fr) is left in place to allow the small hole to seal and form a nephropexy.

Surgical-assisted endoscopic nephrolithotomy can be performed similarly to that described for PCNL, only the abdomen is opened to assist in nephrostomy access closure, to prevent the need for a nephrostomy tube. For both PCNL and surgical-assisted endoscopic nephrolithotomy, because a balloon is used to dilate the renal parenchyma (no incision is performed), minimal nephron loss occurs. PCNL and SENL are considered the most "kidney-sparing" procedures with the highest urolith-free rate and minimal effect on GFR. For these reasons, they are recommended as the first treatment for patients with staghorn calculi according to the American Urologic Association Guidelines.

The author (AB) has performed endoscopic nephrolithotomy in 11 dogs and one cat (16 renal units) using the PCNL approach (n = 4 renal units) or SENL (n = 12 renal units) to remove complicated nephroliths (median diameter 2.5 cm; range, 0.5–5.7 cm). No kidney required conversion to traditional surgical nephrotomy or nephrectomy. Median procedure time was 180 minutes (range, 90–270 minutes). Patients were discharged within 48 hours (range, 48–144 hours). The procedure was successful (resolution of complicated nephroliths) in 14 renal units. Ureteral stents were placed in all cases during the PCNL/SENL and removed after 1–20 weeks minimally invasively. No recurrence was reported during the follow-up period (median duration 557 days). Owners tolerated recovery from the SENL better than the PCNL because a nephrostomy tube was not required.

Overall, this series of cases demonstrates that PNCL and SENL have a greater stone-free rate (93% vs 85%) and lower recurrence rate (0% vs 10%) than ESWL for large problematic nephroliths. The results of this study suggest that the median survival time is higher for dogs with IRIS stage 1, 2 or 4 disease treated with ENL compared to previously reported survival times for the same IRIS stage diseases. However, further prospective studies are required to draw conclusions as this was only a small number of cases.

Ureteroscopy

Contrary to human medicine, ureteroscopy is rarely performed in veterinary patients. For minimally invasive treatment, dogs with a ureteral obstruction could have an endoscopic ureteral stent placed and/or may also undergo ESWL. If the patient is large enough (at least 39.6–44 lb [18–20 kg]), ureteroscopy can be considered. However, most dogs with ureterolithiasis are small terrier or toy breeds, making this an uncommon procedure. If this is to be performed, then the preplacement of a ureteral stent to allow for passive ureteral dilation, prior to ureteroscopy, is typically recommended.

Subcutaneous Ureteral Bypass

Feline ureteroliths are typically more frustrating than canine ureteroliths due to the small diameter of the feline ureter (<0.4 mm) and the endoscopic and surgical limitations. In cats, ESWL is not typically advised and ureteroscopy is not possible.

A subcutaneous ureteral bypass (SUB) involves the placement of a nephrostomy tube and a cystostomy tube that are connected subcutaneously to a shunting port, allowing for urine drainage from the kidney directly to the bladder, bypassing the ureter (Figure 123.19). Initially, this procedure was primarily performed for cats with

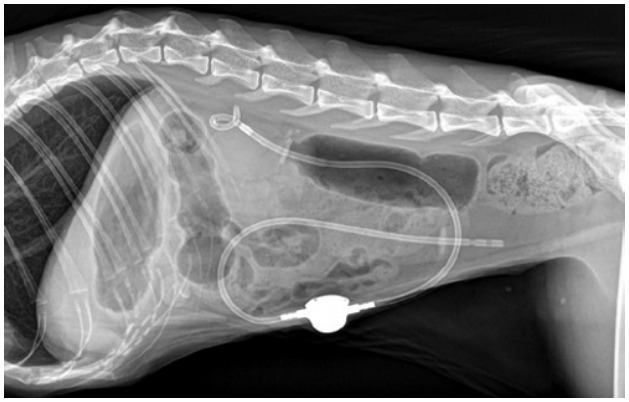

Figure 123.19 Lateral radiographs of a feline patient following the placement of a subcutaneous ureteral bypass.

ureteral strictures, very proximal ureteral obstructions, or in which stent placement was unsuccessful. Based on experience in over 300 cats in the authors' practice, it is now preferred over the feline ureteral stent due to the minimal complications both shortterm and longterm. Over 93% of cats survived to hospital discharge after admission. The longest period for which an SUB device has remained in place is nine years (personal communication AB), and the short- and long-term complications seen with this device are fewer and less severe than those seen with ureteral stents in cats (see Table 123.5).

The use of a SUB device to treat cats with ureteral obstruction has been associated with the highest survival rate to date. In that study, 135 out of 144 (94%) cats survived to hospital discharge, and 90%, 83%, 80% and 74 % of cats were alive after one, three, and six months and one year respectively after SUB placement. The most common complication was stent obstruction (25%) requiring SUB system replacement. However, with the use of tetrasodium ethylenediaminetetraacetic acid (tEDTA) solution, the rate of reobstruction declined to 4.5%.

Prostatic Diseases

Serge Chalhoub, DVM, PhD, DACVIM (SAIM)

Department of Veterinary Clinical and Diagnostic Sciences, Faculty of Veterinary Medicine, University of Calgary, Calgary, AB, Canada

Both male dogs and cats have prostate glands, but cats rarely develop prostatic diseases. Prostatic diseases are relatively common in middle-aged to older, intact male dogs and rare in neutered males, with a higher reported frequency in medium- and large-breed dogs. Most companion male dogs and cats are neutered, which prevents the majority of prostatic diseases.

The prostate is the only accessory sex gland in male dogs, and it surrounds the urethra in the pelvic region caudal to the trigone of the bladder and distal to the internal urethral sphincter. It is oval in shape and bilobed, with the two lobes separated by a prominent median septum (Figure 124.1). The size of the prostate is greatly influenced by hormonal stimulation. Castration of dogs removes the important trophic factors necessary for prostatic growth and function, estrogen and testosterone, and leads to prostatic atrophy (Figure 124.2).

The prostate itself is an exocrine gland that produces continuous secretions that flow into the urethra through multiple prostatic ducts. These secretions make up the largest component of spermatic ejaculate (90–95%). Normal prostatic acini are lined with tall columnar to cuboidal epithelium. The prostate reaches normal size by age 2, but it continues to grow with age in the intact male.

Most problems associated with the prostate result in prostatomegaly, but many of the diseases do not result in pain upon palpation of the prostate or lower urinary tract signs. The most common prostatic diseases are benign prostatic hyperplasia (BPH), bacterial acute and chronic prostatitis, prostatic abscesses, prostatic and paraprostatic cysts, and prostatic neoplasia (discussed in further chapters).

Benign Prostatic Hyperplasia and Prostatic Cysts

Etiology

Benign prostatic hyperplasia is by far the most common prostatic disease in intact male dogs, and it develops due to long-term exposure of the prostate trophic hormone testosterone's active metabolite dihydrotestosterone (DHT). Over time, an imbalance in the ratio of androgens to estrogens develops, and there is also both an increase in prostatic tissue sensitivity to androgens and an increase in androgen receptors. Over 50% of intact male dogs will develop symptoms from BPH by age 5, and by the age of 6 years 80% will manifest symptoms.

Fluid-filled cysts may develop within the prostate and are secondary to the hormonal influences that also cause BPH. Theses cysts may not cause clinical signs until either they get infected and develop into an abscess, or affect the flow of urine through the urethra due to their size.

History and Clinical Signs

Not all dogs with BPH develop clinical signs. In others, as the prostate becomes enlarged, observed clinical signs with BPH include intermittent or continuous serosanguinous discharge or hematuria, and less commonly straining to defecate, and lower urinary tract signs. Dogs may experience pain upon ejaculation, and BPH can lead to infertility in some cases. Dogs with BPH are not usually systemically ill but they do have a higher incidence of developing prostatitis, prostatic abscesses, and urinary tract infections.

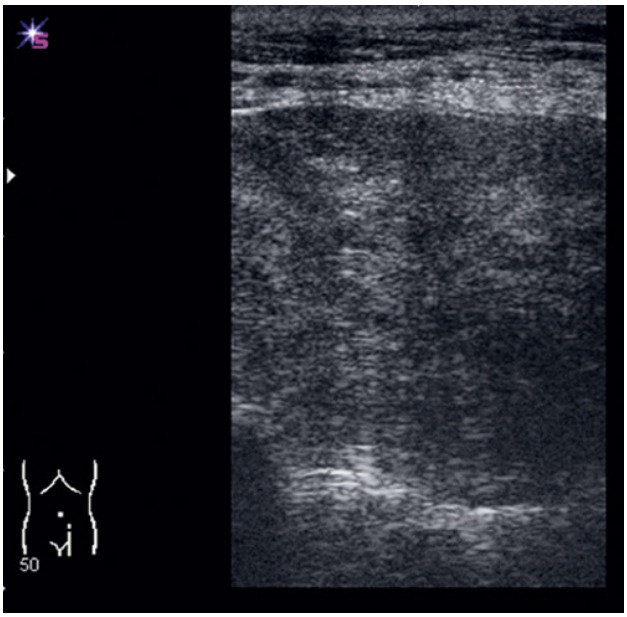
Diagnosis

With all suspected prostatic diseases, it is important to put the entire clinical picture together: history, clinical signs, physical exam, imaging results, laboratory results, and cytology or histopathology.

Performing a rectal examination is of the utmost importance. Neutered males rarely develop prostatic diseases but they can still develop prostatic neoplasia, so it is important not to rule out prostatic diseases in castrated males. In most patients, the caudal portion of the prostate can be palpated on the ventral floor of the colon. This may be difficult in larger dogs. The normal prostate should not be painful and should be soft. With BPH, the prostate tends to feel enlarged but it is smooth, symmetric, and rarely painful. The median raphe may not be as obvious to palpate. The enlargement may cause the prostate to move cranially into the abdominal cavity, and therefore can be difficult to palpate rectally without the help of concurrent abdominal palpation. Prostatic cysts can rarely be identified. Rectal palpation should also include the dorsal portion of the distal colon to feel for enlarged iliac lymph nodes. With BPH, lymphadenopathy should not be present. Constipation may be possible, but the rest of the physical exam is usually within normal limits.



Complete blood count (CBC) and chemistry panel are unremarkable in dogs with BPH and noninfected prostatic cysts. Human prostate-specific antigen (PSA) has not been shown to correlate with prostatic disease in dogs. Abdominal radiographs may reveal an enlarged soft tissue opacity in the caudal abdominal region usually near or within the pelvic canal and caudal to the bladder, especially on a lateral radiograph. Radiographs are not very sensitive or specific for identifying the etiology of prostatic disease but they do give a good indication of size and shape of the prostate. Prostatic mineralization can be seen in both neutered and intact dogs. In neutered dogs, mineralization strongly indicates neoplasia, whereas in intact dogs, mineralization can indicate neoplasia, prostatitis, BPH, and prostatic cysts. Constipation can be noted on radiographs. The prostate is harder to recognize on abdominal radiographs in a neutered male.

Retrograde contrast urethrocystography can aid in the diagnosis of prostatic and urethral disease. Prostatic disease may result in the uptake of contrast into glandular tissue, and the degree of uptake can correlate with severity of disease. With BPH, there should be minimal to no contrast uptake. It may be possible to appreciate a narrowed prostatic urethral diameter due to compression by an enlarged prostate.

Ultrasonography has become the gold standard for visualizing the prostate. In the intact male, the normal prostate usually appears as a bilobed structure on short axis and oval on long axis, its architecture uniform and with a homogenous echogenicity similar to the spleen. In BPH, the prostate appears enlarged and there may be a loss of visualization of the median septum. Echogenicity should not differ from the normal prostate or the prostate may be slightly more hyperechoic (Figure 124.3). Prostatic cysts can be seen within the parenchyma and usually contain anechoic fluid (Figure 124.4). Cysts may vary in size and number.

For a specific diagnosis of prostatic disease, a sample of prostatic cells, fluid, or tissue is recommended. Often with typical clinical signs and diagnostic results, BPH can be tentatively diagnosed and treated, but it is important to note that other diseases cannot be excluded.

(a)

(b)

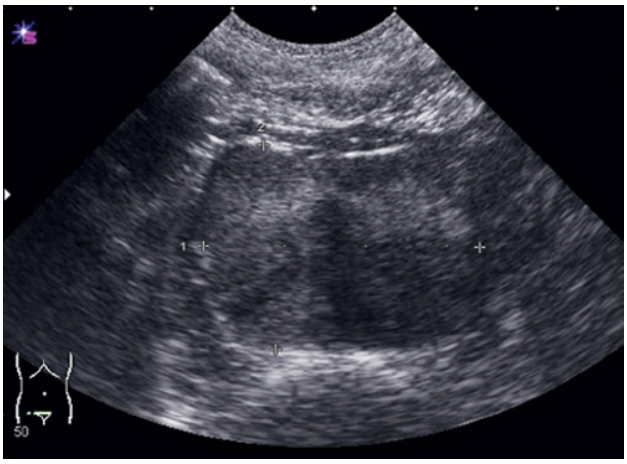


Figure 124.3 Benign prostatic hypertrophy as seen on ultrasound in both transverse and sagittal planes. The prostate is larger than normal and appears slightly more echogenic. *Source:* Image courtesy of Dr Tim Spotswood.

Obtaining a biopsy of the prostate can be difficult due to its location in the caudal abdomen. Biopsies may be obtained using ultrasound guidance and a Tru-Cut biopsy instrument, or surgically via laparotomy/laparoscopy. Biopsies may also be obtained in a blind fashion but this is not recommended. With BPH, histopathology should indicate only evidence of hyperplasia and hypertrophy.

Cytology of prostatic cells and fluid has been shown to agree most of the time with histopathology, and is more sensitive in the detection of infectious processes. However, a negative cytology does not rule out prostatic diseases. Ultrasound-guided fine needle aspirates of the prostate for cytology and culture are possible and relatively easy to do. Other cytology and/or culture techniques include semen collection, prostatic massage and wash, prostatic brush cytology, and traumatic prostatic wash (Table 124.1). Cytology of a normal prostate contains cuboid to columnar epithelial cells in clusters. Cytology of BPH usually reveals normal-appearing epithelial cells arranged in clusters characteristic of a honeycomb appearance.

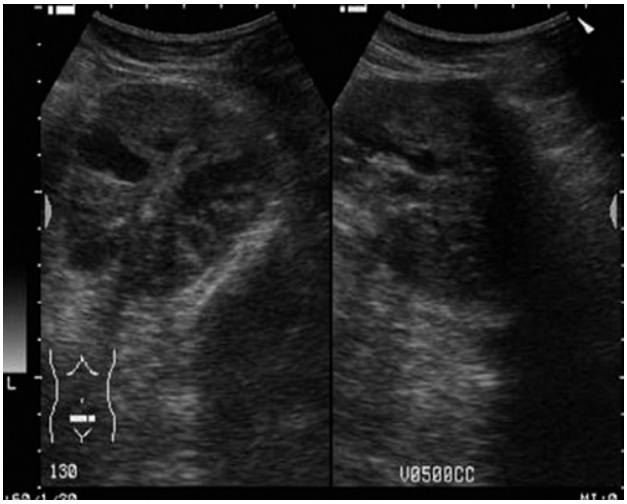

Figure 124.4 Benign prostatic hypertrophy with prostatic cysts as seen on ultrasound in both transverse and sagittal planes. *Source:* Image courtesy of Dr Tim Spotswood.

A urinalysis and urine culture is usually always indicated with any prostatic disease due to the higher incidence of urinary tract infections. With BPH, urinalysis may be normal or show increased red blood cells with an inactive sediment and negative culture.

Therapy

Therapy is not always indicated for BPH as not all dogs develop clinical signs. These patients should be monitored for the development of clinical signs over time by their owners. Surgical castration is the treatment of choice for BPH, and prostatic atrophy begins within days to weeks following surgery, with completion usually by 12 weeks. The larger the prostate prior to surgery, the longer the involution period. Clinical signs begin to resolve before involution is complete. Prostatic cysts will usually resolve with castration unless they are infected. Large prostatic cysts may rarely require surgery.

In breeding dogs, medical therapy can be used to reduce prostatic size and clinical signs of prostatomegaly. Finasteride, a 5-alpha-reductase enzyme inhibitor, is the treatment of choice in men and has been shown to be effective in dogs. The medication blocks the conversion of testosterone to DHT in the prostate. Finasteride does not affect fertility and has no known side-effects in dogs.

Table 124.1 Procedures for collecting cytologic samples from the prostate

Procedure	Specialized equipment	Advantages	Disadvantages
Percutaneous ultrasound-guided aspirate	Ultrasound machine, probe capable of reaching higher frequencies; needles (22 G, 1.5 inch in length) or catheters; syringes (6 cc) and extension set	Quick and relatively effective at obtaining diagnostic samples; can be used to target specific areas of the prostate, more sensitive	May require sedation; technique requires learning curve and specialized equipment; risk of seeding infectious organisms or neoplastic cells into abdominal cavity; risk of abscess rupture
Brush cytology	Bronchoscopy airway brush	Quick and easy to do; minimal learning curve	May not reach the prostate; nondiagnostic sample if more localized disease; brush can only be used once; sedation may be necessary
Ejaculate collection	None	Easy and safe to do; sedation not necessary	Difficult in painful animals; patients may not cooperate; sample only useful for culture and is not specific to prostatic disease
Prostatic wash	Urinary catheters of various French sizes (red rubber catheters, Argyle feeding tube catheters); syringes (30–60 cc) and extension set; nonsterile gloves	Safe, relatively easy; sedation may not be necessary; more sensitive; less risk of bacteria or neoplastic cell abdominal seeding	Urine contamination possible; prostate may be too far to reach; potential risk of abscess rupture; requires multiple people
Traumatic wash	Urinary catheters of various French sizes (red rubber catheters, Argyle feeding tube catheters); syringes (30–60 cc) and extension set; nonsterile gloves	Safe, relatively easy; may yield a more diagnostic sample than simple prostatic wash; less risk of bacteria or neoplastic cell abdominal seeding	Urine contamination possible; prostate may be too far to reach; potential risk of abscess rupture; sedation usually necessary; requires multiple people

However, care must be taken in its administration and the drug may cause birth defects in pregnant women. Dosages range from 0.1–1 mg/kg orally once daily to 5 mg per dog per day, and a decrease in prostatic size by 50–70% is usually seen by 2–3 months. Flutamide is androgen receptor antagonist and prevents DTH from binding to the receptor. It has been reported to be effective at a dosage of 5 mg/kg orally once daily with no known side-effects. Cost is the limiting factor for both drugs.

Estrogen therapy can also be used to treat BPH and will cause a decrease in testosterone production. However, long-term therapy with estrogen may cause bone marrow suppression, symptoms of feminization, and prostatic squamous metaplasia. Estrogen and its derivatives are no longer recommended as first-line therapy to treat BPH.

Lastly, gonadotropin-releasing hormone (GnRH) agonist implants have shown great promise and effectiveness with no reported adverse effects in treating BPH in intact male dogs. Their limited availability limits their use at this time.

Prognosis

Prognosis from uncomplicated BPH causing clinical signs is excellent with surgical castration as treatment is curative, and good with medical therapy depending on response to pharmacologic therapy. Fertility is usually restored with finasteride therapy once the prostate beings to atrophy. Prostatic cysts that are not infected should shrink and disappear with surgical castration.

Paraprostatic Cysts

Etiology

Paraprostatic cysts are fluid-filled structures that develop beside and outside the prostate secondary to the retention of the embryonic muellerian duct system (uterus masculinus). These cysts may become quite large, usually are thin-walled, and contain anechoic to debris-filled fluid.

History and Clinical Signs

These cysts often do not cause appreciable clinical signs, or they may grow large enough to compress and obstruct the urethra or the colon.

Diagnosis

Abdominal ultrasound is the modality of choice for detection of these cysts (Figure 124.5). They often resemble a second urinary bladder.

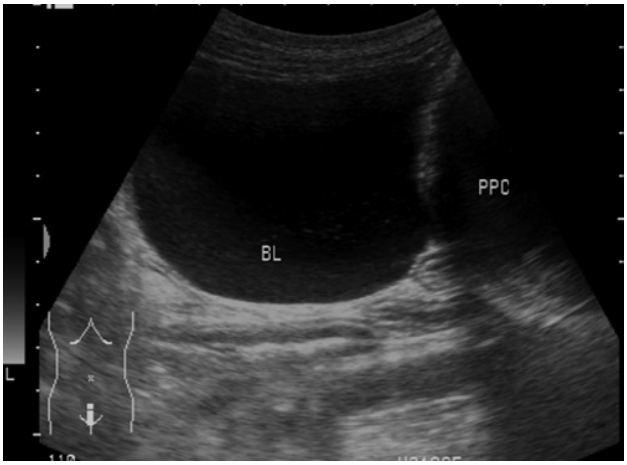

Figure 124.5 Paraprostatic cyst as seen on sagittal ultrasound view. BL, urinary bladder; PPC, paraprostatic cyst. *Source:* Image courtesy of Dr Tim Spotswood.

Therapy

Surgery is required to completely or partially remove these cysts. Concurrent castration is recommended.

Prognosis

Prognosis is good to excellent depending on the ability to surgically remove the cysts.

Prostatitis and Prostatic Abscesses

Etiology

Bacterial prostatitis is usually the result of an ascending infection via the urethra and into the communicating prostatic ducts. The presence of other prostatic conditions such as BPH, prostatic cysts, or prostatic neoplasia may increase the incidence of prostatitis. Alterations in urine flow and urinary tract infections also increase the risk of prostatitis in intact males. Hematogenous infection is also possible but less likely. Prostatitis is reported in all age groups in intact males and is exceedingly rare in neutered males.

The most common bacterial organism to cause prostatitis is *Escherichia coli*. Other common infectious etiologies include *Staphylococcus* spp., *Streptococcus* spp., *Mycoplasma* spp., *Pseudomonas* spp., and *Proteus* spp. Brucellosis is possible secondary to venereal and hematogenous transmission. Prostatic abscesses can develop secondary to prostatitis or within prostatic cysts. Chronic prostatitis is reported to be more frequent than acute prostatitis but with less evident clinical signs.

History and Clinical Signs

Acute prostatitis is usually a very painful condition and these patients tend to have a greater frequency of systemic signs: depression, dehydration, anorexia, abnormal discharge, painful gait, difficulty urinating, inability to mount or ejaculate, and trouble defecating. Lower urinary signs such as stranguria, purulent urethral discharge, hematuria, pollakiuria, and abnormal discharge are often present. Patients may also vocalize when attempting to urinate or defecate. Stool quality may change due to compression of the colon. Other common clinical signs and physical examination findings include fever, vomiting, diarrhea, dehydration, tenesmus, and constipation. Abscesses may rupture within the abdominal cavity and cause symptoms of acute abdomen, endotoxemia, sepsis, and peritonitis.

Dogs with chronic prostatitis may sometimes have no evident clinical signs. History may include decreased mounting behavior, decreased sperm count or quality, recurrent and chronic urinary tract infections, lethargy, decreased appetite, intermittent urethral discharge, and potentially other vague and nonspecific clinical signs.

Diagnosis

Rectal palpation usually reveals either an enlarged and symmetric prostate or the prostate can be abnormally shaped, especially when abscesses are present. Acute prostatitis may be very painful on palpation. Iliac lymph node enlargement is possible.

With acute bacterial prostatitis, the CBC may be normal or may display a neutrophilic leukocytosis of varying severity with a left shift. The biochemistry panel may reveal azotemia of varying degrees which may be a combination of postrenal (secondary to prostatic enlargement and urethral obstruction), intrinsic renal (ascending pyelonephritis) or prerenal (dehydration) factors. Hepatic enzymes, especially alkaline phosphatase enzyme, may be elevated. Urinalysis collected by cystocentesis may reveal hematuria, proteinuria, and an active sediment but this is not sensitive or specific for diagnosing prostatitis. Urine culture is usually positive. Abdominal radiographs may indicate an enlarged and irregular prostate, and mineralization is possible. Peritonitis is sometimes noted caudal to the bladder due to inflammation and secondary to abscess rupture. The bladder may also be pushed cranially into the abdominal cavity. Abdominal ultrasound findings include an enlarged and sometimes irregular prostate that is diffusely heterogenous with or without abscesses, sometimes giving the appearance of being mottled (Figure 124.6). Contrast urethrocystogram may indicate prostatic contrast uptake of varying degree.

Cytology is necessary for a diagnosis and for targeted therapy, but caution must be exercised in obtaining samples (see Table 124.1). Typical cytology findings include free and phagocytosed bacteria, intact and degenerate neutrophils, macrophages, necrotic debris, and hyperplastic epithelial cells with mild anisokaryosis.

Therapy

Targeted antibiotic therapy is indicated in both acute and chronic prostatitis and prostatic abscesses. Antibiotics must be chosen based on culture and sensitivity results as well as their ability to penetrate prostatic tissue. The ideal antibiotic needs to be lipid soluble and have lower serum protein binding to be able to cross into the prostate (Table 124.2). If higher protein binding is a characteristic of a particular desired antibiotic, using a higher dosage range is necessary. While awaiting cytology and culture results, therapy should be started with enrofloxacin.

Figure 124.6 Prostatic abscess and prostatitis as seen on ultrasound transverse image plane. Note the mottled appearance of the prostate surrounding the abscessed region. *Source:* Image courtesy of Dr Tim Spotswood.

There are unfortunately very few clinical data or trials in veterinary medicine looking at the efficacy of specific antibiotics and their effectiveness in crossing into the dog prostate and treating prostatitis. In the presence of sepsis, the antibiotic spectrum should be broadened (beta-lactam, third-generation cephalosporin, aminoglycosides, imipenem). The blood–prostate barrier is compromised in these situations and antibiotics that would not generally penetrate the prostate will do so.

Ciprofloxacin is not indicated in infectious prostatitis as not only does it have poor oral bioavailability in dogs and cats, it also does not penetrate the prostate as well as enrofloxacin. Antibiotic therapy should be continued for a minimum of 4–6 weeks, and prostatic culture should be rechecked 3–5 days after discontinuation of antibiotics. Specific treatment for sepsis and peritonitis is detailed elsewhere, as is the treatment for acute azotemia.

Surgery may be necessary for prostatic abscesses. Medical drainage of abscesses by percutaneous ultrasound-guided aspiration combined with targeted antibiotic therapy rarely results in the resolution of abscesses. However, ultrasound-guided drainage may facilitate stabilization of a patient if surgery is delayed. Multiple surgical techniques have been described including omentalization, marsupialization, placement of drain tubes, and partial or total prostatectomy, with omentalization seeming to offer the best results and fewer complications.

It is always recommended to neuter dogs with prostatitis and prostatic abscesses as this can accelerate recovery and also prevent recurrence. Finasteride therapy may be used in breeding dogs to shrink the prostate but its efficacy in prostatitis is unknown.

Prognosis

Prognosis is good to guarded in acute prostatitis without abscessation or sepsis. Chronic prostatitis may be more

Table 124.2 Antibiotics used for bacterial prostatitis

Antibiotic	Dosage	Route	Notes
Enrofloxacin	10 mg/kg q24h	IV, PO, SC	Risk of permanent cartilage damage in large-breed dogs <18 months; usually the first-line drug of choice
Chloramphenicol	50 mg/kg q6–8h	PO	Dosage listed is at higher end of therapeutic range; monitor CBC for evidence of bone marrow suppression
Trimethoprim-sulfamethoxazole	15 mg/kg q12h	IV, PO, SC	Potential complications include keratoconjunctivits sicca, acute hypersensitivity reactions, polyarthropathy, blood dyscrasias, vomiting, anorexia, hepatopathy and icterus; rarely used as first-line therapy
Clindamycin	11–20 mg/kg q12h	PO, IV, IM, SC	Capsules or divided tablets may cause esophagitis; not usually indicated for prostatitis unless indicated by culture
Erythromycin	10–25 mg/kg q8–12h	PO	May cause anorexia, vomiting, diarrhea; usually not indicated for prostatitis unless indicated by culture

CBC, complete blood count; IM, intramuscular; IV, intravenous; PO, by mouth (*per os*); SC, subcutaneous.

difficult and take longer to treat and there may be a higher incidence of relapse. The prognosis is guarded to poor with abscessation even with surgical intervention.

Squamous Metaplasia of Prostatic Epithelial Cells

This condition is quite rare and usually develops secondary to exogenous estrogen administration (such as to treat BPH or transdermal patches and creams used as hormone replacement therapy in women) or to an estrogen-secreting tumor such as a Sertoli cell tumor. Dogs may be asymptomatic or develop clinical signs similar to dogs with prostatitis. Diagnosis is obtained via biopsies. Treatment involves antibiotic therapy for potential secondary prostatitis, identifying and treating the cause of the metaplasia (surgery and potentially chemotherapy for Sertoli cell tumors, discontinuation of estrogen compounds). Prognosis is guarded as chronic prostatitis may develop.

Management of Chronic Kidney Disease

Jessica Quimby, DVM, PhD, DACVIM (SAIM)

Department of Veterinary Clinical Sciences, Ohio State University Veterinary Medical Center, Columbus, OH, USA

Chronic kidney disease (CKD) is defined as the presence of structural or functional abnormalities in one or both kidneys that has been present for three or more months. In most cases with renal dysfunction, this is a progressive disease, and currently no treatment short of renal transplantation has been shown to reverse or halt declining renal function for any significant period of time. Renal transplant and dialysis are less widely available and are expensive therapies. Additionally, not all CKD patients are acceptable candidates for transplantation or dialysis. Medical management therefore is the mainstay of treatment and can help patients cope with metabolic complications of the disease and improve quality of life.

Disease Staging

The severity of signs associated with kidney disease varies depending on the degree of kidney dysfunction. In order to better tailor therapy to the individual patient and to provide some assessment of prognosis, staging of disease is recommended. The International Renal Interest Society (IRIS), a panel of experts in veterinary nephrology, has developed a staging system for chronic kidney disease in dogs and cats (www.iris-kidney.com) that has been accepted by the American and European Societies of Veterinary Nephrology and Urology. With this system, once diagnosed with CKD, animals are grouped into four stages (IRIS 1–4) based on serum creatinine, as well as substages based on proteinuria and blood pressure. The recent guidelines also incorporate SDMA results. Assessment of kidney function is based on fasted serum creatinine measurements assessed on at least two occasions in a stable, hydrated patient (Table 125.1). Caution should be exercised in staging elderly patients in poor body condition as muscle mass contributes to daily creatinine production; very thin animals may have lower than expected serum creatinine concentrations. The biomarker SDMA is correlated with glomerular filtration rate (GFR) and as it is not affected by muscle mass, has been incorporated into the IRIS guidelines to help determine staging in patients with muscle loss.

Due to variability in normal ranges for serum creatinine, some patients staged as IRIS 1 or 2 may have serum creatinine within the reference range. The patient's overall clinical status should be taken into account and serum creatinine should not be interpreted without a concurrent urine specific gravity. For example, creatinine >1.6 mg/dL in a feline patient with a urine specific gravity <1.035 may be indicative of kidney disease even though it is within a published reference range.

Substaging is performed to further characterize the disease based on the measurement of arterial blood pressure and proteinuria, both of which are a concern as they potentially hasten disease progression. Classification of proteinuria is determined by measuring urine protein:creatinine ratio (UPC) in a culture-negative sample with an inactive sediment (Table 125.2). Unless the UPC is markedly elevated or less than 0.2, classification should ideally be based on multiple UPC determinations (2–3) over at least a two-week period.

Blood pressure substage is determined by incorporating both arterial blood pressure measurement and assessment of the presence of end-organ damage such as retinal lesions and neurologic signs (Table 125.3). With the exception of animals who have a blood pressure >200 mmHg and/or evidence of end-organ damage, blood pressure classification should be determined based on at least three independent measurements, ideally over several days to weeks. The lowest measurement is the one utilized.

Medical Management of Chronic Kidney Disease

Medical management of CKD consists of treatments designed to provide supportive and symptomatic care for the animal, with the goal of correcting nutritional, fluid, electrolyte, endocrine, and acid–base imbalances. These treatments aim to minimize the clinicopathologic and pathophysiologic effects of kidney dysfunction. Unfortunately, medical management is not expected to halt, reverse or cure kidney dysfunction or any associated renal lesions. If any treatable underlying cause of disease is identified, such as infection or obstruction, it is imperative that it be addressed. The management guidelines presented in this chapter are intended for animals with stable chronic disease, not those currently undergoing a uremic crisis.

Nutrition and Dietary Therapy

Several studies have documented the therapeutic value of specially formulated diets in the management of CKD, including evidence of decreased incidence of uremic crisis and increased survival and modulation of biomarkers. It is perhaps a common misconception that the sole purpose of these diets is protein restriction. Other modifications present in these diets are as important, or potentially even more important than protein restriction. In comparison to a maintenance diet, renal diets are typically formulated to contain modified amounts of high-quality protein, increased caloric, soluble fiber and B vitamins, omega-3 polyunsaturated fatty acid and antioxidant content, reduced amounts of phosphorus and sodium, and to have a neutral effect on acid–base balance. In addition, feline renal diets are supplemented with potassium. Recently, early-stage renal diets that are phosphorus restricted but with less restricted protein content have also become available for cats.

The greatest clinical challenge with recommending a renal diet is acceptance by the animal. The failure of the patient to eat the formulated diet negates the benefit of dietary management, and therefore a key therapeutic target for these patients is the maintenance of appetite and food intake. Poor body condition is associated with decreased prognosis in several species and it also has a negative effect on owner perception of quality of life. As animals with CKD often suffer from poor appetite, this should be actively addressed in a management plan. Nonacceptance of renal diets can potentially be overcome by addressing underlying metabolic complications of CKD as well as gradually introducing the renal diet over several weeks. Many animals will readily accept and continue eating a renal diet provided the transition period is adequately slow. Other tips to encourage acceptance of renal diet include increasing owner compliance with education regarding the benefits of the diet, avoiding transitioning to the renal diet during a uremic crisis event to prevent food aversion, trying different temperatures, textures and brand formulations of food, and medically managing nausea and inappetence associated with uremic syndrome.

It is particularly important that the patient eat sufficiently to satisfy caloric requirements. A nutritional assessment should be performed at each visit including body weight, body condition score, muscle mass score, and a thorough nutritional history (www.wsava.org/nutrition-toolkit). Insufficient caloric intake could potentially lead to protein malnutrition as evidenced by decreased muscle mass, anemia and decreased serum albumin or total protein concentrations.

If caloric requirements are not being met, yet metabolic complications are controlled and medical management of inappetence is unsuccessful, supplementation with a diet palatable to the animal or assisted feeding should be considered. Assisted feeding options include placement of an esophagostomy or percutaneous gastrostomy tube for long-term nutritional management. Tube feeding has the additional advantage of allowing the owner to deliver oral water and medications to the patient and can be a valuable tool for long-term management of CKD. Disadvantages of tube feeding include the anesthesia required for placement and tube site complications.

Table 125.3 Classification of blood pressure in cats and dogs

IRIS blood pressure (BP) stage	Systolic BP (mmHg)	Diastolic BP (mmHg)	Risk of target organ damage
Normotensive	<150	<95	Minimal
Borderline hypertensive	150–159	95–99	Mild
Hypertensive	160–179	100119	Moderate
Severely hypertensive	>180	>120	Severe

IRIS, International Renal Interest Society.

Antinausea and Appetite Stimulant Therapy

Patients with CKD can suffer from nausea, vomiting, and inappetence likely as a result of uremic toxins that are sensed in the chemoreceptor trigger zone in the brain. Several potent antiemetic/antinausea therapies are now available. These include the 5-HT3 receptor antagonists ondansetron and dolasetron and the NK1 receptor antagonist maropitant citrate. These drugs work at the chemoreceptor trigger zone and vomiting center in the brain, as well as receptors in gastrointestinal tract, and can be given orally or as an injection.

Maropitant is commonly used for acute vomiting but a pharmacokinetic and toxicity study in cats indicated that longer-term usage appears safe and it is often used for long-term therapy in chronically ill patients. When given daily for two weeks at a dose of 4 mg/cat, maropitant was demonstrated to palliate vomiting associated with CKD in cats with stage II and III CKD. Maropitant citrate is administered at 1 mg/kg.

Ondansetron has been documented to be twice as effective as metoclopramide in palliating uremic nausea and vomiting in human CKD patients. Ondansetron and dolasetron are frequently used as antiemetics, but recent studies have called into question their efficacy at currently recommended doses in cats (0.5 mg/kg BID). Pharmacokinetic studies in cats have demonstrated that oral bioavailability of ondansetron is poor in this species (~35%) and the half-life is very short (approximately one hour), making it most appropriately a q8h medication. Subcutaneous ondansetron had a slightly longer half-life of three hours. Ondansetron is also not appropriate as a transdermal medication as a recent paper assessing transdermal absorption in cats demonstrated no clinically relevant blood levels after administration. The ideal dosing regimen of ondansetron for dogs is also unknown and there is some evidence that oral bioavailable in dogs is extremely poor (<10%). However, a recent study demonstrated that ondansetron had superior antinausea effects in comparison to maropitant in a cisplatin model. Dolasetron has traditionally been recommended as a once-daily medication at doses of 0.5–1 mg/kg; however, a recent paper demonstrated that after a 0.8 mg/kg subcutaneous dose the drug is not detectable in the serum at 12 hours and does not palliate xylazine-induced emesis.

Although more commonly used as an appetite stimulant, mirtazapine also demonstrates antiemetic properties, acting at the 5-HT3 receptor similar to ondansetron. In cats, mirtazapine has been shown to significantly reduce vomiting associated with CKD.

Limiting gastric acidity with the use of H2 blockers like famotidine or proton pump inhibitors such as omeprazole anecdotally appears to palliate inappetence in some CKD patients. However, these medications have never been evaluated in a clinical trial despite famotidine being one of the most commonly prescribed medications in CKD cats. Recent studies of the effect of omeprazole on the gastric pH in normal cats indicate that at 1 mg/kg twice daily, it is superior to famotidine in its ability to inhibit acid production, but again no clinical trials have been performed in CKD cats and CKD cats do not appear to experience hyperacidity as previously assumed. Additionally, proton pump inhibitors have recently been linked to an increased risk of kidney disease in humans. The applicability of this finding to veterinary patients is entirely unknown, and a recent retrospective study found no correlation between acid-suppressing medications and increased risk for kidney disease or progression of disease. Due to lack of evidence for a high incidence of ulcerative gastritis associated with CKD, sucralfate is recommended only if gastric ulceration and hemorrhage are suspected as it is sometimes poorly tolerated and may lead to further inappetence.

In addition to addressing uremic nausea and vomiting, appetite stimulants can also be used to encourage food intake, particularly in late-stage patients. Cyproheptadine has been used for some time as an appetite stimulant and has anecdotal efficacy in many patients, although its efficacy has never been scientifically evaluated. Mirtazapine has become more commonly used, particularly in cats, and recent exploration of its pharmacodynamics and pharmacokinetics has provided information for more effective use in animals. Pharmacodynamic studies in cats have illustrated that it can be a potent appetite

stimulant, but higher doses are more commonly associated with side-effects (hyperexcitability, vocalization, agitation). Smaller, more frequent doses are recommended: 1.88 mg q48h orally in cats with CKD and 0.6–1 mg/kg once to twice daily in dogs. In dogs, twice-daily dosing may be required due to relatively shorter half-life than in other species. Mirtazapine is also amenable to transdermal administration, and has recently become FDA approved for use in cats (Mirataz®, KindredBio).

Owners should be aware that mirtazapine and cyproheptadine cannot be administered concurrently; cyproheptadine is used as an antidote for serotonin effects of mirtazapine overdose and thus negates the efficacy of the latter.

Capromorelin (Entyce®, Aratana Therapeutics), a ghrelin agonist, has recently become FDA approved as an appetite stimulant for dogs.

Systemic Hypertension

Systemic hypertension appears to be common in dogs (31–54%) and cats (20–65%) with CKD, but the exact pathophysiologic relationship is unknown. Systemic hypertension can have deleterious effects such as retinal hemorrhage and detachment, neurologic and cardiac impairment. Therefore, the diagnosis and treatment of hypertension are important in this patient population.

Once hypertension has been classified (see Table 125.3), the decision to initiate therapy is based on the degree of hypertension and the animal's IRIS stage. Patients with CKD stage 2–4 and blood pressure persistently over 160 mmHg are candidates for treatment. Antihypertensive therapy should be considered for IRIS 1 patients with arterial blood pressure persistently greater than 180 mmHg. It is unknown what the optimal arterial blood pressure is for patients with CKD. A general guideline is to reduce the blood pressure to between 100 and 160 mmHg. Aggressive reduction of blood pressure is only necessary in patients experiencing ocular and neurologic complications and otherwise it may take weeks, particularly in dogs, to achieve adequate control.

Treatment strategies for cats and dogs differ slightly based on the efficacy of currently available antihypertensive medications for each species. Currently utilized antihypertensive medications in dogs include angiotensin-converting enzyme (ACE) inhibitors (enalapril and benazepril), calcium channel blockers (amlodipine) or angiotensin receptor blockers (ARB) such as telmisartan. These medications are thought to be most effective at reducing hypertension in dogs although most patients require multiple medications and few studies have been done in this area. ACEI and ARB are also used for the management of concurrent proteinuria. Typical starting doses of ACEI are 0.25–0.5 mg/kg every 12–24 hours with increases based on effect on blood pressure up to 2 mg/kg/day. In dogs, amlodipine doses range from 0.1 to 0.5 mg/kg/day and are typically combined with an ACEI. Recommended dose for telmisartan is 1 mg/kg once daily.

Amlodipine is documented to be an effective treatment for hypertension in the cat and has traditionally been the drug of choice in this species. ACEI have not been demonstrated to adequately reduce blood pressure in cats when used as sole therapy. Amlodipine is prescribed at an initial dose of 0.625 mg/cat <5 kg and 1.25 mg/cat >5 kg. Alternative formulations of the drug have been explored including transdermal amlodipine and a chewable form which may provide some degree of efficacy. Amlodipine has also been documented to decrease proteinuria in cats. Telmisartan is also an effective antihypertensive medication in cats and has recently become approved for this indication in cats (United States) as well as an antiproteinuric (UK and Europe).

For all antihypertensive therapy, blood pressure should be rechecked within 7–10 days after initiating treatment. Monitoring renal values and electrolytes is also important; ACEI can decrease GFR and result in increasing azotemia, in which case therapy should be reassessed. Hyperkalemia is also a common side-effect of ACEI and ARB in dogs and may limit the dose that can be administered. Additional guidelines for the use of ACEI and ARB can be found in the consensus statement for the standard treatment of proteinuria.

Proteinuria

Proteinuria is associated with poorer prognosis in several species. The renal tubular epithelial cells are responsible for processing protein and this increases their metabolic load and oxidative stress. Although reducing proteinuria has been demonstrated to significantly slow disease progression in humans, studies in dogs and cats have documented decreased proteinuria secondary to ACEI administration, but results so far are only suggestive of long-term benefit. Nonetheless, it is considered standard of care that dogs and cats with stage 2, 3 and 4 CKD with UPC greater than 0.5 and 0.4 respectively, and cats and dogs with stage 1 CKD and UPC greater than 2.0 be treated with antiproteinuric drugs such as ACEI or ARB. Additionally, systemic hypertension exacerbates proteinuria and should be addressed as previously described. Therapeutic renal diets are considered to be standard of care and have been demonstrated to be helpful in the management of proteinuric CKD and typically are restricted in phosphorus, contain conservative amounts of high-quality protein, adequate nonprotein calories, as well as omega-3 fatty acids, antioxidants, and buffers to help control acidemia. Management of nutrition to meet caloric intake is a key goal.

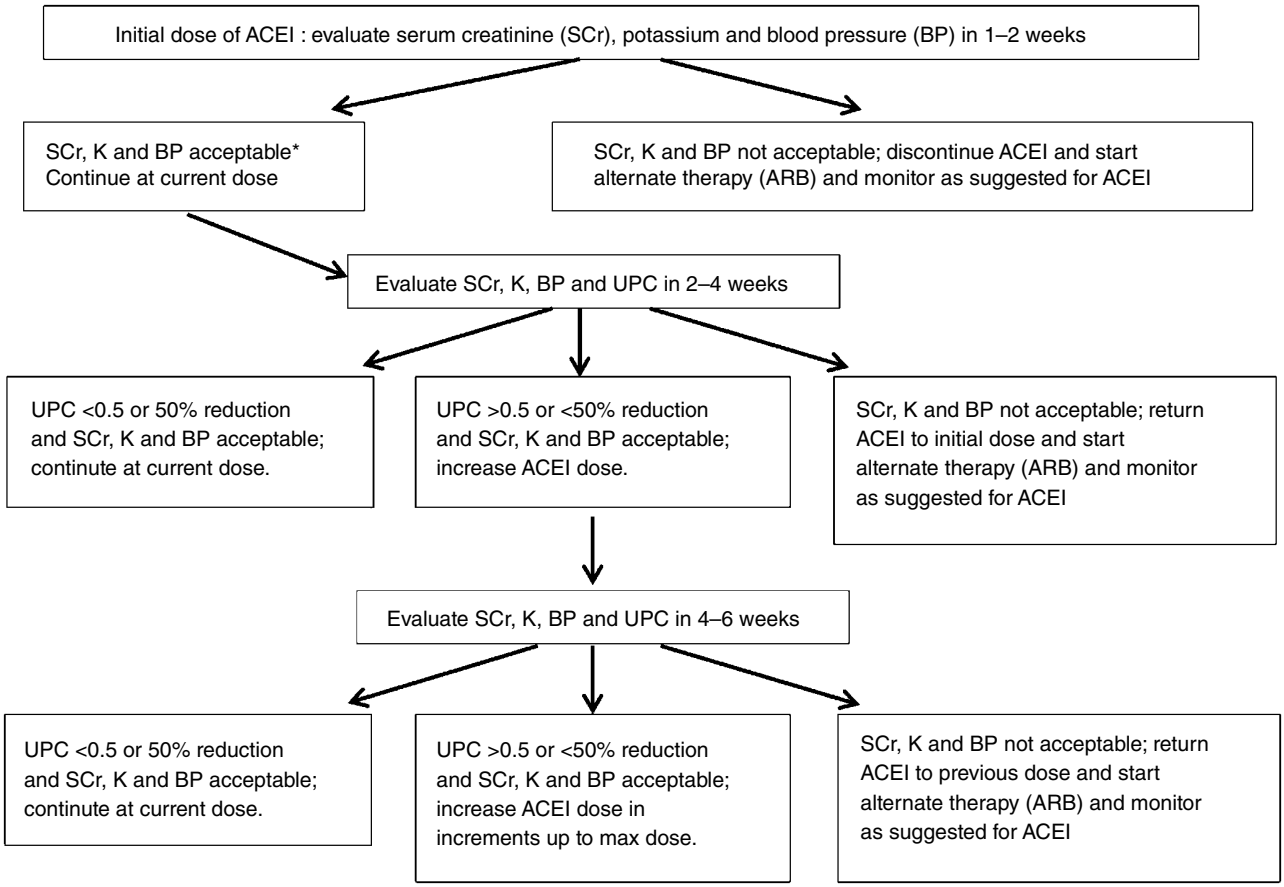

Figure 125.1 Flowchart for adjusting ACEI therapy. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; UPC, urine protein:creatinine ratio. *Source:* Modified from Brown S, Elliott J, Francey T, *et al*. Consensus recommendations for standard therapy of glomerular disease in dogs. *J Vet Intern Med* 2013; **27**(Suppl 1): S27–43.

Angiotensin-converting enzyme inhibitor or ARB therapy is instituted with a therapeutic goal of normalizing (<0.5) or, when impossible, at least reducing the UPC by 50% (Figure 125.1). Dosing, side-effects, and monitoring for ACEI are as described for antihypertensive therapy; starting at the low end of the range and cautiously increasing the dose to maximize effect on proteinuria while monitoring for adverse effects is recommended (see Figure 125.1). Unacceptable side-effects of ACEI or ARB therapy include an increase in serum creatinine >30% in IRIS 1–2 dogs, >10% in IRIS 3 dogs or any increase in creatinine in stage 4 dogs; serum potassium >6.0 mmol/L; blood pressure <120 mmHg. Extreme caution should be used in prescribing ACEI or ARB in dogs with IRIS stage 4 disease. In these patients, side-effects may outweigh benefits at this stage of disease progression.

Additional guidelines for the use of ACEI and ARB can be found in the consensus statement for the standard treatment of proteinuria.

Protein-losing nephropathies are associated with an increased risk for thromboembolism and the prevalence in dogs has been reported to be as high as 25%. Few studies have assessed the efficacy of antithrombotic therapies specifically in glomerulonephropathy (GN) patients. Currently consensus recommendations consist of 1–5 mg/kg low-dose aspirin daily for thromboprophylaxis. Clopidogrel (1.1 mg/kg daily) is likely similarly effective to low-dose aspirin. No studies have demonstrated superior efficacy to justify the higher cost.

Polyunsaturated fatty acids (PUFAs) are antiinflammatory and the underlying process in CKD is inflammatory in nature; supplementation is thought to be beneficial. Several studies have demonstrated evidence of benefit in human CKD patients and rodent models demonstrate decreased oxidative stress, inflammation, and scarring. Many renal diets are now supplemented with PUFAs in appropriate ratios. The need to supplement omega-3 fatty acids beyond that present in renal diets is not fully known at this time. However, supplementation at 0.25–0.5 g of omega-3 PUFA/kg containing eicosapentaenoic acid and docosahexaenoic acid has been described as a dose extrapolated from human literature.

Approximate 50% of dogs with protein-losing nephropathy have immune-mediated disease. The goals of performing a renal biopsy are to identify subtypes of GN that involve immune complexes, guide the decision regarding the necessity of immunosuppressive therapy, and assess prognosis. Renal biopsy should be avoided in patients with bleeding disorders, uncontrolled hypertension, chronic end-stage disease and in very small patients (cats and dogs <5 kg). It is highly recommended that if taking the time and trouble to biopsy, samples are sent to a nephropathologist (International Veterinary Renal Pathology Service, Ohio State University, https://vet.osu.edu/vmc/international-veterinary-renal-pathology-service-ivrps). Immune suppression is indicated when electron-dense deposits are seen on electron microscopy or if there is positive immunofluorescent staining. A typical therapeutic regimen is mycophenolate 10 mg/kg BID and adding prednisolone when rapidly progressing (1 mg/kg BID). Steroids should not be used as monotherapy and the goal in using them is to taper relatively quickly. If biopsy is not possible or safe, empiric immunosuppressive therapy can be considered in patients where standard therapy is not effective, serum creatinine is >3 mg/dL, and there is rapid progression of disease or severe hypoalbuminemia. It is generally considered that if a response to immunosuppressive therapy is not seen in eight weeks, it is unlikely to occur.

Fluid Therapy

As CKD progresses, GFR decreases and azotemia worsens, yet the patient is not able to compensate by concentrating urine and maintaining hydration. Dehydration is therefore a common complication of CKD and can lead to inappetence, lethargy, weakness, constipation, and increased susceptibility to uremic crisis. Owners should be aware that concurrent illness, vomiting and diarrhea, household changes/stress or inadequate water sources promote dehydration and can have more serious effects in CKD patients, potentially precipitating a uremic crisis. Maintaining hydration by administering subcutaneous balanced electrolyte solutions appears to anecdotally improve appetite, activity, and quality of life and reduce constipation in CKD patients, although no clinical trials have been performed. Subcutaneous fluid administration is generally feasible in cats and small dogs and can be a very helpful tool for owners in management of disease, particularly in stage 3 and 4. With instruction, many owners find the procedure to be feasible, and tolerated by the patient. Additionally, feeding canned food instead of dry kibble, or adding water to food is another way to increase water consumption. Paying special attention to water sources in the house – fresh, accessible, water fountains for cats, etc. – is also an important tip for owners.

Anemia

As kidney disease progresses, renal production of erythropoietin decreases and anemia can result. Other factors that can contribute to anemia include poor nutrition, blood loss, concurrent infection, and reduced red blood cell lifespan. Anemia may exacerbate the hypoxic environment in the kidney by reducing oxygen delivery to the area, thus potentiating oxidative stress, renal damage, and progression of disease. Anemia has been identified as a negative predictor of survival in CKD. Therapeutic action should be taken when hematocrit nears or drops below 20%. Although gastric ulceration is thought to be relatively uncommon with CKD, chronic gastrointestinal hemorrhage is suspected when melena, elevated BUN, iron deficiency or anemia disproportionate to level of azotemia is noted. Empiric treatment with antacid and sucralfate with an increase in hematocrit supports the diagnosis.

Hormone replacement therapy is the most effective treatment for anemia secondary to CKD and can be addressed with artificial products such as recombinant human erythropoietin (Epogen®, Amgen) or darbepoetin alpha (Aranesp®, Amgen). Epogen is given as a SC injection and is effective in treating anemia secondary to CKD. However, as it is a foreign protein, approximately one-third of animals will develop antibodies against both the foreign erythropoietin and their own, and potentially become transfusion dependent. For this reason, the product is not recommended until packed cell volume (PCV) falls below 20% and owners should be informed of this risk. Close monitoring of hematocrit is crucial so that possible antibody formation and subsequent drop in hematocrit are caught quickly. If therapy is stopped appropriately, suppressed erythropoiesis may be reversible.

Darbepoetin is a longer-acting form of erythropoietin and appears to have less association with anti-epo antibodies. It is currently the product of choice, but expense can limit its use for some owners. Therapy with darbepoetin consists of an induction phase and a maintenance phase. Initially, darbepoetin is administered 0.5–1.0 μg/kg subcutaneously once weekly. Blood pressure as well as PCV should be checked weekly during the initiation period; hypertension associated with too quick an increase in PCV is the main side-effect. Other reported side-effects include pure red cell aplasia, arthralgia, fever, seizures, polycythemia, and iron deficiency. Previous estimates of treatment success have been 60–65% in cats (multiple concurrent disease) and 85% in dogs. Typical response time is 2–4 weeks.

Once the hematocrit has reached the lower end of the normal range, the frequency of administration can be decreased to every other week to maintain the animal long term. Stimulating erythropoiesis is associated with

a high iron demand and due to the functional iron deficiency associated with CKD, iron supplementation is recommended when therapy is initiated, as well as every few months through the course of therapy. Iron injections (iron dextran 50 mg/cat IM, 10–20 mg/kg dogs IM, typically well tolerated) are considered better that oral iron supplementation as the latter tends to be bitter and likely to exacerbate an already poor appetite, as well as being poorly absorbed from the GI tract. B vitamins are necessary for red blood cell (RBC) synthesis and the degree to which they are deficient in CKD patients and an active contributor to anemia is poorly understood. Given their benign nature, supplementation is unlikely to be harmful but no information about efficacy currently exists. However, B vitamins are not considered effective as sole therapy for anemia.

Hypokalemia

Hypokalemia is a common finding in cats with stage 2 and 3 CKD likely due to a combination of increased urinary loss, inadequate dietary intake, and activation of the renin-angiotensin-aldosterone system. Hypokalemia is less common in stage 4 cats due to markedly decreased glomerular filtration, and less common in dogs due to ACEI therapy. In cats, common presenting signs of profound hypokalemia are hypokalemic myopathy and constipation. Fortunately, profound hypokalemia is less common since the advent of renal diets supplemented with potassium. Hypokalemia is associated with development and worsening of CKD in humans and appears to exacerbate damage to tubular epithelial cells.

Potassium supplementation may be provided orally as potassium gluconate (1–4 mEq/cat twice daily), or potassium citrate (40–75 mg/kg PO divided twice daily), to effect. Various forms of potassium supplements are available including pill, powder, and gel. Potassium citrate has the added advantage of being an alkalinizing agent, but the degree to which this is effective for treatment of metabolic acidosis has not been evaluated. Potassium chloride is not recommended as an oral supplement because it is acidifying and unpalatable, but may be added to subcutaneous fluids at concentration up to 30 mEq/L (higher concentrations can be associated with irritation).

Serum potassium levels are not representative of systemic tissue potassium levels and animals with low normal serum potassium may be systemically depleted, which is exacerbated by metabolic acidosis. Some clinicians advocate prophylactic supplementation even when serum potassium is in the low normal range, with a goal of maintaining serum potassium levels above 4 mg/dL. The value of prophylactic potassium supplementation has not yet been established.

Mineral and Bone Disorder: Hyperphosphatemia

The disturbances in calcium, phosphorus, and magnesium, and associated clinical syndromes in CKD are referred to as CKD-mineral and bone disorder (CKD-MBD). Renal secondary hyperparathyroidism is a major component in this process involving excess phosphorus, parathyroid hormone (PTH), and fibroblast growth factor (FGF)23. The kidneys are the main route of phosphorus excretion and as kidney function declines, hyperphosphatemia develops. Hyperphosphatemia is detrimental because it contributes to renal secondary hyperparathyroidism, tissue mineralization, and progression of CKD. Thus, controlling phosphorus intake through diet and phosphate binders is an important part of CKD management. Feeding a phosphorus-restricted diet is the first recommended step for managing CKD-MBD and studies have demonstrated efficacy in decreasing serum concentrations of phosphorus, PTH, and FGF23 as well as improved outcome. Evidence suggests that feeding a phosphorus-restricted diet even if serum phosphorus is normal is potentially beneficial. If a renal diet is initiated and phosphorus is still elevated after 4–6 weeks, then a phosphate binder is recommended with the goal of keeping serum phosphorus in the low normal range if possible (Table 125.4). These medications bind the phosphorus in the food, making it less bioavailable, so it is critical that the medication is given with each meal. Several different phosphate binders are available, including aluminum hydroxide, calcium carbonate, and lanthanum carbonate, but the main problem with administration is palatability.

Therapy is initiated with a starting dose of 30–100 mg/kg/day for aluminum hydroxide, 150 mg/kg/day for calcium carbonate, and 30 mg/kg/day for lanthanum carbonate. Doses are to effect, and generally therapy begins at the lower end of the dose range and is increased every 4–6 weeks until serum phosphorus concentrations are within the desired range. Use of calcium-containing phosphate binders is potentially associated with the development of hypercalcemia, particularly if calcitriol is also being administered. Serum ionized calcium should be monitored during use.

Table 125.4 Recommended serum phosphorus concentrations at each IRIS stage

Stage	Target serum phosphorus concentration
2	3.5–4.5 mg/dL
3	3.5–5.0 mg/dL
4	3.5–6.0 mg/dL

Calcitriol

Calcitriol, the active form of vitamin D, is produced in the kidney. Production is decreased in CKD and hyperphosphatemia further inhibits its synthesis. Calcitriol is an important inhibitor of parathyroid hormone and low levels lead to renal secondary hyperparathyroidism which has multiple deleterious consequences. In early CKD, controlling phosphorus levels may be sufficient to maintain levels. As kidney disease progresses, supplementation of calcitriol may be necessary. In dogs and people, supplementation of calcitriol has been shown to be beneficial, resulting in slower progression of disease; however, a preliminary study performed in cats was not supportive of supplementation. Further evaluation of calcitriol therapy, or other types of vitamin D analogs is necessary to determine efficacy.

When prescribed, calcitriol therapy is initiated at a dosage of 2.0–2.5 ng/kg daily and should not exceed 5 ng/kg/day. Calcitriol should be given on an empty stomach as administration with food increases calcium absorption and the risk of hypercalcemia. Cost may be a concern for many owners as the drug and required monitoring are costly; careful monitoring of ionized calcium, phosphorus, and PTH levels is required as hypercalcemia can result from oversupplementation. If hypercalcemia results, the daily dose can be doubled and given every other day to decrease intestinal absorption of calcium.

Alkalinization Therapy

Metabolic acidosis is common in animals with overt signs of uremia and may promote progression of disease. In humans with CKD, bicarbonate therapy has been demonstrated to slow progression and improve nutritional status. Blood gas analysis should be used to determine acid–base status and whether treatment is warranted. Therapy is initiated when blood pH and bicarbonate concentration drop below the normal range. Changing to a renal diet may improve acid–base balance as these diets are pH neutral. Potassium citrate administration has the advantage of serving both as an alkalizing agent and a potassium supplement; typical doses are 40–60 mg/kg two to three times daily, but degree of efficacy has not been demonstrated.

Antioxidant Therapy

The kidney is the site of substantial aerobic metabolism that results in the production of reactive oxygen species. Additionally, several processes in the diseased kidney potentially result in increased oxidative stress, including hypoxia, anemia, proteinuria, and inflammation. Oxidative stress has been documented in humans with CKD and potentially contributes to the progression of disease. Oxidative stress and decreased antioxidant capacity have been demonstrated in cats with CKD, and vitamins E, C, and B-carotene have been shown to decrease oxidative stress in CKD cats. Animals with CKD may benefit from antioxidant therapy, but randomized clinical trials are needed to determine the effect on progression and survival.

Fatty Acid Therapy

Omega-3 fatty acids are antiinflammatory and the underlying process in CKD is inflammatory in nature, so supplementation is thought to be beneficial. Several studies have demonstrated evidence of benefit in human CKD patients and rodent models demonstrate decreased oxidative stress, inflammation, and scarring. Many renal diets are now supplemented with fatty acids.

Enteric Dialysis and the Microbiome

Alterations in the gut microbiome and increased production of uremic toxins have been associated with CKD in several species, including cats. Enteric dialysis refers to the oral administration of prebiotic-probiotic bacteria which metabolize urea, creatinine, indoles, and phenols in the gut, preventing absorption and therefore decreasing azotemia (Azodyl®). Enteric dialysis has some demonstrated efficacy in humans and rat models and it is a popular supplemental therapy in feline CKD. A recent study demonstrated that sprinkling the pill in the food, contrary to manufacturer's instructions, negated any potential benefit. Controlled clinical studies are still needed to determine the effect of enteric dialysis on serum creatinine or uremic toxins in dogs and cats.

Monitoring CKD Patients

Chronic kidney disease is progressive and as such, patients' metabolic state, clinical signs, and supportive care needs change over time. Factors such as hypertension and proteinuria may not initially be present at diagnosis, but can develop later in the course of the disease. Patients in stage 1 and 2 CKD are typically monitored every 4–6 months once stable kidney function has been established. Patients in stage 3 and 4 require more frequent monitoring, especially if metabolic complications are present, and should be assessed minimally every 3–4 months. A typical visit should include clinical history, medication review, physical examination, nutritional assessment, and labwork consisting of CBC, serum biochemistry, urinalysis, and blood pressure. Urine cultures and UPC are performed at regular intervals as well. Establishing a relationship and providing client education

regarding the importance of monitoring and follow-up will improve compliance.

Prognosis

Predicting prognosis in CKD can be somewhat challenging as the progression of disease varies substantially between individuals. Poor body condition, proteinuria, hypertension, hyperphosphatemia, and anemia have all been associated with a poorer prognosis and should be targets for disease management to maximize survival. Typically, CKD progresses much more slowly in cats than in dogs. Dogs with stage 3 and 4 CKD quickly progress and within months to a year or two may be euthanized due to the disease. Cats with early CKD can have stable disease, typically for years, and may die of another disease process. Cats with stage 3 and 4 typically progress more slowly than dogs at a similar disease stage and may still live months to years.

The Role of Dialysis

Adam E. Eatroff, DVM, DACVIM (SAIM)

ACCESS Specialty Animal Hospitals, Los Angeles, CA, USA

Peritoneal dialysis, intermittent hemodialysis, and continuous renal replacement therapy are being used in companion animal medicine with increasing frequency for the treatment of both acute kidney injury and chronic kidney disease. Peritoneal dialysis, intermittent hemodialysis and hemofiltration, and continuous renal replacement therapy (the three modalities are hereafter referred to as "dialysis," unless they are discussed as separate entities) are employed with the goals of removing accumulated uremic toxins and fluid and reestablishing physiologic acid–base and electrolyte balance when the kidneys are damaged to an extent that renders them incapable of performing these duties. The goal of this chapter is to introduce the reader to the indications, treatment goals, complications, and prognostic considerations relevant to dialysis. A discussion of the technical aspects of each therapeutic modality is beyond the scope of this chapter, but excellent resources exist for the interested reader.

Dialysis Modalities

Renal replacement therapy is a term used to describe various treatment modalities designed to perform the excretory, regulatory, and, in some cases, synthetic responsibilities of the kidney. Renal replacement therapies can be classified as intracorporeal (e.g., renal transplantation, peritoneal dialysis) and extracorporeal (e.g., intermittent hemodialysis and hemofiltration, continuous renal replacement therapy). Renal transplantation relies on the provision of a donor kidney graft intended to perform the function of the native kidneys, and is reserved for cases of end-stage kidney disease. This modality is not discussed further here.

The remaining modalities are based on the principles of diffusion, convection, and adsorption for uremic solute clearance and restoration of acid–base and electrolyte balance. Diffusion occurs when uremic solutes redistribute in solution from areas of higher concentration (blood) to lower concentration (dialysate). The use of a semipermeable membrane to separate the dialysate from the blood allows for the restriction of movement of larger substances (protein and cellular components), while smaller substances (uremic toxins) are able to redistribute freely through the pores of the membrane. Convection utilizes the application of a hydrostatic or osmotic force to blood to promote fluid (plasma water) movement across a membrane. Any substances dissolved in the plasma water that are small enough to pass through the pores of the membrane are removed. When the removal of fluid, rather than solute, is the primary indication for convective clearance, this modality is referred to as ultrafiltration. Adsorption, which quantitatively contributes the least to uremic solute removal, occurs when substances adhere to the membrane due to physiochemical interactions.

Peritoneal dialysis is performed by infusion of a solution (dialysate) into the peritoneal cavity. The peritoneal membrane serves as a membrane across which uremic solutes diffuse from the blood into the dialysate; solutes (e.g., bicarbonate) of which the patient is deficient can be administered via diffusion from the dialysate across the peritoneal membrane into the patient's blood. Convective clearance of uremic solutes and excess fluid can be achieved by use of hypertonic dialysate, which exerts an osmotic force, drawing plasma water across the peritoneal membrane into the dialysate. Dialysate is intermittently infused and removed from the peritoneal cavity in cycles during peritoneal dialysis. Intermittent hemodialysis and continuous renal replacement rely on the movement of blood through fibers composed of a semipermeable membrane housed in a cartridge (dialyzer for intermittent hemodialysis; filter for continuous

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

renal replacement therapy). The fibers are bathed in dialysate, thus providing an arrangement analogous to peritoneal dialysis, with three major exceptions: solute and fluid exchange occur outside the body, the membrane across which exchange takes place is not native to the patient, and blood and dialysate are typically moved in countercurrent directions (as opposed to dialysate remaining stagnant in the peritoneal cavity) to maximize the concentration gradient for diffusion. For intermittent hemodialysis and continuous renal replacement therapy, convective clearance is achieved by application of negative hydrostatic pressure, which draws plasma water across the dialyzer or filter membrane.

Dialysis for Acute Kidney Injury

In companion animal medicine, dialysis is most frequently employed to treat acute kidney injury of various etiologies, including leptospirosis (dogs), ureteral obstructions (cats), and nephrotoxicity (dogs and cats). However, in a recent publication, the etiology was undetermined in 43 of 93 (46%) dogs treated with intermittent hemodialysis for acute kidney injury. While the high proportion of undiagnosed cases was likely due, in part, to an inability to obtain a serologic diagnosis of leptospirosis or confirm the presence of the organism in tissue or fluid, this statistic underscores the degree of prognostic uncertainty that is frequently present when dialysis is initiated in cases of acute kidney injury. The same study reported ureteral obstructions as the most common underlying etiology in cats undergoing intermittent hemodialysis. Figure 126.1 demonstrates the use of intermittent hemodialysis for the treatment of a cat with bilateral ureteral obstruction, and Figure 126.2 demonstrates the use of continuous renal replacement therapy for the treatment of leptospirosis.

Regardless of the underlying cause of acute kidney injury, the decision to implement dialysis is made based on a multitude of factors, all of which are discussed below.

Azotemia/Uremia

Historically, severe uremia (e.g., blood urea nitrogen and creatinine concentrations of ≥100 mg/dL and ≥10 mg/dL, respectively) was considered a major indication for dialysis. However, recent trends favor initiation of dialysis at less severe degrees of azotemia. The reasons for the lessening of this threshold are twofold. First, as the veterinary community gains experience and proficiency with dialytic techniques, the safety and feasibility of this treatment have improved significantly. Consequently, the value in preventing severe complications (e.g., gastrointestinal, neurologic, pulmonary) of uremia has become evident, and favorable outcomes have become more likely when dialysis is initiated in efforts to prevent these complications, rather than reverse them. The window for prevention of severe uremia usually is present at less severe degrees of azotemia than the thresholds reported above. Therefore, the degree of azotemia should be assessed every 24–48 hours, so that dialysis can be initiated when consecutive days of worsening renal function are documented, despite appropriate conventional medical and/or surgical therapy. Second, analogous to the

Figure 126.1 This cat had hyperkalemic acute kidney injury secondary to bilateral ureteral obstruction. Prior to surgical intervention, the patient was given three intermittent hemodialysis treatments which resulted in resolution of hyperkalemia and azotemia.

Figure 126.2 This dog was diagnosed with leptospirosis and was initially treated with conservative medical management. Worsening azotemia and volume overload, however, prompted initiation of continuous renal replacement therapy.

decision to administer a packed red blood cell transfusion (i.e. the "transfusion trigger"), the decision to implement dialysis is based on a variety of factors in addition to the degree of azotemia (the correlate of azotemia, in the transfusion example, would be the hematocrit). These factors include co-morbid conditions, such as cardiovascular disease, pulmonary disease, or a low seizure threshold, which may be exacerbated with less severe degrees of renal dysfunction.

Fluid Overload/Oliguria/Anuria

Parenteral fluid administration is considered a cornerstone of treatment for acute kidney injury and a variety of other kidney diseases. However, misconceptions regarding the potential benefits and adverse effects of aggressive fluid administration are widespread. In cases of severe renal dysfunction, aggressive fluid therapy with the goal of achieving a positive fluid balance has not been shown to improve renal clearance of uremic solutes. While the serum or plasma creatinine concentration may improve with achievement of a positive fluid balance, this improvement is more likely related to accumulation of fluid in the extracellular compartment, which results in an increase in the volume of distribution of creatinine and a dilutional effect on the serum or plasma creatinine concentration. In human patients with acute kidney injury (AKI), a decrease in serum or plasma creatinine concentration has been shown to be directly proportional to the degree of fluid accumulation. Furthermore, fluid overload has been associated with negative outcomes, including increased mortality and decreased renal recovery. Additional data suggesting the association between fluid overload and outcome exists in a canine intensive care unit (renal and nonrenal cases) are emerging. While fluid overload can occur in a patient with normal urine production or polyuria, this complication is most frequently encountered in oliguric or anuric patients. Even restriction of all parenteral fluid therapy cannot prevent fluid overload in anuric patients, due to the obligate fluid load administered with medications and nutrition.

Once fluid overload occurs and manifestations, such as pulmonary, gastrointestinal, and neurologic complications, are recognized, restoration of normal fluid balance can be difficult to achieve. Diuretic therapy (e.g., loop or osmotic diuretics) is frequently ineffective at promoting fluid excretion in severely compromised kidneys, and some diuretics (e.g., mannitol) may even be contraindicated due to the obligatory solute load that accompanies administration. Therefore, dialysis (ultrafiltration) may be the only effective means of removing excess fluid.

Hyperkalemia

Hyperkalemia is frequently the most immediate life-threatening complication of severe acute kidney injury. Arrhythmias that negatively affect cardiac output or result in death can occur when the serum or plasma potassium increases above 6 mmol/L. The likelihood of a clinically significant arrhythmia is increased when acidemia, uremia, or fluid overload is severe. While there are several pharmacologic approaches to the treatment of hyperkalemia in AKI (e.g., intravenous dextrose ±

regular insulin and intravenous calcium gluconate, β2 agonists), the effects of these treatments are typically modest and transient when renal function is severely compromised. In these cases, rapid restoration of renal function (e.g., surgical removal of ureteral obstructions) or provision of dialysis are frequently necessary to normalize serum or plasma potassium concentration. It should be noted, however, that restoration of renal function is superior to intermittent forms of dialysis in restoring whole-body potassium balance, due to the predominantly intracellular distribution and slow redistribution of potassium when it is removed from the extracellular space (as is the case in dialysis).

Severe Acidemia

In humans, provision of supplemental sodium bicarbonate in solution has not been proven to be of benefit in cases of severe acidemia accompanying acute kidney injury. Furthermore, in cases of oliguria or anuria, the fluid volume administered once sodium bicarbonate has been diluted to a physiologically tolerable osmolality may result in complications associated with fluid overload. Bicarbonate, however, can be administered in therapeutic concentrations as an alkali buffer to patients without an obligatory fluid load when the bicarbonate is a component of the dialysate. During dialysis, bicarbonate diffuses from a medium in which it has a high concentration (the dialysate) to a fluid with a lower concentration (the patient's plasma water), resulting in administration of sodium and bicarbonate ions without fluid. The provision of alkali without a concomitant fluid load can safely restore the extracellular pH to within the normal range, allowing for normal function of metabolic machinery in various tissues.

While these four factors are commonly encountered in cases of AKI, the decision to employ dialysis does not only depend on each factor's presence but its degree of severity. In human medicine, the optimal timing of initiation of dialysis for acute kidney injury has been vigorously debated, and no consensus has been reached regarding the benefit of early versus late initiation of therapy. The data presented in the human literature likely cannot be extrapolated to veterinary patients because the degree of renal dysfunction that falls into the "late" category (typically defined as serum creatinine concentrations in the range of 3.5–5 mg/dL and urea concentrations in the range of 60–100 mg/dL) would be considered "early" or "mild to moderate" dysfunction by most veterinarians. It is the author's impression that in veterinary cases of AKI for which dialysis is initiated early, when the serum creatinine concentration is in the mild to moderate range, outcomes are much improved compared to when dialysis is initiated later (serum creatinine concentration >10 mg/dL). Earlier initiation of dialysis allows for the prevention of the sequelae of fluid overload, hyperkalemia, and severe acidemia. Preventing these complications provides the patient with optimal metabolic stability to facilitate renal recovery and reduces the costs associated with measures required to address complications such as pulmonary edema and cardiac arrhythmias. Initiation of dialysis prior to decompensation of the patient may even allow for a rapid transition to outpatient dialysis treatments, which can reduce client costs even further and extend the client's available financial resources.

Dialysis for Chronic Kidney Disease

Although chronic kidney disease is an infrequent indication for dialysis, compared with acute kidney injury, dogs and (less frequently) cats have been treated successfully with chronic intermittent hemodialysis for prolonged periods of time, ranging from a few months to over a year. For patients with end-stage chronic kidney disease, dialysis may be thought of as analogous to palliative chemotherapy or radiation therapy for patients with oncologic diseases. The goals of treatment are maintenance of an acceptable quality of life, rather than the metrics of tumor response in the case of cancer treatment or precise regulation of uremic, acid–base, electrolyte, and fluid balance in the case of chronic dialysis.

Patients that receive the greatest benefit from chronic hemodialysis are typically those with International Renal Interest Society (IRIS) stage 4 chronic kidney disease (CKD) that are free of co-morbidities (e.g., significant cardiovascular, gastrointestinal, neurologic, or orthopedic disease). Dogs that weigh greater than 5 kg typically tolerate chronic treatment better than smaller dogs or cats. The reason for smaller animals' inability to tolerate chronic hemodialysis as well as larger patients has not been determined. However, the author speculates that this difference may be due two possible factors: (1) the large volume of blood, relative to the body mass, that must be outside the patient's systemic circulation at any given time to fill the dialysis circuit, and (2) the repeated loss of blood endured by the patient, caused by residual blood trapped in the dialysis circuit that cannot be returned at the end of each treatment. Despite treatment with erythropoiesis-stimulating agents, smaller patients are reliant upon multiple red blood cell transfusions that must be administered before, during, or after some or all dialysis treatments. The repeated administration of red blood cell transfusion in such a short period of time (the first 2–3 weeks of treatment) can lead to an increasing probability of clinically devastating transfusion reactions during the subsequent weeks/months of treatment. An

additional limitation of chronic hemodialysis is the financial and logistic responsibility of the owner. Not only can chronic hemodialysis be cost prohibitive for most owners, but the practical considerations may be overwhelming. Patients treated with chronic hemodialysis typically require treatments, lasting as long as six hours, three times per week. If a scheduling conflict prevents as few as one treatment from being performed, the patient may have a high probability of suffering from severe uremic complications (e.g., nausea), fluid overload, or hyperkalemia. Despite these limitations, a properly selected patient and its owner can enjoy an excellent quality of life for several months to years when treated with chronic hemodialysis.

Alternative Indications for Dialysis: Acute Intoxications and Therapeutic Plasma Exchange

An additional, often overlooked indication for dialysis is decontamination following acute toxin exposure. There are a variety of intoxications that can be treated effectively with dialysis. However, treatment success is highly dependent on the pharmacokinetic properties of the toxin and timing of treatment in relation to ingestion/exposure. Small (<500 daltons), freely circulating toxins are efficiently removed from the blood compartment with conventional hemodialysis, which utilizes diffusion as the predominant clearance mechanism. Toxins with small volumes of distribution are typically retained in the vascular or extracellular compartment, and are more efficiently accessed for clearance. However, retention of toxins within the vascular compartment is typically a result of a high degree of protein-binding.

Because dialysis employs membrane-based separation techniques that, for most dialyzers and filters, exclude the movement of proteins across the membrane, alternative techniques must be employed for toxins that are highly protein bound. Charcoal hemoperfusion and therapeutic plasma exchange are alternatives to conventional dialysis modalities, and can be employed to circumvent the limitations associated with dialytic removal of protein-bound toxins. Charcoal hemoperfusion employs a large cartridge that, rather than housing membrane-bound fibers bathed in a dialysate solution, contains activated charcoal around which blood percolates as it is moved through the dialysis circuit. Binding interactions between toxins and the activated charcoal are stronger than between the toxins and plasma proteins, resulting in the transfer of the toxin from the plasma protein to the activated charcoal (adsorption). The large volume of blood that is required to fill the commercially available charcoal columns, along with hematologic changes associated with interactions of cellular blood components with the charcoal, are sources of possible adverse effects of this treatment (e.g., hypotension and thrombocytopenia, respectively). There are multiple hemoperfusion columns in the development of veterinary patients that utilize a more biocompatible substrate for adsorption of exogenous toxins. These columns are also of smaller volume than the previous charcoal cartridges, making them an attractive alternative to the existing charcoal cartridges. Therefore, both the potential harm posed to the patient by the toxin to which it has been exposed and the possible adverse effects of charcoal hemoperfusion must be considered if this treatment is to be employed.

Therapeutic plasma exchange may be considered in lieu of charcoal hemoperfusion due to the smaller dialysis circuit size required and the avoidance of exposure of cellular blood components to a substance as reactive as charcoal. Therapeutic plasma exchange employs the same equipment and convective clearance principles described above to remove an offending substance from the blood. However, it differs from conventional dialysis in that semipermeable membranes have pores that are large enough to allow passage of plasma proteins. Therefore, therapeutic plasma exchange allows for removal of a protein-bound toxin, along with its carrier protein. Disadvantages of this technique include the requirement for replacement of the removed plasma with a fluid that has a similar oncotic pressure to the removed plasma and, if the protein composition of the replacement fluid differs significantly from the removed plasma, the potential for coagulopathy associated with clotting factor depletion.

With regard to the financial considerations of these two treatments, the cost is comparable. Charcoal hemoperfusion and therapeutic plasma exchange have been used most commonly by the author for blood purification following ingestion of massive quantities of various nonsteroidal anti-inflammatory drugs. The reader is referred elsewhere for an extensive listing of intoxications that can be treated with dialysis.

In addition to blood purification for the treatment of acute intoxication, therapeutic plasma exchange may also be of benefit for a variety of immune-mediated diseases. Due to the large pore size of the membranes used, blood components as large as immunoglobulins and immune complexes are easily cleared with convection using these membranes. Historically, therapeutic plasma exchange was performed with dedicated equipment that utilized a centrifugal technique for blood component separation. Availability of this equipment is still limited in veterinary medicine. However, the development of dialysis equipment with a wide selection of

interchangeable filters and software has provided the capability to perform this procedure with devices primarily designed for renal replacement therapy. In the past several years, reports of therapeutic plasma exchange performed for the treatment of diseases such as myasthenia gravis and immune-mediated hemolytic anemia have appeared in the veterinary literature, heralding a new era in the evaluation of this modality for the treatment of immune-mediated diseases.

Availability of Dialysis and Prognosis for Dialysis Patients

The veterinary community has witnessed exponential growth in the number of facilities offering dialysis for small animal patients. Peritoneal dialysis requires equipment that is readily available, and this modality is performed in many emergency and specialty hospitals that offer 24-hour care. Effective implementation of intermittent hemodialysis and continuous renal replacement therapy is limited to hospitals that not only have the proper equipment but also employ properly trained individuals. Nonetheless, due to the low cost and ease of acquisition of the necessary equipment, many veterinary facilities now offer intermittent hemodialysis and continuous renal replacement therapy.

Despite the paucity of literature available describing outcome, it appears that the prognosis for veterinary patients treated with dialysis is variable, and dependent on the underlying disease etiology, severity of illness, and co-morbid conditions. In cases of acute kidney injury of any etiology, the survival to hospital discharge for both dogs and cats is approximately 50% with the use of intermittent hemodialysis. When considering all possible etiologies, choice of modality does not appear to dramatically affect survival rate. Certain etiologies of acute kidney injury treated with dialysis, such as leptospirosis in dogs and ureteral obstructions in cats, have higher survival rates, reaching 80–90%. In contrast, the prognosis for acute kidney injury secondary to ethylene glycol intoxication is poor, with only 20% of dialysis patients regaining sufficient renal function to allow discontinuation of dialysis.

While the current overall success rate for treatment of acute kidney injury with dialysis appears disappointing, closer evaluation of the situation provides cause for optimism. The survival rates achieved in veterinary medicine are similar to those achieved in human medicine. This accomplishment is likely due, in large part, to the etiologic differences between human and veterinary acute kidney injury. Human acute kidney injury most commonly arises as a complication of disorders (e.g., sepsis, advanced cardiac disease) that alone carry a poor prognosis. Therefore, when acute kidney injury does occur, the likelihood of a poor outcome is multiplied. In veterinary medicine, however, many dialysis candidates presented for acute kidney injury secondary to leptospirosis or select intoxications have no preexisting co-morbid conditions that may affect prognosis. Therefore, if the potential benefit of dialysis is recognized early, and these patients are treated with dialysis prior to the onset of severe complications, there is the potential for the veterinary community to significantly improve the current success rate for treatment of acute kidney injury.

Micturition and Associated Disorders

Julie K. Byron, DVM, MS, DACVIM (SAIM)

College of Veterinary Medicine, Ohio State University, Columbus, OH, USA

Physiology of Micturition

The primary purpose of the lower urinary tract is to store urine and facilitate its elimination at an appropriate time. The bladder is in storage phase 99% of the time and in emptying phase only 1% of the time. Coordination of both storage or filling and emptying requires a complex interaction between the somatic and autonomic nervous systems, as well as normal function of the tissues involved.

The three divisions of the peripheral nervous system innervate the urethra. The pudendal nerve carries somatic signals to the striated muscle that makes up the outer layer of the urethral muscles. The pelvic nerve, which is parasympathetic, and the hypogastric nerve, which is sympathetic, innervate the two smooth muscle layers that surround the urethra. Both the somatic and parasympathetic innervation arise from the sacral spinal cord segments, while the sympathetic innervation arises from the lumbar spinal cord. Local reflex arcs exist as well as central controls. Signals are processed in the pontine micturition center of the brainstem and the cerebral cortex to sense bladder distension and determine conscious control of voiding (Figure 127.1). The primary spinal segments involved in micturition are L1–L2, S1–S2 (storage phase), and S1–S3 (emptying phase).

During the normal storage phase, stretch receptors in the bladder wall send afferent signals along the pelvic nerve, which activate a reflex arc through the hypogastric nerve to the urethra. Norepinephrine (NE) is released by postganglionic neurons to activate beta-adrenergic receptors in the bladder wall, allowing for relaxation and continued filling. NE also stimulates alpha-1-adrenergic receptors in the urethra and causes contraction of the smooth muscle surrounding the urethra, thus preventing urine leakage.

An additional urethral reflex, called the guarding reflex in humans, is the somatic-mediated contraction of the striated muscle surrounding the urethra in response to a sudden increase in abdominal pressure, such as during a cough or sneeze. Afferent signals travel up the pelvic nerve and initiate efferent signals down the pudendal nerve, releasing acetylcholine (ACh) and activating nicotinic cholinergic receptors, causing contraction of the striated muscle.

In addition to normal neurologic mechanisms, several other factors are important for maintenance of urinary continence. The integrity of the smooth muscle of the urethra, normal urethral mucosa which creates a watertight seal, associated vasculature, and the support of connective tissues are also key. In females, estrogen appears to have a significant impact on these tissues. Its withdrawal after neutering appears to play a role in urethral sphincter mechanism incompetence seen in neutered female dogs.

During initiation of voiding, stretch receptors send afferent signals along the pelvic nerve to the pontine micturition center. Signals from the cerebral cortex and the hypothalamus are processed to determine if the situation is appropriate for initiation of micturition. If so, signals are sent down the pelvic nerve, leading to ACh release at the postganglionic parasympathetic neurons. ACh binds to receptors and stimulates bladder smooth muscle contraction. At the same time, inhibitory signals are sent to the hypogastric nerve and the urethra relaxes, allowing normal emptying.

Micturition disorders can be divided into those primarily related to storage and those related to emptying of urine.

Disorders of Storage

Storage disorders primarily result in the leakage of urine without intent by the animal. These may result from an anatomic or developmental abnormality or acquired

dysfunction in the spinal cord, urinary bladder, or urethra and surrounding tissues.

Urethral Sphincter Mechanism Incompetence

Urethral sphincter mechanism incompetence (USMI) is the most common storage disorder in dogs. The urethral sphincter mechanism involves the smooth muscle of the urethra as well as the surrounding support tissues, submucosal vasculature, and urothelium. USMI is thought to result from a breakdown in this complex through reduced muscular responsiveness and tone, and structural changes in the periurethral tissues. In female dogs, these changes appear to be associated with a reduction in estrogen and alterations in follicle-stimulating hormone and luteinizing hormone after neutering – thus the term "hormone-responsive incontinence." Previously thought to be distinct processes, it is now understood that USMI and hormone-responsive incontinence are the same entity. The pathophysiology of its development in male dogs is poorly understood, but there may be a relationship to decreased testosterone

levels, and increased follicle-stimulating hormone and luteinizing hormone, since it appears more frequently in neutered than in intact males.

Urethral sphincter mechanism incompetence is most common among neutered female dogs. It is less common in neutered males and rare in cats. It appears to affect up to 20% of neutered females and up to 30% of large-breed dogs over 20 kg. Several breeds have been found to have increased risk including the Doberman pinscher, giant schnauzer, Old English sheepdog, Rottweiler, Weimaraner, and boxer, but any breed may be affected. Recent literature has demonstrated an increased risk of development of USMI in dogs neutered either before 3 months of age or after the first estrus. In addition, it appears that dogs over 15 kg have an increased risk of USMI the earlier they are neutered. It is possible that this is related to the development and sensitivity of the sphincter mechanism tissues to estrogen and other hormones, but the mechanism is incompletely understood. Predisposing factors such as a pelvic bladder, short urethra, or recessed vulva may also be associated with increased risk of developing USMI, but the presence of one of these does not necessarily lead to incontinence.

Signs of incontinence may begin at any time, but appear most often within a few years of neutering. Dogs with USMI usually have normal bladder capacity and are able to urinate normally with complete emptying of the bladder. While most of these dogs are otherwise healthy, clinical signs can worsen dramatically if co-morbidities develop, leading to polyuria or difficulty posturing to urinate. The increased volumes of urine in the bladder, and for longer periods of time, may lead to increased pressure on the already weakened sphincter mechanism and leakage. Lower urinary tract infection can also lead to increased frequency of clinical signs. It is suspected that USMI, and urinary incontinence of any cause, is associated with increased risk of urinary tract infection (UTI), but no studies have been conducted to fully evaluate this.

Owners often seek veterinary care when the frequency becomes bothersome, although on further questioning, it is apparent the signs have been occurring for months or years. It is essential to establish that the animal is passing urine unconsciously. Many owners will complain of "incontinence" when the animal is demonstrating submissive urination or is otherwise consciously urinating in inappropriate places. Dogs with USMI may leak urine when recumbent, sleeping, or after exertion. Although the passage of urine is involuntary, dogs may increase grooming of the perivulvar or preputial area to remove the urine. USMI is an acquired condition, so questioning of the owner regarding the onset of clinical signs is important. Animals that have been incontinent from birth or prior to neutering should be assessed for congenital malformations such as ectopic ureters, prior to making a diagnosis of USMI.

Physical examination of these animals is often normal, with the exception of perivulvar or preputial urine staining. As mentioned above, the conformation of the vulva should be noted, although its contribution to USMI is unclear. The presence of perivulvar dermatitis, regardless of conformation, may increase the risk of urinary tract infection. Rectal examination and palpation of the urethra are normal. Urination is observed to be normal and complete, with little or no residual volume. The assessment of residual urine is essential in male dogs to differentiate USMI from detrusor urethral dyssynergia, a disorder of incomplete bladder emptying (see later).

The presence of urinary incontinence in an otherwise healthy neutered female dog that was previously continent is often adequate for presumptive diagnosis of USMI and a trial of empiric therapy. Due to its lower incidence, intact females, males, and cats with similar histories and clinical signs require additional evaluation before making a diagnosis of USMI (Figure 127.2).

The animal should be observed urinating, if possible. Normal posturing and a full stream without stranguria should be noted. Assessment of residual urine volume may be made by bladder catheterization or estimated using abdominal ultrasound of the bladder. A urinalysis and urine culture should be performed. The presence of isosthenuria or hyposthenuria may contribute to severity of incontinence and may require additional evaluation for an underlying cause. Animals with polyuria may not respond to medical treatment as well as those making normal volumes of urine. As noted above, the risk of urinary tract infection in animals with USMI has not been evaluated, but its presence may lead to worsening signs. Therefore, screening for and treatment of an infection may increase therapeutic success. A complete blood count and serum biochemistry panel may be indicated but are not always necessary for diagnosis of USMI, although they may be helpful when making therapeutic choices, and are important in evaluating animals with polyuria.

If anatomic abnormalities are suspected, imaging such as contrast radiography, abdominal ultrasound, or contrast computed tomography is indicated. Cystoscopic evaluation of the lower urinary tract allows assessment of the entire urethra, ureter placement, and bladder mucosa. Advanced diagnostics, such as urodynamic studies, are designed to quantify the pressure produced along the urethra and the compliance and detrusor function of the urinary bladder. These are available at many referral institutions and are most often indicated in patients with equivocal signs and poor response to therapy, as well as in urologic research.

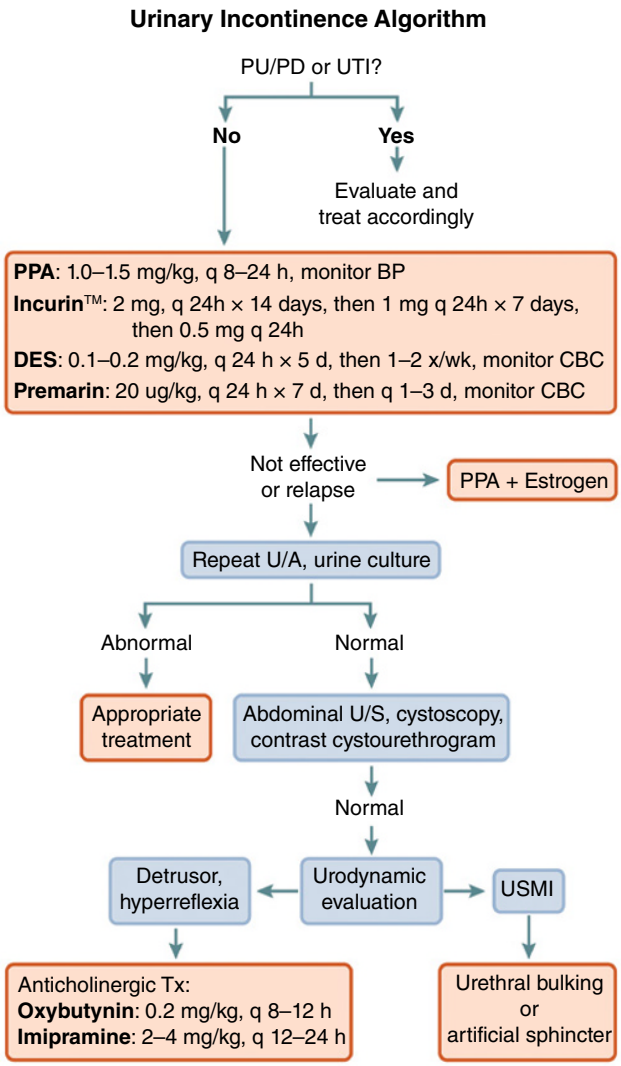

Figure 127.2 Diagnostic approach to the patient with urinary incontinence. The presence of urinary incontinence in an otherwise healthy neutered female dog that was previously continent is often adequate for presumptive diagnosis of USMI and a trial of empiric therapy before proceeding with additional diagnostics. BP, blood pressure; CBC, complete blood count; DES, diethylstilbestrol; PPA, phenylpropanolomine; PU/PD, polyuria/polydipsia; U/S, ultrasound; USMI, urethral sphincter mechanism incompetence; UTI, urinary tract infection.

Medical treatment of USMI in the neutered female dog consists of increasing number and sensitivity of alpha-receptors in the urethral sphincter with estrogen, or by stimulating those receptors with an alpha-agonist (Table 127.1).

The most commonly used estrogens are diethylstilbestrol (DES) and estriol (Incurin™). DES is not available commercially so it must be compounded. Adverse effects associated with estrogen use include mammary gland development, vulvar swelling, and attractiveness to males. These are usually dose related and subside with dose reduction. The more serious adverse event associated with estrogen use is irreversible bone marrow suppression, although the doses most associated with bone marrow suppression are much higher than those recommended to treat USMI.

Phenylpropanolamine (PPA, Proin™) is the alpha-agonist most widely used for the treatment of USMI. It is commercially available in sizes designed for use in dogs. The dose and frequency needed for each animal tend to vary widely and may need to be increased over time to maintain continence. Adverse effects associated with PPA include restlessness, aggression, changes in sleeping patterns, and gastrointestinal signs. These are also usually alleviated by a reduction in dose or frequency. Frequently, both an estrogen and PPA are used in the same patient for severe or refractory incontinence. There is little evidence supporting a synergistic increase in efficacy, but there are anecdotal reports of greater improvement than on a single medication regimen.

Phenylpropanolamine is also frequently used in male dogs and cats with USMI. In addition, neutered male dogs may be treated with testosterone cypionate as monthly injections, although its efficacy is not well documented. Although male dogs with USMI are most responsive to PPA, only 43% show good to excellent response, much lower than in female dogs. Estrogen compounds should not be used in males and are rarely used in cats. Care should be taken to monitor the mammary glands for neoplasia in cats receiving estrogens.

In patients that fail medical therapy, surgical options may be necessary. These are generally only pursued if the animal does not respond to, or cannot tolerate, medical treatment. A number of surgical procedures have been used to treat USMI, many based on the theory of increasing the transmission of abdominal pressure to the proximal urethra. These include colposuspension, transobturator vaginal tape, and urethropexy. These have had variable outcomes and are considered to have poor long-term efficacy. The most promising surgical procedure for USMI is placement of an artificial urethral sphincter which may be adjusted via a subcutaneous port. Recent studies have shown it to lead to a significant increase in continence in female dogs that had failed medical therapy for USMI. In addition, it has been successfully placed in male dogs and, recently, a female cat.

Lower Motor Neuron Bladder

Incontinence as a disorder of storage can also occur secondary to spinal cord injury or disease. Lesions in the S1–S2 region will lead to weakness of the striated muscular sphincter. Disruption of the local reflex arc at these segments leads to an easily expressible bladder which may empty with minor increases in abdominal pressure.

Table 127.1 Commonly used medical therapies for urethral sphincter mechanism incompetence

Drug	Class	Dose	Side-effects	Caution
Phenylpropanolamine (PPA) (Proin™)	Alpha-agonist	1.0–2 mg/kg PO q8–12h	Hypertension, aggression, restlessness, gastrointestinal upset, anxiety	Hypertension, Hyperadrenocorticism, renal disease
Diethylstilbestrol (DES)	Estrogen	0.1–1.0 mg/dog PO q24h for 5–7 days then weekly or as needed	Myelosuppression (rare at these doses), attractiveness to males, mammary/vulvar swelling, behavior changes	Males (can develop prostatic metaplasia)
Estriol (Incurin™)	Estrogen	2 mg/dog PO q24h × 14 days, then reduce to 1 mg q24h	Same as DES	Same as DES
Testosterone cypionate	Testosterone	2.2 mg/kg IM q4–8 weeks	Behavior change, aggression, perianal adenoma, prostatic hyperplasia	Cardiac disease, renal disease, hepatic disease, prostatic disease

IM, intramuscular; PO, by mouth (*per os*).

These animals are identified by decreased anal tone and a poor perineal reflex as well as their easily expressible bladder. Most of these animals are unable to voluntarily void and require intermittent catheterization or manual expression by the owner. Correction of the underlying cause may lead to some return to normal function. Because of the tendency to have incomplete emptying of the bladder with manual expression, these animals are at increased risk of developing urinary tract infection and appropriate monitoring must be in place.

Detrusor Hyperreflexia/Overactive Bladder

Detrusor hyperreflexia/overactive bladder (OAB) is the most common form of urinary incontinence in people, but it has been poorly characterized in domestic species. The true incidence of OAB and its importance as a cause of urinary incontinence in dogs and cats are unknown. In people, it is characterized by sudden urgency to urinate and involuntary loss of urine associated with bursts of detrusor contractions at bladder volumes far below capacity. In dogs, it may manifest as an animal that loses bladder compliance and capacity and thus may need to urinate more often than before without an increase in urine production or inflammation of the lower urinary tract. OAB may be a cause of treatment failure in some dogs treated for USMI, and should be considered in these cases.

Diagnosis of OAB in animals can be challenging and is only definitively made using urodynamic studies such as cystometrography. Response to therapy with antimuscarinic drugs is often used to presumptively diagnose OAB in veterinary species. The most commonly used include oxybutynin and imipramine, the latter of which also has alpha-agonist effects. Adverse effects of these medications include gastrointestinal abnormalities such as diarrhea and constipation, as well as parasympatholytic signs like tachycardia and hyposalivation.

Disorders of Emptying

The inability to completely empty the bladder during a normal void can result from either a functional or mechanical obstruction of the outflow tract and urethra, or an abnormality of the detrusor which impairs its complete contraction. Overflow incontinence can result from the lack of complete emptying, often when the animal is at rest. An owner may not be able to differentiate this from an animal with a storage disorder (e.g., USMI), and it is up to the clinician to determine the underlying process so that appropriate therapy can be instituted. Inability to completely empty the bladder is a risk factor for UTI, and these animals should be monitored for infection.

Detrusor Atony

Complete emptying of the urinary bladder is dependent on normal contraction of the detrusor muscle. In the normal animal, the bladder relaxes during filling with only small increases in intravesical pressure. As the bladder continues to fill, the pressure increases to a threshold which triggers a detrusor contraction and emptying. Loss of adequate detrusor contraction can result from neurogenic or nonneurogenic abnormalities. Injury to the sacral spinal cord S1–S3 or pelvic nerves can lead to bladder atony, and is often associated with weakened urethral tone. These animals often have decreased perineal reflexes and easily expressed bladders.

Treatment of the underlying lesion, if possible, may lead to improved voiding function. However, until normal function returns, careful management of urination must be followed. Male dogs are usually aseptically catheterized 2–4 times a day either in the hospital or at home, and cats and female dogs are often manually expressed. Parasympathomimetic drugs such as bethanechol are not useful in these animals as they require a functional pelvic nerve and associated spinal segments for clinical efficacy.

Direct damage to the detrusor muscle can occur from overdistension due to mechanical or functional outflow obstruction of acute or chronic nature. The muscle fibers of the detrusor transmit action potentials which initiate contraction via tight junctions. With overdistension, these tight junctions are interrupted, leading to an absent or ineffective contraction. The overdistension may be acute, as with obstructive feline idiopathic cystitis in a male cat, or chronic, as with a dog with a functional obstruction of the urethra. Relief of the obstruction and maintenance of a small bladder volume for up to two weeks may allow the junctions to reestablish and the return of coordinated detrusor function. This is usually managed by either indwelling or frequent sterile catheterization of the bladder. Bethanechol may be used in these patients to enhance stimulation of the detrusor contraction since the pelvic nerve is intact. Other medications that have been shown to enhance detrusor function are cisapride and metoclopramide. It is essential that relief of any urethral obstruction, functional or mechanical, be attained before starting medical therapy to enhance detrusor contraction.

Functional Obstruction – Detrusor Urethral Dyssynergy

Functional urethral obstruction, or detrusor urethral dyssynergy (DUD), arises from an abnormality in the reflex arc at the neurologic or muscular level which allows the urethral sphincter to relax at the initiation of

detrusor contraction and urination. It may affect the smooth muscle internal urethral sphincter, the striated external sphincter, or both. It is possible that the lesion is cranial to the associated spinal segments and involves the loss of inhibitory signals to the pudendal and hypogastric nerves, but may be a more local lesion to the nerves, the neuromuscular junction, or the sphincter itself. Unlike the "upper motor neuron bladder" seen in animals with thoracolumbar intervertebral disc disease and other spinal cord lesions, these animals typically have an otherwise normal neurologic examination.

The disorder affects primarily middle-aged, large- and giant-breed male dogs. One case series of 22 dogs reported a mean age of 4.9 years. Clinical signs are similar to those of mechanical obstruction. The animal often postures to urinate and is able to produce a urine stream that quickly becomes attenuated or stops completely. The animal may continue to posture to urinate or make several attempts without fully emptying the bladder. The presence of large amounts of residual urine typically leads to overflow incontinence and may be mistaken for USMI. This leakage can occur because the hypertonicity of the involved sphincter is often dynamic and is triggered by the act of voiding. In chronic cases, bladder overdistension and subsequent atony may develop. Unlike animals with mechanical obstruction, these dogs are typically easy to catheterize and usually do not show increases in urethral pressure on urodynamic evaluation unless actively voiding. Contrast urethrography may be normal or reveal areas of narrowing of the urethra (urethrospasm).

Presumptive diagnosis of DUD is often made by observing the dog urinate with a typical interrupted pattern, documentation of a large residual urine volume, easy passage of a urinary catheter, and ruling out of a mechanical obstruction. Normal residual urine volume in 48 normal dogs was reported to be 0.1–3.4 mL/kg body weight with a mean of 0.2 mL/kg. The author uses <0.5 mL/kg as a general guideline. Ultrasonography is recommended to assess the ureters and renal pelves for dilation secondary to chronic obstruction and ureterorenal reflux of urine. Additional diagnostics, including contrast urethrography, urethroscopy or urodynamic evaluation, may be necessary to verify the diagnosis in patients who fail to respond to medical therapy.

Treatment of the hypertonic urethral sphincter generally consists of alpha-adrenergic blockade with prazosin, an alpha-1-specific antagonist with demonstrated effects on both the internal and external urethral sphincter. Tamsulosin, which is specific for the alpha-1A subtype found in the internal urethral sphincter, has also been successful in these dogs. Some dogs will require additional therapy if the striated muscle is more significantly affected. Benzodiazepines, such as midazolam, or other skeletal muscle relaxants, including acepromazine and methocarbemol, may be more effective if the external urethral sphincter is involved. Midazolam or diazepam is typically administered 30 minutes before voiding to decrease external urethral sphincter pressure. Dantrolene and baclofen have been used in the past as skeletal muscle relaxants; however, the potential for adverse effects has decreased their use in veterinary patients. In severe and refractory cases, intermittent sterile catheterization by the owner at home may be necessary. Medical therapy of associated bladder atony should only be started after adequate relief of the functional urethral obstruction has been reached. Close monitoring of these patients for residual urine volume and UTI is needed to assess efficacy of treatment and prevent complications.

It is possible that patients with controlled DUD will experience relapse in times of stress such as hospitalization or boarding. These animals may need periodic additional therapy or catheterization even if usually able to urinate normally.

Prognosis for recovery of normal voiding is good, but most dogs will require life-long therapy for DUD. Attempts to taper medications to the lowest effective dose may be hampered by relapse of clinical signs after months of normal voiding. Prognosis appears to be worse in patients with bladder atony or UTI secondary to urine retention. Anecdotally, urethral stenting may improve clinical signs, but this is considered a salvage procedure with several potential complications, and indicated only in the most refractory of cases.

Functional Obstruction – Neurogenic

Neurogenic functional urethral obstruction is generally caused by spinal cord lesions cranial to the sacral segment. This leads to loss of inhibitory signals to the hypogastric and pudendal nerves which prevents sphincter relaxation upon voiding. This is the classic "upper motor neuron bladder" in which the patient is unable to urinate normally and is difficult to express manually. The most commonly affected patients are those with intervertebral disc disease and associated paresis. These animals typically have additional neurologic deficits, including paresis and nociceptive loss. Treatment of the underlying lesion typically leads to partial or complete return to normal voiding function after days to weeks. Until normal voiding resumes, the patients are managed as for DUD with alpha-adrenergic blockade, and manual expression or catheterization. Monitoring for overdistension and UTI is critical in these patients, as is nursing care, particularly since the overflow incontinence that can accompany this process may lead to skin breakdown in these recumbent patients.

Dysautonomia

Dysautonomia is a rare condition involving degeneration of the neurons of the autonomic nervous ganglia, leading to sympathetic and parasympathetic dysfunction. It has been most commonly reported in both dogs and cats in the UK and Scandinavia, but small clusters of cases in both species have been seen in the US. Its underlying cause is unknown, but neurotoxin exposure is strongly suspected.

In addition to the classic findings of unresponsive mydriasis and prolapsed nictitans, the abnormalities seen with dysautonomia can range from ileus and constipation to decreased systolic function of the heart. These dogs and cats often have significant voiding dysfunction and urine retention due to bladder atony and overflow incontinence secondary to urethral sphincter incompetence. There is no specific treatment for dysautonomia and spontaneous remission is uncommon.

The prognosis is related to the severity of the clinical signs and the specific organ functions affected. Management of the urinary complications is usually possible, involving bladder expression and/or urethral catheterization, along with parasympathomimetic agents. It is the challenging management of the gastrointestinal components of the disease which often leads to euthanasia.

Urinary Tract Infections

Nicole Smee, DVM, MS, DACVIM

Las Vegas Veterinary Specialty Center, Las Vegas, NV, USA

Etiology/Pathophysiology

The most common isolate from canine urine is *Escherichia coli* which accounts for one-third to half of all positive urine cultures. The next major group of uropathogens includes gram-positive cocci, *Staphlyococcus*, *Streptococcus*, and *Enterococcus*. Remaining uropathogens include *Proteus*, *Klebsiella*, *Pasteurella*, *Mycoplasma*, *Enterobacter*, and *Pseudomonas*. These 10 genera accounted for 95% and 97% of all urinary isolates in male and female dogs, respectively. A retrospective analysis of feline urine cultures submitted to a teaching hospital also found *E. coli* to be the most common pathogen (47%), followed by *Staphlyococcus* (18%), *Streptococcus* (13%), and *Klebsiella* (4%). In both dogs and cats with bacterial urinary tract infection (UTI), 75% of the time there is a single pathogen, in 20% of cases there are two pathogens and ≤5% of the time there are three species. Multiple organism infections are more commonly observed in female dogs.

Epidemiology/Signalment

Bacterial UTI is common; approximately 5–27% of dogs will experience infections of the urinary tract at some point during their lifetime. Female dogs are more commonly affected than males. In contrast to dogs, bacterial UTI is relatively rare in cats. In young, otherwise healthy cats with signs of lower urinary tract inflammation, bacterial UTI is rare (<2%). Incidence of bacterial UTI in cats increases with age and occurs more often in cats older than 10 years.

Urinary tract infections are common in dogs and cats with systemic diseases that may compromise normal antimicrobial defenses. In a retrospective study of 101 dogs with diabetes mellitus (DM) or hyperadrenocorticism or both, 42 (41.6%) had a UTI. Dogs receiving long-term glucocorticoids are also at risk with a reported incidence of 18–39%. Similarly, systemic disease can predispose cats to UTI. In retrospective studies evaluating known predisposing conditions in cats, positive urine cultures were found in 17–30% of cats with chronic kidney disease (CKD), 12–13% of cats with DM, and 12–22% of cats with hyperthyroidism. In one of these studies, decreasing urine specific gravity (USG) was not associated with positive urine culture; however, pyuria and hematuria were associated with positive urine cultures. In addition, Persian breed, females, increasing age, and decreasing body weight were associated with positive cultures.

History and Clinical Signs

Clinical signs associated with a UTI depend on bacterial virulence, status of the host immune system, duration of the infection, and site or sites of infection. The most common clinical signs associated with lower UTI include pollakiuria, stranguria, dysuria, hematuria, and inappropriate urination or periuria. If a UTI occurs secondary to a micturition disorder, such as an ectopic ureter, urethral sphincter mechanism incompetence (USMI), or urine retention, clinical signs associated with the primary condition may predominate. Similarly, in dogs and cats with systemic disease and compromised host defense mechanisms, clinical signs associated with the underlying disease may predominate and the UTI may be relatively asymptomatic.

Dogs with uncomplicated UTI often have unremarkable physical examination findings. Predisposing causes such as vulvar involution, severe perivulvular dermatitis, vaginal stenosis, cystic or urethral calculi, or urethral thickening may be identified in patients with a complicated UTI. Whenever possible, female dogs that present with a UTI should have a digital vaginal examination performed in order to identify an anatomic abnormality

that may alter normal host defense mechanisms. For example, palpation of a persistent paramesonephric remnant may prompt further investigation for ectopic ureters and palpation of vaginal strictures may prompt further investigation for urine retention. Rectal examination may also identify abnormalities such as pelvic trauma, urethral stones, or urethral thickening associated with neoplasia or granulomatous urethritis.

Acute bacterial pyelonephritis, prostatitis, and metritis are often associated with systemic signs such as fever, an inflammatory leukogram, lethargy, and anorexia. In contrast, patients with chronic prostatitis and pyelonephritis may not exhibit systemic signs and therefore it may be more difficult to localize the infection.

Diagnosis

Urinalysis may be helpful in differentiating a UTI from other disorders causing lower urinary tract signs (e.g., bladder neoplasia), making initial antibiotic recommendations, and in some cases identifying potential predisposing disorders (e.g., glucosuria and crystalluria). Urine specific gravity can be variable in patients with a UTI. Dilute or minimally concentrated urine may be observed in patients with concurrent disease predisposing to UTI (e.g., DM or hyperadrenocorticism), or may be observed if the infection involves the upper urinary tract. With a UTI, hematuria and proteinuria are frequently observed on dipstick analysis. The dipstick analyses for nitrite (bacteria) and leukocyte esterase (white blood cells [WBCs]) are designed for use in people, and are not reliable tests for canine and feline patients.

A urine sediment examination should be performed to identify pyuria and bacteriuria. If urine is dilute or the patient is immunocompromised (e.g., suffers from hyperadrenocorticism, or is receiving exogenous corticosteroids), it may be difficult to identify WBCs or bacteria on urine sediment examination. Air-dried, stained sediment evaluations were more accurate than wet, unstained mounts for identification of bacteria when urine culture results were used as the gold standard. This air-dried, stained technique is easily performed in practice by placing one drop of sediment on a glass slide, allowing it to air dry without spreading, and then staining the sample with a commercially available modified Wright's stain. It is important to remember, however, that a culture is required for definitive diagnosis, and will provide additional information (e.g., bacterial identification, number of organisms/mL of urine, and antimicrobial susceptibility results).

Cystocentesis is the method of choice for collection of urine samples, especially if a urine culture is anticipated. In patients presenting with lower urinary tract signs (e.g., pollakiuria and stranguria), collection by cystocentesis may be difficult due to the small size of the urinary bladder. Alternative methods of urine collection may be acceptable if cystocentesis cannot be performed or is contraindicated (e.g., thrombocytopenia, suspected transitional cell carcinoma (TCC) of the urinary bladder or pyoderma of the ventral abdomen). Urethral catheterization provides a superior sample compared with a free-catch voided sample but requires more technical skill, especially in female patients. Care should be taken during catheterization to prevent contamination from external structures by clipping surrounding hair and cleansing the external genitalia prior to the procedure. Based on current recommendations, free-catch urine samples are not acceptable for culture. Urinalysis and urine culture results should always be interpreted in light of the urine collection method.

Although clinical signs and urinalysis findings may increase the index of suspicion for a UTI, a urine culture is the definitive diagnostic test. Ideally, the urine sample for culture should be obtained prior to starting treatment. In patients already receiving antimicrobial therapy, it may be necessary to discontinue treatment for 3–5 days before collection of urine culture. It is also important to consider storage and transport of samples for culture in practices where immediate culture processing is not possible. Sterile containers that do not contain additives or preservatives should be used. Commercially available urine collection kits may be acceptable for up to 72 hours if sample processing is delayed. Bacterial counts can increase in urine stored at room temperature within a few hours. In refrigerated samples, quantitative bacterial counts differed after six hours of storage; however, this was not associated with a change in interpretation of the clinical significance. It is recommended that urine samples be cultured immediately but it is acceptable for urine to be refrigerated in a closed container for up to six hours prior to culture.

Alternatives to sending a urine sample to a commercial laboratory for culture include using a calibrated bacterial loop (0.01 or 0.001 mL volume) to inoculate blood or MacConkey's agar plates in-house. Culture plates are then incubated for 24 hours and if significant numbers of colonies are produced in light of the urine collection method, the plate can be sealed and shipped to a microbiology laboratory for bacterial identification and antimicrobial sensitivity testing. Alternatively, products like UriCult® culture paddles may also be used. In most cases, a quantitative urine culture will aid interpretation of results. In addition to bacterial numbers/mL of urine, knowledge of the normal flora may also be helpful in determining contamination versus infection when methods other than cystocentesis are used.

Not all species of bacteria will induce clinical signs or cause disease.

Classification of Urinary Tract Infections

Asymptomatic Bacteriuria

Bacteriuria is expected in patients with UTI, but may also be observed in healthy dogs and cats if the urine sample has been contaminated with normal flora and/or pathogens from the distal urethra/urogenital tract (voided sample or during urethral catheterization) or if the sample contacts a contaminated surface (e.g., cage floor, examination table). It is important to differentiate urine contamination from a UTI since the former does not need to be treated. Certain organisms are known to be commensal within the lower urinary tract (Table 128.1). There is, however, overlap between normal flora and potential pathogens. Contamination can be ruled out by repeating a urinalysis with urine obtained via cystocentesis or by performing a quantitative urine culture on a voided or catheterized sample. Depending on the method of urine collection, the number of bacterial colony-forming units (cfu)/mL of urine will vary between contamination and UTI (Table 128.2).

Uncomplicated UTI

Uncomplicated UTI occurs in patients where no underlying structural, neurologic, or functional abnormalities exist. A UTI becomes complicated when host defense mechanisms are compromised (e.g., CKD, hyperadrenocorticism, DM, cystolithiasis, USMI). In addition, UTIs are often considered complicated if they occur in cats, male dogs, and intact female dogs, or if they involve the kidneys or prostate.

Recurrent or Reinfection

Recurrent UTIs can be defined as either relapses or reinfections. A relapse is an infection caused by the same bacteria that caused the original infection, and usually occurs within days of cessation of treatment. Relapses are most frequently associated with ineffective antimicrobial treatment. This may be due to improper antibiotic usage (inappropriate selection, dose, duration, or poor owner compliance), emergence of drug-resistant pathogens, or failure to eliminate predisposing causes

Table 128.1 Commensal bacterial genera in the urogenital tract of dogs

Genus	Distal urethra of males	Prepuce	Vagina
Acinetobacter		+	+
Bacteroides			+

that alter normal host defense mechanisms and allow the persistence of bacteria. Relapse UTIs may be associated with a higher degree of antimicrobial resistance compared to the original infection.

Reinfections occur when the initial infection was effectively treated (documented by negative culture after therapy and resolution of clinical signs) and repeat culture confirms another infection. Typically, the time between reinfections is greater than the time between relapses. Reinfections usually indicate that host defense mechanisms are compromised.

Therapy

Ideally, antimicrobial administration should be based on results from culture and susceptibility. Unnecessary or inappropriate usage of antibiotics can lead to antimicrobial resistance, or delay the diagnosis of noninfectious cause of lower urinary tract signs (e.g., like identification of underlying TCC). In addition to susceptibility results, the route and ease of administration, potential adverse effects, cost, and concentration in the urine (or other targeted tissues, e.g., prostate, kidney) should be considered when choosing an antibiotic.

To determine the minimum inhibitory concentration (MIC), serial dilutions of an antibiotic are used to discover the lowest concentration that will inhibit bacterial growth. This concentration is the MIC and although results are reported as susceptible, intermediate, and resistant, they usually also include the actual MIC followed by the breakpoints used to determine susceptibility. The goal of the breakpoint is to predict clinical outcome for an individual patient. Breakpoints are determined by a combination of information including the species, bacteria, disease, antibiotic, dose, route, and frequency. It is important to keep in mind that there are limited data available for veterinary medicine; therefore breakpoints are often determined by using information available from human breakpoints.

A result reported as "susceptible" indicates a high likelihood of treatment success (>80%) with most antibiotics; "intermediate" indicates possible success in treatment with potential alterations in normal dosing; and a "resistant" result indicates that a clinical cure is unlikely to occur with that antimicrobial. The result is considered susceptible if the MIC is in the breakpoint range or below, intermediate if it is at the high end of the breakpoint, and resistant if it is above the breakpoint.

Urine antibiotic concentrations are usually more important than plasma concentrations when treating a UTI. Minimum inhibitory antibiotic concentrations and the anticipated urine antibiotic concentration may be used to guide treatment choices. Clinical efficacy is expected if urine concentration is maintained at greater than four times the MIC of the pathogen between doses. For example, the MIC of ampicillin for a *Staphylococcus* organism is approximately 10 µg/mL. The expected serum and tissue concentrations of ampicillin are 1–2 µg/mL whereas the expected urine concentration of ampicillin is >300 µg/mL. Since the expected urine concentration is >4 times the MIC, sensitivity for a superficial UTI should exist. Minimum inhibitory antibiotic concentration testing based on anticipated urine concentrations is not appropriate for deeper tissue infections (e.g., pyelonephritis, thickened bladder wall) where serum and tissue antibiotic concentrations are expected.

Interpretation of Results

The Clinical and Laboratory Standards Institute (CLSI) is a committee of experts that examines pharmacokinetics, microbiology, pharmacodynamics, bacterial population, MIC distribution, and clinical trial results.

Recommendations from this committee are considered the gold standard for breakpoint determination. Veterinary laboratories (or human laboratories with appropriate susceptibility panels for commonly used veterinary antibiotics) that follow CLSI guidelines should be used for culture and sensitivity testing.

Depending on the laboratory, comparing antibiotics with similar susceptibility (e.g., cephalexin and cefazolin) may be necessary but requires making assumptions. For example, when comparing cefazolin with cephalexin, cefazolin is typically administered intravenously q6h whereas cephalexin is typically administered orally q8–12h. It is also important to remember that *in vitro* culture and sensitivity results may not correlate with *in vivo* efficacy. For example, regardless of the susceptibility results for *Enterococcus*, certain antibiotics including cephalosporins, trimethoprim-sulfamethoxazole, clindamycin, and aminoglycosides should always be considered resistant since they are not effective clinically and do not correlate with *in vitro* results.

In many cases, antibiotic sensitivity testing results provide a clear direction for treatment with an antibiotic that is orally administered, has few potential adverse effects, and reasonable cost. In some cases, sensitivity results demonstrate a high degree of bacterial resistance, and route of administration, high cost, or potential adverse effects of the potentially effective antibiotic may be a concern. Although MIC may be used as a guideline for antibiotic selection, veterinary breakpoints for most antibiotics in the urinary tract of dogs and cats have not been determined. When intermediate results are obtained, it may be possible to achieve a cure if no alternative antimicrobial exists. This would most likely be achieved by using a higher dose of an antimicrobial that is excreted in the urine. In resistant infections, requesting an expanded antimicrobial sensitivity profile (e.g., ceftazedime, carbenicillin) may suggest alternative treatment regimes. Most commercial bacteriology laboratories have a second and third tier of antibiotics for expanded sensitivity testing; however, high cost and parenteral administration may be trade-offs.

Inappropriate antibiotic dosages or unnecessary usage can lead to resistant organisms, affecting not only the individual patient but potentially bacterial resistance in other veterinary patients and owners. Antimicrobials that are excreted in the urine are the mainstay of UTI treatment and initial antibiotic considerations should include amoxicillin, cephalexin or trimethoprim-sulfadiazine. When host defense mechanisms are compromised, previous or current sensitivity results indicate potential resistance, or when the infection involves the prostate or kidneys, second tier antibiotic choices should be considered including potentiated beta-lactams (e.g., amoxicillin-clavulanic acid), fluoroquinolones, or extended-release cephalosporins (e.g., cefovecin). Second-tier antibiotics are not recommended as a first-line treatment for an uncomplicated UTI, without appropriate culture and sensitivity results. However, these may be considered when rapid treatment is necessary to return to function, prevent systemic spread of bacteria, or when penetration into a specific tissue, such as the prostate, is needed. For penetration into prostatic tissue, antibiotics should be lipid soluble, not highly protein bound, and ionize at the pH of the prostatic tissue. Good prostate gland penetration can usually be achieved with fluoroquinolones, trimethoprim-sulfa, and chloramphenicol.

Uncomplicated UTI

Dogs and cats with uncomplicated are typically treated with a 7–14-day course of antibiotics. It is reasonable to assume that shorter durations of appropriate antibiotics (≤7 days) may be effective but clinical trials are needed to further evaluate shorter duration treatments. It is always ideal to treat on the basis of urine culture and sensitivity results, although economic constraints may preclude this in first-time patients with suspected uncomplicated UTI. In these cases, antimicrobial selection should be based on bacterial characteristics observed in the urine sediment (e.g., gram positive vs gram negative, cocci vs rods). For example, if a gram-negative rod or bacillus is seen (e.g., *E. coli*, *Enterobacter*, *Klebsiella*, *Proteus*), cepalosporins would be a good option. With gram-positive cocci (e.g., *Staphylococcus*, *Streptococcus*, *Enterococcus*), amoxicillin and cephalosporin would be options. Clinical signs should resolve within 48 hours with appropriate treatment. Along with resolution of clinical signs, evidence of inflammation in urine sediment should also resolve in 3–5 days of antibiotic treatment.

When empiric antibiotic treatment is used, instructions to owners regarding what to expect as well as follow-up plans are critical. If presenting clinical signs do not resolve quickly, owners should be aware of the need for a follow-up urinalysis and culture and sensitivity. Owners should also be aware of the importance of completing the entire antibiotic regime, even if signs resolve early in the course of treatment. Finally, owners should be instructed to observe their pets closely for signs of UTI recurrence after the treatment regime is complete. Clear communication and understanding of the "game plan" will result in improved treatment outcome and increased client willingness to return in cases of empiric treatment failures.

Short-Course/High-Dose Protocol

Due to concerns with owner compliance during longer treatment protocols, short-course/high-dose protocols have been proposed for the treatment of uncomplicated

UTI in dogs. In a recent study in dogs, a short-course/high-dose protocol of enrofloxacin (18–20 mg/kg once daily for three days) was as effective as traditional-dose amoxicillin-clavulanate (13.75–25 mg/kg twice daily for 14 days) in treating uncomplicated UTI. Preliminary evidence suggests this may be an effective option but additional research may be necessary to incorporate this into routine clinical practice.

Complicated UTI

Antibiotic treatment of complicated UTIs should be prolonged (typically four weeks) and always based on urine culture and sensitivity results. It is possible that shorter duration of therapy may be effective in some or all clinical situations, but further studies are needed to provide more specific recommendations. One week into treatment and one week prior to discontinuing antimicrobials, reevaluation of the urine sediment can help determine response to therapy. When effective, no bacteria or white cells should be observed on sediment exam. Recheck urine culture is again recommended 5–7 days after completion of therapy to confirm successful resolution of the UTI. Prolonged treatment of a complicated UTI may be necessary to sterilize the urinary tract but "buying time" for correction of host defense mechanism abnormalities is another important consideration. If host defense mechanism abnormalities are not corrected, it may be difficult to clear the current infection or, more likely, the patient will experience reinfections.

Ancillary Therapies

Ancillary therapies designed to prevent recurrent UTI are considered in patients where breaches in host defenses are present but are not correctable or in cases where an underlying cause for reinfection is not identified. Care should be taken to treat any underlying infection prior to starting any prevention measures. Owners should watch closely for clinical signs and be advised that frequent rechecks will be necessary to detect and treat any breakthrough infections.

Urinary Antiseptics

The most commonly used urinary antiseptic is methenamine which is converted to formalin in an acidic environment. Methenamine may be considered in patients with recurrent infections or those with potentially untreatable or unresolved breaches in immunity. Just as with the use of cranberry extract, this prophylactic treatment is not recommended as a sole treatment for UTIs. Methenamine should only be used in conjunction with antibiotics for the treatment of current infections or as a preventive once the previous UTI has been cleared. Use should be avoided in patients on sulfonamides or medications that cause alkaline urine. Urine acidifiers added to methenamine cause acidic urine that can also decrease activity of fluoroquinolone and aminoglycoside antibiotics. High doses can cause irritation to bladder mucosa but this is more common in people than dogs.

Prophylactic Antimicrobial Protocols

Prophylactic antimicrobial treatment involves long-term daily administration of low-dose antimicrobials in order to inhibit or minimize uropathogen growth, thus decreasing the opportunity for bacterial adhesion and colonization of the uroepithelium. Unfortunately, there are no studies in dogs that have evaluated the efficacy and adverse effects of these protocols. Due to the risk of creating resistant infections, prophylactic, low-dose antibiotic administration should be reserved for refractory cases and then only after all attempts to resolve correctable problems have been exhausted.

Prophylactic, low-dose antibiotic treatment should only be initiated after standard-dose antibiotic treatment has been successful (negative urine culture). Best results are expected with drugs that are excreted in the urine. Other considerations should include potential side-effects of the drug and previous culture and sensitivity results. Commonly used protocols include fluoroquinolones, cephalosporins, or beta-lactam antimicrobials. The dose used should be one-half to one-third the therapeutic daily dose administered immediately after the last voiding before bedtime. This protocol is typically recommended for a minimum of six months and urinalysis and culture should be performed every 4–8 weeks. If at any point during the treatment a UTI occurs, it is treated as a complicated UTI. Prophylactic, low-dose therapy can be restarted after the reinfection has been resolved.

Cranberry Extract

Proanthrocyanidins, specifically A-type isoforms, found in cranberry juice inhibit *E. coli* attachment by blocking interaction of bacterial P-fimbriae with the surface of uroepithelial cells. Canine studies evaluating the efficacy of cranberry extract (CE) are limited, but some *in vitro* data show promising results. One study demonstrated that *E. coli* in urine from dogs receiving oral CE had decreased ability to agglutinate to human red blood cells. Similarly, a second study demonstrated that *E. coli* in urine from dogs receiving oral CE had decreased ability to adhere to Madin-Darby canine kidney (MDCK) cells. Based on these *in vitro* studies, oral administration of CE may help reduce *E. coli* reinfections in patients with compromised host defense mechanisms. Due to large variations of the active compound in over-the-counter products, it may be of benefit to use canine products dosed according to manufacturer recommendations.

Box 128.1 Ideal steps to follow in the management of UTIs in dogs and cats

1) Diagnosis should be determined on the basis of history, urine sediment, and, ideally, urine culture and sensitivity results. Rule out contamination in voided/catheterized samples with quantitative culture. Cystocentesis is the ideal way to collect urine for culture.
2) Select an antimicrobial agent based on culture and sensitivity. Without culture and sensitivity results, use air-dried sediment findings to guide antibiotic choice (e.g., cocci vs rods).
3) Reculture urine (or at least examine the urine sediment) in 3–5 days to ascertain effectiveness of selected antimicrobial agent. Urine culture should be negative and/or there should be no white blood cells in the urine sediment.
4) Examine urine sediment 3–4 days before discontinuing antibiotic treatment.
5) Repeat urinalysis and culture 5–7 days after cessation of antibiotic therapy. (Steps 4 and 5 are especially important for recurrent UTI.)
6) Patients with recurrent UTIs should undergo imaging studies (e.g., plain and/or contrast-enhanced radiography and/or ultrasonography), a complete blood count, and serum biochemistry profile to determine whether they have local/systemic underlying predisposing factors.
7) Frequent reinfections may need to be treated with low-dose nighttime antibiotic regimes or cranberry extract after the initial inflammation has been cleared up in response to standard-dose antibiotic treatment.

Box 128.2 Reasons for poor therapeutic response in dogs and cats with UTI

- Use of ineffective drugs or ineffective duration of therapy (relapse).
- Failure of owner to administer prescribed dose at proper intervals (relapse).
- Gastrointestinal tract disease, concurrent intake of food and drug resulting in decreased drug absorption, or impaired renal concentrating ability resulting in decreased antibiotic concentrations in the urine (relapse).
- Impaired action of drugs, either because bacteria are not multiplying or because they are sequestered in an inaccessible site (e.g., prostate, neoplasia, or uroliths) (relapse).
- Failure to recognize and eliminate predisposing causes (reinfection).
- Presence of mixed bacterial infections in which only one of the pathogens is eradicated by antimicrobial therapy (relapse).
- Iatrogenic reinfection caused by catheterization (reinfection)
- Development of drug resistance in bacteria (relapse).

Prognosis

Most UTIs are uncomplicated and appropriate antibiotic treatment rapidly clears the infection, resulting in a good prognosis. However, the prognosis for a complicated UTI may be guarded. It is of the utmost importance to correct underlying defects in host defenses whenever possible to achieve the best outcome with a complicated UTI. Following protocols for ideal UTI management and monitoring will improve treatment success and decrease the incidence of recurrent UTI (Boxes 128.1 and 128.2).

Section 11

Oncologic Disease

129

Approach to the Cancer Patient

Lisa DiBernardi, DVM, DACVIM (Oncology), DACVR (Radiation Oncology)

Gulf Coast Veterinary Specialists, Houston, TX, USA

The goal of this chapter is to present an overview of current cancer terminology, patient evaluation, diagnostic techniques, management strategies, and treatment options with emphasis on the application of radiation therapy.

Cancer is a group of diseases that are defined by the uninhibited growth and replication of cells. Cancer arises from an abnormal single cell that has suffered a disruption in its regulatory mechanism for proliferation and self-elimination. Cancer biology will be discussed in subsequent chapters.

Unregulated cellular proliferation is a characteristic of both benign and malignant tumors. Metastasis distinguishes a malignant from a benign tumor. Metastasis is the spread of cancer from one location to a regional or distant location. A tumor is named based on its cell of origin. A cancer that initiates from embryologically derived endoderm, more commonly termed skin or epithelium of the internal organs, is a carcinoma. Carcinoma will have a descriptor, a prefix, based on histology. An example of a carcinoma of the oral cavity is a squamous cell carcinoma. A benign mass within skin or epithelium may be an adenoma, cystadenoma or papilloma. A malignancy of mesoderm – bone, muscle, fat, cartilage, or other supportive structures – is termed a sarcoma. Benign examples include fibroma, lipoma, hemangioma, chondroma, and osteoma. Central nervous system cancers involve the brain and spinal cord and are named after the cells lining the interior and exterior of the brain (glial, meningeal, ependymal cells) or cells from vascular structures (choroid plexus). Lymphoma (lymphosarcoma) and multiple myeloma are malignancies involving immune regulatory cells.

Discrete cell tumor is a term applied to tumors that exfoliate as individual (discrete) cells, which are generally round in shape. This category includes mast cell tumor, plasmacytoma, transmissible venereal tumor, lymphoma, and histiocytic tumors, but is not limited to these tumors. Leukemia results from malignant blood-forming tissues of the bone marrow.

The terminology for some malignancies may be misleading. Examples include those used for lymphoma and melanoma. Lymphosarcoma and lymphoma are terms for the same malignant process. Melanoma may be benign or malignant depending on location, level of invasiveness, and species. A histopathologic description will state malignant melanoma versus melanocytoma (benign melanoma).

The overall mortality due to cancer in dogs is 20–30%, approximately one in four. The dog breed with the highest cancer prevalence in the United States is the golden retriever. Currently the Golden Retriever Lifetime Study is underway in the United States. The study's purpose is to identify the nutritional, environmental, lifestyle and genetic risk factors for cancer and other diseases in dogs (https://www.morrisanimalfoundation.org/golden-retriever-lifetime-study). In Sweden, a retrospective study found boxer and Bernese mountain dogs to be overrepresented in cancer deaths compared with other breeds, including the golden retriever. The selection of desired traits may lead to breed-specific risks for the development of cancer. Boxers, bulldogs, and retrievers are prone to cancer of the skin and subcutaneous tissues. The Siamese cat is predisposed to the development of cutaneous mast cell tumors. Osteosarcoma is historically a cancer of large and giant breeds. The power to identify hereditary influences lies in the pure-bred dog's reduced genetic complexity (diversity). Identification of pathway dysregulation(s) will elucidate potential upstream or downstream therapeutic targets. Current multiinstitutional consortium research is focused on the rapid identification and translation of novel therapies to benefit

dogs and humans. (For more information see www.ccogc.net, www.vai.org, www.akcchf.org and for pet owners wishing to register their affected dogs, http://nationalveterinarycancerregistry.org/).

Initial Assessment

History

Pertinent information should be obtained through open-ended questions using reflective listening and confirming the information by paraphrasing important points. Taking a thorough history incorporates both nonverbal and verbal communication skills. This should include the onset of the current problem, the anatomic location of the problem or body system affected, descriptors of the nature of the problem such as quality, quantity, severity, onset, duration, timing of occurrence, frequency, as well as inciting factors that trigger the occurrence, alter the frequency and severity or improve the event. The duration of the presence of a mass and the rate of growth may facilitate differentiation between benign and malignant processes. Previous medical and surgical conditions, vaccination and administration location, allergies, exercise, travel history, housing, feeding practices, elimination details, administration of medications, vitamins, nutraceuticals, and supplements should also be investigated. This information is vital and may circumvent adverse events associated with polypharmacy. Once the information is obtained and organized, the organ system affected should become evident.

Patient Evaluation

The physical examination is an essential portion of every patient evaluation and should include all major organ systems. Leaving the affected body system for the final portion of the exam may permit minimal patient resistance. Attention should be paid to the demeanor and behavioral responses of the patient for pain assessment, location of primary and/or metastatic disease, site of surgical interventions, musculoskeletal conditions and mobility, neurologic function, and dermatologic conditions. Once the history and physical examination data have been integrated, the subsequent chapters will guide the reader through the most probable differential diagnoses. It is important to bear in mind that the presenting problem may not always reflect the origin of the tumor but rather be a consequence of a tumor-associated change(s) in function. For example, a dog may present for polyuria and polydipsia when the inciting factor is humoral hypercalcemia of malignancy (HHM), a paraneoplastic syndrome associated with particular tumors.

Diagnostic Testing

Based on the generated list of differentials, tailored diagnostic testing may be recommended to support or refute a diagnosis. Clinical features suggestive of a malignant tumor include rapid growth, invasion into deep tissues or overlying skin, fixation, ulceration, and poorly defined margins. If a tumor lacks these clinical features, it should not be assumed to be benign as malignant mesenchymal tumors may appear demarcated when surrounded by compressed normal tissue (pseudocapsule). Through the use of cytology or histopathology, sampling of a mass is required for differentiation.

An open dialogue is paramount when faced with evidence of a malignancy. The general public often has unrealistic expectations regarding the diagnosis and treatment of cancer. It is important to discuss the likelihood of a malignancy versus other diseases, as some families may not have the emotional or financial wherewithal to proceed. Once a diagnosis is made, the anticipated biologic behavior will influence further diagnostics to identify to what extent the body is affected locally, regionally, and distantly. This process is termed staging.

Staging

Staging is necessary prior to treatment for accurate assessment of overall condition, prognosis, and treatment response. The following chapters will illustrate the predicted biologic behavior for specific malignancies. Clinical staging using the World Health Organization (WHO) classification system of tumor-node-metastasis (TNM) has been applied to many canine and feline tumor types. This classification has proven useful in the prognostication of many but not all malignancies. Clinical stage of specific tumor types will include the size of the primary tumor (T), the identification of spread to regional lymph nodes (N), and the presence of metastasis (M). The subsequent chapters will reveal the tumor types for which stage has been shown to be predictive for prognosis. A few examples are canine oral melanoma, apocrine gland anal sac adenocarcinoma, and lymphoma.

Grading

Grading of a tumor is based on the histopathologic features, in particular mitotic index, percent necrosis, invasiveness, nuclear size, overall cellularity, and the presence of inflammation. Grading has also been shown to be predictive for particular tumors. The search for advanced prognostic markers and predictive factors is currently focused on molecular processes such as altered cell cycle progression, cellular proliferation, programmed cell

death (apoptosis), and angiogenesis (generation of blood vessels). Identification and understanding of the altered molecular tumor processes will ultimately reveal reliable markers for diagnosis, and predict the clinical behavior, prognosis, and response to therapy.

Diagnostics

Primary assessment should include evaluation of tumor extent, by clinical examination and appropriate diagnostic imaging or endoscopic techniques. Baseline blood testing and urinalysis rarely lead to a cancer diagnosis but may reveal any co-morbidity, and so revise the decision-making process or prognosis. Species differences must be taken into consideration. A dog with HHM may have lymphoma or an apocrine gland anal sac adenocarcinoma. In contrast, the inciting cause of feline hypercalcemia is more likely a direct action of tumor-induced bone destruction as in multiple myeloma or a carcinoma invading bone rather than HHM which is the result of cytokine- or hormone-induced hypercalcemia. The baseline blood testing for felines should always include retroviral testing. Cats with lymphoma and feline leukemia virus will likely have half the anticipated survival time.

Imaging

Tumor imaging concentrates on assessing the essential morphologic features. Radiography, sonography, computed tomography (CT), and magnetic resonance imaging (MRI) are applied routinely to identify local tumor extent and patient staging. When faced with a choice of diagnostic testing, the sensitivity and specificity should be considered. For instance, clinical examination of a limping Rottweiler with localization of pain to the proximal humerus may suggest a less extensive bone tumor where radiography may be adequate. However, radiography is less sensitive than CT, which is less sensitive than MRI. Be mindful that unless the owner is interested in a limb-sparing procedure, a radiograph may offer enough evidence to proceed with tissue sampling or surgery. Of note is that regional accessible lymph node sampling should be performed when malignant masses are suspected. Sampling completes staging and may assist in establishing a diagnosis.

When a tumor is expected to metastasize through the circulatory system to the pulmonary parenchyma, three-view thoracic radiographs are recommended. In tumors likely to metastasize through lymphatics such as mast cell tumors and lymphoma, ventral-dorsal and right lateral views will often suffice. The importance of clinical staging may be unintentionally disregarded, especially when exploratory surgery uncovers a mass. Any suspicious lesion should be sampled through biopsy or fine needle aspiration (FNA). As mentioned previously, sampling of the regional lymph nodes should also be performed. Any instruments contaminated with tumor or intestinal contents should be discarded. Fresh tissue should be cultured if granulomatous disease is anticipated.

Advanced Diagnostics

Recent advancement in veterinary oncology has provided us with insight into disease processes and an evolution toward targeted treatments. Prognostic information regarding survival time and disease-free interval in canine osteosarcoma was identified through monitoring of serum alkaline phosphatase (ALP) and bone ALP. Diagnostic tests for specific tumors are available: PetScreen® test for lymphoma, CADET® BRAF, CADET® BRAF Plus and V-BTA™ (urine test for bladder tumor analytes/mutations) for bladder cancer diagnosis and monitoring. CADET® HM is a diagnostic test utilizing cytological preparations or formalin fixed parrafin embedded tissue to identify histiocytic diseases. Tests evaluating antibodies for thymidine kinase and serum levels of the protein lactate dehydrogenase can identify an ongoing malignant process. Once sufficient data are accrued, mainstream implementation such as screening, diagnostic, prognostic and as treatment management tools may become possible. Polymerase chain reaction (PCR) and flow cytometry have yielded prognostic information, and guided our treatment choices in lymphoreticular cancers and mast cell tumors. Please refer to these specific chapters for more detail.

Therapy

Curative techniques are treatments that are intended to induce remission of the cancer and may include various therapeutic options such as chemotherapy, surgical extirpation, radiation therapy, and immunotherapy, all with the goal of long-term tumor control. Definitive therapy will both accomplish tumor control and result in alleviation or elimination of pain, whereas palliative therapy is an important tool for control of oncologic pain and improved function, generally with minimal control over the tumor itself.

Ultimately, the treatment choice should be based on several factors that will be individual to each family: time available for hospital visits, feasibility of administering in-home medications, anticipated survival time with and without treatment, acceptable side-effect profile, emotional and financial wherewithal to tolerate treatment, and disease-related side-effects.

Chemotherapy

Fundamentally, local disease requires a treatment to be directed to a specific area, typically surgery or radiation therapy. Chemotherapy is often indispensable when presented with widely disseminated but chemoresponsive disease (lymphoma) or when the development of metastatic disease is highly anticipated (canine osteosarcoma). The application, administration, and response rates achievable through the use of chemotherapy are addressed in their respective chapters.

Treatment Advances

Recent treatment advances have provided the veterinarian with orally administered targeted treatments for mast cell tumors (Palladia™ and Kinavet-CA1®). TANOVEA®-CA1 (rabacfosadine) is the first FDA conditionally approved drug for the treatment of lymphoma in dogs. This drug is delivered intravenously and has been found to inhibit the proliferation of lymphoma cells in vivo. Interventional radiology utilizes fluoroscopy and endoscopy, placing expandable metallic stents in the urethra of dogs with neoplasia, resulting in increased urine flow with tumor obstruction or near-obstruction. Chemoembolization refers to the angiography guided administration of a vascular occluding substance and chemotherapy through a catheter into a pinpointed vessel within the tumor. This technique has shown promise for the treatment of unresectable liver tumors. Hematopoietic stem cell transplantation (HCT) is available for dogs with hematopoietic malignancies. Immunotherapy research collaboration has provided the first USDA-approved canine melanoma vaccine (Oncept®) indicated for aiding in extending survival of dogs with stage II or stage III oral canine melanoma. Other available conditionally licensed vaccines include; Canine Lymphoma Vaccine, a xenogeneic murine CD20 DNA therapeutic vaccine for use in dogs with B-cell lymphoma upon achieving remission through chemotherapy. Canine Osteosarcoma Vaccine for the treatment of dogs one year or older diagnosed with appendicular osteosarcoma. The vaccine is a lyophilized formulation of a modified-live,attenuated, recombinant HER2/neu–expressing strain of *Listeria* that activates cytotoxic T cells. Lastly for our felines, Feline Interleukin-2 (IL-2) Immunomodulator Vaccine may delay postsurgical recurrence of feline fibrosarcoma in adult cats with stage I disease.

We have also had advancements in treatment-related side-effects, with reports revealing protection from tissue necrosis associated with administration of dexrazoxane in patients with chemotherapy extravasation. Entyce®, capromorelin is an orally active small molecule that mimics the action of ghrelin, which causes growth hormone secretion and appetite stimulation. This has significant potential to treat inappetence related to chemotherapy and/or underlying cancer in dogs and possibly cats. Maropitant citrate (Cerenia®) offers an economical addition to the armament for the prevention and treatment of chemotherapy-induced nausea and vomiting. In an effort to avoid chemotherapy related toxicity primarily found in herding breeds an assay is available. These breeds have a higher risk of toxicity from chemotherapeutic agents that are actively transported by the p-glycoprotein pump (e.g., vinca alkaloids, doxorubicin, dactinomycin, taxanes). The assay is noninvasive, and is simply performed through either a blood sample or cheek swab. For more information visit www.vetmed.wsu.edu/depts-vcpl/.

Surgery

Surgical intervention is the backbone of localized cancer treatment and is often used adjunctively in metastatic cancers. Surgical oncology will be addressed in the respective chapters for which is applies.

Interestingly, perioperative anesthetic and analgesic practices, including administration of opioid analgesics and nonsteroidal antiinflammatory drugs (NSAIDs), use of local anesthetic techniques, precipitation of the neuroendocrine stress response, temperature regulation, and transfusion of blood products may influence long-term outcomes such as recurrence and metastasis.

Radiation Therapy

Radiation therapy (RT) utilizes the delivery of radiation from a distance. The delivery of radiation therapy in veterinary medicine is through the use of three machine types: orthovoltage (infrequently employed), cobalt-60 (widely used), and linear accelerators (most common). Pedestal machines are limited to up-and-down movement while isocentric machines rotate around the patient. The advantage permits treatment from a variety of angles. The prescribed radiation dose is expressed as tissue absorbed dose in units of gray (Gy). The total prescribed radiation is delivered in small defined doses called fractions. Radiation therapy is often employed when surgical resection of a tumor is limited by normal surrounding structures, and it is not possible to eliminate microscopic cells. In select cases when normal tissue structures preclude adequate surgical removal, radiation may be performed prior to surgery (preoperative). The majority of radiation therapy is performed 10–14 days postoperatively.

It is important that the radiation oncologist be aware of the original tumor site, including the dimensions and extent of invasion, so as to include all the affected tissue in the planned radiation field. When microscopic

residual disease is outside the treatment field, it is left untreated and recurrence is likely; this is referred to as a geographic miss. The risk increases with multiple surgeries by means of distortion of normal tissue structures. Placement of hemoclips (radiopaque clips) at the margins of the resected tissue benefits treatment planning, decreasing the likelihood of a geographic miss. The majority of radiation-induced adverse effects are often mild and self-limiting. Advanced imaging developments have enhanced our ability to delineate tumor tissue extent and have led to improved treatment outcomes and fewer patient side-effects.

Intensity-Modulated Radiation Therapy (IMRT)

The majority of radiation treatments in veterinary oncology are delivered with radiation beams of uniform intensity in a static field. Collimators are used to limit the treatment beam and provide a rectangular treatment field. Further development has led to the more complex multileaf collimator (MLC) which is made of many metal slats capable of independent movement to shape the field. IMRT has the ability to specifically modulate the weights of small segments within an individual radiation beam. This is referred to as intensity distribution, and allows the beam to conform to the three-dimensional shape of complex tumor target volumes. This technique of RT delivers a nonuniform fluence (beam intensity) to the patient, allowing optimization of dose distribution to the target volume while sparing critical tissues. The MLC uses the superimposition of many subfields that deliver the prescribed dose. The use of IMRT has permitted the radiation oncologist to treat tumors (nasal and prostate) that would otherwise be difficult to control without significant patient side-effects.

Stereotactic Radiation Therapy

Stereotactic radiosurgery (SRS) involves precision delivery of one or several high doses of radiation to the target (tumor) by means of a linear accelerator with a sophisticated treatment planning system, delivery, and positioning device (frame). The conformal nature of SRS permits avoidance of toxicity to normal surrounding tissues. The CyberKnife® Radiosurgery System delivers radiation through a manipulated robot-mounted linear accelerator. At present, SRS is primarily utilized in select canine osteosarcoma patients and veterinary patients with central and peripheral nervous system tumors. Stereotactic radiation therapy (SRT) involves precision delivery of one or several high doses of radiation therapy delivered to the target (tumor) by means of a linear accelerator with a sophisticated treatment planning system, delivery, and positioning device(s). Most linear accelerators are floor mounted and revolve 360 degrees around the patient. The conformal nature of SRT permits avoidance of toxicity to normal surrounding tissues. There are several terms under the umbrella term SRT. SRS (stereotactic radiosurgery) treats the CNS, brain and spine. Despite having surgery in the name, the procedure is noninvasive,and no surgery is involved. SBRT (stereotactic body radiation therapy) treats all other structures than the brain and spine. SRT is used to treat tumors that would otherwise be considered inoperable and classically it is not used to address microscopic disease. At present, SRT use in veterinary patients is expanding beyond the initially treated bone tumors, central and peripheral nervous system tumors.

Radiopharmaceuticals

Radiopharmaceuticals are radioactive substances used to image and/or treat particular cancers. One example is iodine-131, a frequently employed treatment of thyroid adenoma/carcinoma in the cat. Samarium-153 and related compounds have been used for treatment of multilobular osteochondrosarcoma, and osteosarcoma.

Palliative Medical Care

Metronomic Chemotherapy

Metronomic chemotherapy, which is intended to prevent tumor angiogenesis, is based on frequent, low-dose, continuous cytotoxic drug administration lacking the rest period included with conventional chemotherapy. It results in minimal toxicity, is often cost-effective, and convenient. In veterinary medicine, metronomic therapy has become an affiliate to many protocols and usually combines an orally administered cytotoxic chemotherapeutic agent with an NSAID. It is most frequently applied in the treatment of visceral hemangiosarcoma (HSA), transitional cell carcinoma of the urinary bladder, nasal tumors, and metastatic cancers.

Pain Management

It is often difficult for clients to recognize the signs of pain or discomfort in their pets. Unrelieved pain is a major cause of suffering in patients with cancer. Veterinarians managing cancer patients must be vigilant about monitoring for and providing relief from pain, whether caused by the neoplastic process itself or coincidental in nature. Providing adequate management of pain is central to oncologic care and will improve the quality of life of the animal patient.

Palliative Radiation Therapy

Palliative radiation therapy (PRT) is the administration of a radiotherapy dose in a smaller number of treatments (fractions) than would be used in the delivery of curative intent RT (CRT); however, the fraction dose is higher and less percise than SRT. The appeal of PRT lies in

improved quality of life through symptom relief and when compared to CRT, the cost incurred is minimal. The mechanism of radiation-induced pain amelioration is currently undefined. Reduction of inflammatory cells through irradiation inhibits the release of chemical pain mediators and is probably responsible for the rapid reduction in pain seen in some patients. Decreased activity of osteoclasts in the bone microenvironment reduces bone destruction and predicts the relief of pain through irradiation.

Most patients treated with PRT will not be afforded long-term survival. Symptom relief may last 1–3 months. The common early side-effects associated with RT are often easily ameliorated and patient tolerated. While uncommon, late reactions associated with PRT may be undesirable and life-threatening. Tumor reirradiation may be possible but continued treatment will increase the likelihood of deleterious late effects. Aside from the successful alleviation of discomfort in bone tumors, PRT may offer relief for a variety of tumor types especially in patients with tumor-induced pain and limited function.

Adjunctive Techniques

Complementary techniques including acupuncture, massage, and herbal remedies are being evaluated. The actual practice of acupuncture incorporates many forms, including dry needling, laser acupuncture, and electroacupuncture, and may incorporate acupressure or herbal medicine. Specific considerations for acupuncture in the presence of cancer include avoidance of insertion of needles into or near tumors, and attention to the risk of infection in patients who are immunocompromised.

End-of-Life Management

The hospice movement originated in the late 1960s when Dame Cicely Saunders established the first medical hospice that focused on palliative care of the whole patient in an attempt to control distressing symptomatology while also managing the psychosocial aspects of dying for the patient and the patient's family. These ideas are quite applicable to veterinary medicine. The American Veterinary Medical Association's established guidelines for hospice care are available at: www.avma.org/public/PetCare/Pages/hospice-care.aspx

Euthanasia is a valid therapeutic tool in the management of progressive and intractable pain or disease in veterinary patients but it is not one that is applied easily in most situations. Many owners have questions about timing and fear making the wrong decision. The veterinarian managing a terminal patient must be prepared to handle a wide range of physical, financial, and emotional issues. The grieving process is an individual experience, making it essential to be supportive, permitting clients to grieve in a manner we may not understand. Clients may also need encouragement to speak openly with children.

Veterinarians must perform many functions during the course of treatment and palliative care of the oncology patient:

- listening to the goals, fears, and contextual experience of the owners
- demonstrating awareness of the difficult nature of the situation; reflective listening and empathy can help build trust between the client and the veterinarian
- guiding the owners through the expected course of the disease and helping them define an appropriate quality of life for the patient
- providing a peaceful and dignified release from suffering through appropriate methods of euthanasia.

Veterinarians have an inordinate amount of pressure to provide for patients, especially those under protracted care. Attention should be given to the internal struggles that may ensue should compassion fatigue arise.

Biology of Cancer and Cancer Genetics

Mary-Keara Boss, DVM, PhD, DACVR (Radiation Oncology)

Colorado State University, Fort Collins, CO, USA

Veterinary patients develop cancer in all tissues of the body, and these neoplasms are characterized according to their cell type of origin: carcinoma – epithelial; sarcoma – mesenchymal; round cell tumor – typically of the hematopoietic system. Cells can transition from a normal phenotype to malignancy through acquisition of mutations of certain types of genes. Oncogenes are defined as those which code for proteins that allow dysregulated tumor cell growth and proliferation, while tumor suppressor genes, which normally restrain cell growth, allow cancer cells to grow and divide indefinitely when absent or inactivated by mutation. The abnormal characteristics and behaviors of cancerous cells and tissues share commonalities, such that the neoplastic transformations and progression pathways have been defined according to various hallmarks of cancer.

In their 2011 review, Hanahan and Weinberg revised and expanded upon their initially described hallmarks. The original six hallmarks are:

- enabling replicative immortality
- evading growth suppressors
- resisting cell death
- sustaining proliferative signaling
- inducing angiogenesis
- activating invasion and metastasis.

As new developments in cancer biology were discovered, emerging hallmarks that involve the complex tumor microenvironment were added:

- avoiding immune destruction
- deregulating cellular energetics and enabling characteristics crucial to the acquisition of the original hallmark capabilities
- genome instability and mutation
- tumor promoting inflammation.

This chapter on the biology of cancer and cancer genetics is organized in accordance with the hallmarks of cancer. Each section will review the cancer biology and genetics underlying the particular neoplastic characteristic being discussed, followed by examples of the relevance of the abnormality in clinical small animal oncology today. Topics were assigned to a particular hallmark, and although it is recognized that overlaps in content exist, this organization allowed a concise but in no way comprehensive account of how the biology and genetics of veterinary cancer may be conceptualized. Further, the hallmarks are organized in an order that allows the topics to progress from cellular to microenvironmental effects. Clinical aspects of each category will be highlighted; however, for more detailed discussions, see chapters devoted to specific tumor types.

Enabling Replicative Immortality

Cancer cells require the ability to replicate unlimitedly, uninhibited by normal space restrictions, to form a macroscopic tumor. Normal cells will progress through a tightly regulated, limited number of cell divisions; thereupon, they face either senescence, which is an irreversible, nonproliferative, viable state, or crisis (cell death). Cancer cells do not respect the bounds of senescence or crisis, and attain a state of immortality.

The classic *in vitro* demonstration of unlimited replication is the ability to continuously grow and passage tumor cells in cell culture in the laboratory setting. The development and maintenance of cancer cell lines *in vitro* have allowed for molecular characterization of specific tumor types and evaluation of therapeutic responses through experimental manipulations at the cellular level. Recent research utilizing veterinary cancer cell lines includes

Companion website: www.wiley.com/go/bruyette/clinical

studies of canine osteosarcoma, B cell lymphoma, mammary carcinoma, prostate carcinoma, and mast cell tumors, as well as feline vaccine-associated fibrosarcomas.

There are several fields of study devoted to understanding the uncontrolled nature of tumor cell replication. An underlying mechanism by which a cell regulates the number of divisions tolerable over time is through the integrity of chromosomal telomeres. Telomeres are specialized nucleoprotein complexes that "cap" and protect the end of every eukaryotic chromosome against chromosomal fusion, recombination, and terminal DNA degradation. Telomeres become progressively shorter with each doubling until they reach a critically short length and induce replicative senescence. The enzyme telomerase maintains telomeres by synthesizing and replenishing telomeric DNA. Cancer cells exploit this function by expressing telomerase and perpetually replace their telomeres. It is through this mechanism that most cancer cells gain replicative immortality. It has been shown in dogs that telomerase activity is upregulated in a majority of cancers and is absent in normal adult tissue. In fact, according to veterinary oncologic studies, telomerase is present in greater than 90% of canine cancers and is absent from most normal tissues, with the exception of germ cells. Further, it has been suggested that a different form of telomere maintenance, known as alternative lengthening of telomeres (ALT) via homologous recombination, may occur in canine osteosarcoma cells.

Important to the concept of replicative immortality, there has been great interest in studying cancer stem cells. The basis of the cancer stem cell model is that tumor development relies on a subset of stem cells that have the ability to self-renew and generate the diverse cells that comprise the tumor through differentiation. As such, the tumor exists as a heterogenous structure, maintained by cancer stem cells, which are inherently resistant to traditional chemotherapy and radiotherapy. Recently, cancer stem cells have been identified, isolated, and characterized from canine osteosarcoma cells *in vitro*.

Evading Growth Suppressors

The cell cycle is an organized balance of signals promoting and restricting replication and division; however, neoplastic cells exist with dysfunctional growth control mechanisms. The basic phases of the cell cycle have been defined as S phase (DNA synthesis), M phase (mitosis), and gaps, G_1 (between M and S), G_2 (between S and M), G_0 (senescence).

When cells are exposed to damaging agents, such as ionizing radiation or certain chemotherapy drugs, the therapeutic efficacy varies with respect to the phase of the cell cycle. For example, irradiated cells are most sensitive to the treatment during mitosis and most resistant when in the S phase. If treated in or prior to G_1 or G_2 phase, a temporary arrest or "block" in the cell cycle occurs. It is felt that the G_1 and G_2 blocks are necessary in order to repair damage done to fragile DNA prior to duplication of a faulty template or distribution of defective genes to a daughter cell in mitosis. These transient delays are also known as checkpoints. These checkpoints exist as safety mechanisms to limit the propagation of heritable errors and promote the survival of the cell. A well-known tumor suppressor protein, p53, plays a critical role in the G_1 checkpoint and controlling the fate of injured cells. It has been determined that a majority of cancers are affected with mutated p53, which allows cells that have been damaged to proceed through the cell cycle and replicate, creating daughter cells with flawed genetic content.

Chemotherapy drugs can be defined as cell cycle phase specific or cell cycle phase nonspecific. Examples of chemotherapeutics that are cell cycle phase specific include antimetabolites (i.e., gemcitabine, cytosine arabinoside, 5-fluorouracil), which are S phase specific, interfering with the incorporation of nucleotides during DNA synthesis, and vinca alkaloids (i.e., vincristine, vinblastine) which are M phase specific, as they disrupt the assembly of tubulin into microtubules and inhibit cell division.

Understanding these interactions, combination treatment plans, in which chemotherapy and radiation therapy are administered concurrently, can exploit the sensitive phases of the cell cycle, with the goal of improving therapeutic efficacy. A clinical illustration of this practice is the combination of gemcitabine, which kills cells specifically in S phase, with radiation therapy, where cells in S phase are the most resistant. The chemotherapy dose must be reduced with this approach to limit the severity of normal tissue toxicity; however, the combination has been reported for treatment of canine sinonasal carcinoma and feline oral squamous cell carcinoma.

Resisting Cell Death

Conventional cancer therapeutics may kill cells by inducing a lethal, cellular division, known as mitotic catastrophe, or triggering an organized, controlled cell death, known as apoptosis.

Playing a dual role, the p53 tumor suppressor gene, which was described in the previous section as controlling the G_1 checkpoint in managing the cell cycle, is also critical in activating the apoptotic response following cellular damage. As it is very common for malignancies to exist with mutant p53, cancer cells are adept at avoiding death by apoptosis. For example, the incidence of p53 mutations in canine osteosarcoma varies from 24% to 47%.

An alternative mechanism of resisting cell death by cancer cells is through manipulating antiapoptotic pathways. These antiapoptotic pathways are intended to maintain the natural homeostasis of cellular proliferation and deletion within tissues. Widely studied inhibitors of apoptosis include members of the Bcl-2 family and survivin. The distribution of Bcl-2 protein in normal and neoplastic feline tissues has been studied, as well as the expression of survivin in canine urinary bladder transitional cell carcinoma.

In general, mitotic catastrophe is the primary method of cellular killing by radiation exposure and a significant component of cell death by certain chemotherapy agents. A major mode of action of chemotherapy-induced death is the activation of apoptosis. To provide a clinical example, a class of drugs incorporated in cancer therapy protocols which induces apoptosis in a specific cellular population are the bisphosphonates. Bisphosphonate drugs used in veterinary oncology include pamidronate and zoledronate, and these are prescribed for patients that have developed malignancies which involve the destruction of bone. Bone undergoes constant turnover. Homeostasis of the tissue is maintained by the activity of osteoblasts, which create bone, and osteoclasts, which destroy bone. Bisphosphonates inhibit the destruction of bone by reducing osteoclast activities and stimulating these cells to undergo apoptosis. The therapeutic effect of osteoclast inhibition is to slow the malignant destruction of the affected bone, which results in alleviation of pain and improvement of quality of life. Recent examples of clinical research utilizing bisphosphonate drugs for the treatment of veterinary cancer patients include the use of pamidronate in the management of canine appendicular osteosarcoma and zoledronate for treatment of oral squamous cell carcinoma in cats.

Genome Instability and Mutation

In an established neoplasm, mutations have evolved to circumvent effective cell cycle checkpoints and DNA repair mechanisms. This allows the tumor to reproduce in a state of genetic instability, further driving an aggressive phenotype. In veterinary oncology, such genetic instability has recently been studied in canine mammary tumors, where variable rates of microsatellite sequence aberrations were documented among the mammary cancer samples.

A given population of tumor cells is heterogenous by nature, with variable distributions of genetic mutations and phenotypic manifestations of these abnormalities. Genetic and pathologic evaluations of tumors with the same clinical diagnosis exhibit intertumoral heterogeneity due to multiple mutations in oncogenes and tumor suppressor genes, varying environmental conditions, and inherited germline variations. The combination of these factors leads to immense natural heterogeneity in tumor phenotypes, disease outcomes, and response to therapies. The development of new molecular biological tools has expanded the understanding of genetics and the pathophysiology of tumorigenesis.

Gene expression profiling with the use of microarray technology has greatly improved our ability to classify tumors by generating unique molecular fingerprints that have delineated tumor subtypes. DNA microarray technology allows the study of gene activity and gene function at the genome level as a means to analyze the molecular phenotypes and clinical heterogeneity of tumors. The emergence of genome sequences for a variety of veterinary species has allowed for the development of new microarray-based technologies that facilitate whole genome, or gene-targeted, profiling to be performed at a considerably higher resolution and throughput.

The use of microarray-based technology in the veterinary field has become more prevalent. Recently, the utility of gene expression analysis using a cDNA microarray to differentiate metastatic and nonmetastatic soft tissue sarcomas in dogs was investigated. Further, microarray technology was used to characterize the gene expression profile of tumors in a population of dogs with soft tissue sarcomas being treated with radiation therapy and hyperthermia to predict therapeutic response. Comparisons were made between the gene changes that occurred, tumor volume, and functional MRI parameters. Significant correlations were identified between tumor responses and genes involved in telomerase activity, DNA repair, inflammation, and growth factor signaling. In this cohort of canine sarcomas, the gene expression of tumors was affected significantly, but not uniformly, by the combination of radiation and hyperthermia.

Tumor Promoting Inflammation

While it is important to understand the cellular characteristics of a tumor, we must consider that the cells exist in a complex microenvironment. Tumor cells are intimately associated with supporting stromal cells, immune cells, and microvasculature. Solid tumors exist in a state of active inflammation, and conventional cancer therapy can both promote and reduce inflammation. Tumor tissue reacts as a unit to therapeutic interventions; however, responses to treatments are not limited to the neoplasm. There are unique localized and systemic responses to chemotherapy, radiation therapy, and other

treatments that can result in transient or chronic effects. Clinical examples of local and systemic inflammatory reactions to oncologic treatments in veterinary medicine would include localized oral mucositis within the radiation field and generalized intestinal inflammation with certain chemotherapeutic agents, respectively.

The association between chronic inflammation and neoplasia is well established. Some recent interesting examples of chronic inflammatory lesions that progress to cancer in veterinary medicine include biliary tract trematode infection leading to cholangiocarcinoma in cats, superficial corneal squamous cell carcinoma occurring in dogs with chronic keratitis, and traumatic or surgical fracture-associated osteosarcoma development in dogs.

A nonspecific and complex host response to inflammation that has been investigated for its potential use as a prognostic and monitoring tool is the formation of acute phase proteins (APP). APPs are induced by proinflammatory cytokines, and tumor cells produce large amounts of transforming growth factor beta, cytokines including interleukins 6 and 10, and prostaglandin E2. Veterinary studies evaluating the use of APPs include trials with canine and feline lymphoma, canine mammary carcinoma, mast cell tumors, soft tissue sarcoma, and combinations of tumor-bearing dogs and cats.

A targeted approach to inhibiting the inflammatory component of cancer that is commonly used in veterinary oncology is the use of cyclooxygenase (COX) inhibitors, specifically those that inhibit the enzyme COX-2. Overexpression of COX-2 in tumors drives many cancer-associated mechanisms and COX-2 inhibitors are prescribed to prevent or reduce the neoplastic proinflammatory state. The effects of the COX-inhibitor piroxicam have been evaluated in the treatment of canine urinary bladder transitional cell carcinoma, as well as canine oral malignant melanoma, inflammatory mammary carcinoma, prostatic carcinoma, and oral squamous cell carcinoma.

Avoiding Immune Destruction

Cancer develops in the host through deception of the immune system. The roles of the immune cells are defined by their involvement in either innate or adaptive immunity. Cells of the innate pathway include phagocytic, antigen-presenting cells (APC), such as macrophages and dendritic cells, and those of the adaptive pathway consisting of cells with randomly generated antigen receptors, like B and T lymphocytes. Generally, APCs are activated by immunogenic stimuli, migrate to lymphoid organs to present antigen to T cells, and stimulate the adaptive immune response.

The function of effector T cells and APCs can be disrupted by a T lymphocyte type, known as regulatory T cell (Treg). Treg cells are important for immune tolerance through downregulation of self-reactive lymphocytes; however, suppression of antitumor immune responses by Tregs can promote tumor progression and development. Large populations of Tregs have been shown to be present in various human cancers and to correlate with poor prognosis. The involvement of Tregs in veterinary oncology has been investigated in a number of different canine tumor types. In these studies, the numbers of Treg cells in the peripheral blood and tumor-draining lymph nodes were increased in dogs with cancer compared to healthy dogs. Further, Treg cell infiltration was statistically correlated with high histologic grade in canine mammary carcinoma.

Many therapeutic approaches have been developed that utilize the immune system to target and treat cancer, and these techniques have been explored in veterinary oncology. Nonspecific tumor immunotherapies, including biologic response modifiers, such as bacterial strains, oncolytic viruses, and recombinant cytokines, growth factors, and hormones, have been used to treat several veterinary malignancies. Also, specific targeted immunotherapies, such as cancer vaccines, where the immune system detects tumors through tumor-associated antigens, have been utilized for veterinary patients. Clinical examples of veterinary cancer vaccines include the xenogeneic DNA vaccine for canine melanoma and the autologous tumor RNA-loaded, activated B cell vaccine for canine lymphoma.

Inducing Angiogenesis

Tumor vasculature is unique and abnormal. In order for a developing solid tumor to grow into a macroscopic mass, it must induce the surrounding normal tissue to either share its oxygen and nutrient supply or create its own vascular network. The processes by which a tumor forms new blood vessels, known as vasculogenesis, and/or remodels existing vasculature, known as angiogenesis, involve highly integrated signaling and communication between cells of the microenvironment. Tumors stimulate persistent angiogenesis through expression of many factors, one of the most important being the family of vascular endothelial growth factor (VEGF) proteins.

Vascular endothelial growth factor is a growth factor and its signal is transmitted through the tyrosine kinase activity of transmembrane VEGF receptors. Most cancer cells and certain tumor stromal cells express VEGF, and stimulation of VEGF leads to endothelial cell proliferation, migration, and survival. In veterinary oncology, VEGF expression has been recognized as a negative

prognostic marker for a number of tumors, such as canine intracranial meningiomas, osteosarcoma, lymphoma, oral malignant melanoma, and feline invasive mammary carcinoma.

Abnormal tumor vessel morphology includes aberrant architecture and function of blood vessels which often leads to low oxygenation within the tumor, known as intratumoral hypoxia. Tumor hypoxia may stimulate angiogenesis through expression of the transcription factor hypoxia inducible factor-1 (HIF-1). HIF-1 induces several proangiogenic factors such as VEGF. Hypoxic regions within tumors are a significant issue in radiation therapy because hypoxic cells are more resistant than oxygenated cells to treatment. Hypoxic cells are also more resistant to chemotherapy as hypoxic cells are farther from the vasculature and may not be exposed to lethal drug concentrations. Importantly, hypoxia may increase the biologic aggressiveness of a tumor by HIF-1 activation of several neoplastic pathways.

Targeted therapeutic approaches have been developed recently which are intended to disrupt tumor angiogenesis. The use of continuous, low-dose chemotherapy is commonly referred to as "metronomic chemotherapy." Three aspects of angiogenesis that are affected by metronomic chemotherapy are direct cytotoxic effects on the endothelial cells of the tumor blood vessels indirect effect of tipping the influence from proangiogeneic growth factors to inhibitors, thus preventing further vessel expansion, and reducing the recruitment of bone marrow-derived endothelial progenitor cells. The efficacy of metronomic chemotherapy protocols has been studied in veterinary oncology through clinical trials with canine patients treated for splenic hemangiosarcoma and soft tissue sarcoma with the drug combination of cyclophosphamide and piroxicam.

Sustaining Proliferative Signaling

In normal tissues, growth factors regulate cellular proliferation and differentiation. Cancer cells, however, develop a reduced requirement for exogenous growth factors as they become capable of autonomous activation of autocrine and paracrine growth pathways. As the goals for cancer therapy include tumor regression and eradication, this aberrant proliferation must be inhibited to prevent resistance and recurrence.

Some of the key proteins regulating cell survival and proliferation are the transmembrane epidermal growth factor receptor (EGFR) and ligand epidermal growth factor (EGF). EGFR is overexpressed in many tumor types and is associated with aggressiveness and resistance to therapies. EGFR and EGF have been studied in veterinary medicine as potential prognostic indicators and possible therapeutic targets in canine mammary cancer, glial brain tumors, nasal carcinomas, and feline oral squamous cell carcinoma.

Epidermal growth factor receptor belongs to a group of proteins that form the receptor tyrosine kinase (RTK) superfamily. Tyrosine kinases are transmembrane receptors that regulate normal cell signal transduction and maintain cell growth and differentiation. Additional examples of receptor tyrosine kinases include Kit, Met, VEGFR, PDGFR, and FGFR. RTKs are commonly abnormally activated and dysregulated in human and veterinary cancer. For instance, Kit is a receptor found on mast cells, and mutations to Kit in canine mast cell tumors (MCTs) have been shown to drive unregulated proliferative signaling. Up to 30% of all canine MCTs are affected with Kit mutations, and these have been shown to be significantly associated with tumor grade, as the more malignant tumors are more likely to have abnormal Kit receptors. Further, canine gastrointestinal stromal tumors (GIST) have also been characterized as carrying Kit mutations.

Recently, a variety of small molecule inhibitors that target tyrosine kinases, known as tyrosine kinase inhibitors (TKIs), have been approved for the treatment of human cancer. The use of these inhibitors has resulted in significant clinical efficacy, being used as sole therapeutics or in combination therapy protocols. Importantly, TKIs have now been incorporated into veterinary oncology care. Examples of these drugs include Palladia™ (toceranib), and Gleevec® (imatinib). Gleevec has been used to treat cancers in dogs and cats, and Palladia has undergone registrational studies in dogs with MCTs. The molecular targets inhibited by these drugs consist of Kit, VEGF, and PDGFR and they have been used to treat MCTs and sarcomas in dogs and cats, as well as carcinomas, melanoma, and myeloma in dogs.

Deregulating Cellular Energetics

It has been discussed with the preceding hallmarks that tumors adapt and proliferate despite harsh conditions of inflammatory stress and disorganized, ineffective microcirculation. The tumor microenvironment is not only characterized by varying degrees of hypoxia, but also nutrient deprivation and low extracellular pH. The unusual metabolism of cancer cells is intimately involved in creating such an abnormal physiologic state.

Normal tissues are able to sustain routine cellular functions through the oxidation of nutrients to provide energy in the form of adenosine triphosphate (ATP). Glucose metabolism is regulated in response to changes in cellular oxygen levels. Initially, glucose is converted to

pyruvate by glycolytic enzymes. Under well-oxygenated conditions, pyruvate is oxidized in the tricarboxylic acid cycle to form water and a substantial amount of ATP (oxidative phosphorylation); however, under hypoxic conditions, lactate dehydrogenase A converts pyruvate to lactate and generates very little ATP (glycolysis).

It has been shown that glycolysis, under aerobic conditions, is particularly high in aggressive tumors when compared with benign tumors and normal tissues. This discovery of tumor-specific, oxygen-independent glycolysis was labeled the Warburg effect. This peculiar metabolic preference of tumor cells drives a significantly inefficient breakdown of glucose for ATP and creates an acidic microenvironment through the build-up of the byproduct lactic acid.

The increased dependence of cancer cells on the glycolytic pathway provides a biochemical basis for the functional imaging technique positron emission tomography (PET). PET imaging has become increasingly invaluable in human and veterinary oncology. Using the glucose analog fluorine-18-fluorodeoxyglucose (^{18}FDG), the detection of glucose metabolism with PET is associated with the presence of malignant tissue before anatomic evidence occurs. While traditional methods for determining response to therapy in veterinary oncology centers on anatomic changes in measurable target lesions, ^{18}FDG-PET combined with a CT scan can be used as a sensitive marker of tumor response to anticancer therapies via interrogation of cellular glucose metabolism.

Positron emission tomography plays an important role in the diagnosis, staging, image-guided treatment planning, and monitoring of malignant diseases. A recent preliminary study described the use of serial ^{18}FDG-PET/CT to assess the response to toceranib therapy in canine cancer. Multiple types of canine tumors have been evaluated for their avidity for FDG, including mast cell tumor, lymphoma, mammary carcinoma, and hemangiosarcoma. FDG-PET has identified the involvement of metastatic sites not detected on physical examination and has been reported to provide more accurate disease detection for improved diagnosis, staging, and restaging with treatment of companion animals with cancer.

Activating Invasion and Metastasis

The final hallmark to be reviewed is invasion and metastasis, the processes of which are incredibly convoluted and intricate. The properties required to attain the phenotype of an invasive and metastatic neoplasm involve the multistep, coordinated foundation of the previously discussed hallmarks.

Experimental molecular oncology studies suggest that the progression of a solid tumor to a metastatic phenotype is not simply the result of dysregulated signal transduction pathways, but instead is achieved through a stepwise selection process. The adaptation of populations of neoplastic cells to their harsh microenvironment facilitates cancer cell dissemination through the up- or downregulation of critical metastasis-associated genes, such as E-/N-cadherin for epithelial-mesenchymal transition (EMT), uPAR for degradation of the basement membrane and extracellular matrix, HGF/MET for cell motility, and VEGF for stromal interactions, intra/extravasation, and angiogenesis. The systematic alteration of these phenotypic regulators allows cells to escape the hostile microenvironment of the primary tumor and colonize a secondary location.

The role of E-cadherin in metastasis of veterinary cancer has been investigated. E-cadherin is a transmembrane glycoprotein involved in cell-to-cell adhesions of two adjacent cells and is typically expressed by epithelial cells. Metastatic epithelial malignancies are associated with loss of E-cadherin expression and connectivity with their neighboring cells; this leads to EMT, where epithelial tumor cells obtain mesenchymal characteristics, as well as invasive and metastatic properties. In veterinary medicine, studies that have investigated E-cadherin expression have evaluated canine mammary carcinoma and anal sac gland adenocarcinoma for associations with clinical malignancy.

Dissemination of primary tumor cells to a secondary location may result in colonization of any number of anatomic locations. One of the most common metastatic sites is the first regional lymph node or nodes to which the lymphatics from the primary tumor drain; therefore, the disease status of what is known as this sentinel lymph node (SNL) is important in cancer screening. Lymphoscintigraphy, the injection of a radioactive tracer at the tumor site to identify lymphatic drainage, and intratumoral/peritumoral blue dye injection have been used to locate SNLs in veterinary oncology. The SNL can then be evaluated via histopathology for the presence of metastatic disease. In veterinary practice, lymph nodes are generally aspirated or biopsied if palpably enlarged; however, since metastases occur in lymph nodes of normal clinical appearance and in lymph nodes other than those routinely assessed according to the anatomic location of the primary tumor, this advanced technique for metastasis identification has been recommended. Reports describing SNL identification in veterinary medicine include studies investigating canine head and neck tumors and mammary carcinoma.

Conclusion

Hanahan and Weinberg's hallmarks of cancer provides an incredibly useful conceptual framework for understanding the complex biology of cancer, and it is evident that intimate associations link each. The categorical focus of these cancer principles allows the specialized refinement of molecular mechanisms; however, the appreciation that each hallmark operates as part of a greater circuit will promote discoveries that further advance the study of veterinary cancer and clinical oncology. The advancements made by veterinary researchers and clinician scientists featured in this chapter have contributed to a greater understanding of translational oncologic concepts between human and companion animal cancer patients.

Endocrine Manifestations of Cancer

Ectopic Hormone Production

Cory Brown, DVM, DACVIM (SAIM)

VetScan Mobile Diagnostics, Powell, OH, USA

Ectopic hormone production of endocrine origin from nonendocrine tumors is a particular type of paraneoplastic syndrome. Some of the more common manifestations, such as hypoglycemia and hypercalcemia, are covered in Chapter 132. Those more particular to the endocrine system are covered in this chapter.

Cushing Syndrome

Etiology/Pathophysiology

Corticotropin (also known as adrenocorticotropic hormone – ACTH) is produced by the anterior pituitary and stimulates cortisol production by the adrenal cortex. Corticotropin has been demonstrated to be produced by a variety of tumors in human medicine, resulting in a Cushing-like syndrome. Although primarily reported with small cell lung carcinoma, other tumor types include carcinoid tumors of the thymus, gastrointestinal tract, thyroid, pancreas, and adrenal medulla. Ectopic production of corticotropin is not well described in veterinary medicine, although sporadic case reports exist. It is theorized by some that ectopic corticotropin production is underestimated in animals due to diagnostic limitations. Routine pituitary imaging is not typically pursued in dogs diagnosed with Cushing disease. Therefore, dogs with ectopic production of the hormone may be assumed to be pituitary dependent and treated accordingly. Based on this assumption, ectopic corticotropin production may be more prevalent than is currently reported in the veterinary literature.

Diagnosis and Treatment

At a minimum, ectopic corticotropin production should be considered in dogs with neoplastic disorders that show concurrent symptoms of hyperadrenocorticism. The diagnosis of ectopic ACTH production is based on hormonal evidence of pituitary-dependent hyperadrenocorticism (PDH), normal to high endogenous ACTH levels, and normal pituitary imaging. Therapy for ectopic corticotropin production has not been well defined in animals, although treatment of the primary tumor should be attempted. Treatment with trilostane, an adrenal enzyme blocker, resulted in adequate resolution of symptoms in one dog.

Recently, production of sex hormone steroid precursors from adrenal cortical tumors has been identified as a source of Cushing symptoms. These animals may demonstrate typical signs of Cushing disease, including polyuria/polydipsia, polyphagia, weight gain, potbellied appearance, thin skin, and alopecia. Despite the clinical findings consistent with hyperadrenocorticism, these animals test negative for hyperadrenocorticism by conventional screening methods (ACTH stimulation, low-dose dexamethasone suppression test). However, an assay for particular cortisol precursors (such as progesterone and 17-OH-progesterone) may reveal elevated concentrations. Although this condition is classically related to the presence of an adrenal cortical tumor, cortisol precursors may be noted with pituitary-dependent disease as well. This is considered eutopic hormone production as opposed to ectopic, as the hormone produced by the tumor is a product of the tumor itself. However, as the particular hormone being produced is atypical for expected forms of hyperadrenocorticism, it is worthy of mention.

In the presence of a cortical tumor, surgical excision is generally recommended if presurgical staging allows. Abdominal ultrasonography is particularly useful to identify a tumor, local vascular invasion, and metastases. Approximately 50% of adrenal cortical tumors are malignant, and presurgical screening may identify local vascular invasion, metastatic disease to distant organs (particularly the liver), and irregularity of the affected

Companion website: www.wiley.com/go/bruyette/clinical

gland. If surgery cannot be performed, clinical symptoms may be managed with trilostane (Vetoryl®) or op-DDD (Lysodren®). Trilostane is a competitive inhibitor of 3-beta-hydroxysteroid dehydrogenase, thereby reducing cortisol synthesis from the adrenal gland. The inhibition of steroid production is rapidly reversible and dose dependent. Effects on cortisol production will wane within 10–20 hours after cessation of the drug. Lysodren is directly cytotoxic to the cells of the zona fasciculata and zona reticularis of the adrenal cortex. As approximately 50% of cortical adrenal tumors are malignant, op-DDD is the theoretical medical therapy of choice though studies evaluating survival and disease-free interval of dogs with adrenocortical carcinoma treated with trilostane vs op-DDD are lacking.

Management of symptoms may be made easier by the use of trilostane, as the side-effects are generally found to be less severe. Lysodren may be difficult to administer in a clinically ill animal, as it causes nonselective adrenal cortical necrosis and could result in a relative hypoadrenocortical state. This could be difficult to manage in the ill patient due to the length of time needed to recover from excessive adrenal gland destruction. Trilostane, however, will have no effect on delaying the progression of metastatic disease.

Therefore, in the case of nonsurgical metastatic disease, Lysodren may be more effective at prolonging survival due to the cytotoxic effects on metastatic tissue. Trilostane has been used successfully to control clinical symptoms of Cushing disease caused by an adrenal tumor in the absence of metastases. The use of trilostane or op-DDD for the medical management of an adrenal tumor should be carefully considered by the clinician if surgery is not feasible.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Etiology/Pathophysiology

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is commonly discussed but rarely diagnosed in the small animal patient. Much more common in human medicine, SIADH is frequently diagnosed in patients with pulmonary cancer (oat cell carcinoma). Excessive production of ADH by the tumor cells results in inappropriate free water retention. This leads to one of the hallmark signs of the disorder, hyponatremia. Due to excessive volume expansion, many elements within the blood may undergo dilutional effects, such as urea nitrogen and potassium. Serum osmolality is also low, but urine osmolality may be higher than that of serum as free water is being retained by the kidneys.

Diagnosis and Treatment

The finding of a urine osmolality higher than that of serum in the face of hyponatremia is suggestive of SIADH. Careful water restriction will improve clinical symptoms while the cause is elucidated. Water restriction must be monitored closely to avoid rapid fluctuations in serum sodium concentrations. SIADH has been described rarely with tumors in dogs (such as salivary carcinoma). This condition is more common with systemic diseases, such as cholangiohepatitis, congenital hydrocephalus, and meningitis. Therefore, water restriction could lead to dehydration if the patient is clinically ill. With chronic hyponatremia, the serum sodium concentrations should not increase at a rate greater than 0.5 mEq/L/h or 8–10 mEq/day to avoid cerebral fluid shifts. Due to the paucity of reports of this disease in the veterinary literature, the prognosis is unpredictable and dependent on the underlying condition.

Erythrocytosis

Etiology/Pathophysiology

Erythrocytosis is defined as an increase in red blood cell parameters (hematocrit, red blood cell count, hemoglobin). It may also be referred to as polycythemia. This condition may be classified as relative or absolute.

A relative polycythemia is an apparent increase in red blood cell mass that is actually due to a decrease in plasma volume. This is commonly noted with dehydration and may be treated with fluid therapy to offset the reduction in plasma volume. A relative polycythemia would be expected to be associated with normal (or low) erythropoietin levels.

An absolute polycythemia may be subclassified as primary or secondary. Primary polycythemia is independent of erythropoietin influence and arises from progenitor cells within the bone marrow. The expanded red blood cell mass appears morphologically normal, and bone marrow aspiration suggests erythroid hyperplasia. Primary polycythemia is classified as a myeloproliferative disease, and is often referred to as polycythemia vera. It may rarely progress to leukemia.

An absolute polycythemia that is classified as secondary is dependent on erythropoietin influence. This may be an appropriate response, as seen with altitude changes, right-to-left cardiac shunting disorders and hereditary methemoglobin reductase deficiency. An inappropriate polycythemic response may be seen with certain tumors, especially of the kidney.

These tumors may produce erythropoietin ectopically, resulting in a paraneoplastic syndrome of erythrocytosis. Several other mechanisms have been proposed to

explain the rise in hematocrit, including decreased metabolism of erythropoietin and production of erythropoietin-stimulating hormones. Renal hypoxia due to thrombosis or tumor mass may also play a role. This condition is rarely reported with other tumors, but has been described in a dog with cecal leiomyosarcoma.

Diagnosis and Treatment

Erythrocytosis may be approached first by physical examination to assess hydration status, cardiac auscultation, abdominal palpation to screen for abdominal masses, and complete blood count (CBC)/serum chemistry. If the examination and bloodwork suggest dehydration, a fluid therapy trial should result in resolution of the polycythemia. If dehydration is not present, or if fluid therapy does not result in resolution, an absolute polycythemia is present.

In the absence of obvious causes of a secondary absolute polycythemia (including appropriate responses such as right-to-left shunting disorders and altitude changes), evaluation of serum erythropoietin levels will help to differentiate erythrocytosis secondary to a renal (or other) tumor from polycythemia vera (absolute primary polycythemia). In the latter condition, the erythrocytosis is independent of erythropoietin, and erythropoietin levels may be low to normal. The diagnosis of primary erythrocytosis (polycythemia vera) is often performed by ruling out all other causes of secondary absolute polycythemia, as erythropoietin measurements are not often available and the assay is not species specific. Bone marrow evaluation should be considered if an absolute primary erythrocytosis is suspected to rule out marrow neoplasia.

Erythrocytosis secondary to production of erythropoietin from a renal tumor or other neoplasm will demonstrate marked elevations of serum erythropoietin levels. Abdominal radiology or, preferably, ultrasonography will help to detect a neoplasm of the gastrointestinal tract or renal system. Treatment for an absolute erythrocytosis that arises as a manifestation of cancer involves identifying and removing the causative neoplasm (i.e., renal tumor, cecal tumor, etc.). Removal of the tumor will result in resolution of the polycythemia. Phlebotomy may be necessary prior to surgery to relieve symptoms of hyperviscosity and reduce risk for a vascular accident. No more than 20 mL/kg of blood or 25% of blood volume should be removed at a time. A more exact volume to be removed may be calculated by the following formula:

$$\begin{aligned}&\text{Blood to be removed}\,(\text{mL})\\&=\text{body weight}\,(\text{kg})\times\text{blood volume}\,(\text{mL/kg})\\&\times\frac{\text{actual PCV}-\text{desired PCV}}{\text{actual PCV}}\end{aligned}$$

where PCV is packed cell volume. Blood volume for dogs and cats is considered to be 90 and 70 mL/kg respectively.

If tumor removal is not feasible, periodic phlebotomy may control signs of hyperviscosity. In the case of renal tumors, surgical removal alone affects survival, and without surgical intervention the prognosis is poor. In one study evaluating surgical intervention, median survival for dogs with renal carcinoma was 16 months (range 0–59 months), for dogs with sarcomas nine months (range 0–70 months), and for dogs with nephroblastoma six months (range 0–6 months). In the same study, dogs that did not undergo surgery had a median survival of <1 month (range 0–32 months). Additionally, removal of a renal tumor results in resolution of the paraneoplastic polycythemia. For a dog with a reported cecal leiomyosarcoma, phlebotomy helped control clinical symptoms for over two years. It is important to note that fluid replacement is not generally recommended post phlebotomy. In the presence of right-to-left cardiac shunting disorders, volume replacement may be poorly tolerated by the cardiovascular system. In the presence of polycythemia vera, the animal is volume replete prior to phlebotomy.

Treatment for primary polycythemia or absolute secondary polycythemia related to an uncorrectable cause (such as a right-to-left shunt) involves a combination of phlebotomy and hydroxyurea, covered elsewhere.

Zollinger–Ellison Syndrome

Etiology/Pathophysiology

Secretion of excessive gastrin by neoplastic delta cells of the pancreas has been described (gastrinoma). Gastrin is also produced by G cells of the gastric antrum and duodenum, and continued secretion results in hyperacidity. Clinical symptoms are related to excessive production of gastric acid from the continued stimulation of gastric parietal cells. The findings of melena with a microcytic, hypochromic anemia should lead to suspicion for gastrointestinal hemorrhage. This may be accompanied by weight loss, anorexia, and/or vomiting. Dogs may present late in the course of disease, and as such cancer cachexia may be present. Additionally, gastric ulceration may be severe and may predispose to gastric perforation. Endoscopic evaluation of the stomach may reveal an ulcer, which typically is located along the lesser curvature. Although gastrinomas tend to be slow growing, approximately 85% demonstrate metastasis at the time of diagnosis.

Diagnosis

Diagnosis of a gastrinoma can be challenging. Serum gastrin levels may be evaluated, and samples should be

obtained prior to administration of gastroprotectants. Antacids such as famotidine, ranitidine, and omeprazole will artifactually raise serum gastrin levels. Abdominal ultrasonography may identify a pancreatic mass, but as is the case with insulinomas, gastrinomas are often too small to detect. Ultrasonography can be useful to screen for metastatic disease, due to the relatively high rate of metastasis with this tumor. Radioactive scanning with pentetreotide may be useful but has limited availability. Surgical exploration with or without abdominal CT may be necessary if presurgical screening does not identify a mass or obvious metastatic disease. Histopathology is required for an accurate diagnosis.

Treatment

Medical therapy alone may be employed if a patient is a poor surgical candidate. Aggressive antacid therapy is indicated. Often, the author will combine a proton pump inhibitor (such as omeprazole) with an H2 blocker (such as famotidine). In addition, sucralfate may be administered with antacids, preferably 30 minutes to an hour apart. Sucralfate should be administered first, as it reacts with hydrochloric acid to create a protective complex. Administration of an antacid prior to sucralfate may reduce its efficacy.

Motility modifiers may be necessary to control reflux and vomiting. Metoclopramide should be used with caution if a stomach ulcer is present, as it may enhance the potential for perforation. Centrally acting antiemetics, such as ondansetron or maropitant, are preferred. Finally, streptozocin has been advocated as adjunctive chemotherapy to surgical intervention, but should be used with caution due to its toxicity. The prognosis with gastrinoma is typically guarded. Paraneoplastic effects, such as gastric perforation and peritonitis, adversely affect prognosis. However, with aggressive treatment, including surgery, survival times have ranged from 4.5 to 18 months.

These above conditions are particular to ectopic hormone production resulting in endocrine manifestations. Further paraneoplastic syndromes are described elsewhere in this text.

Paraneoplastic Syndromes

Cory Brown, DVM, DACVIM (SAIM)

VetScan Mobile Diagnostics, Powell, OH, USA

Many tumors produce effects on the body that are not related to direct invasion or compression. These effects have become widely recognized as paraneoplastic syndromes. Recognition and treatment of these conditions may allow early detection of occult neoplasia, reduction of morbidity, and prolonged survival. The effects of paraneoplastic syndromes are due to the production and excretion of peptides and hormones as well as immune cross-reaction between tumor and normal cells. This chapter describes the most commonly recognized paraneoplastic syndromes and their treatment. It is important to recognize that the most effective treatment for all paraneoplastic syndromes is removal of the underlying tumor.

Hypercalcemia

Etiology/Pathophysiology

Hypercalcemia remains one of the most commonly encountered paraneoplastic syndromes in the dog and cat. Commonly termed "humoral hypercalcemia of malignancy," this condition must be differentiated from other common causes of hypercalcemia. Although it is often noted with lymphoma (particularly mediastinal lymphoma), multiple myeloma and anal sac adenocarcinoma, it may be observed with a variety of tumors. The most common mechanism resulting in hypercalcemia is release of a peptide by the tumor cells closely resembling parathyroid hormone (PTH), called parathyroid hormone-related protein (PTH-rp). PTH-rp mimics the activity of PTH by binding to PTH receptors within the renal tubule and bone. This leads to decreased calcium excretion from the kidney and increased bone resorption. Other factors involved in hypercalcemia not related to humoral hypercalcemia of malignancy include direct bone invasion resulting in increased osteolysis and production of osteoclast-activating factor by tumor cells.

Diagnosis

Initial investigation should include a thorough physical and rectal examination. Further diagnostic evaluation should include thoracic radiographs and abdominal radiographs or ultrasonography. Ultrasonography is preferred to evaluate for diffuse infiltration of abdominal organs as well as abdominal lymphadenomegaly, as these may be difficult to appreciate radiographically. Aspiration of peripheral lymph nodes may be useful, even when the lymph nodes are not clinically enlarged. Bone marrow aspiration may be considered, especially in the face of peripheral cytopenias, and additional radiographs or bone scintigraphy may be carried out based on the presence of lameness or discomfort encountered during palpation of long bones. Confirmation of an elevated calcium secondary to malignancy may be attempted by evaluating PTH, PTH-rp, and ionized calcium levels in the serum. It is important to note that the ionized calcium level is increased in patients with humoral hypercalcemia of malignancy, and this may be monitored for a more accurate assessment of bioactive calcium levels. Evaluation of PTH-rp with ionized calcium and PTH can also help differentiate humoral hypercalcemia of malignancy from other causes of hypercalcemia (i.e., renal disease, hyperparathyroidism).

Treatment

Common symptoms of hypercalcemia include polyuria/polydipsia, muscle tremors, neurologic abnormalities (including coma), renal dysfunction, and inappetence. Treatment is aimed at reducing the ionized calcium level

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

as cancer therapy is ongoing. Mildly elevated total calcium levels are generally left untreated as cancer therapy is ongoing, but all treatment decisions should take into account the patient's neurologic and renal status. Total calcium levels that approach or exceed 13.5 mg/dL may benefit from saline diuresis and administration of a loop diuretic such as furosemide. Furosemide should only be administered in the volume-replete patient. Therefore, subcutaneous or intravenous saline administration may be necessary if clinical dehydration is appreciated. Glucocorticoids may reduce intestinal absorption of calcium but should only be used once a diagnosis is obtained, as they are directly cytotoxic to lymphoma and myeloma cells. Use of the drug prior to establishing a diagnosis may preclude an accurate diagnosis or require more invasive procedures to obtain an accurate diagnosis.

Finally, total calcium levels that are markedly elevated (>17 mg/dL) constitute a medical emergency and warrant hospitalization for diuresis. Administration of calcitonin may be attempted, although the effects are short-lived. Administration of calcitonin subcutaneously may be considered for a longer acting effect. Bisphosphonates (pamidronate and zoledronate) may be used for persistent hypercalcemia and bone pain. The author generally prefers pamidronate given as an intravenous infusion every 2–4 weeks. In select cases of lymphoma, a chemotherapy trial may be necessary if a diagnosis is elusive or if patient status dictates rapid intervention as laboratory tests are pending. This should be supported by clinical suspicion and after exhaustion of all available diagnostic methods. Serum should be drawn and saved prior to a chemotherapeutic trial. The author prefers L-asparaginase when this approach is necessary.

In all cases, successful treatment of the underlying neoplasm will result in resolution of the hypercalcemia, and the prognosis is dependent on the tumor type and stage. The decline in calcium can be rapid with successful treatment of lymphoma. Calcium levels may then be used as an additional tool to monitor for recurrence of the neoplasm.

Hypoglycemia

Etiology/Pathophysiology

Hypoglycemia as a paraneoplastic syndrome may be related to excessive production of insulin-like substances, direct consumption of glucose by tumor cells and decreased gluconeogenesis due to hepatic parenchymal involvement. Production of IGF-2 (acting as an insulin-like substance) has been implicated as a source of hypoglycemia in nonpancreatic neoplasms. Paraneoplastic hypoglycemia has been associated with tumors such as lymphoma, hepatocellular carcinoma and leiomyosarcoma, as well as renal tumors, mammary carcinoma, oral melanoma, multiple myeloma, splenic hemangiosarcoma, pulmonary carcinoma, and others. Glucose levels may be severely and persistently decreased (20–40 mg/dL) in many cases, and clinical symptoms are related directly to the neurologic effects of the hypoglycemia as well as the concurrent release of counterregulatory hormones such as catecholamines. Many times, the symptoms of hypoglycemia are severe and may predate the diagnosis of the causative tumor.

Common symptoms of paraneoplastic hypoglycemia include ataxia, lethargy, weakness (polyneuropathy), nervousness or collapse, hunger or anorexia, focal neurologic abnormalities, seizures, and/or coma.

Diagnosis

Discovery of a persistent hypoglycemia should lead to investigation for underlying neoplasia. Other etiologies of hypoglycemia, including hypoadrenocorticism, sepsis, congenital and acquired hepatic disorders, insulinoma, malnutrition and toxicity (such as xylitol), should also be investigated. Serum insulin levels should be evaluated in the face of hypoglycemia to assess for an insulin-secreting neoplasm. Normal or elevated insulin levels in the face of hypoglycemia is not a normal finding. Secretion of an insulin-like substance (such as IGF-2) will not be detected when measuring serum insulin levels. Therefore, insulin levels are most often useful in the diagnosis of pancreatic beta-cell neoplasia (insulinoma). Insulin concentrations should be determined on the same sample documenting hypoglycemia. Thoracic radiographs and abdominal ultrasonography are indicated to screen for a pancreatic islet cell tumor as well as intestinal, hepatic, and round cell neoplasia. Abdominal radiographs may be able to identify large intestinal or hepatic tumors. Often, islet cell neoplasms cannot be identified via ultrasonography due to their small size. In these instances, surgical exploration or contrast CT may be required.

Treatment

Treatment of this paraneoplastic syndrome involves controlling clinical symptoms of hypoglycemia as the underlying neoplasm is addressed. Often, it is difficult to obtain euglycemia in the face of extensive or metastatic neoplasia. In this situation, controlling the clinical manifestations of hypoglycemia becomes more important. Management strategies for neoplasia-related hypoglycemia are covered elsewhere.

Anemia/Thrombocytopenia

Etiology/Pathophysiology

Anemia and thrombocytopenia can be grouped together as hematologic paraneoplastic syndromes as they may occur together due to a common pathophysiology. Immune-mediated destruction due to mimicry of cell membrane-associated receptors or other immune cross-reactions tends to be the most widely accepted etiology of secondary immune-mediated hemolytic anemia (IMHA) and thrombocytopenia. Symptoms of anemia and thrombocytopenia are nonspecific to the cause and are covered elsewhere.

Diagnosis

When anemia is considered individually, it must first be determined to be regenerative or nonregenerative. A nonregenerative anemia may suggest bone marrow involvement, especially in conjunction with other cytopenias. Bone marrow disease must be differentiated from an acute anemia in which a regenerative response has not yet had time to develop. Typically, it will take an average of 3–5 days to develop a moderate regenerative response, depending on how suddenly the anemia developed and the degree of anemia. Additionally, clinical signs of anemia tend to be more severe the more acute the onset, as the body has time to adapt to a chronically developing anemia.

A bone marrow biopsy and/or aspirate should be considered in the face of a chronic, nonregenerative anemia. The author prefers to begin with a bone marrow aspirate. If the aspirate is productive, a slide may be reviewed to assess for cellularity. Bone marrow infiltration due to lymphoma or myeloma tends to be highly cellular, and assuming bone marrow elements are observed in a cellular sample, an aspirate may suffice. If the aspirate is nonproductive (i.e., a "dry" tap), a bone marrow biopsy may be obtained. A biopsy may be necessary to obtain a diagnosis of myelofibrosis or other chronically progressive bone marrow disorders. With these chronic conditions, bone marrow elements are replaced by fibrosis and the aspirate may be hemodilute or completely nonproductive.

As most animals present with a moderate to severe anemia, these procedures are generally performed shortly after a component blood transfusion to improve the candidacy for anesthesia. It is important to remember that if a bone marrow aspirate or biopsy is deemed necessary, it should be obtained before or within 12 hours of beginning steroid therapy. Steroids, including prednisone and dexamethasone, are directly cytotoxic to lymphoma and myeloma cells. These are two of the more common cancers that may infiltrate the bone marrow. Thrombocytopenia is not a contraindication to bone marrow sampling, as the associated hemorrhage typically results in an autotransfusion into the marrow, thereby remaining clinically silent. Prolonged external pressure to the incision site within the skin may be necessary, however.

Classically, pancytopenia will develop with a leukopenia followed by thrombocytopenia. Anemia will develop last due to the longer half-life of red blood cells in relation to platelets and white blood cells. This may not be the case in clinical practice, as multiple factors affect the production and destruction of all bone marrow elements. It is not uncommon to encounter myelophthisis in the face of thrombocytopenia alone, and any combination of cytopenias should raise suspicion for bone marrow involvement.

If the anemia is determined to be regenerative, bone marrow sampling is typically not necessary. Red blood cell morphology may identify clues as to the source of the anemia. A morphology review by an experienced pathologist or lab technician should be obtained. Specifically, immune-mediated disease may be confirmed by the presence of a moderate to large amount of spherocytes. Spherocytes are red blood cells that have undergone a loss of membrane due to removal of antigen–antibody complexes by the phagocytic portion of the immune system. This results in a loss of surface area with retention of volume. The consequence of this is the red blood cell changing its morphology from a biconcave disc to a sphere, resulting in the term "spherocyte." Immune-mediated hemolytic anemia may also be diagnosed by identifying gross or microscopic autoagglutination. In the absence of a significant number of spherocytes or detectable autoagglutination, a Coombs test may be performed to identify an immune component to the anemia. In the presence of visibly detectable autoagglutination, a Coombs test is not necessary.

A schistocyte is a red blood cell fragment that may develop due to shearing forces. These fragments do not have a central pallor and are irregular. Schistocytes may be noted in IMHA, but they are most commonly recognized as a consequence of hemangiosarcoma. Red blood cells may be damaged as they travel through the smaller blood vessels and fibrin strands of the tumor, and as such schistocytes should prompt evaluation for an underlying vascular neoplasm. Anemia due to damage to red blood cells as they travel through the smaller capillary beds is often termed microangiopathic anemia. Microangiopathic anemia may be seen with any hypercoagulable disease, and should also alert the clinician to the potential for thrombosis. Fibrin strands and smaller blood clots may be noted with hyperadrenocorticism, pancreatitis and other nonneoplastic disorders, and these may all result in a microangiopathic anemia.

Anemia may result from nonparaneoplastic disorders, such as gastrointestinal blood loss, iron sequestration, and medication. Thrombocytopenia may also be present due to increased utilization, poor bone marrow production and immune-mediated destruction that is unrelated to a neoplastic disorder. The presence of these hematologic disorders should prompt the evaluation of a paraneoplastic disease if the clinical history, signalment, and physical examination are suggestive. As a paraneoplastic syndrome, thrombocytopenia tends to develop due to immune-mediated destruction from mechanisms similar to the development of IMHA, or increased consumption due to large tumors such as hemangiosarcoma.

Treatment

Treatment of secondary IMHA and immune-mediated thrombocytopenia (ITP) is similar to that of primary IMHA, with attention to dealing with the underlying cause. Immune suppression with prednisone is indicated once a diagnosis is established, and may be effective at controlling the anemia as cancer therapy is ongoing. A wide dose range is reported for these disorders (1–4 mg/kg/day), and the author prefers 0.5–1 mg/kg of prednisone twice daily, or 0.3 mg/kg dexamethasone sodium phosphate IV twice daily. A higher dose may be used if steroids are to be employed as sole therapy. Antithrombotic therapy may be initiated with low-dose aspirin, unfractionated heparin or clopidrogel. It should be noted that the use of low-dose aspirin (0.5 mg/kg by mouth once daily) in the dog is considered safe in conjunction with immune suppressive doses of prednisone or dexamethasone. This is the author's treatment of choice in the dog. For cats, the author recommends one-quarter of a 75 mg tablet (18.75 mg) of clopidrogel by mouth once daily. The use of heparin is considered more effective at preventing thrombi, versus preventing the progression of a clot as with aspirin. However, monitoring of heparin therapy is difficult and often expensive. Heparin use should be considered if monitoring is available and feasible. Component blood therapy may be necessary with either disorder, and should be tailored to the patient. Platelet transfusions have typically been found to be ineffective at long-term management of ITP, but they may play a role in preventing active bleeding. This may be important if intracranial hemorrhage is suspected.

Gastrointestinal hemorrhage may result in significant and refractory anemia, especially in the face of thrombocytopenia. This is an unfortunate negative prognostic indicator with ITP and should be differentiated from gastrointestinal ulceration. In the latter scenario, gastroprotectants should be instituted, and any medication that may result in ulceration should be reduced or discontinued if possible. The majority of gastric ulcers will develop due to medication or neoplasia, so if the clinical history does not identify an offending medication, cancer should become a primary differential. More specific therapy for primary IMHA and ITP is covered elsewhere.

Hypertrophic Osteopathy

Etiology/Pathophysiology

Hypertrophic osteopathy (HO) is an uncommon paraneoplastic syndrome. The pathophysiology is unclear, but afferent neurologic stimulation may alter blood flow to long bones. This is supported by case reports demonstrating resolution of lesions following vagotomy. HO is most commonly noted with pulmonary lesions including heartworm disease, but has been reported with nonthoracic neoplasia as well, including transitional cell carcinoma and adrenocortical carcinoma. Typical findings include periostosis and subperiosteal new bone formation along the shafts of long bones. This condition is frequently painful. Affected limbs may be warm and swollen, and radiographs will typically demonstrate the common features of the disorder. Finding radiographic evidence of HO should prompt radiographic evaluation of the thorax. Abdominal ultrasonography may be considered if pulmonary lesions are not identified.

Treatment and Prognosis

Treatment is directed at removal of the underlying neoplasm. Vagotomy has been described but is not typically performed as the primary treatment is to address the underlying etiology. If the neoplasm cannot be treated, pain management must be addressed. Opiates, nonsteroidal medication, steroids, and bisphosphonates have been used alone or in combination to control discomfort. Localized palliative radiation has been described but is not typically recommended due to lack of supportive evidence. If tumor removal is successful, HO lesions may persist for several weeks and require continued pain management during this time. The lesions should resolve given time if a thoracic neoplasm is successfully removed.

Myasthenia Gravis

Etiology/Pathophysiology

Myasthenia gravis is an immune-mediated condition that develops from production of antibodies to nicotinic acetylcholine receptors located on the postsynaptic neuromuscular junction. This prevents neurogenic signal transduction, leading to the hallmark signs of episodic weakness, exercise intolerance, megaesophagus,

and regurgitation. Aspiration pneumonia is a common complication of frequent regurgitation and may result in respiratory symptoms. This paraneoplastic syndrome is most commonly related to the presence of thymoma.

Myasthenia gravis may be focal, generalized or fulminant. As a paraneoplastic syndrome, a generalized form is typically encountered. This type of myasthenia affects skeletal muscle of the limbs, resulting in the aforementioned clinical signs. Ocular muscles may be affected, resulting in a fatigue to repeated palpebral reflexes. Myasthenia may be suspected based on clinical symptoms, and confirmed by evaluated serum levels of anticholinergic receptor antibodies. Administration of edrophonium chloride ("Tensilon test") may provide presumptive support for myasthenia gravis as serum titers are pending. Both focal myasthenia and generalized myasthenia result in megaesophagus, which is easily demonstrated radiographically.

Treatment

Treatment of thymoma can result in resolution of myasthenia, but at times the megaesophagus may be persistent. The reason for this is not known. Anticholinesterase medication, such as oral pyridostigmine or injectable neostigmine, may help ameliorate clinical symptoms. It is important to note that injectable medication may be necessary if severe megaesophagus with frequent regurgitation is present. Alternatively, many dogs may be managed well with a supplemental gastrostomy tube. This can allow delivery of medication and supplemental nutrition into the stomach, thereby circumventing the esophagus altogether. Gastrostomy tubes do not reduce the overall frequency of regurgitation or the risk for aspiration pneumonia, however. Food should be delivered in a standing position, and consistency of the food should be experimented with. Some dogs will tolerate food in a meatball, some as a slurry, and others in a gelatin. Use of a Bailey chair, which encourages an upright position during feeding, may be considered as well. If possible, the dog should be taken for a short walk after each feeding.

Superficial Necrolytic Dermatitis

Etiology/Pathophysiology

Superficial necrolytic dermatitis (SND, or hepatocutaneous syndrome) is a condition characterized by erythema, alopecia, and crusts involving the eyes, nose/muzzle, and extremities. A typical feature of this disorder is hyperkeratosis of the footpads with central necrosis affecting one or multiple pads. Often, the footpads may be so painful that the animal will refuse to walk. The disease has been noted commonly with chronic hepatic disorders as well as chronic administration of large doses of phenobarbital. As a paraneoplastic syndrome, SND may be noted with glucagonoma. In the author's experience, chronic and fibrotic liver disease is the most common disorder associated with SND.

Diagnosis

The finding of footpad hyperkeratosis with or without concurrent clinical findings should prompt abdominal ultrasonography to evaluate the pancreas and liver. An experienced ultrasonographer should be used to evaluate the pancreas for a mass. The liver may have a typical "Swiss cheese" appearance. A liver biopsy may be diagnostic but may need to be obtained via laparoscopy or laparotomy due to hemorrhage risk. Animals with a glucagonoma may have symptoms of diabetes, including polyuria/polydipsia and weight loss (for further information refer to Chapter 144). A poor appetite is often associated with chronic liver disease. Measurement of glucagon levels may be undertaken but the test is not always available, and glucagon levels are not always elevated in the face of a glucagonoma. SND is often associated with a hypercatabolic state which may be manifested with a hypoalbuminemia and/or hypoproteinemia. An amino acid profile may reveal significant reductions in serum amino acids, helping to confirm the diagnosis. Skin biopsy may be characteristic if lesions are present.

Treatment

Treatment is aimed at the underlying cause. Surgical resection of a glucagonoma is best if feasible. With chronic liver disease or nonresectable neoplasia, administration of intravenous amino acids will often help skin lesions to resolve. This may help to reduce discomfort. 10% Aminosyn® (or an equivalent solution) must be administered via a central catheter and over 8–12 hours due to its hypertonicity. It is typically administered weekly until skin lesions resolve.

Skin and footpad lesions should be kept clean and dry. A high-protein diet may be prescribed with supplementation of egg whites or protein powder. Broad-spectrum antibiotics may be administered to control secondary infections, and analgesics may be necessary if discomfort is present. Zinc, omega-3 fatty acids, and niacin have all been suggested as adjunct therapies. These may be difficult to administer in the face of a poor appetite and are considered supplemental therapy.

Paraneoplastic Alopecia

Paraneoplastic alopecia is described in cats affected by pancreatic carcinoma. It may occasionally be seen with hepatic or biliary carcinomas, and is characterized by a

noninflammatory alopecia. Hair may be epilated in clumps, and the underlying skin is often thin and glistening. Affected areas may include the ventral abdomen, thorax, limbs, pinnae, and periorbital region. The cause is unknown, but theorized to be secondary to cytokine production by the tumor resulting in follicular atrophy. Most cats present systemically ill, as the skin lesions typically develop at a later stage of the disease process. Metastases may be present within the liver and/or lungs, and diagnosis may be achieved through imaging (including abdominal ultrasound, abdominal/thoracic CT, and/or thoracic radiographs) and appropriate tissue sampling.

Conclusion

Paraneoplastic syndromes are diverse in their presentation and severity. In fact, many other paraneoplastic conditions exist that are beyond the scope of this text. These include thymoma-related exfoliative dermatitis, peripheral neuropathies, nodular dermatofibrosis, and paraneoplastic pemphigus. Other conditions, such as fever and cachexia, are often considered paraneoplastic but are not specific or unique in their presentation. Prompt identification and treatment of these conditions will aid the clinician in additional diagnoses, maintain patient comfort, and prevent life-threatening sequelae as cancer therapy is ongoing.

Lymphoid Leukemias, Myeloid Neoplasia, and Myelodysplastic Syndrome

Angela R. Kozicki, DVM, DACVIM (Oncology)

Bluepearl Veterinary Partners, Southfield, MI, USA

Lymphoid Leukemias

Etiology/Pathophysiology

Lymphoid leukemias are differentiated as either chronic lymphocytic leukemia (CLL) or acute lymphoblastic leukemia (ALL). CLL is a clonal, neoplastic proliferation of small, mature-looking lymphocytes that manifests as a persistent, often severe lymphocytosis. Three subsets have been recognized based on immunophenotyping. The most common is granular T-CLL which consists of proliferations of cytotoxic (CD8+) T cells. Despite conventional thinking that CLL is always a primary bone marrow disease, granular T-CLL is considered a primary splenic disease which can be verified by expression of a marker for splenic red pulp (CD11d). The second is B-CLL (CD21+, CD79a+) and the third is nongranular/atypical T-CLL (CD3+) in which no consistent pattern of concurrent CD4 or CD8 expression is found. ALL is defined by proliferation of immature lymphoblasts in the bone marrow or peripheral blood. The immunophenotype of ALL is typically B cell (CD21+, CD3-, CD4-, CD8-) with an acute, immature lineage based on expression of CD34, a stem cell marker.

Classification of lymphocytes involves assessment of cell surface antigen (marker) expression that pertains to both lineage and function. This classification is usually performed by immunophenotyping. Immunophenotyping consists of the application of antibodies specific for differentiation antigens of lymphocytes and other immune cells to identify lineages of these cells present in neoplastic or reactive diseases. Immunophenotyping can be performed on cytology smears, blood smears, fluids (blood or bone marrow), formalin-fixed paraffin sections or snap-frozen tissue sections. Immunophenotyping tests include immunohistochemistry (on tissue samples), immunocytochemistry (on cytologic or fluid samples), and flow cytometry in which cell suspensions are stained with specific fluorochromes, analyzed by a focused laser beam and sorted by size and DNA content (ploidy of cells). Immunophenotyping can identify the presence of different blood cell lineages but cannot predict clonality (whether a population arises from a single cell).

It is important to know normal percentages of lymphocyte subsets found in the peripheral blood of dogs and cats to be able to distinguish a benign or reactive process from a malignant one. In general, peripheral lymphocytes of dogs consist of ~80% T cells (CD3+ or CD5+) with 45% being helper T cells (CD4+), 25% being cytotoxic T cells (CD8+) and the remainder being double-negative T cells (CD4-, CD8-). Approximately 15% are B lymphocytes (CD21+) and the remaining lymphocytes are natural killer (NK) cells. Cats are very similar but have slightly fewer T cells (~75%) and a greater percentage of B cells (~25%) in the peripheral blood.

The etiology of lymphoid leukemias is largely unknown. In people, there is no known association with radiation, chemicals or alkylating agents and no viral cause. Genetic factors are suspected in both humans and dogs but immunophenotype of the neoplastic cells in these species is different in that most human lymphoid leukemias are B cell in origin. Therefore, it is unwise to try to make direct correlations between species since different causative factors may be involved. In cats, retroviruses such as feline leukemia virus (FeLV) play a role since ~60–80% of cats with ALL are FeLV+. There is no known association between FeLV and CLL in cats and no evidence of a retroviral cause in dogs.

Epidemiology

In people, CLL is an indolent disease of older adults (>60 years of age) and accounts for 25–30% of all adult leukemias among white populations in North America and

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

Western Europe. Ninety-five percent of CLL in people are B cell in origin. ALL is most common in young children (peak between 2 and 5 years) with a second peak in aged populations and is most commonly B cell. The true incidence of lymphocytic leukemias in animals is unknown. CLL is thought to be less common than ALL but more common than myeloproliferative disorders.

Signalment

In the dog, both ALL and CLL are most commonly seen in middle-aged to older animals with a median age of 10 years. No sex predilection has been found. Golden retrievers and German shepherds are overrepresented in CLL. CLL is rare in cats but seems to occur in elderly cats with a mean age of 14 years. Cats with ALL are usually young and FeLV positive.

History and Clinical Signs

Most CLL animals are asymptomatic and the diagnosis is incidental. When clinical signs are present, they are generally attributable to the degree of lymphocytosis, bone marrow involvement or other organ involvement and may include lethargy, inappetence, and weight loss. Physical exam may show hepatosplenomegaly and mildly enlarged peripheral lymph nodes. Clinical signs of ALL patients are similar to CLL although they are typically more severe. On physical exam, splenomegaly is the most common finding but hepatomegaly and lymphadenopathy can also be present. Signs of life-threatening cytopenias such as pale mucous membranes, pyrexia, and/or petechial hemorrhages are also possible.

Diagnosis

Diagnosis of CLL is commonly made by examination of the peripheral blood and bone marrow by a clinical pathologist. A complete blood count (CBC) generally reveals an absolute mild to marked lymphocytosis (6000 to >100 000 lymphocytes/μL) and cytologically the nuclei appear small and mature with condensed chromatin (Figure 133.1).

Other common hematologic findings include a mild normochromic, normocytic, nonregenerative anemia, a mild thrombocytopenia (>100 000/μL), and rarely neutropenia. The hematologic abnormalities associated with feline CLL have not been well characterized although they are thought to be similar to dogs. A monoclonal gammopathy or hyperglobulinemia in cats has been reported but is uncommon since most CLL are T cell in origin. Bone marrow aspirates show a significant proliferation of small mature lymphocytes (usually >30%) except in granular T-CLL which demonstrates a marked splenic proliferation or infiltration of granular lymphocytes with minimal bone marrow involvement. Other staging tests commonly recommended include thoracic radiographs, abdominal ultrasound, and subsequent aspirate and cytology of any enlarged organ. Immunophenotyping of blood, bone marrow or cytology samples generally reveals the presence of a T cell lymphocyte population with no evidence of CD34 expression (early hematopoietic stem cell marker), confirming the maturity of the lymphocytes in question. The presence of 30% or more lymphoblasts in the bone marrow is considered diagnostic for ALL. Lymphoblasts are intermediate-to-large sized lymphocytes with moderate amounts of basophilic cytoplasm. Lymphoblasts are larger than neutrophils, have a condensed nuclear chromatin pattern, and have a high nuclear to cytoplasmic ratio (Figure 133.2).

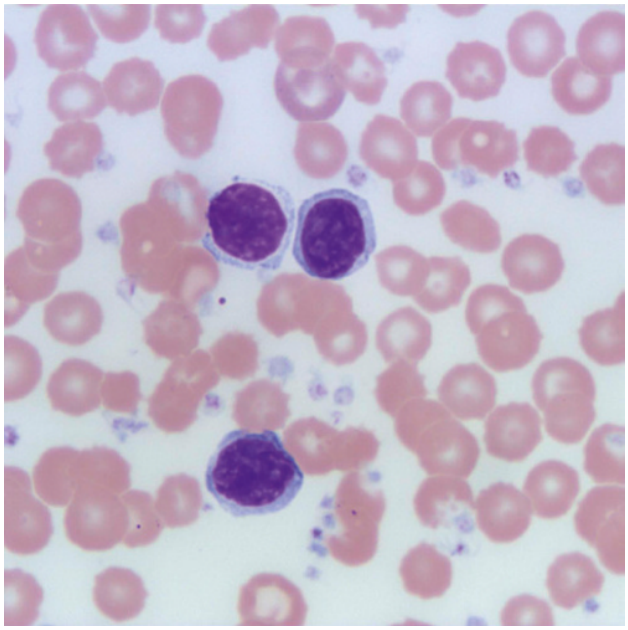

Figure 133.1 Photomicrograph of lymphocytes in the peripheral blood of a dog that has CLL. The lymphoid morphology is predominantly small and well differentiated. Wright Giemsa stain, 1000× magnification. *Source:* Courtesy of Dr Jan Andrews, Antech Diagnostics.

Staging tests recommended for ALL are similar to CLL; however, one of the principal goals is to differentiate ALL from stage V lymphoma by degree of blood and bone marrow involvement, lack of significant lymphadenopathy and, most importantly, its immunophenotypic characteristics. Patients with stage V lymphoma can have a better prognosis since their disease does not originate in the bone marrow. Immunophenotyping, especially flow cytometry, can be very useful in these cases because ALL patients will be CD34+, confirming an early hematopoietic origin. Both stage V lymphoma and CLL patients will be negative for this marker.

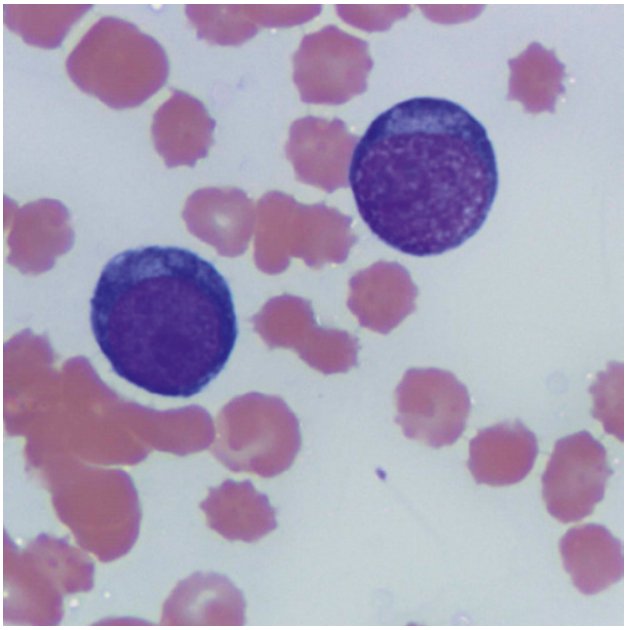

Figure 133.2 Photomicrograph of lymphoblasts in the peripheral blood of a dog with ALL. The cells are characterized by large size with prominent nucleoli. Wright Giemsa stain, 1000× magnification. *Source:* Courtesy of Dr Jan Andrews, Antech Diagnostics.

Other causes of a lymphocytosis (chronic ehrlichiosis, Rocky Mountain spotted fever, and severe babesiosis in dogs; feline immunodeficiency virus [FIV], *Toxoplasma gondii*, and chronic inflammatory bowel disease in cats) should be ruled out if lymphocytic leukemia is not an obvious conclusion.

Therapy

Chronic lymphocytic leukemia can have a protracted clinical course and treatment is not usually instituted until specific criteria are met: the presence of peripheral cytopenias (anemia, thrombocytopenia and/or neutropenia), clinical signs associated with the disease, peripheral lymphadenopathy, organomegaly, and/or a peripheral lymphocytosis of >60 000 (although this is not standardized). The standard treatment for CLL is a combination of the oral alkylating agent chlorambucil and prednisone. The dose and frequency of chlorambucil can vary. In dogs it is typically given orally at 0.2 mg/kg or 6 mg/m^2 orally once daily for 7–14 days, then reduced to 0.1 mg/kg or 3 mg/m^2 every other day thereafter. In cats, 2 mg/cat every 48 hours is commonly used. Oral prednisone is used concurrently with chlorambucil at 1 mg/kg daily for 1–2 weeks, then 0.5 mg/kg every other day thereafter. In cats, 10 mg/cat every 24 hours is commonly used. The addition of vincristine or the substitution of cyclophosphamide for chlorambucil has been used in nonresponsive patients. Treatment of ALL requires aggressive chemotherapy; CHOP-based therapies like those used in lymphoma are the most common protocols. Remission rates of 25% have been reported but remission times tend to be short.

Prognosis

Chronic lymphocytic leukemia is a slowly progressive disease and many patients are monitored for months before any therapy is instituted. Remission rates with treatment are ~70–75% with overall survival times of >1 year. Immunophenotype has been shown to be predictive with survival times for dogs with granular T-CLL, B-CLL, and atypical CLL of 930, 480, and 22 days respectively. Although the prognosis is good in the short term, ultimately, CLL patients can experience an acute blast crisis in which lymphoblasts replace mature lymphocytes (ALL) and response to aggressive treatment is poor. Prognosis for dogs and cats with ALL is very poor. Median survival times of 3–128 days have been reported in ALL dogs with a CD34+ phenotype treated with CHOP-based treatment protocols.

Hematopoietic peripheral blood stem cell transplantation (HSCT) is presently a viable treatment option for dogs with leukemias. Although not widely available, improved survival and cure are possible with this advanced form of therapy.

Myeloid Neoplasia

Myeloid neoplasms arise from clonally proliferating cells in the bone marrow and manifest as either accumulation of neoplastic cells in the blood or lack of normal blood cells. Myeloid neoplasms are divided into acute myeloid leukemia (AML) and myeloproliferative neoplasms (MPNs) which include chronic myelogenous leukemia (CML), polycythemia vera (PV), basophilic/eosinophilic leukemia, and essential thrombocytosis. (Box 133.1).

Acute Myeloid Leukemia

Etiology/Pathophysiology

Acute myeloid leukemia is defined by an abnormal proliferation of clonal cells in the bone marrow and peripheral blood that arise from a single immature blast cell. AML is divided into several subcategories based on the Animal Leukemia Study Group's 1991 proposal which was modeled after the human leukemia French-American-British (FAB) Cooperative Group classifications (see Box 133.1). In this system, myeloid leukemias are divided into phenotypic subtypes based on morphology and cytochemistry profiling using an alphanumeric

Box 133.1 Classification of leukemias in animals as proposed by the Animal Leukemia Study Group

Lymphoid leukemias

Chronic lymphocytic leukemia (CLL)
Acute lymphoblastic leukemia (ALL)

Myeloid neoplasia

Acute myeloid leukemias (AML)
Acute myeloblastic leukemia with minimal differentiation (LMA-M0)
Acute myeloblastic leukemia without differentiation (LMA-M1)
Acute myeloblastic leukemia with maturation (LMA-M2)
Acute promyelocytic leukemia (LMA-M3) (not recognized in animals)
Acute myelomonocytic leukemia (LMA-M4)
Acute monocytic leukemia (LMA-M5)
Acute erythroleukemia (LMA-M6)
Acute erythroleukemia with erythroid predominance (LMA-M6Er)
Megakaryoblastic leukemia (LMA-M7)

Chronic myeloid leukemia (CML)

Chronic myelomonocytic leukemia
Chronic monocytic leukemia
Eosinophilic leukemia
Basophilic leukemia
Polycythemia vera
Essential thrombocythemia

Myelodysplastic syndromes (MDSs)

Myelodysplastic syndrome with excessive blasts (MDS-EB)
Myelodysplastic syndrome with refractory cytopenia (MDS-RC)
Myelodysplastic syndrome with erythroid predominance (MDS-ER)

code of M-#, with the M standing for myeloid. The most commonly reported forms in the dog are acute myeloblastic leukemia (M1 and M2) and acute myelomonocytic leukemia (M4). Monocytic leukemia (M5), erythroleukemia (M6), and megakaryoblastic leukemia (M7) are also recognized in dogs but promyelocytic leukemia (M3) has not been reported.

In dogs, the etiology of AML along with the other myeloid neoplasms is unknown. Genetic and environmental factors such as exposure to radiation, drugs or toxic chemicals are thought to play a role. Defining genetic factors in dogs is difficult because canine karyotyping is an arduous process due to the large number and morphologic similarities of chromosomes and their resistance to banding. Recently, however, advancements in molecular cytogenetic analysis have aided in the discovery of canine chromosomal abnormalities that are similar to human AML which may serve not only as diagnostic and prognostic factors but also as therapeutic targets.

Epidemiology

A lack of veterinary studies examining myeloid neoplasms has led to a deficiency of uniform diagnostic criteria, nomenclature, and ultimately accurate diagnosis. Because of this, correct information regarding incidence and other epidemiologic information cannot be verified until a more uniform classification system is standardized.

Signalment

Acute myeloid leukemia is rare with a variable patient age at diagnosis. Males are more commonly affected than females and large-breed dogs seem to be predisposed. Retrospective studies suggest an increased incidence in German shepherds, golden retrievers, and Labrador retrievers. Small-breed dogs have been represented in single-case reports. The majority of feline AML patients are FeLV positive.

History and Clinical Signs

The clinical course of AML is rapid. Common clinical signs include extreme lethargy, secondary infection, and hemorrhage. Hematologic abnormalities can be severe with a WBC count as high as 150,000 μ/L. Anemia, neutropenia, and thrombocytopenia are also common. Spleen, lymph nodes, and liver are frequently involved but other sites such as heart, kidney or central nervous system (CNS) may be infiltrated as well.

Diagnosis

It is important to understand that AML is a disorder resulting from uncontrolled proliferation or decreased apoptosis of cells incapable of maturation, leading to the accumulation of poorly differentiated or "blast" cells. This is different from other myeloid neoplasms which result from unregulated proliferation of cells that exhibit incomplete/defective maturation, leading to the accumulation of well differentiated cells. The diagnosis of AML is generally made by evaluation of peripheral blood or bone marrow. Confirmation of AML should include consistent hematologic and morphologic criteria, positive staining for myeloperoxidase which is a heme protein synthesized during myeloid differentiation that constitutes the major component of neutrophil azurophilic granules, a consistent pattern of beta-2 integrin expression and absence of lymphoid antigens by immunocytochemistry or flow cytometry (Figure 133.3).

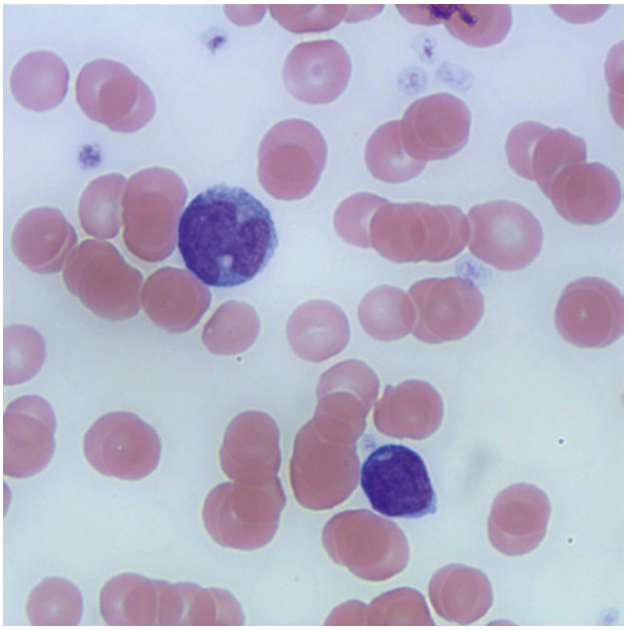

Figure 133.3 Photomicrograph of poorly differentiated blast cells in the peripheral blood of a dog that has myelomonocytic leukemia diagnosed via flow cytometry. The neoplastic cells are large with pleomorphic nucleoli and prominent nucleoli. Wright Giemsa stain, 1000× magnification. *Source:* Courtesy of Dr Jan Andrews, Antech Diagnostics.

Table 133.1 lists immunophenotypic markers for uncharacterized leukemias in animals recommended by the ACVP Oncology Committee.

Therapy

The course of the disease is short, usually only days to weeks, and animals quickly succumb or are euthanized soon after diagnosis. Traditional chemotherapy alone is largely unrewarding due to inadequate or short-term responses. As with other forms of leukemia, HSCT is becoming a viable treatment option for dogs with leukemia. However, owing to limited availability and rapid progression of the malignancy, treatment is often limited to palliative cytoreductive chemotherapy with such drugs as cytosine arabinoside, doxorubicin, vincristine, and cyclophosphamide. Intensive supportive care is commonly necessary and may include blood and/or platelet-rich plasma infusion along with aggressive antibiotic therapy for infection.

Table 133.1 Recommended immunophenotyping markers to differentiate animal leukemias as proposed by the Myeloid Neoplasm Subcommittee of the American College of Veterinary Pathologists

Cell type	Immunophenotypic marker(s)
B lymphocytes	CD79a
T lymphocytes	CD3
Myeloid	MPO, CD11b
Megakaryoblastic	CD41
Dendritic cells	CD1c
Acute leukemia	CD34

Source: McManus PM. Classification of myeloid neoplasms: a comparative review. *Vet Clin Pathol* 2005; **34**: 189–212. Reproduced with permission of John Wiley & Sons.

Prognosis

The prognosis for AML is considered poor. In one study of 16 dogs with confirmed AML, median and mean survival after diagnosis were 7 days and 20 days respectively with a range of 2–138 days. Most of the dogs in the study were treated with chemotherapy. However, protocols were not consistent and some dogs were euthanized before any treatment could be instituted due to rapidly progressive clinical signs. There is one case report of a dog with megakaryoblastic leukemia that demonstrated a lengthy survival of 24 months with treatment so all AML is not necessarily rapidly fatal. For some dogs, HSCT may be feasible. For those animals, HSCT offers the possibility of prolonged survival and cure.

Myeloproliferative Neoplasms

Myeloproliferative neoplasms (MPNs) are defined as overproduction of differentiated bone marrow cells which results in the accumulation of the affected cell (granulocytes and/or monocytes, erythrocytes or platelets).

Chronic Myelogenous Leukemia

Etiology/Pathophysiology

Chronic myelogenous leukemia (CML) in dogs is characterized by a neoplastic proliferation of the neutrophil series and is more similar to human chronic neutrophilic leukemia than human CML. Human CML is associated with the proliferation of several hematopoietic cell lineages due to the presence of a BCR-ABL translocation (Philadelphia chromosome) between chromosomes 9 and 22. The regions of human chromosomes 9 and 22 are evolutionarily related to regions on canine chromosomes 9 and 26 and a canine equivalent to the BCR-ABL mutation (Raleigh chromosome) has been identified in three cases of canine CML. The etiology of most canine and feline CML is unknown.

Signalment

There is no known age, sex, or breed predilection in canine CML. FeLV infection has been associated with CML in cats.

History/Clinical Signs

Many patients have no clinical signs until significant organ infiltration or myelophthisis of the bone marrow

occurs. If clinical signs are present, they are often nonspecific and may include lethargy, inappetence, organomegaly, pale mucous membranes, and hemorrhage caused by severe thrombocytopenia.

Diagnosis

At diagnosis, the peripheral white blood cell count (WBC) count is commonly >100 000/μL. Neutrophils and neutrophilic precursors accumulate in bone marrow, peripheral blood and other organs such as the spleen, liver, and lymph nodes. Eosinophils and basophils may also be increased. CML must be distinguished from a leukemoid reaction caused by inflammation, immune-mediated diseases, and/or a paraneoplastic syndrome. Staging tests such as three-view thoracic radiographs, abdominal ultrasound, and bone marrow cytology can be helpful in making this distinction. Biopsy of the liver or spleen may also be helpful in distinguishing CML from a leukemoid reaction due to its invasiveness.

Therapy

Treatment of CML consists of the chemotherapy agent hydroxyurea at 20–25 mg/kg PO twice daily until the leukocyte count drops to 15 000–20 000 cells/μL. The dosage of hydroxyurea can then be reduced by 50% on a daily basis or to 50 mg/kg given biweekly or triweekly.

Prognosis

Although responders can be managed for several months with chemotherapy, most CML patients will enter a terminal phase of their disease. HSCT offers the only possibility of cure for dogs but may not be feasible or practical. Death is either due to infection or hemorrhage caused by neutrophil dysfunction and thrombocytopenia or secondary to a "blast crisis." Response rates in patients in a blast crisis are low and the prognosis is very poor. It is unknown whether the subset of canine CML patients that have a BCR-ABL chromosome will respond to BCR-ABL kinase inhibitors which have become the standard of care for human CML patients.

Polycythemia Vera

Etiology/Pathophysiology

Polycythemia vera (PV) is a clonal disorder of erythroid precursors in the bone marrow, which leads to the overproduction of red blood cells independent of erythropoietin. PV is rare in the dog and must be differentiated from more common causes of polycythemia such as relative polycythemia which is a result of hemoconcentration or secondary polycythemia which is driven by erythropoietin. Conditions associated with secondary polycythemia include chronic pulmonary disease, congestive heart failure, renal disease, renal neoplasia, and/or right-to-left cardiac shunts.

Signalment

Polycythemia vera generally affects middle-aged dogs and cats with no breed or sex predilection.

History and Clinical Signs

The majority of clinical signs occur secondary to hyperviscosity syndrome which is the sludging of blood due to increased red blood cell mass. These signs may include hemorrhage, exercise intolerance, neurologic signs such as seizures or ataxia, splenomegaly, hyperemic mucous membranes, injected sclera/retinal vessels, and weakness. Cardiac or renal disease may also occur.

Diagnosis

Recommended diagnostic tests to rule out relative or secondary polycythemia include thoracic radiographs, abdominal ultrasound, bone marrow aspiration, arterial blood gas measurements, and serum EP levels if possible. The diagnosis of PV is made by the demonstration of significant erythrocytosis (hematocrit of 60–75%) with normal to decreased serum EP levels. Bone marrow cytology in PV is consistent with erythroid hyperplasia with normal patterns of maturation.

Therapy

Treatment of PV consists of decreasing the red blood cell (RBC) volume and, ideally, suppression of erythroid production in the bone marrow. Phlebotomy with reinfusion of the patient's plasma after removal of the RBCs or administering colloid and crystalloid solutions to replace lost electrolytes is recommended. The PCV should be reduced to 50–60% or by one-sixth of its starting value (15–20 mL/kg body weight can be removed at one time). The drug of choice to suppress erythroid production is hydroxyurea which works by inhibiting DNA synthesis. Hydroxyurea is instituted at 20–25 mg/kg PO given twice daily in dogs (10–15 mg/kg in cats orally once daily). Once the hematocrit is below 60%, hydroxyurea is maintained at every other day dosing with the goal of maintaining a normal or close to normal packed cell volume (PCV).

Prognosis

The prognosis of PV is good with a high response rate and survival times of longer than a year for responders.

Basophilic and Eosinophilic Leukemia and Essential Thrombocythemia

Etiology/Pathophysiology

Basophilic leukemia has rarely been reported in dogs and is diagnosed by an increased WBC count with a high proportion of basophils in bone marrow and/or peripheral blood. The etiology is unknown. It is unclear whether dogs and cats develop eosinophilic leukemia. At this

time, due to lack of useful clonality assays, eosinophilic leukemia and hypereosinophilic syndrome are difficult to differentiate. Essential thrombocythemia has been described in the dog and is characterized by persistent thrombocytosis of >600 000/μL without evidence of circulating blast cells.

Signalment

There is no known age, breed, or sex predilection in any of these disorders.

History and Clinical Signs

A history of lethargy, inappetence, and/or weight loss is common with any of the myeloid neoplasms. Clinical signs are generally vague and may include fever, pale mucous membranes, petechiation, hepatosplenomegaly, and lymphadenopathy.

Diagnosis

Basophilic leukemia must be differentiated from mastocytosis based on morphology. Although these cells are usually easily distinguished from each other, changes in morphology of the nucleus and granules in basophilic leukemia can make this distinction more difficult. Infiltration into other organs is possible, including the liver, spleen and lymph nodes, so evaluation of these organs by abdominal ultrasound and/or cytology can aid in the diagnosis. To make a diagnosis of eosinophilic leukemia, disorders associated with eosinophilia such as skin diseases, respiratory, and/or gastrointestinal tract diseases and parasitism need to be ruled out before considering a neoplastic leukemic etiology. Dogs with essential thrombocythemia can present with hepatosplenomegaly, nonregenerative anemia, and neutrophilia. On examination of bone marrow, megakaryocytic hyperplasia is the most common feature. Diseases that are known to cause secondary thrombocytosis such as chronic inflammatory diseases, rebound from severe hemorrhage and iron deficiency anemia need to be ruled out before making a diagnosis of essential thrombocythemia.

Treatment/Prognosis

Treatment for basophilic leukemia with hydroxyurea has provided complete or partial remissions for several months in case reports. The effective treatment of eosinophilic leukemia is unknown but in one case report, treatment with corticosteroids was effective. Information on treatment for essential thrombocythemia is lacking but in one case report, a dog was successfully treated with a chemotherapy protocol consisting of vincristine, cyclophosphamide, Ara-C, and prednisone. As with all forms of leukemia, HSCT can be considered for suitable dogs if feasible.

Myelodysplastic Syndromes

Myelodysplastic syndromes (MDS) are a heterogeneous group of acquired alterations of hematopoietic stem cells that have been described in humans, dogs, and cats. MDS can be primary or secondary/acquired. Primary MDS result from clonal expansion of a defective pluripotent stem cell and therefore are considered neoplastic. Some refer to myelodysplasia as preleukemia since it can progress to acute leukemia in some cases.

Etiology/Pathophysiology

Several different aberrations can result from a dysfunctional hematopoietic system constituting MDS. In dogs, there are usually cytopenias in 2–3 cell lines in the peripheral blood due to cell death caused by ineffective hematopoiesis. Other blood abnormalities may include dysplastic changes in several cell lines, metarubricytosis, and macrocytic erythrocytes. The bone marrow is usually normocellular or hypercellular. Blast cells in bone marrow make up <30% of all nucleated cells but in people this threshold has been changed to <20%.

Three subtypes of primary MDS have been proposed for dogs and cats: MDS with excessive blasts (MDS-EB), in which blast percentages are >5% and less than 20%, MDS with refractory cytopenia (MDS-RC) with blast percentages <5% and cytopenias in one or more lineages, and MDS with erythroid predominance (MDS-ER) in which the myeloid:erythroid (M:E) ratio is <1. Cases of canine secondary MDS consistently have <5% myeloblasts in the bone marrow. Secondary MDS in dogs has been associated with several conditions including myelofibrosis, neoplasia (lymphoma and multiple myeloma), immune-mediated thrombocytopenia, immune-mediated hemolytic anemia, drugs, and ionizing radiation. In cats, secondary MDS can be associated with FeLV.

Epidemiology

Genetic abnormalities in hematopoietic cells such as mutations in oncogenes and tumor suppressor genes along with chromosomal deletions have been discovered in human MDS patients and are thought to play a role in veterinary patients.

Signalment

MDS-EB is the most common type of primary MDS and occurs most frequently in middle-aged to older dogs. Both MDS-RC and MDS-ER occur in older dogs. No breed or sex predilection is known in any of the subtypes.

History and Clinical Signs

The clinical signs of both MDS-RC and MDS-ER are vague and commonly include lethargy and exercise intolerance. Physical exam generally reveals pale mucous membranes and an anemia-related heart murmur. Clinical signs of MDS-EB tend to be more severe and include depression, anorexia, fever, and diarrhea. These patients commonly have a history of illness that progresses over several months.

Diagnosis

Evaluation of blood and/or bone marrow is needed for diagnosis of MDS. Because primary and secondary MDS cannot be consistently differentiated cytologically, a diagnosis of primary MDS should be made only if secondary causes have been ruled out. The most common hematologic abnormalities in MDS-RC and MDS-ER are nonregenerative anemias without any evidence of thrombocytopenia or leukopenia. MDS-ER differs from MDS-RC by characterization of marked erythroid hyperplasia and the presence of >5% rubriblasts in the bone marrow. Patients with MDS-EB have moderate to severe nonregenerative anemia with evidence of neutropenia and thrombocytopenia. Dysplastic features in all cell lines are commonly found and a hallmark feature of MDS-EB is the presence of increased numbers of myeloblasts (between 5% and 20% of total nucleated erythroid and myeloid cells).

Therapy/Prognosis

There is no standard treatment for primary MDS. In humans, patients commonly receive no treatment because they often do not have clinical signs. Supportive care such as blood transfusions and antibiotics for infections is used as necessary. Growth factors can also be used. In one case report of a dog with MDS-ER, human recombinant erythropoietin was used to treat profound anemia to promote terminal differentiation of dysplastic erythrocytes. The hematocrit increased and that patient remained in remission for >30 months. Dogs with MDS-RC and MDS-ER can have prolonged survivals when treated with chemotherapy (cyclophosphamide or cytosine arabinoside is most common) and supportive care. Patients with MDS-EB can progress to AML and treatment has been less rewarding, with survival times of days to months. For suitable dogs, allogeneic HSCT can be considered. The treatment and prognosis of secondary/acquired MDS are dependent on the underlying cause.

Lymphomas

Kristine Elaine Burgess, DVM, DACVIM (Oncology)

Cummings School of Veterinary Medicine, Tufts University, North Grafton, MA, USA

Canine Lymphoma

Etiology/Pathophysiology

Canine lymphoma is one of the most commonly encountered neoplasms in the dog and is most analogous to non-Hodgkin lymphoma in people. It includes multiple disorders of the lymphoid system, which are characterized by a monoclonal expansion of lymphoid cells. The etiology of lymphoma is currently unknown and is likely to be multifactorial.

Recent advances in molecular cytogenetics have demonstrated various chromosomal aberrations associated with diagnosis and prognosis in canine lymphoma. These results, while in the early phase of research, are similar to those seen in human non-Hodgkin lymphoma with dysregulation of certain molecular pathways.

Environmental Influences

A number of case–control studies have evaluated environmental influences on the development of lymphoma. These studies demonstrated that exposure to 2,4-D herbicides increases the risk of developing lymphoma. Other studies have suggested that exposure to strong magnetic fields or proximity to environmental waste may be risk factors.

Certain viruses have been associated with the development of lymphoma in humans (e.g., Epstein–Barr virus, HIV). No viruses have been identified as a causative agent for the development of canine lymphoma.

Various immune-mediated disorders (immune-mediated hemolytic anemia or thrombocytopenia), organ transplantation or a history of atopic dermatitis have been implicated in the development of canine lymphoma.

Epidemiology

The incidence of canine lymphoma has steadily increased, with approximately 84 per 10 000 dogs diagnosed each year. Certain breeds are considered to have a higher overall lifetime risk of developing lymphoma, suggesting a heritable genetic component. These include boxers, golden retrievers, basset hounds, and bulldogs. Likewise, certain breeds of dogs are considered to be at much lower risk, including dachshunds and Pomeranians.

Signalment

Average age at diagnosis is between 5 and 10 years old with no apparent sex predilection.

History and Clinical Signs

Clinical presentation of multicentric lymphoma is highly variable and will depend on the anatomic location and extent of the disease. An established World Health Organization (WHO) staging scheme for domestic animals assigns patients into five categories based on disease dissemination and anatomic site (Table 134.1). This staging system is used for accurate planning of therapy, provides prognostic information, and allows for comparisons between patients for the purposes of clinical research.

The WHO substage (a/b) is another system used for prognostication and is defined as the presence/absence of constitutional signs at the time of presentation. Constitutional signs of illness include anorexia, vomiting, diarrhea, weight loss, cachexia, fever, etc. Although these signs are somewhat subjective, this system consistently proves to be very prognostic.

Table 134.1 World Heath Organization clinical staging scheme for lymphoma in domestic animals

	Remarks
Anatomic location	
A	Generalized
B	Alimentary
C	Thymic
D	Skin
E	Leukemia
F	Other
Stage	
I	Involvement of single lymph node or lymphoid tissue in a single organ
II	Multiple involved lymph nodes in a single region
III	Generalized lymph node involvement
IV	Involvement of the liver and/or spleen (+/- stage III)
V	Presence of lymphoma in the blood/bone marrow and/or involvement of other organ systems (+/- stage I–IV)
Substage	
a	No systemic signs of illness
b	With systemic signs of illness

The most common presentation is that of an asymptomatic dog with nonpainful but markedly enlarged peripheral lymph nodes which would be classified as stage III, substage a (see Table 134.1).

In general, dogs with stage V lymphoma will present with clinical signs related to the anatomic location of the disease. For example, dogs with bone marrow infiltration may present with cytopenias, fever, sepsis or hemorrhage. Dogs with marked pulmonary involvement may present in respiratory distress.

As lymphoma has the potential to cause a wide array of clinical syndromes, it should be considered as a potential cause of any unexplained disorder in high-risk breeds until proven otherwise.

Diagnosis/Clinical Staging

A diagnosis of canine lymphoma can be achieved via fine needle aspiration (FNA) and cytologic evaluation of an enlarged peripheral lymph node or tumor tissue. Cytology supportive of lymphoma will demonstrate a population of large or intermediate-sized lymphocytes comprising the majority (>50%) of cells. Small cell lymphoma is an exception, as it may not appear cytologically malignant.

It is important to note that the presence of an inflammatory process within enlarged lymph nodes may confound a diagnosis since reactive lymphoid hyperplasia can be difficult to distinguish from lymphoma. This occurs commonly in the mandibular lymph nodes (due to dental disease or ear infections), and evaluation of these nodes should be avoided if possible.

A definitive diagnosis of lymphoma may require further analysis to determine if a clonal population of lymphocytes is present. This can be accomplished via polymerase chain reaction-based assay evaluating antigen receptor rearrangements (PARR). The presence of a clonally expanded population of cells strongly supports a diagnosis of lymphoma as it is uncommon in a reactive process. It should be noted, however, that this test can result in a high percentage (upwards to 25%) of false negatives. An alternative to PARR is a diagnostic test called flow cytometry. This assay relies on monoclonal antibodies and fluorescent markers to help confirm a diagnosis of lymphoma by evaluating for aberrancies and determining the phenotype of leukocytes within a fresh sample of blood or tissue (e.g., lymph node, effusions). Because flow cytometry requires living cells to complete the assay, an abundance of dead or dying cells will confound a definitive result.

Ideally, cytology should be used as a first-line test followed by confirmation with histology. A biopsy of lymph node or other affected tissue can be obtained surgically or via needle core biopsy. An excisional biopsy is preferred, as it allows for a more thorough classification of the type of lymphoma by preserving the architecture of the affected tissue. Biopsy samples also provide adequate tissue to perform immunohistochemical phenotyping for prognostic information by distinguishing between B and T cell forms.

Histologic Classification

Lymphomas are a complex group of diseases that vary clinically from indolent to aggressive, and from poorly controlled to manageable with treatment.

Indolent forms of lymphoma are uncommon and poorly understood. These low-grade forms of lymphoma are relatively slow growing and are associated with long survival times with limited or no therapy. Examples include marginal zone lymphoma, follicular lymphoma, B or T cell small cell lymphoma, and T zone lymphoma.

The majority of dogs have a multicentric intermediate or high-grade variety, with diffuse large lymphoblastic B cell being the most common. While higher-grade lymphomas tend to be more responsive to chemotherapy, the duration of tumor control is short when compared to animals with low-grade lymphoma, in which long survival is often achieved with minimal to no treatment.

Immunophenotype

Immunophenotyping is commonly used to distinguish the population of lymphoid cells that make up the tumor. Cell surface markers, such as CD3 and CD79a, aid in differentiating T cell from B cell lymphomas. It is well established that dogs with a B cell form of lymphoma have better response rates and prognosis compared to those with a T cell phenotype.

Staging

Minimum database including a complete blood count (CBC) with differential blood cell count, serum biochemistry profile, and urinalysis should be completed to evaluate for the presence of paraneoplastic conditions and rule out co-morbid disease.

Potential abnormalities related to lymphoma noted on a CBC include blood dyscrasias such as a nonregenerative anemia, thrombocytopenia, lymphocytosis or presence of circulating lymphoblasts. Bone marrow aspiration is indicated in dogs with blood dyscrasias to confirm lymphoma and rule out an unrelated blood disorder. This may also help to differentiate between multicentric stage V lymphoma and a primary lymphoblastic leukemia, which carries a worse prognosis.

A chemistry profile that includes a serum ionized calcium level is recommended to evaluate for the presence of hypercalcemia of malignancy and to assess liver and kidney function.

A urinalysis is helpful in evaluating renal function and can rule out a subclinical urinary tract infection. It is important to note that dogs with hypercalcemia of malignancy may present with azotemia and isosthenuria, which may not represent primary renal disease but instead is a consequence of the effects of hypercalcemia on renal tubules.

Thoracic and/or abdominal radiographs or abdominal ultrasound are recommended to determine the presence and extent of disease within visceral organs. When present, pulmonary infiltrates typically appear radiographically as diffuse interstitial and/or alveolar patterns. Rarely are there nodules or bronchial changes. Widening of the cranial mediastinum may indicate the presence of mediastinal lymphoma.

Because of the potential for cardiotoxic effects of certain chemotherapy drugs, thoracic radiographs are also important for assessment of cardiac changes.

Therapy

After establishing a diagnosis of lymphoma, a comprehensive discussion with the owner should encompass goals, prognosis, associated costs, and potential complications. It is important to note that many owners have a preconceived notion of cancer and its treatment. Therefore it should be made clear that the majority of dogs who receive chemotherapy will respond to treatment and can achieve a remission in which they are free of clinical signs related to lymphoma. In the author's experience, most owners who decide to proceed with chemotherapy are cooperative, realistic, and appreciative of the efforts made to help their pets.

Treatment options range from multiagent protocols to single-agent prednisone and will be determined by the location of the disease, the overall health of the pet, and the emotional/financial commitment of the owner.

A primary veterinarian can easily manage many dogs with multicentric lymphoma. However, consultation with an oncologist may be helpful in establishing a treatment protocol. Referral to an oncology center may be indicated for atypical cases or for patients that are refractory to treatment.

Multiagent Chemotherapy Protocols

Drugs with established activity include cyclophosphamide (C), doxorubicin (H, hydroxydaunorubicin or doxorubicin), vincristine (O, Oncovin®), and prednisone (P). Protocols incorporating these drugs are called CHOP-based protocols. All CHOP-based multiagent chemotherapy protocols are believed to be superior to any single-agent protocol with respect to remission duration and overall survival time. Multiple studies have demonstrated that approximately 80–90% of all dogs receiving a CHOP-based chemotherapy protocol will experience a clinical remission with an overall median survival time of 10–12 months. While success of treatment is highly variable, the majority of multiagent protocols induce a first remission of >6 months after chemotherapy induction.

Multiagent protocols are typically discontinued 15–19 weeks after the start of therapy. Long-term maintenance chemotherapy has not demonstrated benefit with respect to remission duration or progression-free survival.

A commonly used and well-studied chemotherapy protocol for dogs with newly diagnosed or naive multicentric lymphoma is the University of Wisconsin 19-week discontinuous (short) CHOP protocol. This protocol is simple to administer since it relies on single-agent treatment at each visit, allowing for an assessment of tolerability and efficacy of each drug. At week 19, chemotherapy is discontinued if the dog is in complete remission (Table 134.2).

Single-Agent Chemotherapy Protocols

As noted earlier, multiagent protocol drugs work best when given in combination at the onset of therapy.

Table 134.2 UW-Madison short CHOP lymphoma protocol

Treatment week		Drug, dosage, and route
1	Baseline CBC/chemistry profile/UA	Vincristine (0.5–0.7 mg/M^2) IV Prednisone 2 mg/kg once per day for 7 days
2	Pretreatment CBC/plt	Cyclophosphamide (250 mg/M^2) IV or PO[a] Prednisone 1.5 mg/kg once per day for 7 days
3	Pretreatment CBC/plt	Vincristine (0.5–0.7 mg/M^2) IV Prednisone 1 mg/kg once per day for 7 days
4	Pretreatment CBC/plt	Doxorubicin (30 mg/M^2) IV + Prednisone 0.5 mg/kg once per day for 7 days then discontinue
5		No treatment: consider restaging to assess for response to treatment[b]
6	Pretreatment CBC/plt	Vincristine (0.5–0.7 mg/M^2) IV
7	Pretreatment CBC/plt	Cyclophosphamide (250 mg/M^2) IV or PO[a]
8	Pretreatment CBC/plt	Vincristine (0.5–0.7 mg/M^2) IV
9	Pretreatment CBC/plt	Doxorubicin (30 mg/M^2) IV
10		No treatment
11	Pretreatment CBC/plt	Vincristine (0.5–0.7 mg/M^2) IV
12	Pretreatment CBC/plt	Cyclophosphamide (250 mg/M^2) IV or PO[a]
13	Pretreatment CBC/plt	Vincristine (0.5–0.7 mg/M^2) IV
14	Pretreatment CBC/plt	Doxorubicin (30 mg/M^2) IV[c]
15		No treatment
16	Pretreatment CBC/plt	Vincristine (0.5–0.7 mg/M^2) IV
17	Pretreatment CBC/plt	Cyclophosphamide (250 mg/M^2) IV or PO[a]
18	Pretreatment CBC/plt	Vincristine (0.5–0.7 mg/M^2) IV
19	Pretreatment CBC/plt	Doxorubicin (30 mg/M^2) IV[d]

[a] Administer with furosemide 2 mg/kg SC to prevent sterile hemorrhagic cystitis (SHC). Substitute with chlorambucil at 1.4 mg/kg if SHC develops.
[b] Reduce dose to 1 mg/kg for dogs <15 kg.
[c] Do not exceed 180 mg/M^2 maximum cumulative dose.
[d] If progressive disease is noted at any point in the treatment protocol, rescue chemotherapy should be considered.
CBC, complete blood count; IV, intravenous; plt, platelets; PO, by mouth (per os); UA, urine analysis.

If multiagent therapy is not an option, it is reasonable to incorporate any number of the CHOP drugs and create an individual protocol that suits the dog and the owner. Doxorubicin as a single agent, administered every 2–3 weeks (up to five total treatments), can induce a remission in 50–75% of dogs for a median of 6–8 months. Care must be taken to monitor for cumulative cardiotoxic effects of this drug in the dog, which can result in dilated cardiomyopathy (DCM). It is advisable to avoid this drug in dogs with a preexisting heart condition or breeds that are considered high risk for DCM (e.g., boxer, Doberman pinscher, Great Dane, etc.). Other protocols with similar success include cyclophosphamide, vincristine, and prednisone (referred to as COP).

Dogs which are treated with a palliative protocol of prednisone as a sole therapy can achieve a short-lived remission of approximately 1–2 months. It is important to note that these dogs, when compared to dogs given multiagent therapy from the outset, are more likely to develop multidrug resistance and experience shorter remission and survival times if any subsequent chemotherapy is administered.

Reinduction Chemotherapy Protocols

Reinduction with CHOP-based drugs is recommended provided that the recurrence is temporally far enough from the conclusion of the initial protocol (i.e., ≥ 2 months). Typically, a second or even third remission is achievable with a variable duration of response.

Rescue Chemotherapy

Inevitably, resistance to the CHOP-based chemotherapy drugs will develop, and it is unlikely that continued use of the same drugs will provide a significant benefit. At that point, drugs not used in the initial CHOP protocols are recommended and are referred to as rescue

chemotherapy agents/protocols. Successful induction of an additional remission with rescue protocols varies between 50% and 90% but the length of remission is decreased, at 1.5–2.5 months.

A novel chemotherapy agent, rabacfosadine (Tanovea®), has been conditionally approved for use in dogs with naive or relapse lymphoma. This compound as a single agent has demonstrated excellent efficacy for dogs with B cell form of lymphoma and may be variably successsful for dogs with a T cell variant. Other second-line drugs often used for rescue therapy include lomustine (CCNU), mechlorethamine (Mustargen®), vinblastine (Velban®), dacarbazine (DTIC), and cytosine arabinoside (Cytosar-U®). While each of these drugs has a variable degree of efficacy against lymphoma, the duration of response is considerably lower when compared to standard multiagent protocols.

Complications of Chemotherapy

A majority of dogs tolerate chemotherapy well. Potential adverse effects include mild to moderate nausea, vomiting, or diarrhea, all of which are easily treated with supportive care or symptom management. In rare instances, life-threatening complications related to chemotherapy-induced myelosuppression can develop, requiring hospitalization and aggressive supportive care.

A CBC must be performed prior to every treatment to ensure an adequate white blood cell count. It is generally accepted that an absolute neutrophil count of >2000 cells/μL and >50 000 platelets/μL be present prior to chemotherapy administration to minimize the risk of sepsis or other complications.

Extranodal Forms of Lymphoma

There are instances where a dog will present with lymphoma isolated to a solitary site, such as the alimentary tract, skin, central nervous system (CNS) or nasal cavity. On rare occasions, local therapies such as surgery or radiation therapy may be employed. Careful staging, including bloodwork, thoracic radiographs, +/- abdominal ultrasound, +/- bone marrow aspiration, is essential to ensure multicentric involvement is not present before considering local therapy.

Alimentary Lymphoma

Alimentary lymphoma is an uncommon extranodal lymphoma. Dogs will present with nonspecific clinical signs consistent with gastrointestinal (GI) disease, including weight loss, anorexia, diarrhea, and vomiting. Limited information in the veterinary literature suggests this form of lymphoma is poorly responsive to chemotherapy. In the author's experience, a chemotherapy protocol that incorporates CCNU can be more effective than a multidrug CHOP-based chemotherapy protocol alone.

Cutaneous Lymphoma

A primary cutaneous form of lymphoma can develop within the skin and/or the oral cavity (mucocutaneous). Dogs may present with pruritus, scaling of the skin, and alopecia that will progress to areas of ulceration, nodules, and proliferative plaques. Lesions can be solitary or can involve multiple skin sites. Oral involvement appears as plaque-like lesions or nodules associated with the gums and lips. Multiple punch biopsies of the affected areas are necessary to establish a diagnosis of lymphoma. There are two types of cutaneous lymphoma distinguished histologically and phenotypically: epitheliotropic (T cell) lymphoma (also called mycosis fungoides) and nonepitheliotropic (B or T cell) lymphoma.

Treatment of cutaneous lymphoma depends on the extent and location of disease. Single lesions may be appropriately treated with local therapy consisting of surgery or radiation therapy. Diffuse cutaneous lymphoma is best treated with chemotherapy. B cell cutaneous lymphomas often respond better than T cell, but the response rate with chemotherapy is less than that seen with other forms of lymphoma.

CCNU or multiagent chemotherapy is the treatment of choice, although a recent study has also supported the use of Tanovea when treating dogs for cutaneous forms of lymphoma. While many dogs have an initial response to chemotherapy, the lesions often return or new lesions develop within a short period of time (3–5 months). Many dogs are euthanized within six months of diagnosis due to the discomfort associated with progressive ulceration, bleeding, and pruritus.

Prognosis

Response rates and remission duration for dogs with newly diagnosed lymphoma will vary depending on the clinical picture, biologic behavior, histologic classification, immunophenotype, and treatment protocol. In general, dogs with large B cell lymphoma have better response rates to a CHOP-based chemotherapy protocol than dogs with T cell lymphoma. In fact, due to the variable success in the treatment of dogs with T cell lymphoma, many oncologists are now relying on a modified chemotherapy protocol that incorporates more alkylating agents (e.g., cyclophosphamide or lomustine). This modification is based on the presumption that these agents may be more effective agents for dogs with a T cell form of lymphoma.

Additional Treatment Strategies

Because most dogs ultimately will develop chemotherapy resistance, other methods of lengthening a clinical remission may be employed. These include total and half-body radiation therapy, hematopoietic stem cell

transplantation (bone marrow transplant), and immunotherapy. These treatment strategies have variable success and continue to be an active area of investigation.

Feline Lymphoma

Etiology/Pathophysiology

Lymphoma (LSA) is one of the most common neoplasms in the cat and can present in a variety of ways, depending on the organ(s) affected. An association with retroviral infection has been firmly established, with approximately 25% of feline leukemia virus (FeLV)-positive cats developing lymphoma during their lifetime. Feline immunodeficiency virus (FIV) has also been implicated in the development of lymphoma, although its true contribution has been difficult to determine since it often occurs in conjunction with FeLV. Chronic immunosuppression secondary to retroviral infection is thought to play a role in this association. This correlates with the increased incidence of lymphoma in cats receiving chronic immunosuppressive drugs after renal transplantation. Collectively, these findings parallel an increased incidence of lymphoproliferative cancers in humans with human immunodeficiency virus (HIV) or those receiving chronic immunosuppressive therapy.

The underlying cause of nonretroviral-induced feline lymphoma is not completely understood. It is likely that chronic inflammation plays a role given that feline lymphomas frequently arise in organs or sites affected by chronic inflammation. For example, a correlation between chronic inflammatory bowel disease and alimentary lymphoma has been proposed. Comparatively, humans with celiac disease have a similar predisposition towards lymphoproliferative disorders and cancer.

Recent studies have also demonstrated that chronic exposure to environmental tobacco smoke is associated with an elevated risk for gastrointestinal lymphoma in cats.

Epidemiology

Lymphoma is the most common neoplasm of the hematopoietic system of cats, with an estimated incidence of 200 per 100 000 cats.

Studies have demonstrated that FeLV-positive cats have a 60-fold or greater relative risk of the cancer. FIV infection also increases the relative risk of lymphoma 5–6-fold.

While the incidence of feline lymphoma has not changed with the development of effective antiviral vaccines, the most common presentation of lymphoma is now in older retrovirus-negative cats.

Signalment

There is a bimodal distribution for feline lymphoma in which retroviral-positive cats present with lymphoma at a young age (1–3 years) and virus-negative cats present at an older age (10–13 years). Currently, the median age at presentation is approximately 11 years. There is no sex predilection and any breed of cat can be affected, although Siamese cats are overrepresented, suggesting a genetic susceptibility to the disease.

History and Clinical Signs

Location of the tumor appears to be the determinant of clinical signs and prognosis in feline lymphoma. Consequently, the WHO staging system is not used. Instead, lymphoma is generally divided into different anatomic classifications: mediastinal, gastrointestinal, multicentric, and miscellaneous sites (such as nasal and renal).

Mediastinal Lymphoma

Young cats typically present with a mediastinal form of lymphoma with acute-onset dyspnea, which rapidly progresses as the tumor begins to occlude lymphatics, leading to pleural effusion. Physical examination may reveal a noncompressible cranial thorax and muffled or caudodorsal displacement of cardiac sounds.

Alimentary Lymphoma

Alimentary lymphomas usually involve the stomach and intestines of older cats. Gastrointestinal tumors may be discrete or diffuse. The primary clinical signs are anorexia and weight loss, although some cats may also present with vomiting and/or diarrhea. With these clinical signs, it is important, though often difficult, to differentiate lymphoma from inflammatory bowel disease.

Extranodal Lymphoma

Cats with other forms of lymphoma (e.g., nasal, renal, CNS, laryngeal) will present with clinical signs reflecting the anatomic location.

Diagnosis

As described in dogs, a diagnosis of lymphoma can be achieved via fine needle aspiration or surgical, endoscopic or needle biopsy of affected tissue. As noted previously, a definitive diagnosis via a fine needle aspirate can be confounded by an insufficient or nondiagnostic sample, or if there is a significant component of inflammation present. Because alimentary lymphoma is easily confused with inflammatory bowel disease (IBD), a full-thickness tissue biopsy is often necessary to

establish a definitive diagnosis. A histologic evaluation of the diseased tissue will provide a more accurate evaluation of tissue morphology and degree of invasion. If an equivocal diagnosis is present, techniques such as immunohistochemical or immunocytochemical analysis, flow cytometric analysis and polymerase chain reaction-based clonality assays are available to characterize the disease and refine the diagnosis.

Currently, a histologic classification scheme similar to those described in humans and dogs does not exist for feline lymphoma. There are two histologic forms: high- (or intermediate) grade lymphoma and low-grade (or small cell) lymphoma. These histologic distinctions in combination with anatomic location are the most prognostic and will determine treatment.

Immunophenotype

Immunophenotyping is not commonly used for prognostication purposes in the cat as it is in dogs and humans. It is employed, however, to confirm the presence of a phenotypically identical population of lymphoid cells that make up the tumor. This can be completed on tissue samples via histochemical or cytochemical staining for CD3 (T cell expression) or CD79a (B cell expression). According to some studies, a T cell phenotype is more prevalent in cats with small cell or low-grade alimentary lymphoma and B cell phenotype is more common in large cell or high-grade lymphoma. As mentioned previously, cell morphology (large cell vs small cell) is used more commonly than a phenotypic distinction to determine treatment and prognosis.

Alimentary Lymphoma

Cats with alimentary lymphoma are typically diagnosed via abdominal imaging (e.g., ultrasound), which is abnormal in approximately 60–90% of cats. The appearance is variable, and may be of a circumferential mass with loss of GI wall layering, or of a diffuse small intestinal wall thickening of the muscularis, propria, and submucosa. Mesenteric lymphadenopathy is also common and has been reported in 45–80% of affected cats.

A cytologic or histologic assessment of a needle aspirate or needle biopsy samples from intestinal masses, enlarged lymph nodes or other abnormal-appearing organs is essential to establish a diagnosis. Endoscopic, laparoscopic or incisional biopsy achieved by laparotomy may also be performed. Full-thickness GI biopsies best distinguish inflammatory bowel disease from lymphoma and will differentiate a high- or low-grade intestinal lymphoma.

Mediastinal Lymphoma

For cats with mediastinal lymphoma, a diagnosis can be established via survey thoracic radiographs followed by thoracocentesis with cytologic examination of the fluid. The fluid lymphocyte count is usually greater than 4000/μL, with most appearing as intermediate or large lymphoblasts. In cases where fluid cytology is not diagnostic, aspiration or biopsy of the mass itself can be completed via ultrasound or computed tomography (CT) guidance. Immunophenotypic and clonality assessment may be helpful in equivocal cases.

Nasal Lymphoma

Nasal lymphoma differs from other sites in that it is often non-systemic and confined to the nose and/or sinuses. Nasal CT or magnetic resonance imaging (MRI), rhinoscopy, and biopsy are necessary to establish a diagnosis. Thorough staging with evaluation of regional lymph nodes, thorax, and abdomen is recommended if local radiation therapy is to be considered for sole treatment.

Renal Lymphoma

Renal lymphoma usually causes bilateral renomegaly which may be detected on physical exam. Clinical signs at presentation are a consequence of renal insufficiency. Ultrasound-guided renal biopsy or FNA is recommended to confirm the diagnosis.

Central Nervous System Lymphoma

Spinal CNS lymphoma usually causes hindlimb paresis or paralysis with or without back pain. Most tumors are extradural, and occur in the thoracolumbar or lumbosacral regions. Often there is no radiographic evidence of disease. The clinical signs of brain lymphoma are attributable to the region of brain affected. Advanced imaging with MRI or CT can be helpful in determining extent and location of the lesion, and to evaluate for multifocal disease. Because cerebral spinal fluid evaluation is not always definitive for lymphoma, a diagnosis may be attempted through cytologic evaluation of the bone marrow or kidneys since these organs are also involved in up to 70% of cases.

Staging

As in canine lymphoma, beyond those initial diagnostics performed to establish the diagnosis of lymphoma, additional diagnostics should be considered as part of complete staging.

A complete blood work-up including a CBC with differential blood cell count, serum biochemistry profile, urinalysis, and FeLV/FIV screen should be completed on all cats. While most cats will have an unremarkable blood profile, this is useful to evaluate for the presence of other co-morbid conditions.

A bone marrow aspirate is indicated in cats with blood dyscrasias to confirm the presence of lymphoma and rule out other etiologies. Results of a bone marrow

aspiration may help guide treatment if blood dyscrasias are present.

Thoracic +/- abdominal radiographs or preferably abdominal ultrasound are recommended to determine the presence and extent of disease within visceral organs.

Therapy

There is less known about multicentric lymphoma treatment protocols in the cat relative to the dog. While success of the various chemotherapy protocols is highly variable, the majority are capable of inducing a first remission of >6 months after induction. Protocol choice is based on cell type/grade.

Small Cell or Low-Grade Lymphoma

Cats with a well-differentiated or small cell form of lymphoma can have an excellent prognosis, and may survive for prolonged periods, with chlorambucil and prednisolone.

Large Cell or High-Grade Lymphoma

Similar to the dog, drugs with established activity in intermediate and high-grade lymphomas include cyclophosphamide (C), doxorubicin (H, hydroxydaunorubicin or doxorubicin), vincristine (O, Oncovin®,), methotrexate, CCNU (lomustine) and prednisone (P). Multiple protocols incorporate these drugs as first- or second-line treatments and are considered a COP- or CHOP-based protocol, depending on the drugs used. These multiagent chemotherapy protocols are used commonly for cats with intermediate to large cell (high-grade) lymphoma of any anatomic location (Table 134.3). Currently, few data exist to compare outcomes using the various modifications of treatment for cats; consequently a protocol may be based on client/veterinarian preference.

Unlike canine lymphoma, in which chemotherapy is often discontinued after a period of time as long as the pet continues to be in remission, comparable data do not exist in the cat. Consequently, many cats continue to receive maintenance chemotherapy for up to a year or longer. Also unlike in humans and dogs receiving doxorubicin-based protocols, cats are at low risk for cardiotoxicity though they are susceptible to its renal toxic effect. Renal function must be monitored with BUN, creatinine, and urine specific gravity, ideally before each treatment with doxorubicin. Corticosteroids may exacerbate cardiomyopathy in cats and these drugs should be avoided or used conservatively in patients with clinical or subclinical heart disease.

Renal Lymphoma

Because many cats with renal lymphoma have or will develop CNS involvement, treatment with a multiagent protocol incorporating a drug with CNS penetration (such as CCNU) is recommended.

Central Nervous System Lymphoma

Central nervous system lymphoma should be treated with chemotherapy or radiation therapy emergently as clinical signs, particularly paralysis, may become permanent if treatment is delayed.

Table 134.3 Modified COP protocol for treatment of feline lymphoma

Treatment week	Drug, dosage, and route
1 CBC/chemistry profile/UA as baseline prior to therapy	Vincristine 0.5–0.6 mg/M^2 Cyclophosphamide 200 mg/M^2 Prednisolone 2 mg/kg daily
2 Pretreatment CBC/plt	Vincristine 0.5–0.6 mg/M^2 Prednisolone 2 mg/kg daily
3 Pretreatment CBC/plt	Vincristine 0.5–0.6 mg/M^2 Prednisolone 1 mg/kg daily
4[a] Pretreatment CBC/plt and renal profile with USG if using doxorubicin	Vincristine 0.5–0.6 mg/M^2 Cyclophosphamide 200 mg/M^2 OR substitute with doxorubicin (1 mg/kg) if not in clinical remission Prednisolone 1 mg/kg daily
5/6 Posttreatment CBC/plt	Restage with ultrasound and/or thoracic radiographs
7 Pretreatment CBC/plt	Vincristine 0.5–0.6 mg/M^2 Cyclophosphamide 200 mg/M^2 Prednisolone 1 mg/kg daily
8/9	No treatment
10 Pretreatment CBC/plt	Vincristine 0.5–0.6 mg/M^2 Cyclophosphamide 200 mg/M^2 Prednisolone 1 mg/kg daily
11/12	No treatment
13 Pretreatment CBC/plt	Vincristine 0.5–0.6 mg/M^2 Cyclophosphamide 200 mg/M^2 Prednisolone 1 mg/kg daily
14/15	No treatment Restage when clinically indicated
16 Pretreatment CBC/plt	Vincristine 0.5–0.6 mg/M^2 Cyclophosphamide 200 mg/M^2 Prednisolone 1 mg/kg daily[b]

[a]If a clinical remission has not been achieved by week 4, then substitute with doxorubicin and alternate with vincristine/cyclophosphamide. Use doxorubicin only if adequate renal function has been established with renal profile and urine specific gravity.
[b]Continue every three weeks until relapse or for one year of continuous remission.
CBC, complete blood count; plt, platelets; UA, urine analysis; USG, urine specific gravity.

Nasal Lymphoma

If nasal lymphoma is confirmed to be nonsystemic, local radiation therapy may be indicated as a sole treatment.

Other Anatomic Locations

Other infrequently encountered forms of lymphoma in the cat include laryngeal or tracheal. Cats presenting with disease isolated to these locations can respond positively to local radiation therapy +/- chemotherapy for periods of 6–12 months.

Prognosis

Generally, the overall response rate and survival time in cats are much lower than those achieved in dogs. However, this varies and is determined by the anatomic location at presentation, grade of tumor, and viral status of the cat.

High-grade tumors progress rapidly but are more likely to respond to multiagent chemotherapy for a finite period of time, whereas low-grade tumors progress slowly and can be easily managed as chronic diseases.

Cats with mediastinal lymphoma respond well to chemotherapy initially, but the duration of response is usually short-lived (2–3 months).

Cats with high-grade alimentary lymphoma treated with a multiagent chemotherapy protocol can respond with median survival times of 210 days. A positive response to treatment is the best prognostic indicator. Cats achieving a complete or partial remission have a significantly longer survival time of >2 years.

Cats with nasal lymphoma can enjoy lengthy survival times of 1–3 years or more with radiation therapy +/- chemotherapy.

Central nervous system and renal lymphoma are uncommon but when encountered, cats can experience a short period of clinical benefit from chemotherapy and/or radiation therapy for a median of 2–6 months.

Conclusion

Cats and dogs with lymphoma can respond favorably to chemotherapy +/- radiation therapy. The treatments are generally well tolerated with most animals achieving a clinical benefit for variable periods of time. Prognosis is dependent on location, extent of disease, histologic grade, and phenotype. Cancer treatment in pets can be a rewarding experience. Most pet owners appreciate the dedication of the veterinarian and the additional quality time they gain with their pets.

Plasma Cell Disorders

Orna Kristal, DVM, DACVIM (Oncology)

Kfar Saba, Israel

Etiology/Pathophysiology

Plasma cell neoplasms develop from clonal proliferation of terminally differentiated immunoglobulin-producing B lymphocytes. They typically produce a homogenous monoclonal immunoglobulin which is why they are thought to originate from a single cell. However, not all neoplasms are secretory and some may be biclonal or even polyclonal. Reported plasma cell disorders (PCD) in dogs and cats include multiple myeloma (MM), cutaneous and noncutaneous extramedullary plasmacytoma (EMP), IgM (Waldenström) macroglobulinemia (WM), solitary osseous plasmacytoma (SOP), and plasma cell leukemia.

The etiology of PCD in dogs and cats is largely unknown. No retroviral association was found in cats. Chronic immune stimulation in rodent models and chronic infections in people have been associated with MM. Exposure to ionizing radiation is a well-known risk factor and agricultural chemicals, benzene, and petroleum products have been considered potential risk factors in humans.

Multiple myeloma usually originates from multiple bone marrow sites in dogs. In cats, multicentric noncutaneous EMP with or without bone marrow involvement may present as MM. The neoplastic plasma cells in MM typically secrete abnormal amounts of a single whole or partial (light or heavy chain) immunoglobulin called the M component, or paraprotein. In dogs, the M component is usually IgA or IgG with similar frequency. In cats, the IgG class is four times more common than IgA. IgM overproduction is uncommon in both species and is more often associated with WM, a form of lymphoplasmacytic lymphoma. The abnormal light chains are excreted in the urine and are called Bence Jones proteins.

Uncommon presentations in both species include biclonal gammopathies, nonsecretory MM, monoclonal gammopathies without hyperglobulinemia and cryoglobulinemia. Cryoglobulins are immunoglobulins that precipitate in temperatures below 37 °C, so they are usually lost in the clot when the blood is allowed to clot at room temperature.

Multiple myeloma negatively affects many organ systems as a result of tumor infiltration, high levels of circulating or deposited M component, production of cytokines by tumor cells or bone marrow microenvironment and the effects on the immune system.

Abnormal immunoglobulins can lead to hyperviscosity syndrome (HVS) when high protein levels are reached. The incidence of HVS is highest with IgM (WM) which is a pentamer and has a high molecular weight, followed by IgA-secreting myelomas which are dimers that can polymerize. IgG-associated HVS occurs less frequently. Increased serum viscosity leads to "sludging" of blood in the vasculature that results in hypoxia and bleeding diathesis leading to organ damage. HVS occurs in about 30% of dogs with MM and most commonly affects the central nervous system (CNS), eyes, cardiovascular system, and coagulation system.

Bleeding disorders are common in dogs with MM and the mechanism is likely multifactorial. Coating of platelets with paraproteins leads to decreased adhesiveness, failure to release platelet factor III, and thrombocytopathia. Paraproteins can also interfere with clotting factors and lead to abnormal fibrin polymerization. Thrombocytopenia due to bone marrow infiltration (myelophthisis) or immune-mediated disease may also contribute to bleeding. Approximately 33% of dogs and 25% of cats with MM have clinical evidence of bleeding.

Nonregenerative normocytic normochromic anemia is the most common hematologic abnormality in MM patients, present in about 66% of dogs and cats. Etiologies may include myelophthisis, decreased erythrocyte life span due to coating with paraprotein, blood loss, production of inhibitory cytokines by myeloma cells and decreased erythropoietin production due to renal

Companion website: www.wiley.com/go/bruyette/clinical

dysfunction. Thrombocytopenia and neutropenia may also occur.

Suppression of normal immunoglobulin production is common and is suggested to result from normal feedback inhibition induced by the monoclonal gammopathy. In people, maturation of normal B cells to plasma cells is suppressed as well as T helper cell number and function. These abnormalities can lead to immunosuppression and, combined with neutropenia, increased risk for bacterial infections.

Osteolytic bone lesions are induced by secretion of osteoclast-activating factors from the bone marrow microenvironment and myeloma cells. These factors include the cytokines interleukin (IL)-1 beta, tumor necrosis factor (TNF)-beta, and IL-6. Osteolytic lesions may cause pain, lameness, spinal compression due to extradural tumor masses, or vertebral fractures which can lead to paresis or paralysis. Lytic bone lesions are detected in 50–60% of dogs with MM. In cats, skeletal involvement is more variable, noted to occur in 8% of cases in one case series and in up to 58–67% in other reports.

Hypercalcemia occurs in 15–20% of dogs and 9–25% of cats with MM. Hypercalcemia was present in 50% of dogs with MM at diagnosis when ionized calcium rather than total calcium was measured. The main proposed mechanism is direct bone osteolysis, although skeletal lytic lesions are more common than hypercalcemia. Hypercalcemia may be worsened by concurrent renal disease.

Renal disease is one of the serious complications of MM, reported in 30–50% of dogs and about 25% of cats. Light chains that are filtered by the glomerulus precipitate in the renal tubule, causing interstitial nephritis. Hypercalcemia, infiltration of the kidneys by myeloma cells, decreased renal blood flow secondary to hyperviscosity, amyloidosis, glomerulonephritis, and pyelonephritis following immunosuppression may also contribute to renal dysfunction.

Cardiac disease, a less common complication, may be explained by increased peripheral vascular resistance, excessive cardiac workload, and myocardial hypoxia secondary to hyperviscosity.

Waldenström macroglobulinemia is a rare disease in animals and is considered a form of lymphoplasmacytic lymphoma involving the spleen, lymph nodes, and bone marrow along with serum IgM-related signs of hyperviscosity or cryoglobulinemia. Osteolytic bone lesions and hypercalcemia are not present and Bence Jones proteinuria is uncommon.

Solitary PCD include EMP and SOP. They are defined as local accumulation of neoplastic monoclonal plasma cells without evidence of systemic PCD. Canine EMPs are distinct, usually solitary tumors unrelated to MM. The skin, especially the head, and extremities are affected most commonly, followed by the mucous membranes of the oral cavity (Figure 135.1) and the colorectal junction.

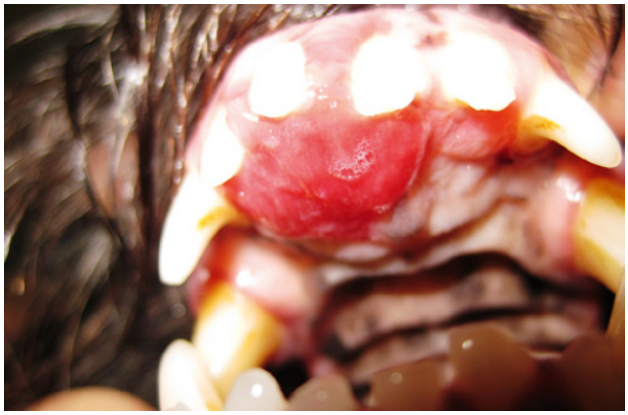

Figure 135.1 Oral extramedullary plasmacytoma in the maxilla of a dog.

Other sites such as gastrointestinal, trachea, larynx, eye, genitalia, and others are rare and comprise 1% of all EMP cases. Cutaneous, oral, and colorectal EMPs are usually benign but can be locally invasive and cause bone destruction in the oral cavity. In humans, cutaneous EMP is uncommon and is often part of a multicentric disease. In dogs, MM rarely exhibits cutaneous involvement. Fewer reports exist regarding solitary EMP in cats but their behavior and site distribution appear similar to dogs. The multicentric EMP as part of MM is more common in cats than dogs although incorporating abdominal ultrasound and cytology into the staging of MM may prove abdominal organ involvement is more common than previously thought. A recent study showed that 57% of dogs with MM that underwent abdominal ultrasound were cytologically confirmed to have liver, spleen, or abdominal lymph node involvement. Amyloid deposits of immunoglobulin origin occur in 3–13% of EMPs.

Solitary osseous plasmacytomas have been reported in the dog affecting the appendicular skeleton, zygomatic arch, and vertebrae. In humans (and probably in dogs), the prognosis is much better than for MM but about 50% of SOPs will eventually develop into MM.

Epidemiology

Multiple myeloma is uncommon in both dogs and cats, representing less than 1% of all malignancies. It comprises about 8% of all hematopoietic tumors and 3.6% of all primary and secondary bone tumors in dogs. The incidence in both species is lower than in humans.

Signalment

Multiple myeloma affects older animals with a median age of 8–9 years (range, 2–15) in dogs and 12–14 years in cats

(range, 4–18). There is no breed or sex predilection in dogs. In cats, it is most common in domestic short-hairs and a slight male predisposition has been reported. EMPs usually occur in middle-aged to older dogs (median age 9–10 years). The cocker spaniel and West Highland white terrier seem to be at increased risk. Solitary EMPs are less common in cats and SOP is rarely reported in both species.

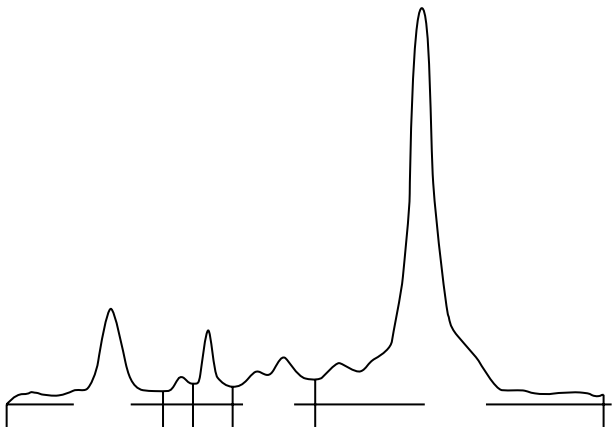
History and Clinical Signs

Clinical signs of MM are variable, with a median duration of one month prior to diagnosis. In dogs, the most common presenting sign is lethargy and weakness (62%). Skeletal lytic lesions lead to lameness, pain and paresis or paralysis with vertebral involvement (47%). Bleeding disorders most commonly present as epistaxis or gingival bleeding (37%). Ocular and CNS abnormalities are caused by HVS, systemic hypertension or both. Ocular signs include retinal bleeding, enlarged tortuous retinal vessels, retinal detachment (35%), and acute onset of blindness. Hyphema, episcleral injection, corneal edema, and aqueous flare may also occur. CNS signs include dementia, personality changes, disorientation, and seizures (12%). Polyuria/polydipsia (25%) may develop secondary to renal disease and hypercalcemia. Cardiopulmonary signs (syncope, cyanosis, congestive heart failure [CHF]) are less common. Vomiting, anorexia, and weight loss have been seen in dogs with hypercalcemia and/or renal disease. Some dogs may present with secondary infections such as cystitis.

Physical examination findings may include pale mucous membranes, dehydration, fundic changes, neurologic deficits, fever, and cranial organomegaly.

In cats, lethargy, anorexia, and weight loss are the most common clinical signs. Vomiting and diarrhea, as well as cranial organomegaly and cutaneous or subcutaneous masses are more common than in dogs.

Cutaneous and mucosal EMPs usually appear as pink or red, raised, alopecic and sometimes ulcerated solid nodules, about 1–2 cm in diameter (see Figure 135.1), but they can range from 0.2 to 10 cm in diameter. The majority of tumors are single, but some dogs may develop more than one tumor simultaneously or sequentially. Oral EMPs can cause bleeding and decreased appetite. Colorectal EMPs can lead to hematochezia, rectal bleeding, tenesmus, and rectal prolapse. SOPs cause pain, lameness, or neurologic symptoms.



Diagnosis

Suspicion of MM usually arises in an animal presenting with appropriate clinical signs and hyperglobulinemia. Initial evaluation includes CBC, full chemistry panel, and urinalysis. Additional findings on these tests such as anemia, hypoalbuminemia, renal dysfunction, and hypercalcemia should prompt work-up for MM (Table 135.1).

Table 135.1 Frequency of abnormal diagnostic test results in dogs and cats with MM

Test abnormality	Dogs (%)	Cats (%)
Anemia (nonregenerative)	68	41–69
Thrombocytopenia	33–45	50
Leukopenia	25	37
Circulating plasma cells	10	5–27
Hypoalbuminemia	65	36
Hypocholesterolemia	Not reported	68
Renal azotemia	33	23–36
Hypercalcemia	17–50	9–25
Proteinuria	35	77
Bence Jones proteinuria	40	44–50
Hyperviscosity	32	35–44
Bone lysis (radiographs)	50	8–56

Serum protein electrophoresis (SPE) separates proteins based on their size and electrical charge. The immunoglobulins are contained in the beta and gamma fractions and monoclonal gammopathies produce a narrow peak in one of these fractions (Figure 135.2). Rarely,

Fractions	%	Ref. %	g/L	g/L
Albumin	12.9	55.8–66.5	16.4	43.0–51.0
Alpha 1	2.3	2.9–4.0	2.9	1.0–2.0
Alpha 2	5.3	7.1–14.5	6.7	5.0–8.0
Beta	9.8	8.6–14.8	12.4	6.0–9.0
Gamma	69.7	9.2–18.2	88.5	6.0–11.0

Figure 135.2 Serum protein electrophoresis results in a dog with MM. The albumin peak is on the far left and there is a tall, narrow spike in the gamma region on the right consistent with monoclonal gammopathy. Total protein level was 12.7 g/dL. *Source:* Courtesy of Dr Roni Minke, American Medical Laboratories, Hertzeliah, Israel.

MM produces a biclonal gammopathy. A dog with MM may still have a normal globulin level due to suppression of normal globulin production. Therefore, if findings support MM, SPE should be done even if total globulin level is normal. When monoclonal gammopathy is demonstrated, immunoelectrophoresis can determine the antibody type.

Urinalysis provides information on renal function, urinary tract infection, and proteinuria. However, urine dipsticks only measure albumin. Special heat precipitation methods are required to detect Bence Jones proteins. This is a qualitative test associated with a high rate of false-positive and -negative results in people. Urine electrophoresis or immunoelectrophoresis may be more reliable.

Bone involvement may appear on radiographs as multiple osteolytic lesions affecting mainly the axial skeleton, or as diffuse osteoporosis (Figure 135.3). Plain survey skeletal radiographs are recommended for detection of these lesions. It is best to start with thoracic, lumbar spine, and pelvic radiographs, unless pain is localized to other bones. Skeletal CT can be more sensitive than radiographs for detection of small lesions and spinal cord compression. Radionuclide bone scans are not recommended because MM lesions are primarily lytic and may be undetectable. Abdominal ultrasound is recommended in all cats and in dogs without bone marrow plasmacytosis. Most common abnormalities are splenomegaly, hepatomegaly, and changes in echogenicity or nodules in these organs.

Bone marrow aspiration is required for a definitive diagnosis of MM and is taken from routine sites. In some cases, aspiration or a needle core biopsy is taken directly from a lytic lesion if it is large enough and accessible. This is especially pertinent in cases of SOP. Normal bone marrow contains less than 5% plasma cells. Finding of >10% plasma cells in the marrow, especially if cellular atypia or clustering is present, is used to diagnose MM by some investigators, while the majority agree that >20% plasma cells is a more reliable value. The morphology of neoplastic plasma cells varies from normal to large pleomorphic cells with large cytoplasm, high mitotic index, and multinucleation (Figure 135.4). In cats (and less often in dogs), bone marrow infiltration may not be severe enough and visceral organ infiltration may be diagnostic instead.

In patients with hypercalcemia, ionized calcium is indicated for confirmation because binding of calcium to paraproteins will increase total calcium while ionized calcium remains normal. Hypocholesterolemia was reported in 68% of cats with MM in one study. A possible explanation is downregulation of cholesterol production by the liver to maintain oncotic pressure in the face of hyperglobulinemia. When HVS is suspected, serum viscosity can be measured in relation to water. Normal canine serum viscosity is 1.6–1.8 times that of water. Clinical signs of HVS usually appear when serum viscosity is greater than five times that of water.

Differential diagnoses for monoclonal gammopathy include B cell lymphoma, mainly chronic but also acute B cell lymphoid leukemia, WM, chronic infections such as *Ehrlichia canis* and leishmaniasis in dogs, feline infectious peritonitis (FIP) in cats, and monoclonal gammopathy of unknown significance (MGUS). The latter is a benign process, well recognized in humans but only a few cases have been reported in dogs and cats.

Diagnosis of EMP and SOP is made by tissue biopsy or fine needle aspirate. Most EMPs are not well

Figure 135.3 Lateral radiograph showing well-demarcated small "punched out" lytic lesions and a "lacy" trabecular pattern in the cervical vertebrae due to diffuse osteopenia in a dog with MM.

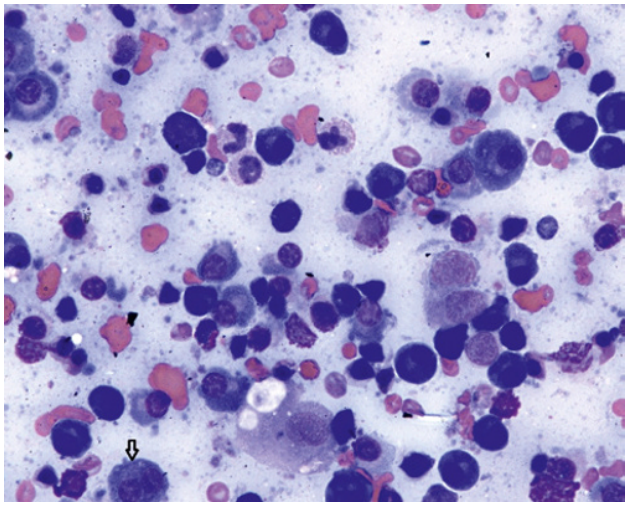


Figure 135.4 Bone marrow aspirate from a dog with multiple myeloma showing abundant plasma cells with a typical paranuclear clear zone of the golgi apparatus. A single bincucleate cell is present (*arrow*). *Source:* Courtesy of Dr Sharon Kuzi, Koret School of Veterinary Medicine, Israel.

differentiated and can be difficult to differentiate from other round cell tumors. Immunohistochemistry (IHC) is sometimes utilized in these cases to detect light and heavy chains. The majority of EMPs stain for lambda light-chains, similar to the physiologic distribution of light chains in normal canine and feline plasma cells. Staining for multiple myeloma oncogene 1/interferon regulatory factor 4 (MUM1/IRF4) is highly sensitive for EMPs but 21% of B cell lymphomas stain positive as well. It is therefore recommended to use it in combination with other round cell markers together with morphology of the cells. SOP, GI EMP, and multiple cutaneous EMPs in dogs can metastasize, or develop into MM. Therefore, it is important to fully stage them at diagnosis. Staging includes SPE (even if total globulin level is normal), bone marrow aspiration, survey skeletal radiographs, and abdominal ultrasound.

Therapy

Chemotherapy with melphalan and prednisone is the treatment of choice for MM in dogs. Although cure is unlikely, response to treatment is achieved in most dogs often for relatively long periods of time. Melphalan is prescribed at a dose of 0.1 mg/kg PO once daily for 10 days, then 0.05 mg/kg PO once daily continuously. An alternate pulse protocol with melphalan at 7 mg/m$_2$ (rounded to the nearest whole 2 mg tablet) given once daily for 5 days every 21 days is also used. Prednisone is given at a dose of 0.5 mg/kg PO once daily for 10 days, then 0.5 mg/kg PO on alternate days indefinitely or discontinued after 60 days. These protocols are usually well tolerated and the main toxicity of melphalan is myelosuppression, most commonly thrombocytopenia.

It is generally accepted that a reduction in serum levels of the M component by at least 50% is a reasonable therapeutic goal. In addition, clinical signs and clinical pathology abnormalities should also improve, usually within 2–4 weeks. Radiographic improvement of skeletal lytic lesions may take several months, and may only be partial. Routine monitoring of response to treatment and toxicity is usually done with a complete blood count (CBC), total globulin level, and Bence Jones protein (if originally present) every two weeks. A CBC should be checked at least once on day 7 of the pulse protocol. Once a good response is achieved and no cytopenias have been identified, follow-up can be done less often.

Melphalan and prednisone have also been used in cats but melphalan is more myelosuppressive than in dogs, and may cause prolonged neutropenias. Ideally, melphalan should be compounded for cats to allow accurate dosing and avoid hazardous exposure of humans. Use of chlorambucil, cyclophosphamide, CCNU, or multidrug therapy may be more suitable in cats with MM than melphalan and responses have been documented.

Chlorambucil has been recommended for the treatment of WM at a dose of 0.2 mg/kg PO once daily, although treatment with melphalan and prednisone may be effective as well.

Rescue therapy after disease relapse may be attempted with other alkylating agents including cyclophosphamide, chlorambucil, or CCNU. The VAD protocol which includes vincristine, doxorubicin, and dexamethasone has been extrapolated from humans, while others have used CHOP-based lymphoma protocols. There are only anecdotal data regarding these rescue protocols, but it appears that while response rate is quite high, most responses are of short duration.

Symptomatic animals presenting with severe complications of MM require supportive care simultaneously with diagnosis and initiation of antitumor therapy. Animals with severe signs of HVS (altered mentation, hemorrhage, retinal detachment, or CHF) can be treated with plasmapharesis. Renal dysfunction, especially with concurrent hypercalcemia, is treated with IV fluid diuresis until symptoms improve. Severe hypercalcemia can be treated with calcitonin in addition to fluid diuresis or with IV bisphosphonates if diagnosis is delayed. Prednisone is highly effective in treating hypercalcemia but it should not be started prior to making a definitive diagnosis as it may obscure results. Hypercalcemia usually resolves quickly after starting chemotherapy. Dogs with extensive lytic lesions should have exercise restriction and analgesia.

Bisphosphonates (BP) inhibit osteoclast activity and in human. They have been shown to reduce bone pain, the incidence of pathologic fractures and prolong time to first event. The more potent amino-bisphosphonates such as pamidronate or zoledronate also appear to have antitumor activity and zoledronate has shown a survival advantage over placebo and other BP in patients with symptomatic MM. Pamidronate or zoledronate probably have a role in the treatment of animals with osteolytic MM, but they have not yet been critically evaluated.

Large lesions can be treated with radiation therapy (RT). In addition, fractures in weight-bearing bones or vertebrae require surgical stabilization alone or combined with RT. Healing can occur, although it can be very slow and only if local tumor control is achieved. Patients presenting with a fever, other evidence of infection, or severe neutropenia should be treated with broad-spectrum antibiotics. Samples for culture and sensitivity prior to antibiotic therapy should be collected if infection is suspected.

The treatment of choice for EMPs is usually surgical resection. The cutaneous and mucosal EMPs are usually benign and complete surgical excision carries an

excellent prognosis. In some cases, RT has been used for nonresectable or recurrent EMPs as well as melphalan and prednisone alone, or combined with RT. In cases with SOP, surgical excision when possible or RT is the treatment of choice. Fracture repair, or spinal cord decompression and vertebral stabilization, followed by RT could be considered when appropriate. Chemotherapy may be used when RT is not available. Both modalities have resulted in prolonged local control that is not necessarily accompanied with bone remodeling.

Prognosis

Two larger case series of dogs with MM, treated with melphalan and prednisone, have been published to date, 32 years apart. One compared continuous and pulse protocols and found no statistically significant difference in any of the outcome variables, although a small cohort size and high numbers of censored dogs could have impacted the results. In both studies, some dogs received an initial dose of cyclophosphamide as well. In the first study (Matus et al), a complete response (undetectable serum monoclonal Ig) was observed in 43% of dogs, partial response (≥ 50% decrease in Ig) in 49% and no response in only 8%. The median survival time (MST) of all 37 dogs was 540 days and the addition of cyclophosphamide did not affect survival. In the second study (Fernandez et al), overall response rate was similar (86%), but most were defined as having a complete response. Median survival time for all 38 dogs was 930 days, almost double the time in the first study. Additionally, twelve dogs in the first study were treated with prednisone alone and their MST was 220 days. Matus reported that a response to treatment with chemotherapy was positively associated with survival. Hypercalcemia, Bence Jones proteinuria and extensive bone lesions were negative prognostic indicators for survival. Fernandez showed that renal disease and a high blood neutrophil to lymphocyte ratio around the time of diagnosis also negatively impacts survival. Ionized hypercalcemia and osteolytic lesions among other factors evaluated were not prognostic.

In cats, data are based on small numbers. Overall remission rate is lower and survival times shorter compared to dogs. A MST of 9.5 months was reported in one study and no cat lived more than six months in another.

The prognosis for solitary cutaneous and mucocutaneous EMPs in dogs is generally good. Surgical excision is curative in most cases. Local recurrence rate is reported to be approximately 5% (higher for oral tumors), nodal or systemic disease develops in 2% and new cutaneous EMPs occur in less than 2% of dogs. Cell type, proliferation rate, presence of amyloid, and cyclin D1 reactivity have no prognostic significance in dogs. Dogs with multiple cutaneous EMPs in the absence of MM have been assigned a diagnosis of cutaneous plasmacytosis (CP) based on the rare syndrome in humans, that usually follows an indolent course. In the first reported series, 21 dogs with CP were treated with chemotherapy, most with melphalan and prednisone. The overall response rate was 74%, complete response was 37%, median progression free survival was 143 days, but median overall survival was longer at 542 days. None of the dogs progressed to develop MM. In cats, EMP behavior is less predictable. Some remain localized and surgical excision can lead to long-term control while others progress rapidly to MM.

As in humans, veterinary patients with successfully treated SOP eventually develop local failure, new lesions or MM but they can enjoy long disease-free periods until progression. It is important to thoroughly stage them at initial diagnosis and to monitor routinely for local and systemic relapse with serum globulin levels, careful attention to bone pain, and additional diagnostics if indicated.

Central Nervous System Tumors in Dogs and Cats

David Ruslander, DVM, DACVIM (Oncology), DACVR (Radiation Oncology)

Veterinary Specialty Hospital of the Carolinas, Cary, NC, USA

Etiology/Epidemiology/Signalment

Central nervous system (CNS) tumors are infrequently seen in dogs and cats but with increased imaging capabilities (computed tomography, magnetic resonance imaging [MRI], etc.) and increased awareness of specific disease entities, there appears to be a subjective rise in the incidence of diagnosis. By definition, the CNS includes intracranial structures (brain and pituitary gland) as well as spinal cord. In these locations, tumors are typically classified as either primary or metastatic.

Intracranial

The incidence of primary intracranial neoplasia in veterinary patients has been estimated to be 14.5/100 000 in dogs and 3.5/100 000 in cats. The most common type in the dog is meningioma, but glial tumors (astrocytoma and oligodendroglioma), histiocytic sarcoma, choroid plexus tumors, primitive neuroectodermal tumors (PNET), and lymphoma can also occur. Meningioma and lymphoma, followed by pituitary tumors, are the most common primary tumors in cats.

Most dogs with primary neoplasia are >5 years of age with the exceptions of lymphoma, which can occur at any age, and glial tumors, which can occur in young dogs due to their purported genetic predisposition. In the cat, lymphoma can occur at any age, especially in young feline leukemia virus (FeLV)-positive cats.

Some dogs appear to be at higher risk for glial tumors, such as boxers and other brachycephalic breeds. In one recent study, it was reported that boxers represented 50% of all dogs receiving radiation therapy for a brain tumor. In dogs, genetic mutations have been identified in glial tumors, including the P53 tumor suppressor gene. Other mutations that are commonly seen in human brain tumors, including abnormal chromosome copy number aberration (CAN), have also been reported, indicating a possible similar etiology.

Historically, metastatic lesions to the CNS were regarded as uncommon but with improvement in treatment of primary tumors and increased diagnostic capabilities, there appears to be a subjective rise. It is now estimated that up to 50% of intracranial neoplasia in dogs are metastatic in origin. The most common tumor types are carcinomas, malignant melanoma, hemangiosarcoma, and lymphosarcoma.

Spinal Cord

The incidence of spinal cord neoplasia in both species has not been reported. In general, spinal tumors can be described in terms of their anatomic location: extradural, intradural/extramedullary, intramedullary, or mixed compartment. In one large retrospective study of 399 histopathologically confirmed spinal cord tumors in dogs, 48% were extradural, 13% were intradural/extramedullary, 6% were intramedullary, and 33% were mixed compartment.

The most common extradural primary spinal cord tumor in the dog is meningioma, whereas in the cat it is lymphoma followed by meningioma. Intramedullary spinal cord tumors are more likely to be primary (glial) than metastatic, especially in younger dogs. Metastatic intramedullary tumors are reported in both species and are more common in older animals.

Spinal nephroblastoma is a specific malignancy that arises from the embryonic remnants of the immature kidney and typically occurs in young dogs (<3 years of age). This tumor has a predilection for golden retrievers, German shepherd dogs, and arctic breeds. It is most

Companion website: www.wiley.com/go/bruyette/clinical

often intradural/extramedullary and is located in the caudal thoracolumbar region.

Spinal lymphoma often affects young cats, is associated with FeLV, tends to occur in an extradural location in the thoracic and lumbar spine, and is usually present in multiple locations outside the CNS. In dogs, CNS lymphoma is sporadically identified. It is most commonly the T cell phenotype and located extradurally but can be seen in any location.

Solitary spinal plasmactyomas (benign and malignant proliferation of plasma cells) have been described in both dogs and cats. Some lesions will remain solitary although progression to systemic or multiple myeloma is possible. Please refer to Chapter 135 for more information.

Carcinomas and hemangiosarcoma are the most commonly reported secondary spinal cord tumors in dogs. Osteosarcoma is the most commonly reported in cats. While initially thought to be very rare, the incidence of metastatic lesions in the CNS has risen as diagnostic imaging capabilities and control of the primary disease have improved.

History and Clinical Signs

Intracranial

Most patients with CNS neoplasia will present with altered neurologic function (dull, nerve deficits, paresis, etc.) but this is not universal. Some present with only subtle symptoms such as lethargy, depression or neck pain. Headaches are a common presenting symptom in humans but recognition of this symptom in veterinary patients is extremely difficult. Seizure or seizure-like activity as a presenting clinical finding is more common in dogs than in cats.

Cats and dogs with pituitary tumors may present with a variety of symptoms, many of which are nonneurologic and relate to the endocrine abnormalities of hyperadrenocorticism (polyuria/polydipsia). In cats, unregulated diabetes secondary to acromegaly is common due to excessive growth hormone production. Initially, neurologic abnormalities may be subtle and limited to mild lethargy and disorientation but often progress to more severe abnormalities (seizures, mentation changes, neurologic deficits) with time.

Spinal Cord

Spinal cord neoplasia should be suspected in any patient with a history of forelimb or hindlimb paresis or paralysis. Those presenting with spinal pain should also be suspect as pain is a common presenting symptom in both cats and dogs. Onset of signs may be acute, as with lymphoma, but may be slowly progressive with more slowly growing neoplasia such as meningioma.

Diagnosis

Intracranial

All patients with neurologic symptoms should be considered as possible oncology cases. As such, a stepwise approach is encouraged to allow for accurate staging and identification of a primary tumor, if one exists, prior to surgical intervention, radiation therapy or chemotherapy. Full blood analysis, urinalysis, three-view thoracic radiographs, and abdominal ultrasound should be performed prior to or in conjunction with advanced imaging (CT/MRI/positron emission tomography [PET]).

Magnetic resonance imaging has dramatically changed the ability of the clinician to identify small subtle lesions and as such is the preferred method of diagnosing brain and spinal cord neoplasia. Improvement in technology has increased the utility of CT imaging but MRI is still recommended if available. Involvement and consultation with a radiation oncologist early in the process will allow for proper positioning of the patient should radiation therapy be pursued. With MRI, the majority of dogs and cats will have a hypo- to isointense lesion on T1-weighted and hyperintense on T2-weighted images with a variable amount of peritumoral edema. Contrast enhancement with gadolinium is variable and more common with high-grade neoplasia given the disruption of the vasculature. Cystic lesions are more common with meningioma. The presence of a "dural tail" on contrast-enhanced T1 images has historically been associated with meningioma but can be seen with any neoplasia. This finding results from thickening and contrast enhancement of dural tissue extending from the primary tumor in a tail-like fashion. Other MRI and CT features of specific brain neoplasia types have been described but there is considerable overlap among tumors (Figures 136.1 and 136.2).

With the exception of lymphoma, cerebrospinal fluid (CSF) analysis is rarely useful in distinguishing neoplastic intracranial/spinal cord disease from inflammatory lesions as it rarely reveals neoplastic cells. Analysis often reveals increased protein levels, sometimes with elevated cell counts. If CNS lymphoma is suspected, more advanced testing of CSF such as antigen receptor gene rearrangement and/or flow cytometry should be pursued.

Histopathologic diagnosis of intracranial tumors requires biopsy and the use of stereotactic CT guidance in obtaining the sample. This advanced procedure has become more commonplace. Associated complication rates are reported to range from 12% to 27% with a 5–9%

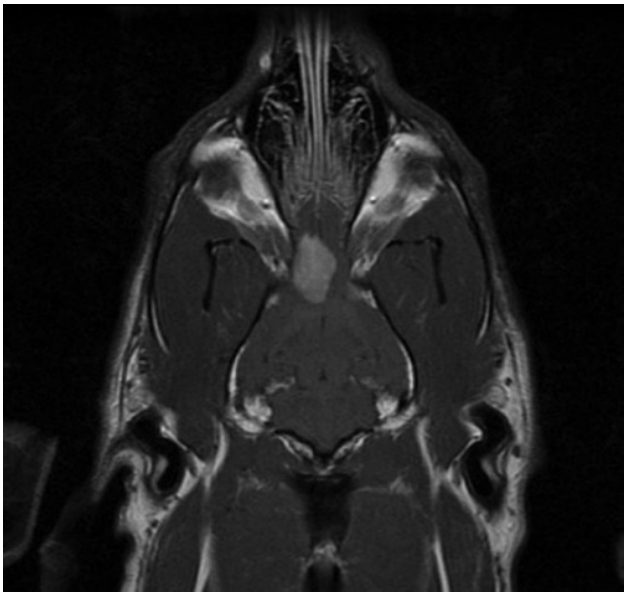

Figure 136.1 T1-weighted post-contrast (gadolinium) coronal image of a frontal lobe mass in a 9-year-old, male, golden retriever. Surgical excision was performed. Histopathology was consistent with histiocytic sarcoma. The dog's only symptom was acute onset of seizures.

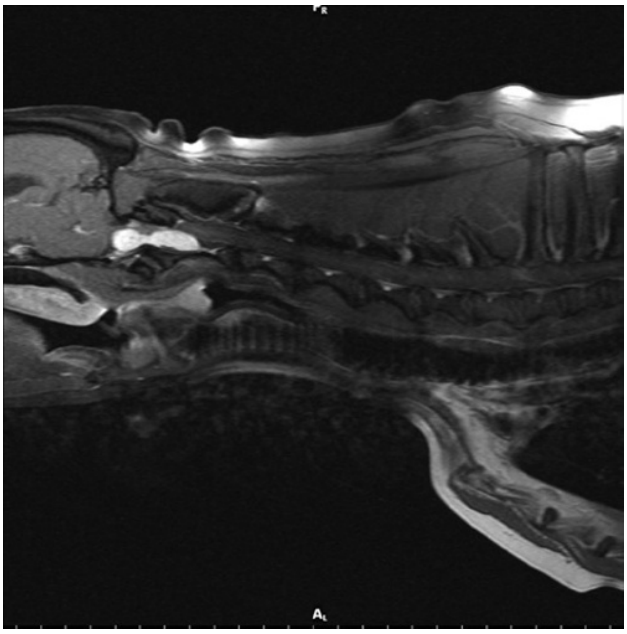

Figure 136.2 T1-weighted postcontrast (gadolinium) sagittal image of a cervical spinal cord tumor in an 11-year-old male castrated boxer, presenting for acute tetraparesis with associated neck pain. The mass is consistent with a meningioma given the extraaxial location and presence of a dural tail at the caudal extent of the mass. Surgical excision and biopsy were not performed. The dog received 48 Gy radiation therapy (16 × 3 Gy) and adjuvant hydroxyurea with nearly complete resolution of the neurologic signs/neck pain and was alive two years following treatment.

mortality rate, but will continue to decrease as experience with the procedure increases. Currently, not all patients receive histopathologic confirmation due to the cost and risk of potential complications. To mitigate some risk, cytology can be considered instead but this too is not commonly performed. Hence many patients are treated without a true diagnosis.

Dogs with suspected hyperadrenocorticism and cats with suspected acromegaly or insulin resistance should be evaluated with CT or MRI. Small pituitary masses may escape detection with CT but larger lesions can be detected with CT especially with newer generation CT imagers.

Spinal Cord

As with intracranial neoplasia, full staging including three-view thoracic radiographs, full blood analysis, urinalysis, and abdominal ultrasound should be performed before or in conjunction with advanced imaging (CT/MRI/PET). Survey spinal radiographs should be performed to evaluate for possible bony lysis. Although rarely helpful, lysis may be present and may indicate a neoplastic process is emanating from outside the CNS with secondary invasion to spinal cord, as in the case of skeletal neoplasia (osteosarcoma, chondrosarcoma) or rarely soft tissue tumors (soft tissue sarcomas, carcinomas). As with intracranial tumors, due to cost, need for advanced diagnostic equipment and risk of potential complications, many patients with spinal neoplasia are treated without a definitive diagnosis.

Treatment/Prognosis

Central nervous system neoplasia, like other tumors, can be managed with a combination of surgery, radiation, and chemotherapy. However, the veterinary literature is limited to uncontrolled and retrospective studies based on relatively small numbers of patients.

Medical Management

Nonspecific treatment options include antiinflammatory doses of corticosteroids for peritumoral edema and anticonvulsant therapy if seizures are a component of the clinical presentation. Phenobarbital, Keppra® (levetiracetam), and zonisamide are all options for control of seizures. Unfortunately, supportive care alone is associated with a poor prognosis in the vast majority of patients. Published survival times in such a group are generally between one and 10 weeks but individual patients may far exceed this.

Surgery

Intracranial

Depending on the location, surgical intervention is recommended as a sole therapy for well-circumscribed meningiomas or a prelude to postoperative radiation therapy and/or chemotherapy. Surgery alone for meningioma in dogs is associated with a median survival time of 4.5–7 months. Radiation therapy in the postoperative setting has increased that median to 16–30 months. Other surgical techniques such as ultrasonic aspiration or endoscopic-assisted surgical resection have resulted in survival times of 41 and 70 months in dogs, demonstrating the utility of more aggressive approaches. Surgery as sole therapy for nonmeningioma tumors is more variable, case dependent, and generally results in median survival times of months rather than years.

Meningioma in the cat is often less aggressive and invasive compared to the dog. Hence, the prognosis with surgery as sole therapy is good to very good with median survival times of 23–28 months.

Surgical approaches to the pituitary gland (transsphenoidal hypophysectomy) have been described but management is usually accomplished with fractionated external beam radiation therapy or more recently radiosurgical techniques in both dogs and cats.

Spinal Cord

Outcomes in dogs and cats with spinal cord neoplasia are understandably highly variable and there is considerable perioperative mortality due to poor return to function. Overall median survival in one study of 37 dogs was 240 days if they survived 20 days following surgery, but 40% did not survive to that point. In a separate study evaluating surgery for intraspinal meningioma, clinical improvement was noted in all dogs surviving the perioperative period but recurrence of clinical signs was at a mean of 19 months. Only a minority were disease free long term, thus indicating the need for postoperative radiation therapy. Postoperative radiation therapy did appear to have a benefit based on time to neurologic deterioration but recurrence of signs and/or tumor was still noted anywhere from 18 to 36 months. In cats undergoing surgical treatment of spinal cord tumors, improvement was reported in 25/26 cases but the median survival time for those with malignant neoplasms was 110.5 days, compared with 518 days for those with benign tumors. In this study, the vast majority of cats eventually succumbed to disease-related problems.

Radiation Therapy

Radiation therapy has evolved over the past several decades from relatively unsophisticated planning techniques to the current state utilizing 3D computer planning and modern technology. Long-term efficacy of radiation therapy alone is limited given the tolerance of the brain and as macroscopic tumor control is generally not as rewarding as adjunctive treatment following cytoreductive surgery. Table 136.1 gives a summary of treatment-related outcomes of CNS tumors.

Recently, stereotactic radiosurgical (SRS) approaches have been employed which allow for one or two fractions of high-dose radiation to be delivered rather than the conventional 15–25 daily fractions of lower doses per fraction. This high dose per fraction is limited to the tumor and a small volume of normal surrounding tissue. This form of treatment theoretically minimizes the risk of complications to normal tissues while providing ablative doses to the tumor. SRS is still in the investigational stage in veterinary oncology and direct comparison to conventional fractionated radiation therapy has not been performed. However, preliminary results in the literature are encouraging and the shortened overall treatment times and minimal dose to noninvolved tissues are attractive to both clinicians and owners and SRS likely represents the future of radiation therapy for brain neoplasia.

Side-Effects

Acute and late developing radiotherapy side-effects vary depending on total dose given, dose per fraction, and the total volume and specific tissue type being irradiated. Late-term side-effects are rare (<20%) but when they occur, management is challenging as they are often life-threatening. Of the late effects, brain necrosis is the most common but others including spinal cord myelopathy can occur. Unfortunately, the clinical distinction between these late side-effects and tumor recurrence is difficult and often requires histopathology.

Acute side-effects of CNS irradiation are rare and often limited to surrounding normal structures in the treatment field such as the oral cavity, otic and ocular structures, and gastrointestinal tract. A syndrome of delayed acute CNS effects can be seen several months after completion of radiation therapy and are manifested by responsiveness to corticosteroids. This syndrome is thought to be a transient demyelination of the white matter rather than true necrosis which is the more classic delayed effect.

Intracranial

Due to the limitations of available veterinary clinical studies, the prognosis following irradiation of many primary intracranial tumors, especially those of glial origin, is largely unknown (see Table 136.1). Based on what has been reported, median survival time following irradiation may range from four months to greater than four

Source: Adapted from Warren E, Narak J, Axlund T, Smith A. Treatment of intracranial tumors. In: Twedt D, Bonagura J, eds. *Kirk's Current Veterinary Therapy XV*. St Louis, MO: Elsevier, 2014, pp. 1039–47.

years depending on tumor type, prescription dose, and other variables. Regardless, the long-term efficacy of radiation therapy when delivered as sole therapy is limited given the tolerance of the CNS and macroscopic tumor control is generally not as rewarding as when delivered as adjunctive treatment following cytoreductive surgery. For meningioma in the dog, a median survival of approximately one year can be anticipated with radiation therapy. When radiation therapy is delivered as an adjunct to surgery, median survival increases to 16–30 months.

For cats and dogs with pituitary macroadenoma or macroadenocarcinoma, radiation therapy has been recommended and results in good outcomes with both fractionated therapy and radiosurgical techniques. Conformal three-dimension radiation therapy has been described for this tumor in both species and outcomes have been very good to excellent for control of both neurologic signs in affected patients and endocrine abnormalities. Of note, the endocrine manifestations may take several months to improve, which necessitates ongoing monitoring.

Spinal Cord

Radiation therapy of spinal cord tumors has been described in the veterinary literature but studies are limited by low case numbers and lack of histopathologic confirmation in the majority of patients. As with intracranial irradiation, a similar limitation of dose is encountered in the spinal cord and control times are affected by the spinal cord tolerance.

In one study, primary radiation therapy for spinal cord tumors (no histopathologic confirmation) resulted in median control of nine months. In a separate study evaluating surgery for spinal meningioma, those that underwent postoperative radiation therapy appeared to have a benefit based on time to neurologic deterioration but recurrence of signs and/or tumor recurrence was noted anywhere from 18 to 36 months. It is important to recall that deterioration of neurologic condition may be related to tumor recurrence but may also be related to spinal cord damage/necrosis. Therefore, documentation of true tumor recurrence is recommended prior to considering repeat irradiation and/or surgical intervention.

Chemotherapy

There is very little in the veterinary literature regarding chemotherapy for CNS neoplasia with the exception of standard chemotherapy for canine and feline lymphoma. The blood–brain barrier represents a significant obstacle to the delivery of chemotherapy to the brain and spinal cord. Survival times of dogs with unconfirmed (no biopsy) brain tumors treated with lomustine (CCNU) were very similar to patients treated with supportive care alone (93 vs 60 days).

Hydroxyurea is an alkylating agent most commonly used in veterinary medicine for the management of polycythemia. Recently, it has been used as an adjuvant to surgery and/or radiation therapy for dogs with intracranial and spinal meningioma. In one such study, oral hydroxyurea in combination with glucocorticoids was administered to 33 dogs with MRI-diagnosed meningioma, resulting in a significantly longer survival time than observed in 10 dogs treated with glucocorticoids alone.

Temozolamide has recently been evaluated in management of canine glial tumors. Although the data in veterinary oncology are preliminary and no strong recommendations can be made regarding efficacy and comparison with other chemotherapy approaches cannot be made, results in the human literature are encouraging.

For patients with CNS lymphoma, options in addition to standard chemotherapy include lomustine, hydroxyurea, and the antimetabolite cytosine arabinoside which cross the blood–brain barrier. The role of chemotherapy specifically for spinal cord neoplasia is not known, but similar chemotherapeutics are recommended depending on final diagnosis when possible.

Newer Therapies

With increased understanding of how the immune system functions in tumor environments, immunotherapy, in particular tumor vaccination and gene therapy, has recently been developed to aid in the treatment of canine brain tumors but these approaches remain investigational.

Oral Tumors

Etiology/Pathophysiology

A wide variety of malignant and benign cancers develop in the oral cavity. In dogs, the most common malignant oral tumors in order of frequency are malignant melanoma, squamous cell carcinoma, and fibrosarcoma. In cats, squamous cell carcinoma is the most common oral cancer, with fibrosarcoma second. Risk factors for the development of oral squamous cell carcinomas in cats include flea collars and high intake of either canned food or, specifically, canned tuna fish.

Oral malignant melanoma (OMM) is a highly malignant tumor with frequent metastasis to regional lymph nodes and lungs. Metastasis has been reported in 80–100% of cases, and is associated with site, size, and stage of tumor. Squamous cell carcinoma (SCC) frequently invades bone in both the dog and cat. The metastatic rate for nontonsillar SCC in the dog is approximately 20% but nearly 100% of cases with tonsillar SCC metastasize to the retropharyngeal lymph nodes. The metastatic rate of oral SCC in the cat is unknown, as control of local disease in cats is rarely achieved. Oral fibrosarcomas (FSA) are locally invasive but rarely (<30%) metastasize to regional lymph nodes or lungs. At times, these tumors may histologically appear benign and may be reported as a fibroma or low-grade fibrosarcoma. A well-described syndrome in large-breed dogs, occurring most commonly on the hard palate and maxillary arcade, has been termed "histologically low-grade, biologically high grade" fibrosarcoma. Despite the benign histologic appearance of these tumors, they tend to grow rapidly, metastasize, and invade bone. Rapid recurrence is common.

Epulides are relatively common neoplasms in dogs, but rare in cats. Epulides appear similar to gingival hyperplasia. In general, four types of epulides have been described in the dog: fibromatous, ossifying, acanthomatous, and giant cell. The nomenclature is unfortunately confusing and varied, and the clinician is encouraged to speak directly to the pathologist if there are any questions over terminology. The term *epulis* strictly refers to expansile gingival lesions; more recently, it has been shown that some of these tumors do not involve the periodontal ligament, with many of the fibromatous and ossifying types being derived from the gingiva only. Periodontal odontogenic fibroma has recently been accepted as the correct terminology to use to classify both the fibromatous epulis and ossifying epulis, as these epulides are variations of the same lesion. Also, the acanthomatous epulis has recently been renamed acanthomatous ameloblastoma. A study in 2011 characterized the clinicopathologic features in 153 dogs with oral tumors of possible ondontogenic origin and found that the three most common lesions were canine acanthomatous ameloblastoma, peripheral odontogenic fibroma, and focal fibrous hyperplasia which is a reactive lesion resulting from chronic inflammation.

Acanthomatous ameloblastoma is a benign tumor with aggressive local behavior and frequent invasion into underlying bone. The rostral mandible is the most common site. Fibromatous and ossifying epulides, unlike acanthomatous ameloblastoma, are noninvasive. They are slow-growing, firm masses and are usually covered by intact epithelium. Ossifying epulides usually have a broad base attachment and are less pendunculated than fibromatous epulides. These two epulides vary histologically by the presence or absence of bone formation within the tumor.

Epidemiology

The oral cavity is the site of approximately 6% of all neoplasms in dogs, and oral cancer is the fourth most common cancer overall. In cats, cancer of the oral cavity accounts for 3–12% of all cancers.

Signalment

In contrast to other malignant oral tumors, OMM tends to occur in smaller breed dogs as well as some large breeds, with an average age at presentation of 12 years. Cocker spaniel, miniature poodle, Anatolian sheepdog, Gordon setter, chow chow, and golden retriever are overrepresented. The average age of a dog presenting with an oral SCC is 8–10 years, while the average age for a cat is 10–12 years. Oral FSAs tend to occur in large-breed dogs, particularly the golden and Labrador retriever. The average age at presentation is 7–9 years and there appears to be a male predisposition. Dogs presenting with fibromatous and ossifying epulides are typically 8–9 years, and a male predisposition has been reported. Shetland and old English sheepdogs are predisposed to acanthomatous ameloblastomas. The average age at presentation is 7–10 years, and a sex predisposition is not reported.

History and Clinical Signs

Cats and dogs with rostral oral cancer commonly present for a mass noted by the owner. Cancer in the caudal oral cavity is rarely noted by owners and the animals often present at an advanced stage of disease, resulting in fewer options for treatment. Clinical signs may include hypersalivation, exophthalmos or facial swelling, epistaxis, weight loss, halitosis, bloody oral discharge, dysphagia or pain on opening the mouth. Occasionally, cervical lymphadenopathy (especially in squamous cell carcinoma of the tonsil) is also found. Complete oral examinations should always be performed during health exams as early intervention may allow for more treatment options and an improved prognosis.

Diagnosis

Due to the wide range of cancer behavior and recommended treatment options for oral cancers, diagnostic evaluation is critical. A biopsy is required for the definitive diagnosis, and this will assist the clinician in determining the biologic behavior and prognosis of the tumor. Impression smear or fine needle aspirate cytology preparations of the tumor are generally not rewarding, as many oral tumors are associated with a high degree of necrosis and inflammation. Most animals will require a short general anesthesia for careful mass evaluation, regional radiographs, and biopsy. An incisional biopsy of the mass is recommended.

Advanced imaging is recommended for oral tumors arising from the maxilla, palate, and caudal mandible. Computed tomography (CT) scans are generally preferred to magnetic resonance imaging (MRI) because of superior bone detail. Both provide more information on the local extent of the tumor than regional radiographs. Information obtained from CT or MRI is critical in the planning of definitive surgery and radiation.

Regional lymph nodes should be carefully palpated for enlargement or asymmetry. Caution should be exercised, however, when making clinical judgments based on palpation alone, as lymph node size is not an accurate predictor of metastasis. Lymph node aspirates should be performed in all animals with oral cancers, regardless of their size or mobility. Three-view thoracic radiographs are recommended to evaluate animals for evidence of pulmonary metastatic disease. Thoracic CT scans should be considered for animals with highly metastatic tumor types such as OMM, since CT scans are more sensitive for detecting pulmonary metastatic lesions. Based on these diagnostic steps, oral tumors are then staged according to the World Health Organization's staging scheme (WHO) (Table 137.1).

Table 137.1 WHO staging system for oral tumors

Stage	Tumor size and metastasis status
I	<2 cm diameter tumor
II	2 to <4 cm diameter tumor
III	>/= 4 cm diameter tumor and/or lymph node metastasis
IV	Distant metastasis

Therapy

Surgery

Surgical resection is the gold standard for oral tumors and is the most commonly used modality for achieving local control. The surgical approach depends on tumor type and location. The majority of tumors involving the maxilla, mandible, and hard palate will have underlying bone involvement so surgical resection should include bony margins to increase the likelihood of complete excision. Minimum margins of at least 2 cm, and preferably 3 cm, are recommended for malignant tumors such as SCC, OMM, and FSA in the dog.

Radiation Therapy

Radiation therapy can be used with palliative or curative intent, or as an adjunct to surgery for incompletely resected tumors or tumors with aggressive local behavior. Radiation therapy can be considered a primary treatment of canine oral SCC, OMM, and some benign tumors such as epulides. These tumors are radiation responsive, even when treated in the setting of gross disease. Radiation protocols used for the treatment of these tumors have involved daily or alternate-day treatments

consisting of 2.7–4.2 Gy per fraction with a total dose ranging from 48 Gy to 57 Gy. More recently, stereotactic radiation is being used as treatment of non-resectable oral tumors. Protocols typically consist of 1-3 high doses of radiation precisely targeted at the tumor, with rapid dose fall off outside of the tumor. These protocols are proving to provide durable control of disease, with decreased acute side effects when compared to traditional radiation protocols; however published studies are still limited.

When using radiation therapy alone, tumor control is better achieved with smaller lesions (T1 or T2 tumors). With megavoltage radiation, local recurrence is reported in up to 30% of cases. When compared to T1 tumors, tumor progression is three times more likely with T2 tumors and 5–8 times more likely with T3 tumors. Local tumor control and survival time, however, can be improved by combining surgery and radiation therapy.

Acute radiation side-effects are common during treatment of oral tumors, but these are generally self-limiting. They can include alopecia and moist desquamation, oral mucositis, dysphagia and ocular changes such as blepharitis, conjunctivitis, keratitis, and uveitis. Late side-effects are rare (<5%), but are much more serious as they are permanent. Late side-effects include skin fibrosis, bone necrosis and oronasal fistula formation, development of a second malignancy within the radiation field, keratoconjunctivitis sicca, cataract formation, and ocular atrophy.

Chemotherapy

Frontline treatment for most oral tumors is control of local disease with surgery and/or radiation therapy. Chemotherapy is indicated for some tumors due to their high metastatic potential. OMM and tonsillar SCC are both highly metastatic tumors, but unfortunately their response to chemotherapy is low.

The nonsteroidal antiinflammatory drug piroxicam, a COX-2 inhibitor, has been shown to have some effect against canine oral SCC. Expression of COX-2 has also been noted in feline oral SCC, but no improvement has been seen in the management of these tumors when piroxicam has been used.

Immunotherapy

A DNA vaccine against tyrosinase is now commercially available for the adjunctive treatment of dogs with OMM. To maximize chances of long-term survival, it has been found that the vaccine is most effective when residual disease is minimized and local regional control has been achieved. Adverse reactions following administration of the vaccine have been found to be minimal, with the most notable side-effects consisting of bruising and hematoma formation.

Prognosis

Malignant Melanoma

The prognosis for dogs with oral malignant melanoma is guarded. In one study, median survival time (MST) of dogs with untreated oral melanomas was two months. Aggressive resection by mandibulectomy or maxillectomy can be effective for control of these tumors but postsurgical recurrence has been reported to develop in 8–85% of dogs and metastasis to regional lymph nodes, lungs, or other viscera may develop in as many as 95%. Metastasis, particularly to the lungs, is the most common cause of death, being reported in 15–67% of dogs. Median survival times for dogs with OMM treated with surgery are approximately 17–18 months, 5–6 months, and three months with stage I, II, and III disease, respectively.

Coarse fraction radiation treatment effectively achieves local control in dogs with melanomas. Reduction in tumor size is attained in 83–100% of dogs, and a complete response rate has been reported to be as high as 70%. In a retrospective study of 140 dogs with OMM treated with radiation therapy, it was found that systemic chemotherapy had no impact on the development of metastatic disease, time to first event, or survival. In the same study, tumor location, bone lysis, and tumor volume were all variables identified to predict time to first event and survival. If none of these risks were present, median survival for dogs with malignant melanomas treated with radiation therapy was 21 months, and if one, two, or three risk variables were present, median survival time was 11 months, five months, or three months, respectively.

The use of immunotherapy for malignant melanoma is showing some promise, but most results involve small numbers of dogs in phase I trials. Xenogeneic vaccine studies for dogs with stage I–III OMM report median survival times of almost three years when local regional control had been achieved and patients received vaccine versus 1.5 years when patients were given the same vaccine, but failed locally.

Canine Squamous Cell Carcinoma

Following mandibulectomy for canine nontonsillar SCC, the median survival ranges from 19 to 26 months versus 10–19 months following a maxillectomy. Tonsillar SCC carries a graver prognosis. Due to higher local recurrence and metastatic rates, studies report one-year survival times of only 10%.

Full-course radiation therapy, either alone or as an adjunct following incomplete surgical resection, is also a successful treatment modality for the management of oral SCC in dogs. With full-course radiation, a study of 39 dogs reported an overall median progression-free

survival time of 36 months. Local tumor recurrence was a more common cause of first treatment failure than regional metastasis to lymph nodes. Dogs with T1, T2, and T3 tumors had a progression free, one-year survival rate of 89%, 83%, and 41% respectively, and a three-year progression-free survival rate of 74%, 53%, and 23%, respectively. A study of 14 dogs treated with full-course radiation therapy as the primary treatment modality reported median disease-free interval and survival of 12 and 14 months, respectively. The median disease-free interval was 16 months in dogs 9 years or less, and seven months in dogs older than 9 years of age.

Feline Squamous Cell Carcinoma

The prognosis for feline SCC is poor, as there is no known consistent, effective treatment for gaining local control. In one series of 52 cats, the one-year survival rate was less than 10% with median survival times of three months for surgery, surgery and radiation therapy, radiation therapy and low-dose chemotherapy, and radiation therapy with hyperthermia. Other studies investigating surgery alone, have reported median survival times of 5.5–7.5 months, but only tumors of the mandible were considered resectable. In a separate study the combination of surgery and radiation reported a survival time of 14 months. All cases were arising from the mandible.

Radiation therapy alone is generally ineffective in the management of cats with oral SCC. However, the combination of radiation with radiation sensitizers or chemotherapy has resulted in response rates from 70% to 100% and median survival times of approximately 3–6 months. A recent prospective study including 31 cases of oral SCC in cats evaluated the effectiveness of an accelerated radiation therapy protocol and concomitant carboplatin for treatment. Median survival for all cats in this study was 5.4 months, while cats with tumors of tonsillar origin or cheek responded best to therapy with a mean survival of two years.

Fibrosarcoma

The prognosis for dogs with oral fibrosarcoma is guarded. Multimodal treatment with surgery and radiation therapy of the local disease results in the best survival rates. Following maxillectomy or mandibulectomy alone, local recurrence is reported in up to 60% of dogs with a median survival time of 10–12 months and a one-year survival rate of 50%. Oral fibrosarcomas are considered to be radiation resistant. A smaller tumor size improves the outcome following radiation therapy, with the median progression-free survival time of 45 months for dogs with T1 tumors compared to 31 months and seven months for T2 and T3 tumors, respectively. When radiation therapy is used as an adjunct to surgery, a median survival time of 18–26 months is reported. A study completed in 2011 reported the outcome in 29 dogs with oral fibrosarcomas treated with surgical excision with or without adjuvant radiation. The median survival time in this study was reported to be approximately two years with a one- and two-year progression-free survival rate of 88% and 58%, respectively.

Epulides

The prognosis for dogs with epulides is excellent following treatment with either surgery or radiation therapy. In contrast to fibromatous and ossifying epulides, wide local excision of adjacent soft tissue and bone is necessary for cure of acanthomatous ameloblastomas. Local recurrence rate following bone-removing surgery is less than 5%.

Radiation therapy is indicated for acanthomatous ameloblastomas that are not curable with surgery alone. In a prospective clinical trial, 47 dogs with acanthomatous ameloblastomas (39 dogs) or fibromatous or ossifying epulides (eight dogs) were treated with 12 fractions of 4 Gy, three times a week to a total dose of 48 Gy. Clinical stage was the only significant prognostic factor, with dogs that had stage T3 tumors having a 7.9 times higher risk of tumor recurrence than dogs with stage T1. In a 2004 study of 57 dogs treated with radiation therapy, the median overall survival time was four years.

Intralesional bleomycin has also been described for the treatment of acanthomatous ameloblastomas. With this treatment, a complete response was sustained in all four dogs treated for greater than one year with no local recurrence.

Nasal Tumors

Etiology/Pathophysiology

Carcinomas, including adenocarcinoma, squamous cell carcinoma, and undifferentiated carcinoma, comprise nearly two-thirds of nasal tumors in the dog while sarcomas, including fibrosarcoma, chondrosarcoma, osteosarcoma, and undifferentiated sarcoma, comprise the bulk of the remaining tumors. In the cat, lymphoma and carcinoma are the most common tumors of the nasal cavity. It has been speculated that dogs living in urban environments may be at higher risk for developing nasal tumors, and some studies have also associated the exposure of environmental tobacco smoke as an increased risk factor, but this finding is not consistent. Nasal lymphoma in cats is typically feline leukemia virus (FeLV) antigen negative, and definite risk factors have not been reported.

Nasal tumors are locally invasive tumors that carry a relatively low metastatic rate. Metastasis at the time of diagnosis is seen in approximately 10% of animals, but may be as high as 40–50% at the time of death. Death, however, is usually attributable to local disease progression rather than metastatic lesions. Most common sites of metastasis are the regional lymph nodes and lungs. Less common sites include bones, kidneys, liver, skin, and brain.

Epidemiology

Nasal tumors account for approximately 1% of all neoplasms in dogs and cats.

Signalment

The average age at the time of diagnosis for canine and feline nasal tumors is 10 years. It appears that medium- and large-breed dogs may be more commonly affected. Also, a slight male predilection has been suggested in dogs, and dolichocephalic breeds may be at an increased risk.

History and Clinical Signs

The most common clinical signs associated with nasal tumors include epistaxis, bloody or mucopurulent nasal discharge, facial deformity, sneezing, dyspnea, stertorous breathing, exophthalmia, and ocular discharge secondary to obstruction of the nasolacrimal duct. The average duration of clinical signs before diagnosis is three months. All of these clinical signs can overlap with other intranasal diseases, but a strong suspicion for cancer should be made in older animals with an intermittent and progressive history of initially unilateral and/or mucopurulent discharge.

Diagnosis

Definitive diagnosis of a nasal tumor requires a tissue biopsy but historical information and diagnostic imaging can be highly suggestive of cancer. Conventional radiography can be helpful in the diagnostic evaluation of dogs, but CT is preferred as it provides improved anatomic detail, determination of the extent of the tumor, and identification of nasal cavity abnormalities. A CT scan also allows for detection of CNS invasion. Certain findings on CT are correlated with a diagnosis of cancer in dogs, but none of these alone or in combination are definitively diagnostic. A tissue biopsy is always required. Once a definitive diagnosis has been made, fine needle aspirates of regional lymph nodes should be completed, along with three-view thoracic radiographs.

Several staging systems based on radiographic or CT findings have been proposed in canine nasal tumors but their prognostic significance remains controversial. The Adams modified staging system developed in 2009 is the most recent system that has been adapted (Table 137.2). With this system, dogs with unilateral intranasal involvement confined to the nasal cavity had the longest median survival time of 23.4 months when treated with definitive radiotherapy. Those with cribriform involvement had the shortest median survival time of 6.7 months.

Therapy

Treatment of nasal tumors is directed primarily at the control of local disease. Unfortunately, the disease is often extensive. Curative surgery is not possible as bone invasion occurs early in the course of the disease. Hence, radiation therapy is the standard of care. The combination of a cytoreductive surgery followed by radiation therapy for the treatment of nasal tumors has been evaluated, but has not been shown to improve clinical outcome in dogs when compared to megavoltage radiation alone.

With definitive or curative intent radiation, the goal of treatment is to deliver the maximum radiation dose to the tumor while minimizing the dose to surrounding normal tissues. Most radiation therapy done in veterinary medicine involves the use of conventional computerized treatment planning. However, with advances in the field of radiation oncology, the use of intensity-modulated radiation therapy (IMRT) has proven to be a very good option for the treatment of nasal tumors. IMRT allows for the optimization of radiation dose delivery to complex tumor volumes with rapid dose drop-off to surrounding normal tissues. When IMRT is used, normal tissue toxicities are greatly reduced while higher cumulative doses of radiation are delivered to the tumor. Traditional definitive protocols involve the administration of a total radiation dose of 40-57 Gy in 10-19 fractions of 3-4.2 Gy, over a 2-4 week period.

Table 137.2 Adams 2009 modified staging system for canine nasal tumors

Stage	Remarks
T1	Confined to one nasal passage, paranasal sinus, or frontal sinus with no bony involvement
T2	Any bony involvement, but no evidence of orbital, subcutaneous, or submucosal mass
T3	Involvement of orbit or subcutaneous or submucosal mass
T4	Tumor extension into the nasopharynx or cribriform plate

Computerized treatment planning using CT images of the patient are recommended to enhance normal tissue sparing while ensuring appropriate dose distributions within the tumor. For IMRT, CT and computer planning is required. Stereotactic radiation, which is similar to IMRT, is the specific treatment of choice for most nasal tumors. Protocols consist of the precision delivery of curative intent therapy in 1-3 high dose fractions.

With stereotactic and/or traditionally fractionated IMRT, acute toxicities that effect the rapidly dividing tissue of the oral cavity, nasal cavity, skin, and eye can be seen, but are typically very limited. Oral antibiotics, analgesics, and/or artificial tears can be used as needed to counteract and support any treatment related side effect. Life limiting late side effects such as bone or brain necrosis are possible, but the risk is expected to be less than 5%.

Palliative radiation therapy can also be considered for the treatment of nasal tumors. With palliative radiation protocols, side-effects are limited. Alleviation of clinical signs has been reported in up to 95% of dogs treated, with median survival times reported to be approximately 4–6 months. Chemotherapy has also been evaluated for the treatment of nasal tumors in dogs. Clinical responses are seen with chemotherapy, but the response is usually not durable.

Prognosis

Canine Nasal Tumors

The long-term prognosis for dogs with nasal tumors is very dependent on the treatment pursued. A retrospective study of 139 dogs with nasal tumor evaluated those that did not receive therapy. Their overall median survival time was approximately three months. This study also found that dogs presenting with epistaxis had a significantly shorter median survival time than those without epistaxis. Surgery as the sole treatment of nasal tumors results in a median survival time of only 3–6 months, with a high rate of acute and chronic morbidity. Curative-intent, high-energy megavoltage radiation alone results in a median survival time of 8–19.7 months, with one- and two-year survival rates ranging from 43% to 60% and 11% to 44%, respectively. The combination of surgery followed by postoperative radiation reports survival times ranging from 4.1 months to 15.2 months, adding no benefit to radiation therapy alone. In a small series of 13 dogs that underwent preoperative radiation followed by surgical exenteration of residual disease, a survival advantage was demonstrated (MST 47 months). However, these patients experienced significant late side-effects including rhinitis (bacterial and fungal), osteomyelitis, and fistula formation. A study in 2011 evaluated definitive reirradiation of nine dogs with nasal tumors and found that reirradiation is a viable treatment option for canine nasal tumors with tolerable acute and late side-effects. The MST time for the patients in this study was 30 months.

Feline Nasal Tumors

Reports of treatment for feline nasal tumors are lacking. One study including 16 cats with nonlymphoproliferative neoplasms treated with a definitive course of radiation to a total dose of 48 Gy reported a MST of 12 months. This treatment resulted in minimal acute side-effects and modest chronic ocular side-effects. When radiation therapy protocols are used for the treatment of feline nasal lymphoma, long-term control of local disease is favorable and it has been reported that higher total doses (greater or equal to 32 Gy) of radiation therapy may confer an additional survival benefit. The role of chemotherapy for the treatment of feline nasal lymphoma is undefined. Median survival times for cats receiving radiation therapy +/- chemotherapy for the treatment of nasal lymphoma range from 13 to 31 months.

Cancer of the Pharynx

Pharyngeal tumors are rare and little information has been reported in literature. In cats, lymphosarcoma is the most commonly reported. In dogs, extramedullary plasma cell tumor, osteosarcoma, chondrosarcoma, fibrosarcoma, and carcinomas have all been reported. Malignant tumors of the pharynx are more common; however, benign tumors have been reported in dogs. These include rhabdomyoma, angioleiomyoma, and oncocytoma. Rhabdomyomas are minimally invasive and have a predilection for young male dogs.

Surgery is the treatment of choice for pharyngeal tumors. Many benign tumors can be removed while preserving function, while radical procedures such as permanent tracheostomy and complete laryngectomy are required for malignant tumors. Chemotherapy and radiation therapy can also be considered. Surgical removal of pharyngeal rhabdomyoma is often considered curative.

Tumors of the Eye and Ocular Adnexa

Tumors of the Ocular Adnexa

Tumors of the eye, orbit, or adnexa may be painful and disfiguring, impair vision, and elicit concern that life-threatening disease may be present elsewhere in the body. Even benign ocular tumors may cause blindness and loss of the eye simply by virtue of their location. Although both ocular and periocular tumors are reportedly uncommon, their actual frequency is undoubtedly greater as most presumably benign ocular tumors, especially those affecting the canine eyelid, are not histologically examined. Histopathologic examination, however, is essential to ensure proper diagnosis and treatment.

Eyelids, Third Eyelid, Conjunctiva, and Cornea

The etiology of ocular adnexal tumors is poorly understood but suspected causes include chronic inflammation, exposure to ultraviolet light, and viral infection (e.g., papillomavirus). In dogs, more than 85% of eyelid and conjunctival neoplasms consist of sebaceous or meibomian gland adenomas and epitheliomas, papillomas, and melanomas. The substantial majority of these tumors are benign. Even histologically malignant canine eyelid tumors rarely metastasize, although they may be more locally invasive and likely to recur after surgery. In cats, however, most feline eyelid and ocular surface tumors are malignant.

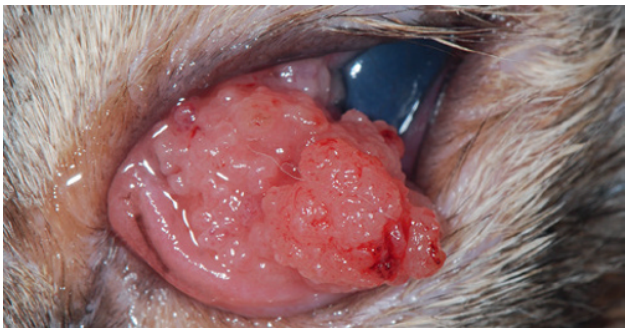
Meibomian Gland Adenoma/Epithelioma

Although rare in other species, benign meibomian gland adenomas and epitheliomas are the most common eyelid margin tumor in middle-aged to older dogs. They may grow rapidly, first starting as a nodular swelling of the meibomian gland and eventually appearing as a proliferative mass exiting the meibomian gland orifice on the lid margin.

Papillomas

In contrast, viral papillomas appear as verrucous masses originating from the conjunctiva in young dogs. They are well demarcated, superficial, and grow rapidly. Surgical manipulation has been reported to disperse new papillomas over the ocular surface. Papillomas, like histiocytomas, usually resolve spontaneously in young dogs, although persistence in older dogs is common. Other forms of benign papillomas in dogs include squamous papillomas, which are of unknown etiology and occur at any age, as well as reactive papillomas, which are seen secondary to other conditions that result in chronic irritation.

Squamous Cell Carcinoma



Squamous cell carcinoma (SCC) has a predilection for the lower eyelid and medial canthus of white cats, and comprises the majority of feline eyelid and third eyelid tumors. It is less frequently reported in dogs, however, in both species it tends to affect older animals. Predisposing factors include exposure to solar radiation, lack of adnexal pigmentation, and chronic ocular surface irritation. Ocular surface SCC has a predilection for the limbus, although it may also invade the cornea. SCC appears as a focally thickened, roughened, pink-to-red lesion or as an ulcerated lesion which is slow to heal. Metastasis to regional lymph nodes occurs late in the course of disease and distant metastasis is uncommon. SCC of the third eyelid tends to more readily invade the orbit than ocular surface or eyelid SCC (Figure 138.1a).

Hemangioma/Hemangiosarcoma

Adnexal vascular endothelial tumors are uncommon in dogs and rare in cats. As with ocular surface SCC, solar radiation is believed to be a risk factor. They usually arise from the nonpigmented conjunctiva of the lateral

limbus or leading edge of the third eyelid and appear as relatively superficial, focal, raised, soft, red masses with visible feeder vessels (Figure 138.1b). Ulceration is common in larger masses. Metastasis of primary conjunctival vascular tumors, even when classified as hemangiosarcoma, is rare although it may recur following simple excision. It is critical to differentiate a primary ocular hemangiosarcoma from a metastatic lesion.

Melanocytoma/Melanoma

Dermal melanocytic tumors of the eyelid are common and typically benign in dogs, while in cats they are rare and more malignant. Melanocytic tumors of the conjunctiva are infrequent and malignant in both species (although distant metastasis tends to be uncommon). Conjunctival melanomas involving the nictitating membrane and superior palpebral conjunctiva may have greater metastatic potential. In both cats and dogs, conjunctival melanomas often locally recur following surgical excision, and may invade the orbit and spread to regional lymph nodes or lungs.

Adenoma/Adenocarcinoma

Adenocarcinomas are the most common tumor of the gland of the third eyelid. They appear as a localized, firm, smooth, pink swelling arising from the posterior surface of the nictitans. They mimic prolapse of the gland of the nictitans (i.e., cherry eye), but a key differentiating feature is their occurrence in older dogs and cats. Recurrence is common if the entire gland is not removed, and metastasis, especially to the regional lymph nodes and orbit, is possible.

History and Clinical Signs

In addition to a mass lesion, other clinical signs of eyelid or ocular surface tumors may include epiphora, conjunctival vascular injection, ocular discharge, elevation of the third eyelid, conjunctival/corneal erosion or ulceration, and corneal vascularization or pigmentation. Palpebral conjunctival masses often protrude when they no longer can be accommodated by the space between the eyelid and globe. Advanced tumors invading the orbit may result in exophthalmia or enophthalmia, depending on their location. Large tumors and sebaceous adenomas often have a substantial inflammatory component and may be secondarily infected.

Diagnosis

The extent of conjunctival involvement should be determined by everting the eyelid (and third eyelid if affected). Careful palpation of the lesion by inserting a lubricated finger in the conjunctival cul-de-sac can aid in determining the full extent of the tumor and whether bony involvement has occurred. Nasolacrimal lavage and possibly positive contrast dacryocystorhinography may help characterize medial canthal masses. Fluorescein staining should be used to determine the integrity of the ocular surface.

Small eyelid and ocular surface tumors are best diagnosed and treated by excisional biopsy. Fine needle aspiration (FNA) or incisional biopsies of larger tumors aid in determining prognosis and planning definitive therapy. Orbital ultrasound, skull radiographs, computed tomography (CT), magnetic resonance imaging (MRI), regional lymph node cytology, and thoracic radiographs may be required to localize or clinically stage potentially malignant tumors such as SCC, third eyelid adenocarcinomas, and conjunctival melanomas.

Therapy

Specific therapy varies with tumor type, size, location, and extent; whether the eye still has vision; the animal's

expected lifespan; the amount of discomfort due to the mass; and any financial constraints of the owner. All eyelid tumors, whether benign or malignant, may affect vision or ocular comfort. Excision is indicated for all eyelid tumors in cats, rapidly growing masses, those irritating the eye or impairing eyelid function, if the owner is concerned, or the mass is cosmetically unappealing. In young dogs, even large papillomas or histiocytomas that are nonirritating may be monitored as spontaneous regression is common.

Tumors involving less than one-fourth to one-third of the palpebral fissure length are best treated by a V-plasty (wedge) or four-sided (house) excision. In the latter technique, the incision is made perpendicular to the eyelid margin (rather than obliquely), resulting in superior apposition of the eyelid margins and greater wound stability, especially in larger tumors. It may be possible to shrink large tumors that are infected or inflamed with antibiotic or antiinflammatory therapy such that a wedge or four-sided excision becomes possible. Electrosurgical excision may result in substantial scarring of the eyelids. Carbon dioxide (CO_2) laser ablation may be appropriate for some smaller tumors.

Tumors greater than one-fourth to one-third of the eyelid typically require reconstructive blepharoplasty or other therapeutic modalities. Depending on tumor type, alternative therapies include systemic chemotherapy (e.g., lymphoma, mast cell tumors), local infiltration with chemotherapeutic agents (e.g., SCC), and/or local radiation therapy (e.g., SCC). These modalities may completely eliminate the tumor or reduce it so that a less extensive surgical procedure is possible. Reconstructive blepharoplasty, however, is the procedure of choice if surgical cure is a possibility, other modalities are unlikely to substantially reduce the tumor, or if the tumor type requires extensive margins.

Liquid nitrogen cryosurgery may be an alternative to extensive blepharoplasty for some eyelid and corneal tumors. It is fast, technically simpler than reconstructive blepharoplasty, and usually allows the nasolacrimal puncta and canaliculus to be preserved. Often cryosurgery can be performed with only sedation or local/topical anesthesia, which is helpful in older or debilitated patients. After sedation/anesthesia, the mass is isolated with chalazion forceps and debulked flush with the lid margin. Using a closed probe that approximates the diameter of the mass as much as possible, an iceball is formed and allowed to extend 3–5 mm beyond the visible margins of the mass in a double freeze-thaw cycle. If the tumor is large, the iceballs should overlap. If complete regression is not achieved 2–3 weeks after the first session, additional treatments may be performed. Marked postoperative swelling and usually transient depigmentation of the frozen tissue are expected.

Tumors involving the conjunctiva and third eyelid (especially conjunctival hemangiosarcomas, melanomas, and third eyelid adenocarcinomas) are best treated by wide surgical excision, sometimes to the point of exenteration. Excision of the entire third eyelid may result in keratoconjunctivitis sicca. Cryosurgery may allow the third eyelid to be spared in papillomas and early SCC. It can also be a useful adjunct to excision in advanced canine conjunctival melanomas and SCC. Superficial keratectomy/sclerectomy, often followed by cryosurgery, is preferred for many corneal and scleral tumors, although some tumors require full-thickness corneal/scleral resection and placement of a donor graft.

Prognosis

With treatment, the prognosis for most canine primary eyelid tumors is excellent. Even histologically malignant primary lid tumors rarely metastasize, and recurrence rates are low. Recurrences, however, need to be differentiated from new primary eyelid tumors as these are common. The prognosis for feline eyelid tumors is guarded, as most eyelid tumors in cats are malignant. Conjunctival melanomas and adenocarcinomas of the third eyelid frequently recur even if all clinically visible tumor is removed. Conjunctival hemangiosarcomas most likely have a good prognosis because total excision may be curative, although recurrence and loss of the eye may occur.

Limbal (Epibulbar) Melanoma

Limbal melanomas are typically benign, sessile, heavily pigmented masses originating from melanocytes in the limbal sclera or subconjunctival connective tissue of middle-aged dogs and cats. The majority are located in the superior limbal region, suggesting that solar radiation may be a risk factor. Growth is slow and confirmed metastasis has not been reported. Clinical signs are generally mild and may include localized corneal invasion, epiphora, and mild conjunctival irritation. Differential diagnoses include conjunctival melanoma, uveal melanoma invading the sclera, metastatic melanoma, and staphyloma or coloboma. Gonioscopy and ocular ultrasound aid in differentiating invasive intraocular tumors from limbal melanomas.

Therapy should be considered if the tumor has invaded the eye, the animal is painful, or if growth is rapid. Observation alone is often an appropriate approach in older dogs given the benign nature and usually slow

growth rate of these tumors. If intervention is required, lamellar keratectomy/sclerectomy with graft placement, cryosurgery or laser photocoagulation may be curative or reduce the size of the mass such that it no longer threatens vision for the remainder of the animal's life. Cryotherapy or beta-irradiation may also substantially reduce the risk of recurrence following local excision. Enucleation is curative and indicated if the mass has entered the eye and there is ocular discomfort.

Intraocular Tumors

Primary Tumors

Primary intraocular tumors occur more frequently than metastatic intraocular neoplasms in dogs and cats. They most commonly originate from the uvea, and their etiology is poorly understood.

Canine Anterior Uveal Melanocytoma/Melanoma

Intraocular melanocytomas arising from the iris or ciliary body comprise the majority of canine intraocular tumors. Most tumors are benign and detected in older dogs (7 years of age or older) although more rapidly growing pigmented iridal masses have been described in young dogs. Malignant intraocular melanomas may be locally invasive but distant metastasis (usually hematogenously) is rare.

Ocular melanosis of cairn terriers is a distinct clinical entity that resembles a diffuse and benign form of uveal melanoma. It is a bilateral disorder in which the iris becomes thickened and more darkly pigmented, followed by release of pigment into the aqueous and pigment deposition in the sclera/episclera. Secondary glaucoma is common. Some cairn terriers may have overt uveal melanocytic tumors, but in most dogs the pigmented cells are nonneoplastic (Figure 138.2).

Choroidal Melanocytoma/Melanoma

These rare melanocytic tumors generally originate from the peripapillary choroid and appear as well-delineated, raised, subretinal pigmented masses. They may remain virtually static for many years, although others may extend into the overlying retina, sclera,

optic nerve, and orbit. Although usually considered benign, such invasion warrants a more cautious prognosis. Small tumors are typically asymptomatic although larger tumors frequently present with chronic uveitis, secondary glaucoma, retinal detachment, intraocular hemorrhage, or blindness. Ocular ultrasonography may be required to identify the mass in these patients. Therapy is usually enucleation if the mass is progressive or the eye is painful. Diode laser ablation is an alternative treatment for small masses that do not involve the optic nerve.

Feline Diffuse Iris Melanoma

Diffuse iris melanomas are the most common primary intraocular tumor in cats. Although the prodromal period may be quite long, most cats are 9 years of age or older at the time of diagnosis.

The most common clinical sign is slowly progressive diffuse iridal hyperpigmentation. Occasionally, a pigmented iridal nodule or amelanotic mass is seen. The diagnosis is generally made clinically, and is based on the presence of progressive iridal hyperpigmentation and thickening or irregularity of the iris surface or pupil (Figure 138.3). Secondary glaucoma may occur. Diffuse iris melanoma is differentiated from chronic anterior uveitis with iridal hyperpigmentation by the absence of other signs of uveitis and a more protracted course.

(a)

(b)

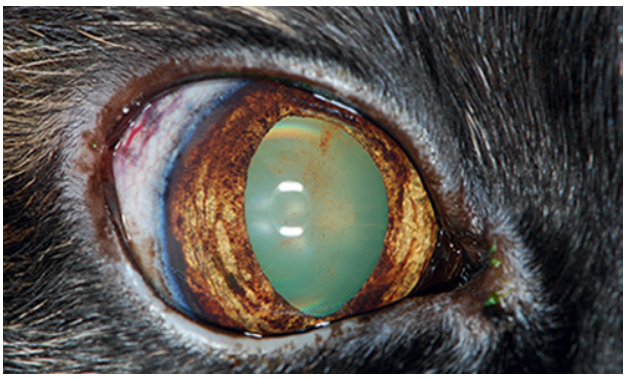

Figure 138.3 (a) Feline diffuse iris melanoma. The right iris is diffusely and heavily pigmented and the pupil is slightly more dilated due to stromal invasion of neoplastic cells (anisocoria). The left iris has multifocal nevi (freckles). (b) Exfoliated pigment from the iris is present on the anterior lens capsule. *Source*: Courtesy of University of Wisconsin-Madison Comparative Ophthalmology Service Collection.

Diffuse iris melanoma has the potential to distantly metastasize, especially to the liver and lungs. Iris hyperpigmentation, however, is typically very slowly progressive, often requiring months to years to progress to the point at which the eye must be enucleated, and an additional 1–3 years after that before metastatic disease may become evident. No single morphologic feature is predictive of outcome, but metastasis has been linked to a greater mitotic index, larger tumors, extension through the iris into the ciliary body stroma, and involvement of the scleral venous plexus.

The treatment of diffuse iris melanoma is controversial. Because these eyes initially retain vision and are comfortable, in the ideal setting, enucleation would be delayed until just prior to malignant transformation, invasion into other ocular structures, secondary glaucoma, or metastasis. Such precise timing; however, is seldom possible. Enucleation is recommended if iris hyperpigmentation progresses to involve virtually all of the iris surface, pigmented cells are present in the aqueous humor and trabecular meshwork, the pupil is distorted (indicating iridal stromal invasion), invasion into the ciliary body or scleral appears imminent, or intraocular pressure is elevated. However, it is unknown whether early enucleation leads to increased survival.

As an alternative to enucleation, some veterinary ophthalmologists have attempted to ablate small, focal, hyperpigmented foci with a diode laser in an effort to preserve vision and the eye. The long-term success rate and side-effects of this procedure, however, are unknown.

In practice, slowly progressing lesions, especially in older cats with other life-limiting disorders, are often simply monitored, ideally by comparison to baseline photographs. In many cats, the progression may be so slow that the patient can be followed for many years to a decade or more without apparent metastasis.

Iridociliary Epithelial Tumors

Primary iridociliary epithelial tumors (e.g., ciliary body adenomas, adenocarcinomas, pleomorphic adenocarcinomas) are occasionally observed in middle-aged to older dogs and cats. Most are benign, fairly well-delineated, slow-growing masses that originate from the ciliary body or the posterior iris epithelium (Figure 138.4). They are often nonpigmented, although some epithelial tumors are pigmented and clinically indistinguishable from anterior uveal melanocytomas.

Figure 138.4 Canine iridociliary epithelial tumor. There is a nonpigmented, vascular ciliary body adenoma filling the posterior chamber and pushing the inferior iris forward. *Source:* Courtesy of University of Wisconsin-Madison Comparative Ophthalmology Service Collection.

Clinical signs include a retroiridal mass that may displace the iris or lens and in advanced cases, secondary glaucoma, intraocular hemorrhage, and ocular pain.

Tumors that invade the sclera are typically classified as adenocarcinomas and have anaplastic features, but metastasis is uncommon and occurs late in the course of the disease, if at all. However, a few cases of truly malignant pleomorphic adenocarcinomas with fatal metastasis have been reported in dogs. Dogs affected with this rare form usually have long-standing ocular disease that was initially thought to be inflammatory or traumatic in origin.

Due to the possibility of malignancy, early enucleation of ciliary body tumors has been recommended, although benign adenomas may remain static for years. This makes enucleation controversial for small tumors unassociated with secondary ocular disease. Local intraocular resection or laser photoablation in an effort to preserve vision and ocular comfort has been described.

Feline Ocular Posttraumatic Sarcoma

A unique entity in cats, sarcomas following ocular trauma are second only to melanomas in frequency as a primary feline ocular tumor. Most cats are middle-aged to older and the latency period following ocular trauma to tumor development averages six to seven years. There are three morphologic subtypes: spindle cell sarcoma (the most common), round cell, and osteosarcoma/chondrosarcoma. The cell of origin in the three subtypes is unclear, although damage to the lens and chronic uveitis are common historical complaints.

Most eyes are blind from the preceding trauma or chronic inflammation, and the most common presenting signs are white, tan, or pink mass filling the anterior chamber and distortion of the globe. Extension beyond the sclera or into the optic nerve may be seen ultrasonographically and are poor prognostic indicators. Growth along the optic nerve into the chiasm and brain, invasion of regional lymph nodes, and distant metastasis have been reported. Early enucleation of suspicious globes with removal of as much of the optic nerve as possible is recommended, although it is unclear if this prolongs survival.

History and Clinical Signs

Common presentations of intraocular tumors include a visible mass involving intraocular tissues, sclera or occasionally the orbit, as well as glaucoma, hyphema, or anterior uveitis. Intraocular neoplasia should always be considered in animals with hyphema, glaucoma, or both when there is no history of trauma or coagulopathy. Small masses frequently have no clinical signs. Pigmentation is not a reliable indicator of tumor type.

Diagnosis

Usually, the clinical or ultrasonographic appearance (if the media are opaque) is strongly suggestive of intraocular neoplasia. It may be difficult to differentiate organizing blood clots from neoplastic mass lesions and more invasive diagnostic procedures may be required. Because most anterior uveal brown or black masses are cystic and not neoplastic, transillumination or ultrasonography should be attempted before resorting to more invasive procedures. Uveal cysts typically are spherical, may be attached to the ciliary body or free-floating in the anterior chamber, and allow bright light to pass through them (see Figure 138.2a). Once suspected, most primary canine intraocular tumors that are not blinding nor causing discomfort are observed for progression, although occasionally FNA (with its risks of inflammation, infection, and hemorrhage), intraocular resection, or enucleation are used for diagnostic purposes. It is also important to rule out metastasis from another primary site (e.g., oral cavity or nailbed) to the eye, or from the eye to other organs (especially lungs and liver).

Therapy

Because the risk of metastasis is low and the ability of enucleation to prevent metastasis in the few malignant

tumors that have been reported is unproven, it is difficult to automatically advise enucleation of normotensive, noninflamed, visual eyes. Therefore, canine primary intraocular tumors are generally photographed and carefully followed for progression. Enucleation is advised if malignancy is a concern or if intractable uveitis, chronic hyphema, or secondary glaucoma is present. Isolated primary masses involving only the iris or a portion of the ciliary body may be amenable to local resection by sector iridectomy/cyclectomy with preservation of the globe, but this procedure requires an accomplished ophthalmic surgeon and often has unsatisfactory long-term results. Transscleral and transcorneal Nd:YAG or diode laser therapy may induce remission in small to moderate-sized primary intraocular tumors while also preserving vision.

Prognosis

The prognosis for histologically benign intraocular tumors is excellent. Enucleation is curative but blinding. Attempts at local excision or laser photoablation may only be palliative, especially if the ciliary body or trabecular meshwork is involved.

Secondary Uveal Neoplasms

Because the uveal tract is highly vascular, numerous malignant tumors have been reported to metastasize to the eye. Lymphoma is the most common secondary intraocular tumor in the dog and cat, with ocular lesions affecting approximately one-third of dogs with the disease. Common clinical signs include a severe uveitis, in which the amount of anterior chamber cell/flare is disproportionally severe compared to the degree of conjunctival hyperemia and pupillary miosis. Other clinical signs include secondary glaucoma, retinal hemorrhage and detachment, hyphema, conjunctivitis, and keratitis characterized by corneal infiltrates, edema, vascularization, and intrastromal hemorrhage. Exophthalmia from orbital invasion and vision loss due to optic nerve or central nervous system (CNS) disease may also occur. Dogs with intraocular lymphoma survive only 60–70% as long as dogs without ocular involvement when treated with cyclophosphamide, vincristine, and prednisolone (COP), or with doxorubicin. Ocular signs may be palliated by topical or systemic corticosteroid therapy, but the most effective therapy is systemic chemotherapy directed at the cancer itself. Enucleation may be necessary for pain relief in some patients.

Tumors of the Orbit and Optic Nerve

Orbital neoplasia may be primary, secondary to extension of adjacent tumors into the orbit, or the result of distant metastasis. In cats and dogs, 90% or more of orbital tumors are malignant, and regional infiltration (including into the CNS) or distant metastasis is common. Numerous types of orbital tumors have been described in cats and dogs. Tumors involving the optic nerve are rare, although secondary invasion of the nerve may occur in feline posttraumatic sarcomas, feline SCC, canine choroidal melanomas, and canine meningiomas.

Primary Orbital Tumors

Sarcomas

Mesenchymal tumors are among the most common canine primary orbital tumors. These include osteosarcomas, fibrosarcomas, reticulum cell sarcomas, and neurofibrosarcomas. Orbital tumors should be histologically graded for a more accurate prognosis but most sarcomas are locally invasive and carry a poor prognosis.

Canine Lobular Orbital Adenoma

Lobular adenomas, perhaps originating from the lacrimal gland, may involve the anterior orbit in dogs. They typically present as soft, smooth conjunctival swellings, or space-occupying orbital lesions that can cause either enophthalmia or exophthalmia. Lobular orbital adenomas are composed of multiple friable lobules, making complete surgical excision challenging. Although benign, recurrence is common, often 1–2 years after excision.

Meningioma

Canine orbital meningiomas are uncommon tumors which tend to grow slowly and rarely metastasize. Invasion of surrounding tissues, including bone and the CNS, is possible.

Glioma

Gliomas are rare primary optic nerve tumors in dogs. The metastatic potential of gliomas appears to be low, but invasion into the retina or the ventral aspect of the brain is possible.

History and Clinical Signs

Orbital neoplasia is typified by slowly progressive exophthalmia, absent to minimal pain on opening the mouth, difficulty in retropulsing the eye, and deviation of the globe. Nasal or sinus tumors that suddenly erode into the orbit occasionally result in acute exophthalmia and substantial orbital pain. If the mass is anterior to the equator of the globe, enophthalmia may occur. Chronic epiphora secondary to obstruction of the nasolacrimal duct, exposure keratoconjunctivitis, palpable orbital masses, or unexplained orbital pain also suggest orbital neoplasia. Measurement of corneal diameters and

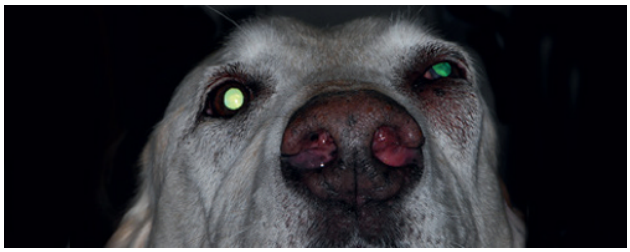
intraocular pressure (IOP) allows differentiation of buphthalmia from glaucoma (large corneal diameter and high IOP) and exophthalmia (normal corneal diameter and IOP).

Optic nerve lesions may result in unilateral or bilateral blindness (the latter if the optic chiasm is affected), which may be sudden in onset, as well as optic nerve head pallor, papilledema, or marked protrusion and congestion of the optic disc on ophthalmoscopy. Relatively mild exophthalmia with vision loss suggests optic nerve neoplasia because other orbital tumors typically cause profound exophthalmos before visual loss. Tumors affecting more posterior portions of the optic nerve may not cause exophthalmia or a visible change in the optic nerve head.

Diagnosis

Differential diagnoses include nonneoplastic orbital inflammatory diseases such as granulomas, cellulitis, abscesses, and myositis of the extraocular and masticatory muscles. Inflammatory orbital disorders typically exhibit marked pain on opening the mouth. The location of an orbital mass can usually be determined by careful physical examination, including determination of the direction of malposition of the eye, retropulsion of the globe, palpation of the orbit, and oral examination caudal to the last molar.

In addition to physical examination, cytology of regional lymph nodes, orbital imaging (computed tomography, magnetic resonance imaging, orbital ultrasound), thoracic radiographs, and possibly abdominal ultrasonography should be performed. In one study of cats with orbital neoplasia, 59% had orbital bone lesions on skull radiographs and 15% had evidence of metastasis on thoracic radiographs. CT or MRI offers far superior visualization of the orbit and facilitates planning of either radiation or surgical therapy (Figure 138.5).



Histologic characterization by FNA or needle core biopsies (performed via the mouth or through the periocular skin), with ultrasound or CT guidance if necessary, is essential for arriving at a definitive diagnosis. It is important to avoid the globe, major orbital blood vessels, and optic nerve when collecting these samples. If less invasive methods of obtaining specimens are nondiagnostic, exploratory orbitotomy or exenteration may be required. If the optic disc appears normal, electroretinography, MRI, and cerebrospinal fluid taps may aid in distinguishing optic nerve neoplasia from sudden acquired retinal degeneration syndrome and posterior optic neuritis.

Therapy

Primary orbital and optic nerve tumors that have not disseminated elsewhere may be amenable to surgical excision. If bony involvement is not present, orbital exenteration by widely dissecting around the mass (stripping periorbita if necessary) is usually preferred, as the advanced stage of the tumor at the time of diagnosis typically makes it impossible to completely excise the mass and preserve a functional or comfortable eye. If periorbital bones are involved, a radical orbitectomy, which resects the affected orbital tissues and surrounding bones, may be considered. When treating optic nerve tumors, as much of the orbital optic nerve as possible should be removed in an attempt to obtain clear margins.

If preservation of a comfortable eye and vision appears possible, a variety of orbitotomy techniques have been described, ranging from small incisions through the eyelid or mouth to reflection of the zygomatic arch, temporalis muscle elevation, and zygomatic process osteotomy. Postoperative complications are common and may include secondary enophthalmia with entropion, diplopia (double vision), facial nerve palsy, and severe orbital hemorrhage. Surgical debulking can be palliative in some patients, and some dogs may survive a year or more with minimal therapy.

The value of chemotherapy and radiation therapy (RT), either alone or as an adjunct to surgery, is unclear, although chemotherapy for orbital lymphoma may be effective. Systemic corticosteroids may reduce perineuronal swelling and permit some patients with optic nerve meningioma to maintain vision for several weeks to months. RT may be helpful in the case of nasal tumors with orbital extension, in subtotally excised or recurrent tumors, and in other select cases.

The ocular side-effects of conventional external beam RT for nasal and periocular tumors can have a substantial impact on an animal's quality of life. Common complications include keratoconjunctivitis sicca, corneal ulceration, enophthalmia, entropion, cataracts, retinal hemorrhages, retinal detachments, and blindness. Intensity-modulated RT (IMRT), which uses conformal avoidance, significantly decreases the ocular toxicity seen in dogs treated by RT for sinonasal and orbital tumors.

Prognosis

The prognosis for most tumors involving the orbit and optic nerve is poor with conservative treatment, especially if there is bony involvement. Recurrence at the original site and involvement of adjacent or distant sites are common, often occurring within weeks to a few months. Even benign-appearing tumors such as lobular orbital adenomas and orbital meningiomas may be locally invasive and tend to recur following wide excision.

Secondary Orbital Tumors

Most feline orbital tumors are epithelial in origin, with invasive SCC being the most common. Lymphoma is another common secondary orbital tumor affecting both cats and dogs. Orbital lymphoma should be considered part of a systemic process, and further diagnostics are warranted.

Cancer of the Heart

Nick A. Schroeder, DVM, DACVIM (Cardiology)[1] *and Lisa DiBernardi, DVM, DACVIM (Oncology), DACVR (Radiation Oncology)*[2]

[1] *LeadER Animal Specialty Hospital, Cooper City, FL, USA*
[2] *Gulf Coast Veterinary Specialists, Houston, TX, USA*

Etiology/Pathophysiology

Cardiac neoplasia in small animals is usually associated with pericardial effusion. Most of the time, rupture of a cardiac tumor occurs which leads to hemopericardium and cardiac tamponade. In dogs, the majority of cases are secondary to malignant hemangiosarcoma. Cats most commonly have cardiac lymphoma. Diagnosis is frequently based on echocardiographic location of the mass lesion, taking into account the age and breed of the animal, and only rarely is histopathologic confirmation achieved via surgical biopsy. Given the current rate of change in treatment modalities, consultation with a veterinary oncologist is recommended.

Tumors of the heart typically arise from the myocardium, the heart base or the pericardium and are commonly associated with pericardial effusion. Pericardial effusion is a relatively common condition in the dog, much less so in the cat. Normally, there are only a few milliliters of fluid present in the pericardial space, which serves to lubricate the epicardial surface. The pericardium is a tough, fibrous membrane. The purpose of the pericardium is to stabilize the position of the heart within the thorax and provide some diastolic function. When significant amounts of fluid accumulate within the pericardial space, cardiac function may be compromised, and affected animals may start to show clinical signs as described below. The most common causes of pericardial effusion are cardiac neoplasia and idiopathic pericardial effusion.

Malignant transformation of vascular endothelial cells results in hemangiosarcoma (HSA). Cardiac HSA typically arises from the tissue of the right atrium (RA) and/or right auricle (RAu), though other regions of the heart may occasionally be affected. Spontaneous hemorrhage causes hemopericardium.

Heart-based tumors (HBTs) constitute approximately 5% of cases of cardiac neoplasia in the dog and up to 3% in cats and are commonly identified as incidental findings. Most of these are aortic body tumors (ABTs, chemodectoma or paraganglionoma). These tumors arise from chemoreceptor cells sensitive to blood oxygen and carbon dioxide tension. Most ABTs are locally invasive and up to 21% are malignant, metastasizing to lung, liver, left atrium, pericardium or kidneys. Approximately 5–10% of all heart-based tumors are ectopic thyroid carcinomas or parathyroid tumors. These are rarely secretory or functional. Hemopericardium may be present due to spontaneous hemorrhage from the mass itself. Alternatively, a hydropericardium with a modified transudate may develop secondary to obstruction of lymphatic drainage of the pericardial sac.

The myocardium may be infiltrated with neoplastic lymphocytes (LSA), occasionally causing pericardial effusion, typically a modified transudate. Cardiac lymphoma may be primary or multicentric.

Pericardial effusion may develop secondary to pericardial mesothelioma. Pleural effusion may also occur in affected animals with mesothelioma, often concomitant with pericardial effusion.

Other miscellaneous and rarely reported cardiac tumors include intrapericardial lipoma, rhabdomyosarcoma, cardiac mxymoma, and other sarcomas.

Epidemiology

The prevalence of cardiac neoplasia in the dog has been cited at 0.19% and is less than 0.03% in cats. Primary cardiac neoplasia constitutes 84% of cases, with 16% representing metastatic lesions (most commonly hemangiosarcoma and adenocarcinoma).

Most of the information available is derived from small case series and retrospective data.

Signalment

Golden retrievers and German shepherds are predisposed to cardiac HSA. Afghan hounds, English setters, American cocker spaniels, Doberman pinschers, Labrador retrievers and miniature poodles have been reported to be at increased risk as well.

English bulldogs, Boxers, and Boston terriers are the most common breeds diagnosed with HBTs. Brachycephalic breeds are predisposed, but HBTs may develop in other breeds.

Cats of all breeds may develop cardiac lymphoma. Cardiac lymphoma is quite rare in the dog.

History and Clinical Signs

Dogs that have acute cardiac tamponade from sudden hemorrhage by RA/RAu HSA into the pericardial space typically pant, may collapse or experience hemodynamic shock. Cardiac tamponade occurs when the intrapericardial pressure exceeds the diastolic right atrial and ventricular pressures. This leads to collapse of the right ventricular outflow tract, right atrium and right ventricle (RV). Typically, the left atrial (LA) and left ventricular (LV) pressure exceeds the intrapericardial pressure, preventing collapse. Collapse of the right-sided chambers leads to impaired filling, decreased pulmonary blood flow and decreased filling of the left atrium and ventricle. Even a small amount of fluid, if it suddenly develops can result in serious hemodynamic compromise, whereas slow accumulation can lead to signs that are insidious in onset. Chronic pericardial effusion leads to hepatic venous congestion and functional right heart failure, and may result in a large, pendulous abdomen from ascites as well as dependent subcutaneous edema.

On physical examination, dogs classically have decreased or muffled heart and ventral lung sounds as well as weak pulses. Other potential findings include a fluid wave on palpation of the abdomen, hepatomegaly and pitting edema of the rear limbs. Beck's triad of clinical signs associated with cardiac tamponade is hypotension, distended jugular veins, and muffled heart sounds. Attention should be paid to the quality of femoral pulses as the pulses may noticeably get weaker with inspiration and stronger with expiration. This phenomenon, due to intrathoracic pressure changes and the subsequent effects on the pulse pressure, is termed pulsus paradoxus and is highly suggestive of pericardial effusion.

Many HBTs are discovered incidentally with no apparent clinical signs. Patients that are symptomatic typically have signs referable to pericardial effusion or outflow obstruction to the right side of the heart, either of which may result in ascites.

Patients with LSA may have weight loss or signs associated with pericardial effusion. Occasionally, the patient may present with symptoms referable to congestive heart failure. These include difficult or labored breathing, exercise intolerance, coughing, inappetence or lethargy.

Most patients with mesothelioma have symptoms associated with pericardial and/or pleural effusion. As a result, many present with dyspnea or increased respiratory rate and effort. An abdominal component to the respiratory effort may be noted.

Rhabdomyosarcoma has been reported to be associated with right-sided congestive heart failure (CHF) but not pericardial effusion, and some patients may be completely asymptomatic. Patients with intrapericardial lipomas are typically asymptomatic.

Diagnosis

Diagnosis of pericardial effusion can be made unequivocally with cardiac ultrasound (echocardiography). Hemangiosarcoma is usually diagnosed via echocardiography, revealing the presence of a mass lesion on the RA/RAu or RV junction of mixed echogenicity with irregular anechoic regions. Patients may be hypotensive. Radiographs typically reveal a globoid cardiac silhouette with pulmonary vascular underperfusion, but may be deceivingly normal or only show mild cardiomegaly.

Electrocardiography (ECG) commonly reveals sinus tachycardia. The QRS complex may be of lower amplitude (low-voltage QRS). These comprise the most common electrocardiographic abnormalities associated with pericardial effusion. The R-waves may vary in amplitude from beat to beat, a phenomenon known as electrical alternans. This occurs as a consequence of the heart swinging back and forth in the fluid-filled pericardium. The angle of the vector of LV depolarization is varied due to the positional changes, subsequently altering the amplitude of the QRS complex. This generally happens when the heart rate is between 90 and 140 bpm. Ventricular premature complexes, accelerated idioventricular rhythm, ventricular tachycardia, paroxysmal atrial flutter or atrial fibrillation, atrioventricular block, bundle branch blocks and other conduction system disturbances may occasionally be encountered on ECG in patients with cardiac neoplasia. The ECG may also be completely normal. Often, physical examination is more reliable than radiographs and ECG. Cardiac magnetic

resonance imaging (MRI) has not been shown to improve the diagnosis of cardiac neoplasia when compared to conventional echocardiography.

Testing of the pericardial effusion tends to be of limited diagnostic utility. Cytology of hemorrhagic effusions does not reliably differentiate between neoplastic and nonneoplastic disease. Neoplastic effusions have been associated with lower pH, bicarbonate and chloride levels and higher lactate, hematocrit, and urea nitrogen as compared with serum values. Serum cardiac troponin I levels have been shown to be elevated in dogs with neoplastic pericardial effusions.

On necropsy, HSA appears as a red to black, blood-filled mass on the epicardium. Histopathologic confirmation is rarely obtained antemortem but is marked by scattered, elongated plump neoplastic endothelial cells. By the time of diagnosis, most cases have associated metastasis and in general HSA should be considered a systemic/disseminated disease. The clinician should always assume that HSA is more advanced than what is evident based on imaging modalities. Cardiac troponin I levels have not been shown to be a reliable diagnostic screening tool. Definitive diagnosis requires surgical biopsy.

Heart-based tumors are most commonly diagnosed via echocardiography. Typically, these are visualized as masses of mixed or homogenous echogenicity immediately adjacent to the ascending aorta, aortic arch and proximal branch pulmonary arteries. Thoracic radiographs may show a ventral deviation of the caudal aspect of the intrathoracic trachea, resulting in a "hook-like" appearance if a large HBT is present. Cytologic evaluation of pericardial effusion when present is rarely diagnostic. Definitive diagnosis requires histopathologic evaluation of surgically obtained biopsies, often taken during palliative pericardectomy.

It is common for cats affected with LSA to have large amounts of pericardial effusion, requiring pericardiocentesis. The pericardial effusion should be submitted for fluid analysis/cytology as lymphosarcoma may be easily diagnosed. Most often, lymphosarcoma of the heart produces infiltrative myocardial lesions. Echocardiography may reveal irregular mottling and echotexture to the myocardium with focal areas of thickening, and concentric left ventricular hypertrophy may mimic hypertrophic cardiomyopathy. Grossly, white, pale lesions arise from the myocardium.

Patients affected with pericardial mesothelioma may reveal focal thickening and irregularity of the pericardial sac on echocardiography. However, normal pericardial adipose tissue may mimic infiltrative lesions. It is very common to have associated pleural effusion, and the presence of a modified transudate in the pleural and pericardial cavities for no obvious underlying reason should alert the clinician to the possibility of mesothelioma. Unfortunately, cytology of the effusion is rarely diagnostic as nonneoplastic reactive mesothelial cells are difficult if not impossible to cytologically differentiate from exfoliated neoplastic mesothelial cells. Pericardial and/or pleural biopsies are typically required for confirmation of diagnosis.

Pericardial lipomas may be diagnosed on thoracic radiographs with the appearance of an adipose density within the cardiac silhouette. Echocardiography generally reveals a homogenously echogenic mass within the pericardial sac with variable degrees of compression of the right heart chambers. Ultrasound-guided fine needle aspiration may be attempted, although definitive diagnosis generally requires surgical biopsy.

Cardiac myxomas, rhabdomyosarcomas and other cardiac sarcomas require surgical biopsy for confirmation of diagnosis.

Therapy

Once hemodynamically important pericardial effusion is confirmed, immediate pericardiocentesis is warranted. Ideally, an intravenous (IV) catheter is placed and a shock bolus of fluids is administered, but patients may require immediate pericardiocentesis and a IV catheter and fluids may need to follow.

Frequently, the fluid grossly resembles port wine which appears similar to venous blood. The presence of dark, hemorrhagic pericardial effusion is classically seen with HSA, but its presence is not pathognomonic for HSA or other cardiac neoplasia. Less commonly, the fluid may be serosanguinous from CHF or neoplasia. Rarely, it may be grossly purulent from pericarditis. Commonly, any residual fluid will leak into the pleural cavity from the hole that has been created in the pericardium. Complications associated with pericardiocentesis include puncture of a cardiac chamber, laceration of a cardiac tumor or coronary artery with subsequent intrapericardial hemorrhage. Most commonly, transient arrhythmias may occur, though they tend to be self-limiting and only rarely require antiarrhythmic therapy.

In select cases of cardiac HSA, surgical excision may be attempted (RA appendectomy +/- inflow occlusion via right thoracotomy or median sternotomy), but in the majority of cases complete surgical excision is not achieveable. Pericardectomy alone is not advised due to the risk of exsanguination and dissemination of tumor cells into the pleural cavity and has not been shown to affect recurrence of clinical signs or survival. Various chemotherapeutics (doxorubicin, dacarbazine, cyclophosphamide, vincristine) have been attempted with a positive trend in overall survival time and time to metastasis.

Metronomic chemotherapy, which is intended to prevent tumor angiogenesis, is based on more frequent and low-dose drug administration lacking a rest period compared with conventional chemotherapy. Metronomic chemotherapy lends itself to minimal toxicity and is often cost-effective and convenient.

One small study evaluating canine splenic HSA compared the use of low-dose chemotherapy in combination with piroxicam versus the standard of care chemotherapy, doxorubicin. This study found no statistical difference in survival between the groups, leading to the conclusion that low-dose orally administered chemotherapy may be an effective alternative to conventional chemotherapy. A group at Washington State University used daily dosing of an alkylating agent, lomustine, with or without nonsteroidal antiinflammatory drugs (NSAIDs) to evaluate the toxicity. The majority of the 81 dogs in this study had macroscopic tumor and/or metastasis with osteosarcoma and visceral HSA most prevalent. Thirty-six percent of dogs experienced stable or improved disease. Although minimal, mild to moderate adverse hematologic and gastrointestinal events occurred and an unexpectedly higher number experienced azotemia (13%). Currently, there are no placebo-controlled studies available for cardiac HSA. Tyrosine kinase-mediated proliferation inhibition has been observed in cell lines of canine HSA when exposed to dasitinib and imatinib alone and in conjunction with doxorubicin. The use of tyrosine kinase inhibitor therapy alone or in combination with standard or metronomic chemotherapy has yet to yield improved survival times in the treatment of cardiac HSA.

Early surgical excision is the preferred method of treatment for heart-based tumors. However, in the majority of cases complete surgical excision is not possible. Palliative pericardiocentesis and partial pericardiectomy are viable treatment options for patients with pericardial effusion secondary to HBT. A retrospective study of 6 dogs treated with stereotactic body radiation therapy (SBRT) for heart-base tumors confirmed or presumed to be chemodectomas was performed at the North Carolina State University Veterinary Hospital. Respiratory and motion management was key to the accurate delivery of a minimum of 30 Gray (Gy) delivered in three 10 Gy fractions. Four tumors were assessed after SBRT; tumor volume decreased by 30-76%. Possible treatment-related complications included cough, tachyarrhythmias, and congestive heart failure. Two dogs experienced sudden death 150 and 294 days after SBRT. Three dogs were alive at the time of the report (408 and 751 days after SBRT) and one dog died of unrelated disease 1,228 days after SBRT. While this protocol offered rapid tumor reduction, cardiac arrhythmias assumed to be tumor or treatment related and sudden death commonly occurred after SBRT. SBRT may be ideal for select patients and likely not of benefit for dogs lacking cardiovascular disturbances and/or incidentally diagnosed. As the use of SBRT evolves we will recognize appropriate candidates, and better define the survival benefit. Standard and metronomic chemotherapy alone or combined with small molecule inhibitors may be attempted, especially if metastasis is evident.

In patients affected by cardiac lymphoma with clinically significant pericardial effusion, palliative pericardiocentesis is required. Considered to be stage V, substage B, cardiac lymphoma may be treated with CHOP-based chemotherapy protocols.

Mesothelioma patients may have a palliative pericardectomy performed, but clinically significant pleural effusion typically develops, and pericardectomy has not been shown to decrease the occurrence of clinical signs or survival time. In patients affected with mesothelioma, carcinomatosis or sarcomatosis (with or without malignant effusion), short-term benefit has been obtained with intracavitary chemotherapy. Intracavitary carboplatin and/or mitoxantrone yielded a 333-day median survival time. Three dogs with pleural mesothelioma treated with intracavitary cisplatin had complete resolution of their effusions for 129, 289 and over 306 days. Resolution of effusion occurred within one or two treatments for all three dogs.

Intrapericardial lipomas may be addressed surgically if clinically important right-sided inflow obstruction of the heart is documented.

Prognosis

The prognosis for cardiac HSA is generally considered to be grave. Median survival times (MST) with palliative pericardiocentesis alone have been reported at 11 days (range 0–208 days). A MST of 43 days was achieved in eight dogs undergoing pericardiectomy and surgical resection of a RA HSA. In eight dogs with pericardiectomy and RAu masses, MST was 90 days. This difference in MST may be explained by the smaller size of auricular masses. In a separate report, 15 dogs with pericardiectomy and RA mass resection experienced a MST of 42 days. In eight postoperative patients, the addition of doxorubicin-based chemotherapy significantly improved MST to 175 days. In nonsurgical cases doxorubicin-based protocols may offer MST of 120 days. Pericardiectomy may be performed by one of two techniques: surgical (thoracotomy) or thoracoscopic-assisted pericardiectomy. However, if mass removal is intended, thoracotomy would be the ideal approach based on the experience level of the surgical team.

Heart-based tumors have a fair prognosis, but this is highly dependent on the presence or absence of pericardial effusion, secondary outflow obstruction, or other cardiac function abnormalities. Patients having undergone palliative pericardectomy had a MST of 730 days (42 days with palliative pericardiocentesis alone).

The prognosis for cardiac LSA is guarded, but variable based on response and severity. Twelve dogs with cardiac lymphoma were evaluated and dogs treated with combination chemotherapy had a MST of 157 days compared to a 22-day MST in untreated dogs. Three of the treated dogs survived >328 days. There is no evidence that primary cardiac LSA should be treated differently from other bulky aggressive lymphomas arising at other anatomic sites.

Patients suffering from pericardial mesothelioma generally have a fair to guarded prognosis. Many patients may survive months to years with palliative centesis +/- corticosteroid administration alone.

A variety of primary and secondary cardiac tumors have been reported in the veterinary literature. With technologic advancement, we will gain a more detailed picture and begin to unearth important factors regarding biologic behavior, treatments and prognosis.

Cancer of the Airway and Lung

Joanne L. Intile, DVM, DACVIM (Oncology)

College of Veterinary Medicine, North Carolina State University, Raleigh, NC, USA

Cancer of the Airway

Etiology/Pathophysiology

Tumors of the larynx and trachea are rare in dogs and cats. The most common primary tumors of the canine larynx are carcinomas, with squamous cell carcinoma occurring most frequently, followed by oncocytoma and rhabdomyoma. Other reported laryngeal tumors include mast cell tumor, extramedullary plasmacytoma, chondrosarcoma, osteosarcoma, melanoma, lipoma, adenocarcinomas, fibrosarcoma, and papilloma. Metastatic tumors from a distant site are rarely reported.

Feline primary laryngeal tumors include lymphoma, squamous cell carcinoma, and adenocarcinomas. Leiomyoma, basal cell carcinoma, and polyps are also reported.

Secondary invasion of the larynx can result from ingrowth of primary thyroid tumors or regional lymphoma.

The most common tracheal tumors in dogs include benign tracheal osteocartilaginous tumors, leiomyoma, adenocarcinomas, mast cell tumor, and extramedullary plasma cell tumor. In cats, adenocarcinomas, squamous cell carcinoma, and other carcinomas are the most commonly reported.

Epidemiology

There are no known etiologic or epidemiologic factors predisposing animals to developing laryngeal and tracheal tumors.

Signalment

Other than a predilection for younger dogs to develop oncocytomas, for older cats to develop malignant laryngeal tumors, and a possible overrepresentation of Siamese cats developing tracheal tumors, there is no typical age, breed, or sex predilection for laryngeal and tracheal tumors in dogs and cats. However, younger animals with active osteochondral ossification sites are at increased risk for developing benign tracheal osteocartilaginous tumors.

History and Clinical Signs

Patients with laryngeal tumors typically present with signs directly related to the primary tumor, including stridor, dyspnea, change in bark or voice, exercise intolerance, weakness, or dysphagia. Ptyalism may also be noted.

Patients with tracheal tumors present with similar symptoms as those with largyneal tumors, but are more likely to cough.

Diagnosis

The diagnosis of a laryngeal tumor is often made upon direct visualization on awake or sedated oral exam. Oral exam provides limited information regarding the extensiveness of the tumor, but the advantage is that tissue biopsy samples can be obtained in a relatively noninvasive and economical manner.

Cervical radiographs are helpful in localizing tumors of the distal portions of the larynx or trachea. Images may show a discrete soft tissue mass within the lumen of the trachea, and/or a calcified mass in cases of osteochondromas/chondromas. Thoracic radiographs are recommended to evaluate for the presence of metastatic disease and also to assess for evidence of aspiration pneumonia, which may occur secondary to laryngeal dysfunction. Cervical ultrasound and tracheoscopy may be

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

helpful to determine the extent of tumors and can also be used to obtain histopathologic samples. Computed tomography (CT) and magnetic resonance imaging (MRI) provide three-dimensional localization of the tumor as well as its proximity to other vital structures within the cervical region. This detailed imaging may facilitate a diagnosis but is often required for treatment planning.

Laryngeal/tracheal lymphoma should be considered part of a systemic disease process, therefore warranting complete staging as part of a diagnostic plan.

Therapy

There is limited information regarding the treatment of laryngeal tumors in dogs and cats. In dogs, benign tumors of the larynx such as a rhabdomyoma or cyst can be removed surgically. Some cases require placement of a temporary tracheostomy tube. Smaller benign masses can be removed via a transoral approach or through a ventral laryngotomy. Postoperative inflammation and obstruction may necessitate temporary tracheostomy. For larger and/or more invasive tumors, a partial or complete laryngectomy with a permanent tracheostomy can be considered. Permanent tracheostomy, providing relief of upper airway obstruction, is a form of treatment for humans but has limited use in veterinary medicine.

Reported complications of complete laryngectomy in dogs include stomal collapse, the formation of a tracheoesophageal fistula, pharyngeal dehiscence, and ablation of the parathyroid glands. Permanent tracheostomy in cats carries a 67% complication rate with 29% in-hospital mortality. A temporary gastrostomy tube should be considered for any patient undergoing aggressive laryngotomy.

Radiation therapy is used for treating invasive or nonresectable tumors and is effective for treating lymphomas and plasma cell tumors. However, limited evidence-based information exists. Chemotherapy, with or without surgery, may also be effective.

Tumors of the trachea should be treated with surgery, which is curative for benign osteochondral tumors. Experimental evidence indicates that up to 50% of the length of the trachea can be removed with successful closure. Tension on the site of anastomosis is the limiting factor. Intraluminal stenting or bronchoscopic debulking can be palliative measures for relieving obstruction. As with laryngeal tumors, the efficacy of radiation and/or chemotherapy for non-hematologic tumors remains unproven but can be considered when surgery is not feasible.

Prognosis

Benign tumors of the larynx and trachea have a good prognosis when treated with surgical resection alone. Long-term survival is also expected with treatment of extramedullary plasmacytomas and granular cell tumors. Unfortunately, information is too limited to provide specific prognosis' for dogs with other malignancies of the airway.

Similar to dogs, little information is available regarding the prognosis for cats. In one reported study, the median survival time for 27 cats with a variety of laryngeal and tracheal tumors was only five days, with only 7% of patients alive 12 months after diagnosis.

Cancer of the Lung

Etiology/Pathophysiology

Primary lung tumors are rare in dogs and cats compared to humans. The most common primary lung tumor in dogs is bronchoalveolar carcinoma, followed by adenocarcinoma, adenosquamous carcinoma, and squamous cell carcinoma. Other primary lung tumors include histiocytic sarcoma, neuroendocrine tumors, and primary pulmonary sarcomas. Benign primary lung tumors include adenomas and fibromas. The most common primary lung tumor in cats is adenocarcinoma, followed by bronchoalveolar carcinoma, squamous cell carcinoma, and adenosquamous carcinoma.

In both cats and dogs, primary lung tumors can spread via hematogenous or lymphatic routes. This may occur regionally, to intrathoracic lymph nodes, other lung lobes, and the pleura, or distantly throughout the body. More than three-quarters of cats with pulmonary tumors will develop metastasis. Local invasion of tumors within the adjacent pulmonary parenchyma can occur.

In some cases, it is difficult to determine if a pulmonary tumor represents a primary cancer versus a metastatic lesion from a distant site. Immunohistochemical stains can be helpful in such cases, as can complete and thorough staging to evaluate for disease at distant sites.

Epidemiology

The relationship between environmental carcinogens and the development of lung tumors in dogs has been studied. One study showed that 75% of dogs with primary lung tumors live in urban environments, but the results of two other studies did not support this finding. The risk of exposure to second-hand smoke and development of lung cancer in dogs has also been evaluated with conflicting

results. The association in natural settings appears to be weak, but the risk may be increased in brachycephalic dogs compared to dolichocephalic dogs. It is hypothesized that dolichocephalic dogs possess greater surface area for filtration of inhalant carcinogens.

There are no known epidemiologic factors influencing the development of primary pulmonary tumors in cats.

Signalment

The average age of dogs with primary lung tumors is approximately 11 years (range 2–18 years). The risk of developing lung cancer rises after the age of 13. Males and females are equally susceptible. Tumors occur more frequently in larger dogs, with 60% of cancers developing in dogs weighing 20–30 kg. In cats, the average age at diagnosis is 12–13 years (range 2–20 years) with most cats being >5 years of age. No breed or sex predisposition is consistently found in felines.

History and Clinical Signs

Between 52–93% of dogs with primary lung tumors present with a chronic nonproductive cough. Other signs include dyspnea, lethargy, weight loss, tachypnea, pyrexia, inappetence, and lameness. Many dogs are diagnosed with primary lung tumors without any obvious clinical signs during routine geriatric screening tests (e.g., thoracic radiographs). Pleural effusion may occur secondary to direct invasion of the tumor into the pleura or regional pulmonary lymphatics. This may occur with primary or metastatic tumors within the lung tissue. Pneumothorax and hemoptysis may rarely occur.

Signs related to the respiratory system are detected in one-quarter to two-thirds of cats with lung tumors. Vomiting is reported in 20% of cats. Cats with lung tumors are more likely to show nonspecific signs such as lethargy, malaise, and inappetence compared with dogs.

Hypertrophic osteopathy is a known paraneoplastic syndrome associated with primary and metastatic lung tumors in dogs and cats. Animals present with lameness of one or more limbs. Radiographs will show periosteal proliferation occurring perpendicular to the shaft of the long bones. Hypertrophic osteopathy can resolve following removal of a primary lung tumor. Other known paraneoplastic effects in dogs include hypercalcemia, polyneuropathy, polymyopathy, fever, and ectopic adrenocorticotropic hormone production leading to hyperadrenocorticism.

Metastasis to the digits is a well-described clinical consequence of primary pulmonary tumors in cats and some feline patients are initially diagnosed with bony lesions within the phalanges prior to diagnosis of a pulmonary tumor. Metastasis occurs more commonly to the weight-bearing digits. Multiple digits and multiple limbs are commonly affected.

Diagnosis

Many dogs with primary and metastatic lung tumors are diagnosed via thoracic radiography. Most dogs will show a solitary pulmonary mass that is well circumscribed and located in the caudodorsal lung lobes. Diffuse and alveolar infiltrative forms are also described. Radiographs may also show regional lymphadenopathy or extension of tumor into the surrounding pulmonary parenchyma.

Computed tomography is being more frequently utilized for the diagnosis of pulmonary neoplasia in dogs and cats and is ideal for surgical planning. Thoracic CT scan is superior to thoracic radiography for the detection of tracheobronchial lymph node metastases and for detecting pulmonary metastases. The accuracy rate for thoracic CT in detecting tracheobronchial lymph node metastases was 93%, compared to 57% for radiographs. In another study, thoracic radiographs detected only 9% of CT-detected pulmonary metastases. Twenty one of 33 (64%) dogs had pulmonary nodules or masses detected on CT. Of the dogs that had positive CT findings, 17 of 21 (81%) had pulmonary nodules or masses detected on radiographs by at least one interpreter. In another study using CT as the gold standard diagnostic tool, the sensitivity of radiography for detecting pulmonary metastases ranged from 71% to 95%, and specificity ranged from 67% to 92%. Radiography had a positive predictive value of 83–94% and a negative predictive value of 65–89%. This increased accuracy of CT for detecting lesions is likely, in part, due to its higher resolution for identifying smaller lesions (e.g., thoracic CT can detect lesions of 1 mm in size) compared to radiographs (can detect lesions only when >7 mm in size). MRI of the thorax is not recommended due to excessive motion artifact.

Pleural effusion is more common in cats, and is identified in approximately one-third of patients. The diagnostic utility of cytology of pleural effusion in providing a diagnosis of pulmonary neoplasia is variable, but if effusion is detected, it is recommended to submit a sample for analysis as this is a relatively noninvasive technique that can provide significant information.

Bronchoalveolar lavage can be considered and has been found to be superior to transtracheal wash for diagnosing lung cancer in dogs.

Fine needle aspiration of lung tumors is safe, but there is a theoretical risk of seeding tumor cells within the thoracic cavity during this procedure. Studies indicate fine

needle aspirate cytology is diagnostically accurate in up to 90% and 100% of dogs and cats with pulmonary tumors, respectively. Ultrasound and/or CT-guided aspiration has been described, as well as techniques utilizing thoracoscopic or keyhole lung biopsy methods.

Therapy

Surgery is the treatment of choice for solitary pulmonary tumors in dogs and cats. For unilateral tumors, surgery can be performed through either an intercostal thoracotomy or median sternotomy approach. Thoracoscopic and keyhole techniques have also been described. Complete lung lobectomy is the preferred surgical approach, but techniques for partial lung lobectomy are described. The use of automatic stapling equipment allows for decreased surgical time with minimal complications, but is more difficult in small patients. It is important to note that biopsy of hilar lymph nodes at the time of thoracic surgery should be performed to complete staging.

Pneumonectomy is considered for lesions that have extended to all lobes of one lung while the contralateral side is unaffected. The resulting physiologic alterations are much greater than performing a single lobectomy. Dogs can survive a 50% decrease in lung volume, but not 75%. Therefore excision of all lung tissue on the left side can be tolerated since it represents less than 50% of total lung volume.

There is little information regarding the utility of chemotherapy for treating primary lung tumors in dogs and cats. In dogs, doxorubicin and mitoxantrone have been shown to provide little to no response. Two of seven dogs with measurable pulmonary tumors showed a partial response to treatment with vinorelbine. Single-agent vinorelbine was also evaluated in the microscopic disease setting in three dogs, and survival time for those patients was 112, 169, and >730 days.

Inhalational therapy has also been evaluated in dogs, resulting in complete and partial responses for dogs with metastatic tumors compared to stable to progressive disease for dogs with solitary ones.

Intracavitary chemotherapy with cisplatin, carboplatin, or mitoxatrone, as well as sclerosing agents such as talc, has been used to treat malignant effusions in dogs.

In people with non-small cell lung cancer, treatment benefits have been obtained using targeted therapy with either monoclonal antibodies or tyrosine kinase inhibitors directed against cell signaling pathways. The role of such targeted therapy in veterinary patients is unknown.

The role of radiation therapy, interventional radiology, and regional chemotherapy remains relatively unexplored for veterinary patients with pulmonary neoplasia.

Prognosis

Most information regarding prognosis for animals with pulmonary tumors is derived from the behavior of epithelial tumors.

The median survival time of 24 beagle dogs diagnosed with pulmonary carcinomas treated with symptomatic care alone was 10 months (range five days to 42 months). The prognosis for dogs with pulmonary tumors treated surgically is variable and depends on a number of factors, some of which can only be determined postoperatively (e.g., histologic grade and completeness of excision). An older study reported a median survival time of 13 months with lung lobectomy alone. For dogs with incompletely excised tumors, median survival time was only about 1–2 months compared to 11 months for completely excised tumors.

Several specific prognostic factors have been identified in dogs with pulmonary tumors (Table 140.1). Tumor stage is prognostic: T1 (solitary tumor) = median survival time of 26 months, T2 (multiple tumors) = median survival time seven months, and T3 (invasive into surrounding tissue) = median survival time of three months. The presence of metastatic disease within intrathoracic lymph nodes is a negative prognostic factor for dogs with primary lung tumors (11–15 months if no metastatic disease present; 1–2 months if metastases are detected). The presence of clinical signs at the time of tumor detection is also a negative prognostic factor: 18 months with no clinical signs compared to eight months when clinical signs are present. Tumor size and location are also prognostic. Dogs with tumors $<100\,cm^3$ and those with peripherally located tumors have longer survival times compared with dogs with tumors $>100cm^3$ or encompassing entire lung lobes.

Histologic grade is a prognostic factor for both dogs and cats. The median survival time for dogs with well-differentiated, moderately differentiated, and poorly differentiated tumors was 28 months, eight months, and five days, respectively. The median survival time for cats with well-differentiated tumors treated surgically was 23 months, compared to 2.5 months for cats with poorly differentiated tumors. Other prognostic indicators for cats include the presence of clinical signs (median survival time of 4 days if present vs. 78 days if not), pleural effusion (median survival time 2 days vs. 31 days), and the presence of metastatic disease (median survival time 3 days vs. 60 days.)

Table 140.1 Prognostic factors and associated median survival times for dogs with lung tumors

	Median survival time	
Prognostic marker for dogs with lung tumors	**Present**	**Absent**
Lymph node metastasis	1 month	15 months
Microscopic disease following surgery	1 month	11 months
Metastases	<1 month	15 months
Clinical signs at diagnosis	8 months	18.1 months
Median survival time		
Histologic grade		
Grade 1	26.3 months	
Grade 2	8.3 months	
Grade 3	<1 month	
Histologic type		
Squamous cell carcinoma	8 months	
Adenocarcinoma	19 months	
Solitary tumor	26 months	
Multifocal tumors	7 months	
Tumors invading into surrounding tissue	3 months

Cancer of the Esophagus and Stomach

Avenelle I. Turner, DVM, DACVIM (Oncology)

Veterinary Cancer Group, Culver City, CA, USA

Etiology/Pathophysiology

Esophageal sarcomas have been reported secondary to infection with *Spirocerca lupi*, an esophageal worm found sporadically in the tropic warm temperate areas and throughout the United States. There is no known cause for the more commonly seen esophageal carcinomas. In cats, squamous cell carcinomas (SCC) are located in the middle third of the esophagus, just caudal to the thoracic inlet. These tumors are locally invasive and metastasis to regional lymph nodes occurs early.

No definitive etiology has been identified in the development of gastric cancer but experimentally, long-term administration of nitrosamines may induce carcinomas in dogs.

Epidemiology

Cancer of the esophagus and stomach is rare and accounts for less than 0.5% and 1% of all malignancies respectively.

Esophageal tumors can be primary or metastatic. Metastatic tumors are three times more common than primary esophageal tumors and occur through local invasion from the stomach, thymus, thyroid, and heart base as well as from mammary adenocarcinoma and lymphoma. In dogs, the most common primary esophageal tumors are SCC, osteosarcoma (OSA), fibrosarcoma (FSA), and leiomyosarcoma. Sarcomas are seen more commonly in areas where *Spirocerca lupi* is endemic. In cats, the most common primary esophageal tumor is SCC which is seen more commonly in females.

The most common gastric tumor in the dog is adenocarcinoma. Belgian shepherds, chow chows, rough-coated collies, and Staffordshire bull terriers appear predisposed to gastric adenocarcinoma, implying a genetic component. The average age of patients affected with carcinoma is 8 years with a 2.5:1 male-to-female ratio. Other tumors affecting the stomach are lymphoma (LSA), leiomyoma, leiomyosarcoma, gastrointestinal stromal cell tumor (GISTs), extramedullary plasmacytoma (EPC), mast cell tumor (MCT), and carcinoid. Leiomyomas occur in older dogs (mean age >15) as a discrete, often pedunculated lesion in the cardia or gastroesophageal junction. Recent studies utilizing immunohistochemistry to detect CD117 (c-kit protein), a transmembrane receptor with a tyrosine kinase component, have shown up to 50% of leiomyomas and leiomyosarcomas are reclassified as GISTs. Leiomyosarcomas do not express the c-kit protein.

Lymphoma is the most common gastric tumor in cats and males are more commonly affected. Gastric LSA is covered in more detail in another section. Chronic gastritis, *Helicobacter*, and common heritage have been implicated in feline gastric cancer.

Signalment

Most animals with esophageal cancer are older and no breed predilection is evident. The average age for dogs diagnosed with gastric carcinoma is 8 years. Males are diagnosed 2.5 times more often than females. Cats with gastric carcinoma are typically older with mean ages reported between 10.6 and 12.6 years.

History and Clinical Signs

Clinical signs associated with esophageal cancer are generally noted late in the course of disease. Symptoms occur when the tumor is large and has caused an obstruction or motility dysfunction. This can result in dysphagia and

Companion website: www.wiley.com/go/bruyette/clinical

regurgitation. Other symptoms include weight loss, anorexia, halitosis, pain, and aspiration pneumonia. In some cases, respiratory signs may be the only symptom. The paraneoplastic syndrome hypertrophic osteopathy has been reported secondary to *S. lupi*-induced sarcomas.

A history of progressive vomiting, often with digested blood "coffee grounds" or tinged with fresh blood, is common in cases of gastric cancer. Weight loss, anorexia, and cachexia are often noted over a period of weeks to months. Paraneoplastic hypoglycemia can be seen secondary to leiomyomas or leiomyosarcomas and is likely due to the production of insulin-like growth factors. EPCs may be associated with hyperproteinemia, monoclonal gammopathy, and hypercalcemia. On occasion, occult blood or melena can be documented in the feces.

Diagnosis

Staging for tumors of the esophagus should include thoracic radiographs (three-view), minimum database (complete blood count [CBC], serum biochemistry profile, and urinalysis) and an abdominal ultrasound to rule out a possible primary tumor when the esophageal tumor is suspected to be metastatic.

Thoracic radiographs of the cervical region and thorax may be helpful in localization of esophageal tumors and/or secondary aspiration pneumonia. Esophageal tumors appear as a homogeneous mass in the region of the esophagus, with gas retention and dilation proximal to the lesion. Some esophageal tumors may appear calcified. Positive contrast esophagrams with barium will usually demonstrate the lesion with or without fluoroscopy. Lesions appear as a rounded or lobulated, smoothly elevated filling defect.

When available, esophagoscopy is definitive because it can locate the lesion and obtain diagnostic tissue samples for histopathology. Esophageal tumors are typically submucosal over which the mucosa is usually freely movable. Narrowing of the lumen is common, while stenosis and obstruction are rare. Computed tomography (CT) or magnetic resonance imaging (MRI) may be helpful in determining extent of involvement, location, and invasiveness. Leiomyoma can be presumptively diagnosed based on endoscopic examination and CT results that indicate a well-defined, round-to-ovoid encapsulated mass, with no ulceration of the overlying mucosa or evidence of local invasion. Endoscopic biopsies are contraindicated with leiomyomas, as they increase the risk of complications and mucosal perforation during surgery. Endoscopic fine needle aspiration is effective for obtaining a tentative diagnosis and does not affect surgical outcome. EPCs have a predilection for the terminal esophagus and cardia. A thoracotomy or cervical exploration can be performed to obtain a biopsy.

Staging for gastric tumors includes abdominal ultrasound, thoracic radiographs (three-view) and minimum database. Abdominal radiographs rarely reveal gastric tumors. Anemia is the most common laboratory abnormality. Paraneoplastic hypoglycemia can be seen with leiomyomas or leiomyosarcomas. Sporadically, elevated liver enzymes and elevated gastrin levels can be documented.

Grossly, there are three variations of gastric carcinoma that have been identified. Diffuse neoplastic infiltration of the gastric wall can produce a thickened, nondistensible stomach known as "leather bottle stomach." Gastric adenocarcinoma may also manifest as a discrete, polypoid lesion or as mucosal plaques with ulceration. Histopathologically, gastric adenocarcinomas may be classified as a diffuse type with randomly arranged, malignant epithelial cells or an intestinal type with neoplastic cells that are well organized into distinct, glandular structures. The clinical significance of these histopathologic types is not currently known.

Ultrasonography is a useful imaging modality. Carcinomas tend to be sessile and occur most commonly on the lesser curvature and gastric antrum. Benign lesions are pedunculated or well circumscribed and often occur at the cardia. Sometimes, it is easier to find gastric lymphadenopathy secondary to metastasis than the primary gastric lesion. An ultrasound-guided fine needle aspirate or Tru-Cut biopsy can be utilized to obtain a diagnostic sample.

Gastroscopy with a flexible endoscope is the most sensitive and specific noninvasive way to identify and localize lesions and obtain biopsies. When obtaining biopsies, multiple samples should be taken from multiple sites because the majority of gastric tumors have significant necrosis, ulceration and inflammation, making histopathologic examination difficult.

Barium contrast gastrograms can often document infiltrative disease of the gastric wall, but these contrast studies are cumbersome and take a relatively long time to perform. Poor motility, delayed gastric emptying time and/or prolonged adherence of contrast material to ulcerated tissue are common findings. It should be noted that it could take over 24 hours for barium to completely leave the stomach, which would delay the ability to perform gastroscopy.

Open surgical biopsy is the most definitive method of diagnosis. Leiomyoma/leiomyosarcmas should be stained with CD117 (c-kit) to differentiate GISTs.

Therapy

There are limited therapeutic options for esophageal cancer. Intrathoracic access is challenging and surgery usually results in tension on the anastomosis site and

postoperative complications. Esophageal surgery is prone to serious complications, including stricture, dehiscence, infection, regurgitation, esophagitis, and fistula formation. This has been attributed to many factors, including esophageal movement during swallowing, high wound tension, lack of a serosal layer and the presence of a segmental blood supply to the esophagus. After esophageal surgery, use of a gastrostomy tube is recommended to decrease the amount of motion occurring at the surgical site and facilitate mucosal healing. *En bloc* resection is associated with the best prognosis but submucosal resection to debulk the mass without a full resection and anastomosis can be an acceptable treatment with successful outcomes for leiomyomas/low-grade leiomyosarcomas. Short-term palliation can be achieved with placement of a gastric or percutaneous endoscopic gastrostomy tube. In people, palliation is commonly achieved by the placement of an endoluminal stent. An interventional technique to perform this procedure in veterinary patients is potentially possible.

Radiation therapy is of limited use due to the tissue tolerance of the surrounding structures. In humans, radiation therapy alone is used as a palliative treatment for esophageal tumors or following surgery. Results following radiation therapy alone are short-lived and universally poor unless done in combination with surgery and chemotherapy.

Complete surgical excision is the treatment of choice for gastric adenocarcinomas but is typically complicated due to advanced disease, predilection for the lesser curvature, antrum and pylorus, extensive gastric involvement and/or metastasis to regional lymph nodes and liver. Surgical approaches such as a Billroth I (partial gastrectomy and gastroduodenostomy) or Billroth II (partial gastrectomy and gastrojejunostomy) can provide immediate relief of gastric outflow obstruction and clinical improvement in the early postoperative period. Careful staging prior to pursuing surgery is recommended to insure the morbidity associated with the procedure can be justified.

The beneficial effects of chemotherapy alone or in the adjuvant setting for gastric adenocarcinoma are largely unknown. Reported chemotherapy protocols utilizing 5-fluorouracil, 5-fluorouracil and cyclophosphamide, 5-fluorouracil, doxorubicin and cyclophosphamide (FAC protocol) or cis-platinum appeared to provide some clinical benefit in a few cases. Comparatively, 80% of people with metastatic or nonresectable GISTs had a favorable response with the use of imatinib (Gleevec®), a selective tyrosine kinase inhibitor. This resulted in stabilization or resolution of disease for a median of 20 months. Two tyrosine kinase inhibitors are currently approved for use in veterinary medicine (Palladia™, Pfizer, and Kinavet-CA1®, AB Science) and may also prove to be effective against GISTs in dogs.

Prognosis

The prognosis for esophageal cancer is very poor. These cancers are usually not diagnosed until they are advanced, by which time they are typically difficult or impossible to resect and often are metastatic. Photodynamic therapy has been attempted, but with modest results. The median survival for dogs with esophageal sarcoma following surgery and doxorubicin chemotherapy was 267 days. Interestingly, in many cases, the cause of death was secondary to aspiration pneumonia due to abnormalities in esophageal motility.

The prognosis for gastric adenocarcinoma is poor following the onset of clinical signs. Without treatment, animals usually succumb to their disease within 1–3 months. Surgery affords the best chance for improving the long-term prognosis. Animals that survive the perioperative period have reported median survival times of 4–6 months but a small number of long-term survivals of greater than 36 months have been reported. Most patients eventually succumb due to recurrent or metastatic disease. Leiomyosarcomas and GISTs have a slightly better prognosis with reported median survival times of 6–12 months. Surgery can be curative for benign lesions that are completely resected. EPCs have an excellent prognosis with surgery and chemotherapy. Information on long-term follow-up is lacking in the literature, but a dog treated with surgery and doxorubicin chemotherapy was alive and asymptomatic 30 months post diagnosis. Less than 10% of cases of gastric MCT, regardless of treatment(s) utilized, lived beyond six months. Occasionally, there are cases of gastric MCT that appear to do significantly better than this, suggesting there may be a less aggressive variant of this disease. This supports the palliative use of systemic chemotherapy in patients with minimal clinical symptoms and a reasonable quality of life.

Cancer of the Small and Large Intestine

Edwin Brodsky, DVM, DACVIM (Oncology)

Veterinary Medical Center of Long Island, West Islip, NY, USA

Etiology/Pathophysiology

The majority of canine intestinal lymphomas are primary in nature, although extension from multicentric lymphoma can occur. Most intestinal lymphomas in dogs are multifocal or diffuse throughout the intestinal tract with lesions located in the mucosa, submucosa, and lamina propria. The majority of intestinal lymphomas in dogs have been found to be of T cell origin on immunohistochemistry

Small intestinal adenocarcinoma is uncommon in dogs and the small intestine in general is an uncommon site for cancer in dogs and people. Some possible explanations for this include rapid transit times through the small intestine decreasing exposure to carcinogens, large volume of mucosal secretions diluting out carcinogens, a microbial population incapable of activating carcinogens, and microsomal enzymes in the small intestine that may detoxify some carcinogens.

Forty seven percent of intestinal adenocarcinomas expres COX-2 in the neoplastic epithelium. The presence of the COX-2 enzyme has been found to contribute to tumorigenesis in rodent models and is a potential target for nonsteroidal antiinflammatory drugs (NSAIDs).

Leiomyosarcoma is a slow-growing, locally invasive, malignant tumor originating from smooth muscle and is generally slow to metastasize. A recent study reclassified some dogs previously diagnosed with intestinal leiomyosarcomas as gastrointestinal stromal tumors (GISTs) based on the expression of the tyrosine kinase growth factor receptor, KIT. It is thought that activating mutations in c-kit are involved in the pathogenesis of these tumors. Differentiating between a leiomyosarcoma and a GIST may have implications for both biologic behavior and treatment of the neoplasia.

Both adenocarcinoma and leiomyosarcoma of the small intestine have the potential to metastasize (43.5% and 16–50%, respectively). The most common site of metastasis for an adenocarcinoma is the regional lymph node and the most common site for a leiomyosarcoma is the liver or the mesentery. Russell *et al*. reported a metastatic rate of 7% for canine GISTs based on immunohistochemical staining for CD117.

Feline intestinal lymphoma is generally not associated with feline leukemia virus (FeLV) infection. An increased incidence of feline lymphoma, specifically nasal and intestinal, was found in cats exposed to environmental tobacco smoke. Another possible cause of intestinal lymphoma is chronic inflammation, as there has been an association between low-grade or small cell intestinal lymphoma and inflammatory bowel disease. It is thought that intestinal lymphoma derives from the mucosa-associated lymphoid tissue (MALT). However, the tumor can progress and invade the submucosa and muscularis layers of the gastrointestinal (GI) tract. Lesions can be solitary, multifocal or diffuse throughout the intestinal tract. Involvement of mesenteric lymph nodes is common and dissemination to other organs such as the liver, spleen, kidneys, mediastinal lymph nodes or bone marrow can occur as the disease progresses. Intestinal lymphoma may either be small cell/lymphocytic (low-grade) or large cell/lymphoblastic (high-grade). Reports are mixed regarding the prevalence of low- versus high-grade alimentary lymphoma in cats. Earlier reports indicate that high-grade lymphomas were more common, but more recent reports indicate the low-grade lymphomas are more prevalent.

Feline small intestinal adenocarcinoma usually affects the jejunum and ileum. Approximately 50% of cats with intestinal adenocarcinoma experience metastasis. The most common sites of metastasis include the regional lymph nodes, peritoneum, omentum, mesentery, liver, and lungs. Ascites may be present secondary to carcinomatosis.

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

The intestinal lesion with feline intestinal mast cell tumor can be diffuse, solitary or multifocal. The neoplasia may be either intraluminal or intramural. The small intestine is the most common location for feline intestinal mast cell tumor but colonic involvement can occur. Widespread metastasis is common at the time of diagnosis. One study found that 64% of cats with intestinal mast cell tumor had multiorgan involvement. The most common sites of metastasis include lymph nodes, liver, spleen, and rarely lung. Intestinal mast cell tumors can be difficult to diagnose because their cytoplasmic granules may not stain. This may be due to their anaplastic nature or degranulation. It has been suggested that mucosal mast cells are different from mesenchymal mast cells and require special fixation to enhance the metachromasia. Diff-Quik staining of feline mast cell tumors sometimes fails to reveal cytoplasmic granules. Circulating mast cells are uncommon with intestinal mast cell tumors, although peripheral eosinophilia has been reported.

Adenomatous polyps and carcinoma *in situ* are usually solitary. However, multiple and diffuse varieties have been identified. Furthermore, malignant transformation to invasive carcinoma has been reported.

Canine colorectal adenocarcinoma generally can be grouped into three categories based on its gross appearance: pedunculated, cobblestone, and annular. When metastasis does occur with colorectal adenocarcinoma, it usually travels via lymphatics to the local lymph nodes and may sometimes seed the peritoneum, leading to carcinomatosis. The metastatic rate for colorectal adenocarcinoma ranges from 0% to 80%. Malignant transformation from *in situ* tumors has been reported in 17–50% of dogs.

Approximately 75% of cats with colonic adenocarcinoma have metastasis. Half have distant metastasis and half are local. Metastatic sites included the colonic lymph nodes, mesenteric lymph nodes, liver, omentum, and lungs. Carcinomatosis may also occur.

Epidemiology

Small intestinal tumors are in general, uncommon in dogs. According to most reports, lymphoma is the most common specific type. The intestinal tract is the most common extranodal site for this malignancy, affecting 5–7% of all dogs diagnosed. Intestinal adenocarcinoma and leiomyosarcoma are the two most common nonlymphomatous small intestinal tumors in dogs. In particular, leiomyosarcoma is the most frequently diagnosed intestinal sarcoma and it commonly involves the jejunum and cecum.

Recently, it was found that tumors previously categorized as leiomyosarcomas were in fact derived from the interstitial cells of Cajal. Interstitial cells of Cajal are the pacemaker cells of the intestinal tract and regulate peristalsis. Tumors derived from these cells are called gastrointestinal stromal tumors (GISTs). GISTs can be distinguished from leiomyosarcomas based on the expression of c-kit (CD117). In one recent study, two-thirds of dogs diagnosed with intestinal leiomyosarcomas were reclassified as GISTs based on positive staining for CD117. In this study, GISTs were most common in the cecum and large intestine (64%) as compared to the stomach and small intestine (36%). In oposition to GISTs,leiomyosarcomas appear to develop more commonly in the stomach and small intestine (90%) and are less common in the large intestine (10%).

It is reported that up to 60% of all intestinal tumors in dogs are located in the colon and rectum. Dogs are typically middle-aged to older with males reported to be affected more frequently than females. Unlike in the small intestine, adenomatous polyps and carcinoma *in situ* are commonly identified in the large intestine. Malignant tumors, such as those that develop in the small intestine also occur.

Lymphoma is the most common intestinal neoplasia in cats. It is the most common anatomic form of lymphoma in cats since the advent of FeLV vaccine as well as routine FeLV testing and separation of FeLV-positive cats. Anatomic forms of feline lymphoma generally associated with FeLV infection, such as the mediastinal and nodal forms, are becoming less prevalent. Adenocarcinoma is the second most common small intestinal tumor in cats. Siamese may be overrepresented. Intestinal mast cell tumor is the third most common intestinal tumor in cats. Colonic adenocarcinoma (along with lymphoma) is one of the two most common neoplasias that develop in the feline large intestine.

Other less common intestinal tumors include extramedullary plasmacytoma, extraskeletal osteosarcoma, and hemangiosarcoma.

Signalment

The median age for dogs with all types of lymphoma, including intestinal, is 6–9 years. Small intestinal neoplasia should be considered a differential diagnosis in a middle-aged to older dog with signs consistent with intestinal obstruction. The median age of onset for canine intestinal leiomyosarcoma/GIST is 10.5 years. They are reportedly more common in female dogs. Dogs with colorectal polyps have a mean age of 7–8 years. Colorectal adenocarcinoma most commonly affects older male dogs. Feline intestinal lymphoma is more common in older cats with a median of age of 10–12 years. Domestic short-hairs are more commonly affected. The average age of cats with small intestinal

adenocarcinoma is 10–11 years. Siamese may be overrepresented. Feline intestinal mast cell tumors tend to affect older cats with a mean age of 13 years. Feline colonic adenocarcinoma generally affects older cats with no discernible sex or breed predilection.

History and Clinical Signs

Clinical signs for most small intestinal neoplasias in dogs and cats are similar and include one or more of the following: anorexia, vomiting, diarrhea, weight loss, melena, and lethargy. Signs may be subacute, acute or chronic in nature, depending on the underlying disease process. A patient may present with acute vomiting, anorexia, and abdominal discomfort secondary to a gastric or small intestinal obstructive lesion or with a history of chronic weight loss, decreased appetite and intermittent vomiting over the course of months if a low-grade intestinal lymphoma is the underlying problem. Therefore, the chronicity of signs should not dissuade the clinician from keeping neoplasia on the differential list for many common GI presentations. Some patients may present in shock if a GI perforation occurs secondary to underlying intestinal neoplasia. Dogs with intestinal leiomyosarcomas may present with signs secondary to paraneoplastic hypoglycemia, such as weakness, ataxia, and seizures. Some patients with intestinal tumors may present with signs referable to anemia such as weakness and lethargy secondary to gastrointestinal bleeding.

Diagnosis

A complete blood count, biochemistry profile, and urinalysis are recommended as part of a minimum database but are not helpful in establishing a definitive diagnosis. Anemia can be seen in up to ~64% of dogs with intestinal neoplasia and is associated with intestinal hemorrhage or anemia of chronic disease.

The chemistry panel can reveal a paraneoplastic hypoglycemia in dogs with intestinal leiomyosarcoma. When a dog presents primarily for signs secondary to hypoglycemia, rather than gastrointestinal signs, a serum sample should be held for simultaneous blood glucose and blood insulin levels to rule out inappropriate insulin secretion secondary to an insulinoma (beta-cell tumor of the pancreas). Hypoproteinemia is a common laboratory finding secondary to malabsorption or intestinal loss in dogs and cats with diffuse intestinal lymphoma. Cobalamin and folate should be assessed to evaluate for malabsorption and small intestinal bacterial overgrowth. Animals with intestinal extramedullary plasmacytomas should be thoroughly staged for systemic disease with serum electrophoresis, bone marrow aspiration/evaluation, abdominal ultrasound, and survey skeletal radiographs. In cats with intestinal lymphoma or intestinal carcinoma, an abdominal mass can be palpated in over 50% of cases. Abdominal radiographs may show an obstructive pattern or abdominal mass. Three-view thoracic radiographs should be performed but are usually negative for metastasis at the time of diagnosis.

The imaging test that will give the clinician the most useful information is abdominal ultrasound which provides information regarding size and location of the mass as well as evidence of metastatic spread. It also provides a means to achieve a diagnosis through less invasive procedures such as ultrasound-guided aspiration and ultrasound-guided biopsy. Ultrasound-guided aspirates and biopsies both can result in a false negative if a cystic, necrotic or inflammatory area of the tumor is sampled.

As with any neoplasia, biopsy and histopathology is the preferred method of diagnosis. Occasional misdiagnosis of neoplasia can occur with aspiration/cytology, where a tumor may be aspirated and the cytology is consistent with one type of neoplasia (i.e., carcinoma) but when a biopsy and histopathology are performed, the diagnosis changes to another tumor type (i.e., lymphoma). This can occur when the aspiration contains cells which are not representative of the underlying lesion, the tissue sampled does not exfoliate well or in order to make a correct diagnosis of neoplasia the evaluation of the tissue architecture is needed, not just evaluation of the cell type. Endoscopy and colonoscopy may be helpful in diagnosing proximal small intestinal lesions and colorectal lesions respectively. However, endoscopic biopsy may underdiagnose intestinal lymphoma in dogs and cats. Ultimately, abdominal exploratory surgery with either incisional or excisional biopsy and histopathology may be necessary to obtain a definitive diagnosis.

Immunohistochemistry for the expression of c-kit (CD117) is recommended in dogs with intestinal sarcomas to differentiate between GISTs (CD117 positive) and leiomyosarcoma (CD117 negative). The differentiation between GISTs and leiomyosarcomas can have both prognostic and therapeutic implications.

Routine immunohistochemistry has identified that T cell is the most common immunophenotype of intestinal lymphoma in dogs. Feline intestinal lymphoma can be either T cell or B cell in origin.

Therapy

Surgical excision via intestinal resection and anastomosis, with or without adjuvant chemotherapy, is the primary treatment for most animals with intestinal neoplasia. Intestinal lymphoma is the one notable exception,

where chemotherapy is the primary treatment recommendation. Surgery is only recommended in patients with intestinal lymphoma when there is evidence of intestinal perforation or obstruction. It is recommended that 5–6 cm of normal intestine on either side of the tumor be excised. For animals with colonic tumors, subtotal colectomy may be necessary. One study found that cats that had subtotal colectomy for colonic adenocarcinoma had improved survival times over cats that had just mass resection or mass biopsy. The authors of the study do not suggest that every cat with a colonic mass should receive subtotal colectomy but wide surgical margins are recommended. Biopsy of the local lymph nodes, liver, and any other abnormal-appearing abdominal organ is recommended to assess for metastasis. For dogs and cats with rectal tumors, a transanal pull-through procedure has been found to be effective. A combined abdominal-transanal approach may be necessary for tumors located at the cranial extent of the rectum extending to the descending colon.

The benefit of postoperative chemotherapy is unknown for dogs with small intestinal adenocarcinoma. However, due to the moderate to high metastatic rate, the inclusion of adjuvant chemotherapy with doxorubicin-based protocols would be logical. Approximately 50% of intestinal adenocarcinomas in dogs expres COX-2. The products of the COX-2 enzyme have been associated with protumorigenic effects such as angiogenesis, cell proliferation, and inhibition of apoptosis. Therefore, the author recommends including NSAIDs in the treatment protocol for dogs with intestinal adenocarcinomas as they have antineoplastic activity that may help improve response and survival. The metastatic rate of small intestinal carcinoma in cats is also high. Postoperative chemotherapy is recommended to help control metastasis and to prolong survival. A study evaluating cats with large intestinal carcinoma did show a survival advantage for those that received doxorubicin chemotherapy postoperatively. Whether this chemotherapy protocol is beneficial in cats with small intestinal carcinoma has yet to be determined but it is a logical choice for postoperative therapy.

As with small intestinal adenocarcinoma, the use of postoperative chemotherapy in dogs with small intestinal leiomyosarcoma has yet to be investigated in a randomized clinical trial. However, based on the moderate to high metastatic rate (16–50%), chemotherapy should be included in the treatment protocol. Surgical removal alone results in prolonged survival times (over three years) for dogs with GISTs. However, for those few cases in which GISTs are nonresectable or metastatic, adjuvant treatment with tyrosine kinase inhibitors may be useful. In humans with nonresectable or metastatic GISTs, treatment with tyrosine kinase inhibitors has been shown to result in longer survival times compared to other treatments. Therefore, the use of tyrosine kinase inhibitors in dogs with nonresectable, recurrent or metastatic GISTs is reasonable as GISTs in both species express KIT/CD117. Activating mutations have been found involving c-kit in both dogs and humans and are thought to be the driving force for GIST development. There are two oral tyrosine kinase inhibitors in veterinary medicine, toceranib phosphate (Palladia™) and masitinib mesylate (Masi). Only Palladia, is approved for use in dogs with mast cell tumors in the USA. Regardless, both inhibit KIT but their use in dogs with GISTs has yet to be investigated.

Chemotherapy is the primary treatment for intestinal lymphoma in dogs due to the multifocal or diffuse nature of the disease. Although CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone)-based protocols are considered the standard of care for dogs with multicentric lymphoma, due to the poor response of dogs with intestinal lymphoma other alkylating agent-based protocols, including MOPP (mechlorethamine HCL, vincristine sulfate, procarbazine, prednisone), lomustine or DTIC/lomustine, may provide improved survival times.

In cats with intestinal lymphoma, the treatment protocol varies depending on whether they have low-grade versus intermediate to high-grade lymphoma. The treatment of low-grade lymphoma consists of the administration of prednisolone and chlorambucil. One study evaluating cats with low-grade intestinal lymphoma found that 78% were cobalamin (vitamin B12) deficient, thus requiring cobalamin supplementation. Cobalamin is absorbed exclusively in the ileum, complexed with intrinsic factor. Low cobalamin is associated with metabolic derangements and low concentrations of several amino acids. Intermediate to high-grade lymphomarequires more aggressive therapy. The best response, remission duration, and survival time is generally achieved with CHOP-based chemotherapy protocols. Eventually, most cats relapse and/or develop resistant disease. If relapsing after completing their initial CHOP chemotherapy protocol, it can be restarted. The second remission is generally about half the duration of the first. Once they fail CHOP, rescue chemotherapy can be attempted. The most successful rescue chemotherapy protocols include MOPP and lomustine.

If a solitary mass is present and there is no evidence of metastatic disease, surgical removal can be attempted in cats with intestinal mast cell tumors. Due to the high rate of disseminated disease with intestinal mast cell tumors, postoperative chemotherapy is recommended based on the likelihood of residual micrometastasis. If the intestinal mast cell tumor is not resectable or metastatic disease is present at the time of diagnosis, chemotherapy

can be attempted. A study evaluating lomustine for cats with a variety of mast cell tumors (cutaneous, splenic, intestinal) found that two cats with intestinal mast cell tumors responded. Whether lomustine would be effective in a large population of cats with intestinal mast cell tumors is unknown. Other chemotherapy agents used in dogs with mast cell tumors include vinblastine, cyclophosphamide, hydroxyurea, and prednisone. Their effectiveness in cats with mast cell tumors is unknown.

Many cat mast cell tumors have mutations in the gene c-kit leading to constitutive activation of the tyrosine kinase growth factor receptor KIT. Activating mutations of c-kit have been implicated in mast cell tumor development and progression in dogs. Small molecule targeted therapies (toceranib phosphate and masitinib meslyate) have been approved for use in dogs with mast cell tumors. As mentioned previously only toceranib phosphate is approved for use in the USA. These targeted therapies inhibit the activation of the abnormal growth factor receptor KIT, resulting in cessation of cell growth and proliferation and potentially leading to cell death through apoptosis. A recent study evaluating Palladia in cats with mast cell tumors reported a clinical benefit in 76% (13/17) of those with the gastrointestinal form. However, further studies are necessary.

Aside from definitive treatment with chemotherapy and/or a tyrosine kinase inhibitor, all patients with intestinal mast cell tumors should receive prednisolone or prednisone as well as a histamine receptor 1 and 2 antagonist.

For dogs with colorectal polyps, the use of NSAIDs has been found to be of benefit in reducing clinical signs and may be an alternative treatment to surgical excision. The author recommends placing dogs that have had surgical removal of colorectal polyps on NSAIDs postoperatively in an attempt to prevent local recurrence, development of additional polyps or malignant transformation of polyps. Although there are no clinical studies evaluating the use of NSAIDs in this particular setting, NSAIDs have been found to have various antineoplastic properties.

Surgical excision of colorectal plasmacytomas is curative in most cases. Plasmacytomas of other areas of the intestinal tract can have a high metastatic rate and if metastasis is observed, follow-up chemotherapy in the form of prednisone and melphalan is recommended. Extraskeletal osteosarcomas are both locally and systemically aggressive. Adjuvant chemotherapy has been shown to help prolong survival in dogs with extraskeletal osteosarcoma. Therefore, postoperative carboplatin is recommended for intestinal extraskeletal osteosarcoma. Visceral hemangiosarcoma is an aggressive disease with a high rate of metastasis. Adjuvant doxorubicin chemotherapy is recommended after surgical resection of intestinal hemangiosarcoma.

Many animals with intestinal neoplasia need supportive medications for nausea, decreased appetite, gastrointestinal protection, and diarrhea. The most commonly used antiemetics include maropitant, ondansentron, dolasetron, and metoclopramide. Appetite stimulants include capromorelin, mirtazapine, cyproheptadine, and megestrol acetate. Effective gastroprotectants include famotidine, omeprazole, and sucralfate. Common antidiarrheal medications include metronidazole, tylosin, sulfasalazine, and loperamide.

Prognosis

The prognosis for dogs with intestinal lymphoma is generally much worse than for dogs with multicentric lymphoma. A recent study using a CHOP-based protocol with consolidation resulted in a 56% response rate (50% complete response, 6% partial response). The median survival time for the entire study population was 2.5 months. The response rate for dogs with multicentric lymphoma is up to 90–95% with median survival times of 12–18 months. Another study evaluating dogs with intestinal lymphoma treated with multiple treatment modalities revealed very poor survival, with a median survival time of 13 days. In dogs with intestinal lymphoma, the presence of diarrhea and lack of response to chemotherapy were negative prognostic factors

In dogs treated with surgical excision for small intestinal adenocarcinoma, the presence of metastasis at the time of surgery is associated with statistically shorter survival time (median survival time three months, 20% survival at one year) when compared to dogs without metastasis (median survival time 15 months, 66.7% survival at one year).

Long-term survival has been reported in dogs with metastatic intestinal leiomyosarcoma. In one study, 50% of dogs with intestinal leiomyosarcomas had metastasis at the time of surgery. The median survival time of the entire study population was 21.3 months. Another study revealed a median survival time of 1.1 years for dogs with small intestinal leiomyosarcoma that survived the immediate postoperative period, with 29% of the dogs dying of leiomyosarcoma. The results of these historical studies should be viewed in light that some might have been GISTs that had been misdiagnosed. In one study evaluating both GISTs and leiomyosarcomas, the median survival time for dogs with GISTs that survived the perioperative period was 37.4 months, whereas the median survival time for dogs with leiomyosarcomas was only 7.8 months. Further, 7% of the dogs with GISTs developed metastasis. There were no reports of metastasis in those with leiomyosarcomas.

Recurrence of clinical signs is uncommon with removal of colorectal adenomatous polyps (17%). However, recurrence of clinical signs after removal of carcinoma *in situ* is fairly common (55%). The presence of multiple lesions was also associated with recurrence of clinical signs. Malignant transformation has been reported with rectal polyps, although more commonly with carcinoma *in situ* (17–50%).

The prognosis for dogs with colorectal adenocarcinoma has been linked to the gross appearance of the tumor. The mean survival time for those with pedunculated lesions is 32 months, cobblestone lesions 12 months, and annular lesions 1.6 months.

Cats with small cell, low-grade intestinal lymphoma treated with prednisone and chlorambucil have a good prognosis with response rates of 69–95% and median survival times of 18–24 months.

Cats with intermediate to high-grade intestinal lymphoma have a worse prognosis compared to those with the low-grade intestinal type. When compared to other anatomic sites, cats with intermediate to high-grade intestinal lymphoma tend to have the second best prognosis, after nasal lymphoma. However, the response rate, remission duration, and survival time for cats with intermediate to high-grade intestinal lymphoma are generally less than dogs with multicentric intermediate to high-grade lymphoma. The response rate for cats treated with multiagent (CHOP-based) chemotherapy is 50–86% (complete response rate of 50–70%) with a median remission duration of 4–9 months and a median survival time of up to 7–9 months. Response to therapy, FeLV status, substage, anatomic site, and chemotherapy protocols that include doxorubicin have been linked to remission duration and survival. Unlike dogs, immunophenotype (T cell vs B cell) is not a prognostic factor in cats with lymphoma.

The prognosis can be fairly good for cats with small intestinal adenocarcinoma that survive the postoperative period, with average survival times of 15 months reported. In one study, even those that had lymph node metastasis at the time of surgery and survived the perioperative period fared well (average survival time of 12 months). In the study, recurrent adenocarcinoma was the cause of death in 50% of long-term survivors.

The prognosis for intestinal mast cell tumor has historically been considered to be poor due to the high percentage of patients that present with metastatic disease. However, a recent study of cats indicated that the prognosis may be better than once thought (median survival time 531 days).

Reported cats that had subtotal colectomy for colonic adenocarcinoma had significantly longer survival times than cats with either mass resection or biopsy. Median survival time with subtotal colectomy was 138 days versus 68 days and 10 days for mass resection and biopsy respectively. In the study, the presence of metastasis was also associated with a shorter survival time (median survival time 49 days) compared to those cats that did not have metastasis (259 days). Finally, cats that receive doxorubicin chemotherapy appear to have a significantly longer survival time (median survival 280 days) compared to those that do not receive doxorubicin (56 days).

Exocrine Pancreatic Cancer

Avenelle I. Turner, DVM, DACVIM (Oncology)

Veterinary Cancer Group, Culver City, CA, USA

Etiology/Pathophysiology

Nearly all cancers of the exocrine pancreas are epithelial and most are adenocarcinoma arising from either the ductal or acinar epithelium. This is in contrast to insulinomas which arise from the islet cells of the endocrine pancreas. Insulinomas are covered in more detail in a different section. There are no known causes for exocrine pancreatic cancer (EPC) in veterinary medicine. Experimentally, intraductal administration of N-ethyl-N'-nitro-N-nitrosoguanidine induces EPC in dogs.

Epidemiology

Exocrine pancreatic cancer is rare and accounts for less than 0.05% of all cancers in the dog and cat. Older female dogs, spaniels, and Airedales have been described in previous publications as being at higher risk. In humans, EPC remains the fourth most common cause of cancer-related death in the United States and it occurs most commonly in people who smoke or have chronic pancreatitis or diabetes mellitus. It is not clear if this is true in veterinary medicine but recently there have been several published reports of diabetes mellitus and EPC in cats which are suggestive of a possible association. It is unknown whether diabetes mellitus develops secondary to compression of islet cells by tumor, secondary to cortisol-induced beta-cell degeneration, or secondary to decreased carbohydrate metabolism, which is common in humans with pancreatic carcinoma.

Signalment

The median age at diagnosis is 10 years for dogs and 12 years for cats. It occurs almost equally in both sexes.

History and Clinical Signs

Symptoms associated with EPC are nonspecific and may mimic pancreatitis. Anorexia, weight loss, lethargy, weakness, vomiting, maldigestion syndrome, abdominal distension, abdominal effusion, and icterus are common findings. In cats that presented with EPC, 75% had anorexia, 63% vomiting, and 38% abdominal pain, a palpable abdominal mass, and/or jaundice. Duration of clinical signs appeared to be bimodal, with 50% of cats having signs for <7 days and the other 50% having signs for >1 month.

Paraneoplastic alopecia is a rare syndrome seen in cats with pancreatic neoplasms. The pathogenesis of this dermatologic disease is unknown. Alopecia begins acutely and typically starts with loss of clumps of hair on the ventrum, and then spreads to the legs and eventually the face. Dorsal alopecia is uncommon. Other changes noted are poor, dry, thinning hair coat and focal areas of erythema. Often, there is a characteristic appearance to the skin and in areas where cats groom, the skin can appear shiny. Lesions develop rapidly over 2–10 weeks and spread over much of the body. They appear in association with the tumor and in one case resolved with tumor removal.

Histopathologically, the skin changes are characterized by loss of the stratum corneum and severe follicular atrophy with miniaturized hair bulbs. The majority of cases die or are euthanized within eight weeks of development of lesions so the presence of this condition on physical examination is highly suspicious for EPC and appears to be a poor prognostic factor.

Diagnosis

Staging for EPC includes radiographs of the thorax (three-view), abdominal radiographs (two-view), minimum

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

database (complete blood count, biochemistry profile, urinalysis) and abdominal ultrasound. In cases where an aspirate is going to be obtained, a clotting profile is advisable as prolongation in partial thromboplastin time (PTT) and clotting disorders have been described in cats and people with EPC respectively. In cases where surgery is being considered, a computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen may be useful in preoperative planning and identifying metastatic disease.

Laboratory findings are generally nonspecific but can include leukocytosis, anemia, hyperglycemia, and elevations in liver enzymes. Dogs with pancreatic neoplasia may have significant elevations in serum lipase with only minimal elevations of serum amylase, implying tumor production of lipase. These findings are inconsistent, however. In a small case series of eight cats with EPC, 50% had neutrophilia, 33% had elevations in serum alkaline phosphatase activity, and 57% had increased alanine aminotransferase. Mild hyperglycemia was identified in 63% of cats.

Physical examination findings can include abdominal pain, icterus, abdominal distension, and/or ascites. In small dogs or cats, palpation of a cranial abdominal mass can occasionally be appreciated.

Survey abdominal radiographs may show decreased serosal detail or a cranial abdominal mass effect. The sensitivity for the detection of pancreatic tumors in dogs has been reported to be 19% for radiographs and 75% for ultrasound. Abdominal radiographs were helpful in identifying abdominal disease in cats with EPC. In one study, abdominal radiography was able to identify abdominal disease in all cases of pancreatic adenocarcinoma.

Ultrasonography is superior to abdominal radiographs for detecting EPC in both dogs and cats. It is a useful diagnostic tool for localization of the tumor, confirmation of ascites, and documentation of lymphadenopathy and metastasis. In cats, the ultrasound findings seen with nodular hyperplasia of the pancreas are similar to changes seen with malignant pancreatic neoplasms. There was a trend, however, for malignant masses to appear as a single, larger lesion exceeding 2 cm in at least one dimension. Hyperplastic nodules typically did not measure more than 1 cm in diameter and were numerous. Differentials for masses of the pancreas are insulinoma, gastrinoma, adenocarcinoma, adenoma, pancreatic pseudocyst, abscess, pancreatitis, and lymphoma.

When effusion is present, cytology and fluid analysis may reveal a modified transudate and neoplastic cells indicating carcinomatosis. Solitary masses can be diagnosed with cytology. Cytologic samples obtained with ultrasound guidance correctly diagnosed EPC in 92% of cases.

Therapy

The majority of EPCs are diagnosed at an advanced stage. Fifty to seventy percent of animals have metastatic disease to regional lymph nodes and distant sites documented at the time of diagnosis. In a study where necropsy findings were documented in cats with EPC, metastases to the liver, abdominal lymph nodes, lung, heart, diaphragm, tracheobronchial and cranial mediastinal lymph nodes were found. The incidence of metastasis seemed to be unrelated to the duration of clinical signs. Cats with the longest history of clinical signs were equally likely to have metastasis noted at necropsy as cats with short histories. This suggests that the duration of clinical signs prior to diagnosis is not a negative prognostic indicator.

Complete pancreatectomy or pancreaticoduodenectomy (Whipple procedure) has been described in humans and in dogs but carries a high perioperative morbidity and mortality without significant cure rates.

Chemotherapy and radiation therapy have shown limited value in humans and animals and information regarding the use of chemotherapy in veterinary medicine is scarce. In humans, external beam radiation therapy (EBRT) alone does not provide optimal tumor control and local failure rates are as high as 72%. These dismal results have spawned efforts to improve outcomes by the concurrent administration of drugs that act as radiation sensitizers, including 5-fluorouracil, gemcitabine, and, most recently, paclitaxel.

Palliative therapy to address effusions can be attempted with regular, periodic abdominocentesis and intracavitary chemotherapy. Protocols utilizing cisplatin and carboplatin have been described and appear to provide palliation for select patients. When effective, this can result in temporary relief from discomfort, slow the reaccumulation of the effusion, and possibly delay progression of the disease. Palliative responses, when seen, are generally short-lived.

Prognosis

The prognosis of EPC is generally poor, with few animals living beyond a year although a small percentage of dogs and cats have experienced long-term survival. In dogs, a unique variant of EPC described as hyalinizing pancreatic adenocarcinoma appears to be biologically less aggressive. The neoplasm is generally a solitary mass usually involving the right limb of the pancreas. Dogs without postoperative complications or concurrent life-threatening diseases survived longer than expected (four months, 16 months, and >19 months).

In a retrospective study evaluating 34 cats with EPC, metastatic disease was confirmed in 11 cats and overall median survival was 97 days. The median survival times for patients who received chemotherapy or had their masses surgically removed was 165 days. Patients with abdominal effusion present at diagnosis had a median survival of 30 days. Interestingly, however, three patients survived over one year.

A cat with metastatic EPC to the spleen treated with partial pancreatectomy and splenectomy was reported to be alive and disease free >2 years later. Therefore, the prognosis for EPC in select dogs and cats may not be as dismal as previously reported.

Comparatively, about 45 220 people develop cancer of the exocrine pancreas each year in the US, and almost all are expected to die from the disease. The median survival is 8–12 months for patients with locally advanced disease and less for those with metastatic disease at presentation. Five-year survival rates are consistently <18%. The majority of these tumors (85%) are adenocarcinomas arising from the ductal epithelium. Surgical resection offers the only chance of cure. However, only 15–20% of patients have resectable disease at diagnosis, approximately 40% have metastatic disease, and another 30–40% have locally advanced unresectable tumors.

Pancreatic Endocrine Tumors

Karen Eiler, DVM, MS, DACVIM (SAIM)

VCA West Los Angeles Animal Hospital, Los Angeles, CA, USA

Insulinoma

Etiology/Pathophysiology

The pancreas is made up of endocrine and exocrine tissue. The endocrine pancreas is composed of islets of Langerhans, which make up approximately 1–2% of the mass of the pancreas. Within the islets there are four cell types: alpha, beta, delta, and polypeptide cells. Beta-cells secrete various hormones, with insulin being the primary product. Approximately 60–75% of the islet cells are of beta-cell origin.

Insulin is the hormone that is primarily responsible for regulating blood glucose concentration. Insulin does not influence entry of blood glucose into beta-cells, as in other tissues. Entry of glucose into the beta-cell is proportional to the blood glucose concentration. Beta-cells are extremely sensitive to glucose concentrations and therefore the regulation of insulin secretion.

The central nervous system (CNS) has limited glycogen storage and is unable to use energy sources other than glucose. Thus, it is dependent on blood glucose to maintain its energy requirements. With hypoglycemia, cells within the cerebral cortex are affected first due to their higher metabolic rate. Counterregulatory hormones such as catecholamine, glucagon, growth hormone, and cortisol are secreted in response to hypoglycemia and aid in recovery from the hypoglycemic episode.

Insulinomas (beta-cell insulin-secreting tumor, beta-cell adenocarcinoma/adenoma) are insulin-secreting tumors of the pancreatic beta-cells. They are the most common endocrine pancreatic tumor in companion animals and are usually malignant.

Insulinomas can be found in both the right and left lobes of the pancreas with equal frequency. Occult insulinomas are most frequently found in the pancreatic body.

Epidemiology

Insulinomas are uncommon in dogs and rare in cats. One estimated report cites an incidence of 17.8/100 000 patient-years in the dog and 12.6/100 000 patient-years at risk in the cat. Insulinomas have been associated with multiple endocrine neoplasia (MEN) type I in people. This is an inherited disease that also results in parathyroid and pituitary tumors. Although we do not have a clear understanding of the epidemiology of canine insulinomas, there have been rare cases of canine MEN that involve an insulinoma.

Signalment

In dogs, middle-aged to older, medium to large breeds are predisposed. Large-breed dogs are overrepresented. Breed predispositions have not been noted in cats.

History and Clinical Signs

Clinical signs are predominantly related to hypoglycemia, resulting in neuroglycopenic manifestations and, less commonly, stimulation of the sympathoadrenal system. The degree and onset of clinical signs are related to the severity and rate of development of hypoglycemia. Gradual or chronic hypoglycemia may go unnoticed. When chronically affected by hypoglycemia, some animals adjust to blood glucose levels of 20–30 mg/dL. Clinical symptoms consistent with hypoglycemia include seizures, lethargy, weakness, coma, and ataxia. Catecholamine release can cause tachycardia, muscle fasciculations, hunger, and restlessness. Exercise causes rapid consumption of glucose and may precipitate an episode of collapse or seizure.

Diagnosis

Differential diagnosis for other causes of hypoglycemia include hypoadrenocorticism, juvenile hypoglycemia, sepsis, growth hormone deficiency, nonpancreatic tumors, insulin overdose, hepatic disease, glycogen storage diseases, artifacts related to sample handling, and toxins. Other types of neoplasms that can lead to paraneoplastic hypoglycemia include hepatocellular carcinoma, hepatoma, leiomyosarcoma, leiomyoma, lymphoma, myeloma, and hemangiosarcoma.

A minimum database (complete blood count, serum chemistry, urinalysis) should be collected to rule out other causes of hypoglycemia. Nonspecific findings that may be associated with insulinomas include elevated liver enzymes, hypokalemia, and hypophosphatemia. Radiographs may help rule out other causes of hypoglycemia. However, radiographic changes directly related to insulinomas should not be expected. Sensitivity of identifying insulinomas with abdominal ultrasound can be as low as 36%. It may be more beneficial in identifying metastasis in the liver and local lymph nodes. Failure to identify a pancreatic mass does not rule out an insulinoma. Serum insulin concentrations that are normal to high in the presence of hypoglycemia support a diagnosis of insulinoma.

Insulin:glucose and glucose:insulin ratios have high false-positive rates and are not recommended. Rather, insulin concentration should be measured on a serum sample taken when the blood glucose is below 60 mg/dL. Insulin concentrations should be low or undetectable at this blood glucose concentration. The serum glucose and insulin are evaluated as a pair. Animals may need to be fasted in order to obtain the appropriate samples and serial samples may need to be drawn every 2–4 hours until the blood glucose concentration is below 60 mg/dL. Provocative testing is not recommended as it has not been shown to be more sensitive than paired insulin and glucose measurement and can be dangerous due to potentiation of hypoglycemia.

Additional preoperative and intraoperative methods of tumor identification may be utilized. Nuclear scintigraphy with indium 111-labeled pentetreotide has been used to image somatostatin receptors in dogs with insulinomas. Insulinomas express high-affinity somatostatin receptors of subtype sst2 (SST2), thus allowing abnormal foci of activity to be detected. Direct intraoperative ultrasonography and intravenous injection of methylene blue may also be beneficial in identifying insulinomas. Methylene blue concentrates in the neoplastic tissue. However, side-effects including Heinz body anemia and renal failure have been reported to occur.

Therapy

Surgery is the mainstay of treatment. However, even when resectable, a cure is still unlikely. Gross or occult metastasis should be expected. Debulking of gross disease may significantly assist in controlling clinical signs. The goal of surgery is to remove as much neoplastic tissue as possible. Special attention should be given to regional lymph nodes and the liver. Complications include hyperglycemia (diabetes mellitus), continued hypoglycemia, exocrine pancreatic insufficiency, and pancreatitis.

First-line medical management is glucocorticoid therapy. In particular, prednisone administered at 0.25–3 mg/kg orally twice daily can be utilized. The dose should be increased as needed to control hypoglycemia. Prednisone is used with small frequent feedings (four times daily) and limited exercise. Exercise leads to an increased peripheral demand for glucose in spite of impaired gluconeogenesis and glycogenolysis. As a result, insulin secretion continues even as blood glucose falls.

Diazoxide decreases insulin release from beta-cells and stimulates epinephrine release from adrenergic cells. The result is decreased insulin release and increased hepatic glycogenolysis and gluconeogenesis. It is effective in 64–85% of dogs. The recommended dose is 5 mg/kg every 12 hours but may be increased up to 30 mg/kg every 12 hours if necessary. Thiazide diuretics potentiate the effects of diazoxide. The most common side-effects of diazoxide are gastrointestinal in nature.

Octreotide is a somatostatin analog that activates somatostatin receptors resulting in the inhibition of synthesis and secretion of insulin. Octreotide is only effective if the malignant beta-cells are expressing somatostatin receptors (~60% in people). It is given at a starting dose of 2 µg/kg SC twice daily. The dose can be increased to three times daily. Limited studies suggest that long-term efficacy is poor. Side-effects are limited but the drug is costly.

Streptozotocin is a chemotherapeutic agent that has direct toxic effects on pancreatic beta-cells. It is nephrotoxic and therefore intravenous fluid diuresis is required. It is administered once every 2–3 weeks at a dosage of 500 mg/m^2 for five treatments. If diabetes mellitus occurs, treatment is discontinued. In one study on the use of streptozotocin in dogs with insulinoma, controls lived for 90 days. Dogs had a median duration of normoglycemia of 163 days when given streptozotocin every three weeks. In another study, streptozotocin was given every two weeks and the average return of hypoglycemia was 196 days.

Prognosis

The World Health Organization (WHO) classification for tumor staging is prognostic for insulinomas. Factors that affect prognosis include presence or absence of tumor (T0 or T1), regional nodal involvement (N0 or

N1), and distant metastasis (M0 or M1). Therefore, full staging (thoracic radiographs, abdominal ultrasound, serum chemistry, complete blood count, and urinalysis) is recommended.

Overall, the prognosis is guarded because of the high rate of metastasis and recurrence of clinical signs. Approximately 36–51% of dogs have detectable metastatic disease at the time of surgery. With surgery alone, stage I (T1N0M0), II (T1N1M0), and III (T1N0M1 or T1N1M1) dogs have an expected median survival of 19 months, nine months, and six months respectively.

Survival time for dogs treated medically is less than when surgery combined with medical management is used. In one study, medical management with prednisone and dietary change alone resulted in a median survival time (MST) of 74 days. In a separate study, the median survival time for dogs that had a partial pancreatectomy was reported at 496 days. In a subset of nine dogs that received postsurgical medical treatment (diazoxide and prednisone) at the time of relapse, the median survival time was extended to 1316 days.

Streptozotocin therapy, especially as an adjunctive to surgery, should be considered. Although data are limited, normoglycemia has been shown to be prolonged with use of streptozotocin when compared to dogs that were medically managed with diet and prednisone (163 versus 90 days respectively). In addition, reduction in metastatic lesions and resolution of hypoglycemic polyneuropathy in dogs have been reported.

Persistent postoperative hypoglycemia has also been reported to be prognostic. In one study, dogs that became normoglycemic postoperatively had a median survival of 680 days compared to those that remained hypoglycemic, which had a MST of 90 days.

Glucagonoma

Etiology/Pathophysiology

Alpha-cells secrete glucagon and constitute about 20–25% of the endocrine pancreas. Glucagon has a profound hyperglycemic effect. In people, glucagonomas are commonly associated with diabetes mellitus and severe paraneoplastic dermatologic disease. Dogs with glucagonomas can have a similar dermatologic syndrome called superficial necrolytic dermatitis, necrolytic migratory erythema, or metabolic epidermal necrosis. This dermatologic disease has been identified in multiple dogs with glucagonomas but it is more commonly associated with liver disease and is not pathognomonic for a glucagonoma.

Glucagon has catabolic effects and opposes the effects of insulin. It causes gluconeogenesis, glycogenolysis, and lipolysis that cause the conversion of glycogen to glucose, resulting in elevation of blood sugar. The catabolic effects of glucagon result in hypoaminoacidemia. Requirements for histidine and lysine-rich keratohyalin granules in the stratum granulosum make the epidermis susceptible to hypoaminoacidemia.

Epidemiology

Glucagonomas are rare in people (<250 reported) with only a few case reports in dogs. They have not been reported in cats.

Signalment

The typical signalment is an older dog. There are no reported breed dispositions.

History and Clinical Signs

Dermatologic manifestations include lesions of the footpad, pressure points, periocular area, and mucocutaneous junctions such as the perineum, genitalia, and muzzle. Hyperkeratosis of the footpads also occurs. Weight loss is associated with the catabolic effects of the glucagon. Hyperglucagonemia can cause diabetes mellitus resulting in polyuria and polydipsia.

Diagnosis

An elevated plasma glucagon level in the absence of hypoglycemia is supportive of the presence of a glucagonoma. Histopathology of skin biopsies will be consistent with superficial hydropic dermatitis and marked parakeratosis. A definitive diagnosis is obtained through histopathology of the pancreatic tumor. In animals with skin lesions, elevations in liver enzymes and hypoalbuminemia may also be present.

Therapy

Surgical debulking or resection is the treatment of choice. Octreotide may be helpful in animals that have alpha-cells that are expressing somatostatin receptors. Streptozotocin has been used with limited success in people for palliative treatment. When dermatologic lesions are present, a high-quality protein diet such, as Hill's Science Diet a/d should used in nonencephalopathic animals. Supplementation with 3–6 egg yolks per day may also be beneficial. Intravenous amino acid therapy has been useful. A 10% crystalline amino acid solution (Aminosyn®, Abbott Labs) at 25 mL/kg over 6–8 hours repeated every 7–10 days has been used to treat hypoaminoacidemia. Ideally, the hypertonic amino acid solution is administered via a central vein to decrease

risks of thrombophlebitis. Supplementation with zinc and fatty acids may also be indicated. Corticosteroids should be avoided as development of diabetes mellitus worsens the prognosis.

Prognosis

The prognosis for pancreatic glucagonomas is poor.

Gastrinoma

Etiology/Pathophysiology

Gastrinomas in dogs and cats are nonislet cell pancreatic tumors that secrete gastrin. In humans, the majority arise in the duodenum and less commonly the pancreas. There is only one report of a duodenal gastrinoma in the dog.

Parietal cells are stimulated to release acid by gastrin, acetylcholine, and histamine. The primary effect of hypergastrinemia is acid hypersecretion resulting in gastrointestinal ulceration. In humans, it is referred to as Zollinger–Ellison syndrome.

Epidemiology

Gastrinomas are rare in dogs and cats.

Signalment

Dogs are typically middle aged and cats are typically older. No breed dispositions have reported.

History and Clinical Signs

Common clinical signs are vomiting and weight loss. Other clinical signs may include hematemesis, diarrhea or melena, lethargy, and pale mucous membranes. Prolonged elevation of circulating gastrin can cause gastric antral hypertrophy. Perforated ulcers can result in shock and peritonitis.

Diagnosis

A minimum database should be collected. Abnormalities are typically associated with gastrointestinal bleeding, vomiting, and liver metastasis. Biochemical abnormalities may include anemia, hypokalemia, hypochloremia, hypoalbuminemia, hypoproteinemia, and increases in liver enzymes and hyperbilirubinemia.

Unless a perforated ulcer is present, abdominal radiographs are of limited use. Contrast may be useful in identifying areas of thickened gastric wall.

Transabdominal ultrasonography is of limited use because the tumors are typically small in size. Abnormalities that may be identified include a primary pancreatic tumor, evidence of metastasis in the liver and regional lymph nodes and a thickened gastric wall.

Endoscopic evaluation of the upper gastrointestinal tract may reveal esophagitis, esophageal and gastroduodenal ulcerations, and a thickened pylorus. Biopsies may reveal inflammation, gastric mucosal hypertrophy, and loss of the mucosal barrier.

Serum gastrin concentrations are typically three times the upper normal range. However, they can be in the normal range. In cases of suspected gastrinoma with normal gastrin levels, provocative testing can be used. Intravenous secretin or calcium infusion can stimulate gastrin release.

A definitive diagnosis is obtained via biopsy. Histopathology and immunohistochemistry will confirm a gastrinoma.

Therapy

Surgery is typically only palliative due to the high metastatic rate. Surgical treatment may be limited by the small size of the tumor making identification difficult. The techniques used to identify the mass are similar to those used for identification of insulinomas and include transabdominal and intraoperative ultrasound, magnetic resonance imaging, and computed tomography. Most gastrinomas express somatostatin receptors on the cell surface. Therefore, indium 111-labeled octreotide nuclear scintigraphy has been used. Methylene blue injection has been used for tumor identification in humans.

The goal of medical management is gastric acid reduction and treatment of gastroduodenal ulceration. Histamine receptor antagonists and proton pump inhibitors are used. Proton pump inhibitors block all three gastric acid secretory pathways. Octreotide has two beneficial effects: it suppresses tumor gastrin release and inhibits gastrin from stimulating the parietal cells.

Prognosis

The prognosis is guarded to poor as approximately 76% of cases have metastatic disease at the time of diagnosis. In animals that receive both surgical and medical management, survival times range from one week to 18 months.

Liver and Biliary Tract Tumors

Amanda K. Elpiner, DVM, DACVIM (Oncology)

VCA Great Lakes Veterinary Specialists, Cleveland, OH, USA

Etiology/Pathophysiology

The etiology of hepatobiliary tumors in dogs and cats is largely unknown although human cases are often linked to infection with the hepatitis virus (B and C) and cirrhosis. Cirrhosis, which may be secondary to chronic disease or alcohol consumption in people, is rare in dogs and a viral etiology has not been documented in dogs or cats. Other theories behind the development of hepatocellular carcinoma (HCC) and other hepatobiliary tumors include exposure to chemical carcinogens (aflatoxins or nitrosamines, for example) and chronic infections or inflammatory diseases of the liver. Trematodes are thought to be involved in the development of bile duct carcinomas in people and this link has also been explored in dogs and cats but seems unlikely to be a major cause or concern. More recently, somatic genetic alterations are thought to likely play a role in tumor development, such as mutations in p53, PIK3CA, beta-catenin, and others which have been documented in people.

There are four main histologic categories of primary hepatobiliary tumors in both dogs and cats: hepatocellular, bile duct, neuroendocrine (carcinoid), and mesenchymal (sarcoma). Within in each individual category is an array of both malignant and benign tumors. In general, dogs are thought to be more likely affected by malignant tumors whereas cats more often have benign tumors.

Primary hepatobiliary neoplasms can also be described using three morphologic subtypes: massive, nodular, or diffuse. The definition of a massive liver tumor is a large, solitary mass confined to a single liver lobe; nodular tumors have discrete nodules scattered throughout multiple liver lobes; diffuse tumors consist of coalescing nodules within all liver lobes or widespread infiltration of the hepatic parenchyma by neoplastic cells. As we will discuss further, the histologic and morphologic features of hepatobiliary tract tumors help us to make determinations about prognosis for both dogs and cats.

Hepatocellular Tumors

Hepatocellular tumors develop from the hepatocyte. These tumors include hepatocellular adenomas and hepatocellular carcinomas. Hepatocellular adenomas are benign tumors and while they can be found in both dogs and cats, they are more common in the cat. Hepatocellular adenomas are typically considered incidental findings and rarely cause clinical signs in affected patients. Adenomas can, however, reach a large size, necessitating surgical removal. These tumors are also difficult to clinically distinguish from a massive HCC without the aid of a biopsy.

Hepatocellular carcinoma is the most common primary liver tumor in the dog and the second most common in the cat. The majority of HCCs are morphologically massive (53–84%) followed by nodular (16–25%) and diffuse (0–19%) presentations. The left side of the liver is more commonly affected than the right, with over two-thirds of tumors arising from the left lateral, medial, and papillary process of the caudate lobe. HCCs have the ability to metastasize but the likelihood of metastasis is largely based on the morphologic subtype. Massive HCC have a low reported rate of metastasis (0–37%) whereas the nodular and diffuse subtypes have dramatically higher metastatic rates of 93% and 100% respectively. Metastasis is most commonly reported to the regional lymph nodes, peritoneum, and lungs.

Bile Duct Tumors

There are two primary tumors that can arise from the bile duct epithelium in dogs and cats: bile duct adenomas and biliary carcinomas. Bile duct adenomas are also called

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

biliary cystadenomas or hepatobiliary cystoadenomas. These are considered benign tumors and are the most common hepatobiliary tumor found in the cat (accounting for 50% of all feline hepatobiliary tumors). Similar to hepatocellular adenomas, biliary adenomas typically do not cause clinical signs in affected patients unless they reach a large enough size to cause abdominal discomfort, necessitating surgical removal. Male cats are thought to be overrepresented.

Bile duct carcinomas (also called cholangiocarcinomas) are malignant tumors in both dogs and cats. They have an aggressive clinical course with metastasis detected in 60–80% of affected patients. Metastasis to the local lymph nodes and lungs is most common but other intraabdominal sites have been reported. In cats, metastasis resulting in diffuse carcinomatosis can occur in 67–80% of cases. Bile duct carcinomas can be intrahepatic, extrahepatic, or occasionally within the gallbladder itself. Morphologically, bile duct carcinomas are similar to HCC in that 37–46% are massive, 0–46% are nodular and 17–54% are diffuse. In dogs, females and Labrador retrievers are thought to be predisposed whereas there is no sex or breed predisposition yet confirmed in cats.

Neuroendocrine Tumors

These tumors arise from the neuroectodermal cells. They are considered rare tumors in both the dog and cat and are often referred to as carcinoids. Carcinoids have a tendency to occur in younger animals compared to other hepatobiliary tumors. They have an aggressive clinical course and carry a poor prognosis, primarily due to the fact that early metastasis is found in >90% of patients diagnosed. The most common sites of metastasis were the peritoneum and lymph nodes. These tumors are typically intrahepatic and have a predilection for a nodular or diffuse presentation, making surgical resection often difficult or impossible. A small number of extrahepatic neuroendocrine tumors of the gallbladder have been reported for which surgical resection was performed but long-term follow-up is unavailable.

Mesenchymal Tumors (Sarcomas)

Mesenchymal tumors, also called sarcomas, arise from the stromal cells of the liver. They are considered rare, making up less than 15% of all primary hepatic tumors. There are several different subtypes of sarcomas that have been reported in the canine and feline liver including hemangiosarcoma (most common in the dog), leiomyosarcoma (most common in the cat), fibrosarcoma, osteosarcoma, rhabdomyosarcoma, and liposarcoma. Primary hepatic sarcomas carry a poor prognosis due to their aggressive clinical course and high rate of metastasis. Metastasis to the lungs and spleen is most common and is reported in 86–100% of cases. Morphologically, approximately 36% of mesenchymal tumors are massive and 64% are nodular. Bear in mind that the liver is also a common site for secondary sarcomas including metastatic hemangiosarcoma and disseminated histiocytic sarcoma.

Epidemiology

As discussed earlier, liver tumors in the dog and cat can be of either primary or secondary origin. In the dog, retrospective studies have indicated that the prevalence of primary hepatic neoplasia is low (0.6–1.5% of all canine tumors). Secondary neoplasia, the result of metastasis to the liver, is a much more common occurrence. Tumors originating in the spleen, pancreas, and gastrointestinal tract are the most likely to result in metastasis to the liver. However, other systemic neoplasms such as lymphosarcoma, malignant histiocytosis or systemic mastocytosis often involve the liver as part of their widespread clinical course.

In cats, the prevalence is similar, with 1.0–2.9% of all feline tumors being of primary hepatic origin. However, when one study excluded hematopoietic neoplasms, the prevalence increased to 6.9%. There are currently no studies documenting the frequency of metastatic disease to the liver in cats.

Signalment

Hepatobiliary tumors are most common in older animals (over the age of 10), the exception to this being carcinoids which are typically found in younger animals (71% of dogs were under the age of 10). Some studies indicate that miniature schnauzers may be overrepresented for the development of HCC and Labrador retrievers may be predisposed to bile duct carcinomas but there are no other known breed propensities in either species. One study documented a male predilection for canine HCC and a female predilection for bile duct carcinoma. In cats, some studies have indicated a male predominance for carcinoids and bile duct tumors.

History and Clinical Signs

In dogs with hepatobiliary tumors, clinical signs are often lacking or will be somewhat vague. These may include things such as anorexia, weight loss, lethargy, and vomiting. Less frequently, symptoms such as abdominal

discomfort, polyuria, polydipsia, diarrhea, seizures, weakness, ataxia, dyspnea, hematochezia or melena may be observed. If neurologic symptoms do occur in an affected patient, they may be caused by secondary hepatic encephalopathy or paraneoplastic hypoglycemia.

Physical examination may reveal the presence of a cranial abdominal mass affect in up to 75% of patients. However, some massive tumors or nodular and diffuse tumors may not cause any obvious physical exam changes and can be easily missed. Occasionally, a patient may become jaundiced secondary to a hepatobiliary tumor or develop ascites. Overall, dogs and cats with malignant tumors are more likely to become symptomatic than those patients with benign tumors.

Diagnosis

Laboratory Tests

There are no distinguishing complete blood count abnormalities found in patients with hepatobiliary tumors. Hematologic profiles most often show mild and nonspecific changes such as anemia, leukocytosis, and thrombocytosis. A mild, nonregenerative anemia is most common (present in 20–53% of patients). The cause is largely unknown but speculated to be secondary to anemia of chronic disease, red blood cell sequestration, microangiopathic destruction through torturous tumor vessels, or iron deficiency. A leukocytosis may also be present and can be caused by inflammation or necrosis of any large tumor. Thrombocytosis has been reported in approximately 50% of dogs diagnosed with a massive HCC. The cause of this is not fully understood but is speculated to be secondary to anemia, inflammatory cytokine production, chronic iron deficiency, or a paraneoplastic process.

Similarly, serum biochemical profiles often show nonspecific changes. Liver enzyme elevations are commonly found in dogs with hepatobiliary tumors but there is no association with the magnitude of elevation and the severity of disease. These abnormalities are also in no way specific to hepatobiliary neoplasia as many other clinical conditions can affect these values. There are, however, some trends that may be helpful. Alkaline phosphatase (ALP) and alanine aminotransferase (ALT) are the most common values to be elevated in dogs with primary hepatic neoplasia whereas aspartate aminotransferase (AST) and bilirubin are more commonly elevated in metastatic neoplasia, with >90% of dogs having elevations in more than one liver enzyme. In cats, one study showed that ALT, AST, and bilirubin were higher in cats with malignant tumors compared to benign tumors The ratio of liver values to one another has also been examined. An AST:ALT ratio of less than 1 is most common with HCC or bile duct carcinoma whereas a ratio greater than 1 is more likely with a neuroendocrine or mesenchymal tumor.

Other biochemical abnormalities commonly seen with hepatobiliary neoplasia include hypoalbuminemia, hyperglobulinemia, hypoglycemia, and elevated bile acids. In cats, azotemia has been reported as the most common biochemical abnormality. Studies have not clarified the cause of the azotemia though it may represent concurrent and unrelated chronic renal disease.

Imaging

Abdominal radiographs may be helpful at confirming the presence of a large hepatobiliary mass but can easily miss small, nodular or diffuse tumors. In some cases, radiographs may show the presence of mineralization within the biliary tree of dogs with bile duct carcinoma although this is a rare and nonspecific finding. Therefore, ultrasound is the recommended method of imaging for both dogs and cats. Ultrasound also allows for the detection of intraabdominal metastasis, ascites, and the location of the disease and its relationship to other anatomic structures. Most importantly, ultrasound will allow us to determine the morphologic features (massive, nodular, or diffuse) of the tumor and help guide whether surgical resection should be attempted.

Ultrasound images alone, however, are not adequate to diagnose histologic tumor type. An ultrasound-guided fine needle aspiration (FNA) or needle biopsy is recommended, and is especially useful in cases of nodular or diffuse disease. An accurate diagnosis is possible using these techniques in approximately 60% of FNA samples and 90% of needle biopsy samples. Both of these procedures are considered minimally invasive. In some cases, laparoscopic biopsy may be considered more appropriate and is also an excellent means of determining histologic tumor type. In cases of massive tumors, it may not be clinically warranted to know the histologic diagnosis of a particular tumor prior to proceeding with exploratory surgery since the mass will most likely be fully removed and biopsied postoperatively anyway. Advanced imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) are the primary imaging modalities utilized in human medicine for hepatobiliary tumors but have not been fully evaluated in veterinary medicine.

Therapy and Prognosis

Hepatocellular Carcinoma

The prognosis for patients with HCC is dependent primarily on the morphologic subtype. Massive HCC generally carries a good prognosis as it is confined to one

liver lobe and is therefore amenable to surgical resection. In addition to surgical resectability, other prognostic factors for massive HCC include the side of the liver affected (right side worse than left side), pretreatment ALT and AST elevations, and ratio of ALP:AST and ALT:AST. In a paper evaluating surgery in 42 dogs with massive HCC, the median survival time after liver lobectomy was 1460 days versus 270 days for dogs managed medically only. Many of the dogs that underwent liver lobectomy were lost to follow-up as they were still alive or went on to die of other unrelated causes at the end of the study period. Right-sided liver tumors are considered to have a worse prognosis because of their proximity to the caudal vena cava, resulting in an increased risk of intraoperative death. Massive HCC has a low metastatic potential (0–37%) and a low recurrence rate (0–13%) after surgical resection.

In contrast, the prognosis for dogs with nodular or diffuse HCC is poor. This is primarily because that these tumors are not typically surgically resectable due to the involvement of multiple liver lobes and they have a high metastatic rate (93% and 100%, respectively). It is often not possible to clinically determine if nodular and diffuse types of HCC are secondary to intrahepatic metastasis prior to diagnosis or represent multiple foci of disease.

There is little information in the veterinary field about chemotherapy for the treatment of nonresectable HCC. In general, HCC is thought to represent a chemoresistant cancer as response rates of less than 20% are reported in the human literature. This is thought to be secondary to the development of drug resistance within the hepatocytes, owing to their role in detoxification, or through the expression of P-glycoprotein. A recent paper evaluated the chemotherapy agent gemcitabine (2',2'-difluorodeoxycytidine), which has been used in human medicine for the treatment of solid tumors, including HCC. This study did not find a statistical improvement in survival time for those patients with nodular, diffuse or nonresectable massive HCC with the use of gemcitabine but the overall survival time of this small patient population was 983 days. Other treatment techniques that have been explored more recently include arterial chemoembolization, immunotherapy, and antiangiogenic medications.

Bile Duct Tumors

Initial treatment for bile duct tumors should be surgical resection if they are confined to one (or two) liver lobes with no evidence of distant metastatic disease. The prognosis for surgically excised adenomas is excellent with no reports of local recurrence of metastasis. On the other hand, bile duct carcinomas carry a guarded prognosis even when surgically excised due to their high rate of metastasis and local recurrence. The median survival time for patients with bile duct carcinoma is less than six months despite surgical removal. Chemotherapy can be considered to slow disease progression but specific chemotherapy protocols and recommendations have not been effectively evaluated to date in veterinary medicine. There is also no known effective treatment for nodular or diffuse tumors which cannot be surgically excised.

Neuroendocrine Tumors

Neuroendocrine tumors carry a poor prognosis. Metastatic disease is documented in greater than 90% of patients at the time of diagnosis. These tumors are often morphologically nodular or diffuse, limiting the ability to surgically excise them. There is currently no known effective treatment or chemotherapy protocol and the role of these treatments is largely unknown.

Hepatic Sarcomas

Liver lobectomy is recommended if tumors are confined to a single liver lobe. Hepatic sarcomas, however, carry a poor prognosis despite surgical resection due to their high metastatic rate (86–100%). The role of chemotherapy is still under investigation but protocols utilizing doxorubicin and ifosfamide as well as antiangiogenic protocols should be considered to slow disease progression based on their use in sarcomas in other locations such as the spleen.

Tumors of the Urinary Tract

Pedro A. Boria, DVM, MS, DACVIM (Oncology)

Blue Pearl Veterinary Partners, Northfield, IL, USA

Tumors of the Urinary Bladder

Etiology/Pathophysiology

Tumors of the urinary bladder are uncommon in dogs and rare in cats. Transitional cell carcinoma (TCC) is the most common primary tumor of the urinary bladder in both species. Other tumors reported include squamous cell carcinoma, leiomyosarcoma, leiomyoma, undifferentiated carcinoma, lymphoma, hemangiosarcoma, rhabdomyosarcoma, fibroma, and other mesenchymal tumors.

Transitional cell carcinoma is most often located in the trigone region of the bladder in dogs and at the apex in cats. Mass lesions and thickening of the bladder wall can lead to partial or complete urinary tract obstruction. Urethral and prostatic involvement has been reported in 56% and 29% of cases respectively. At the time of diagnosis, lymph node involvement is reported in 16% of cases, with 14% demonstrating spread to distant sites. The overall metastatic rate is 50%.

Epidemiology

The overall incidence of bladder tumors is 2% of all reported malignancies in the dog. In cats, bladder cancer is rarely reported. Risk factors associated with the development of TCC include exposure to older-generation topical flea and tick control products (i.e., flea and tick dips), lawn herbicides and pesticides, obesity, female sex, and a strong breed-associated risk. The female:male ratio of dogs with TCC has been reported to range from 1.71:1 to 1.95:1. The risk is higher in neutered dogs than in intact dogs of both sexes. New-generation spot-on flea control products do not appear to be associated with TCC.

Signalment

Affected dogs and cats are usually older, with an average age of 11 years and 13 years respectively. The most commonly affected breeds include West Highland white terriers, beagles, dachshunds, Shetland sheepdogs, and Scottish terriers which have an 18-fold risk of developing TCC.

History and Clinical Signs

The most common clinical signs associated with TCC are stranguria, pollakiuria, hematuria, dysuria, and urinary incontinence. Urinary tract signs may present for weeks to months prior to diagnosis. Temporary relief of these signs may be associated with the use of antibiotics. In more severe cases, abdominal palpation may reveal a palpable caudal abdominal mass. Rectal examination abnormalities include urethral thickening or sublumbar lymphadenopathy. TCC can also metastasize to the inguinal lymph nodes, so palpation of the inguinal fat pads may reveal firm masses. Other lower urinary tract conditions resembling bladder TCC include other types of neoplasia, cystitis, polypoid cystitis, polyps, granulomatous cystitis/urethritis, and cystic calculi. Rarely, dogs have shifting leg lameness or warm, swollen, and painful limbs due to paraneoplastic hypertrophic osteopathy.

Diagnosis

Diagnostic evaluation of a patient with suspected TCC should include deep abdominal palpation and rectal evaluation. Rectal examination may reveal thickening of the urethra and enlargement of internal lymph nodes. The complete blood count and serum biochemical panel may reveal signs of renal involvement. Urine sediment

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

reveals malignant cells in only 30% of cases. In cases with high index of suspicion for a bladder mass, cystocentesis should be avoided to decrease the chance of tumor transplantation or bladder rupture. Concurrent urinary tract infection is prevalent in TCC cases, therefore urine culture is recommended.

Diagnostic imaging is essential for documentation of a bladder mass. Abdominal radiographs are usually unrewarding unless the lesion is mineralized. However, radiographs may show sublumbar lymphadenopathy, prostatomegaly, a caudal abdominal mass or bony metastases. Thoracic radiographs demonstrate pulmonary metastasis in 17% of cases at the time of diagnosis. Pulmonary changes may include nodular interstitial or lobar interstitial opacities and alveolar infiltrates.

Ultrasonography is a sensitive diagnostic tool to evaluate the urinary tract and has largely replaced the use of double-contrast cystography. Ultrasonography can also confirm ureteral obstruction when there is dilation of the renal pelvis alone or accompanied by hydronephrosis.

Histopathology is the gold standard for the diagnosis of TCC. However, cytology can also be utilized. There are multiple methods for obtaining bladder tissue samples such as cystotomy, cystoscopy, and traumatic catheterization. Due to sampling size, multiple tissue samples should be submitted to increase the diagnostic yield. Most recently, A DNA based assay to detect genetic mutations specifically in the *BRAF* gene has proven to be highly sensitive and specific for the diagnosis of TCC (CADET® *BRAF, Sentinel Biomedical*). The test evaluates malignant cells naturally shed and is therefore performed on voided urine samples. However, the assay is limited TCC and experimentally it has been found that up to 15% do not have the mutation.

Therapy

Because the trigone and urethra are most commonly involved in dogs, complete removal of the tumor is usually not possible. In addition, many dogs develop multifocal bladder lesions. As a result, most dogs with bladder tumors are managed medically, with chemotherapy, radiation and/or photodynamic therapy.

If a patient is suffering from urinary obstruction, surgery may be considered to reestablish urine flow or place a cystostomy tube. The most common disadvantages of tube cystostomy are recurrent urinary tract infections and premature removal of the tube by the patient. Urethral stents are gaining favor over cystostomy tubes. Stents are placed surgically and nonsurgically using fluoroscopy. The most common indication for urethral stenting is luminal obstruction secondary to tumor infiltration. In a series of 12 cases, urethral stents relieved obstruction in all cases. The outcome was fair to excellent in 10/12 cases. Urinary incontinence is the most common complication.

The use of radiation therapy for the treatment of TCC of the bladder is limited. The reported one- and two-year survival rates following intraoperative radiation therapy were 69% and 23%, respectively. Therapy-related complications include urinary incontinence, pollakiuria, and stranguria, all of which affect the patient's quality of life. A report of weekly course fractional external beam radiation therapy in combination with mitoxantrone and piroxicam was well tolerated but results were no better when compared to medical therapy alone. However, 90% of the dogs had amelioration of their clinical signs.

The mainstay treatment of TCC in dogs is systemic medical therapy with cyclooxygenase (COX) inhibitors alone or in combination with chemotherapy. Cure rates are relatively low but several different drugs can lead to remission or stable disease. In dogs, single-agent therapy with piroxicam or cisplatin has shown a response rate of 20% with a median survival time of approximately six months. Although the concurrent use of cisplatin and piroxicam combination therapy has shown a response rate of 70%, the high incidences of renal failure lead to early termination of the protocol.

The most commonly used chemotherapy combination in dogs is mitoxantrone (5 mg/m^2 IV q3 weeks) and piroxicam (0.3 mg/kg once a day). This combination has a documented response rate of 35% and median survival of 291 days. Indications to continue therapy include positive response such as complete or partial remission. Stable disease is considered a positive response as long as the patient has no detrimental effects associated with chemotherapy administration and a good quality of life.

Deracoxib (Dermaxx®, Novartis), a COX-2 inhibitor, at a dose of 3 mg/kg/day, has shown positive responses, with 17% of dogs having a partial response and 71% of dogs having stable disease.

Prognosis

The prognosis for TCC in dogs will largely depend on tumor size, location, and metastasis at the time of diagnosis. Multiple different treatments have been identified that result in remission and stable disease for several months. Most of these patients will have an excellent quality of life while on treatment. Prognostic factors for survival are tumor stage at the time of diagnosis (Box 146.1), younger age (increased risk of distant metastasis), prostate involvement (increased risk of distant metastasis), and higher T stage (increased risk of nodal and distant metastasis). Information regarding prognostic factors in other bladder tumors is limited. Prognostic factors for bladder tumor in cats have not been well

Box 146.1 TNM clinical staging system for canine bladder cancer

T – primary tumor

Tis	Carcinoma *in situ*
T0	No evidence of a primary tumor
T1	Superficial papillary tumor
T2	Tumor invading the bladder wall, with induration
T3	Tumor invading neighboring organs (prostate, uterus, vagina, and pelvic canal)

N – Regional lymph node (internal and external iliac lymph node)

N0	No regional lymph node involvement
N1	Regional lymph node involved
N2	Regional lymph node and juxtaregional lymph node involved

M – Distant metastases

M0	No evidence of metastasis
M1	Distant metastases present

defined. The reported median survival of cats treated with surgery and adjunctive therapy (i.e., chemotherapy or NSAIDs) was 269 days.

Urethral Tumors

Most tumors affecting the urethra are malignant. Transitional cell carcinoma and squamous cell carcinoma are the most commonly reported tumor types. Smooth muscle tumors (e.g., leiomyosarcoma) have been reported less frequently. Granulomatous urethritis, a benign condition of the urethra, must be differentiated from malignant tumors due to the different treatment approaches and prognosis. Treatment recommendations and response rates for urethral tumors are similar to those of the bladder.

Renal Tumors

Etiology/Pathophysiology

Primary renal tumors are uncommon in dogs and cats. The majority of these tumors are malignant and more than half are epithelial in origin. In cats, lymphoma is the most common renal tumor and can affect both kidneys. In a report of 54 dogs with renal tumors, the most common was renal cell carcinoma. Other tumors that can occur in the kidney include TCC, nephroblastoma, hemangiosarcoma, other sarcomas, and lymphomas. An unusual syndrome in female German shepherd dogs consists of slow-growing dermal fibrosis and fibromas, concomitant renal cystadenocarcinoma, and uterine tumors. This syndrome is similar to Birt–Hogg–Dubé syndrome in humans.

Pulmonary metastases have been detected radiographically in 16–34% of dogs with primary renal tumors at the time of diagnosis. At death, metastases were detected in 69% of dogs with carcinomas, 88% of dogs with sarcomas, and 75% of dogs with nephroblastomas.

Epidemiology

The etiology of renal tumors in dogs and cats is unknown. The previously mentioned syndrome in German shepherd dogs is the result of a dominantly inherited missense mutation of a tumor suppressor gene. In cats, feline leukemia virus (FeLV) is strongly associated with development of renal lymphoma.

Signalment

Most renal tumors occur in older dogs (mean age 8 years) but nephroblastoma may occur at any age. The male to female ratio of dogs with epithelial renal tumors has been reported to be 1.2:1. In cats, the median age at diagnosis was 11 years with a similar number of male and female cats.

History and Clinical Signs

Clinical signs associated with renal tumors are not specific. Presenting complaints may include weight loss, polyuria, lethargy, hematuria, abdominal pain or signs suggestive of renal failure (vomiting, anorexia). Physical examination may reveal a midabdominal mass and occasionally bilateral renal enlargement.

Diagnosis

Clinicopathologic findings include mild anemia alone or accompanied with marked neutrophilia, or abnormalities consistent with renal azotemia. Paraneoplastic syndromes such as polycythemia, neutrophilia, and hypertrophic osteopathy have been reported.

Ultrasonography is highly sensitive for the diagnosis of renal neoplasia. Tissue samples can be obtained by ultrasound-guided percutaneous biopsy or at the time of surgery.

Therapy and Prognosis

Nephrectomy is the treatment of choice for dogs with unilateral renal tumors without evidence of azotemia or distant metastasis. Excretory urography, computed tomography (CT), and evaluation of glomerular filtration rate (GFR) via scintigraphy may also be useful,

especially for surgical planning. Evaluation of possible tumor extension into the vena cava is important if surgery is considered.

The reported median survival time for dogs with renal cell carcinoma treated with nephrectomy is eight months. Standardized chemotherapy as an adjunct or in the metastatic setting for renal carcinoma has not been well defined. In humans, sunitinib, a multikinase receptor inhibitor, has shown antitumor activity against metastatic renal cell carcinoma. At this time, controlled studies using tyrosine kinase inhibitors against renal carcinoma in veterinary patients are lacking. Toceranib phosphate, a multikinase receptor inhibitor similar to sunitinib, is approved for mast cell neoplasia in veterinary patients and may be considered for the treatment of metastatic renal carcinoma.

Chemotherapy treatment for renal lymphoma is similar to protocols used to treat lymphoma in other organs. Approximately 60% of cats achieve complete remission. Negative prognostic factors included involvement of other organ system (CNS), FeLV infection, and severity of renal failure.

Tumors of the Male Reproductive System

Trina Hazzah, DVM, DACVIM (Oncology)

VCA West Los Angeles Animal Hospital, Los Angeles, CA, USA

Testicular Tumors

Etiology/Pathophysiology

Testicular tumors are the most common cancer found in the male reproductive tract and are typically considered nonaggressive. Primary testicular neoplasia commonly arises from three separate areas of the testis: the sustentacular cells of Sertoli (Sertoli cell tumors), interstitial cells (Leydig cell tumors), and germinal epithelium (seminoma). A recent study evaluated 345 testicular tumors; seminomas (33.9%) were the most common followed by interstitial cell tumors (33%), and lastly Sertoli cell tumors (26.4%). Although less frequently seen, other tumor types can be found such as lymphoma, hemangiosarcoma, and others.

Epidemiology

The prevalence of testicular tumors in dogs is 27%, which has increased from previous years. A cryptorchid testicle has an approximately 10 times increased risk of developing cancer compared to a descended testicle. This effect may be in part due to the higher temperature of the retained testis within the body. Of retained testes tumors, 34% are seminomas and 54% are Sertoli cell tumors. Other risk factors are age, breed, and exposure to environmental carcinogens. In one study, intact dogs over 6 years of age had an increased incidence of testicular tumors. Collies and Shetland sheepdogs were five times more likely to develop testicular tumors, specifically Sertoli cell tumors. Environmental carcinogen exposure has also been a proven risk factor.

Military working dogs in the Far East that were exposed to chemical sprays like Agent Orange, herbicides, and dioxin demonstrated an increased risk of seminomas.

Signalment

Testicular tumors are diagnosed in older dogs, with a median age of approximately 10 years. No specific breed predilection has been consistently described.

History and Clinical Signs

Sertoli cell tumors are often large (1–5 cm). Atrophy of the contralateral testicle is common. Dogs with Sertoli cell tumors can present with bilateral dorsal alopecia, hyperpigmentation of the skin or scrotum, enlarged nipples, squamous metaplasia of the prostate, gynecomastia, and thinning of the skin. Many of these clinical signs are associated with hyperestrogenism which causes signs of feminization and is found in approximately 20% of cases. Severe bone marrow hypoplasia leading to life-threatening pancytopenia can result from the excessive endogenous estrogen production from the tumor.

Leydig cell tumors are relatively small (usually under 2 cm) in size, and can be found as either solitary or multiple and unilateral or bilateral.

Seminomas are larger tumors (can be greater than 5 cm) and often appear as nodules. They can occur along with interstitial and Sertoli cell tumors. Hyperestrogenism is rarely seen with this tumor type although a recent case study described a 5-year-old Yorkshire terrier with confirmed hyperestrogenemia and secondary alopecia.

Diagnosis

Staging with full blood analysis, urinalysis, thoracic radiographs, and abdominal ultrasound should be performed in all patients with testicular tumors. Results typically reveal no abnormalities unless the presence of hyperestrogenemia results in blood dyscrasias or pancytopenia.

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

The metastatic rate for seminomas and Sertoli tumors is approximately 10%. Metastasis occurs through lymphatic invasion. Therefore, evaluation for regional metastasis is warranted prior to surgery. There are reports of aggressive seminomas in dogs with distant metastasis to the spleen, lungs, meninges, eyes, and skin. Testicular ultrasound is recommended in dogs with clinical signs of testicular neoplasia and nonpalpable disease. For dogs with signs of feminization, obtaining serum levels of estradiol-17-beta may help support a diagnosis of functional testicular tumor. Paraneoplastic hypertrophic osteopathy, although rare, has been reported in a dog with a Sertoli cell tumor. Therefore, extremity radiographs should be performed in dogs with Sertoli cell tumors with concomitant lameness.

Therapy

Castration, including scrotal ablation, is considered the treatment of choice for testicular tumors and is curative for dogs with nonmetastatic disease. However, when metastatic disease is present, adjunctive chemotherapy or radiation therapy is necessary. The use of cesium-137 external beam radiation therapy for regional lymph node metastasis in four dogs with seminoma has been described and shown to be 100% effective. There is limited information regarding the usefulness of chemotherapy, but there is suggested efficacy with both cisplatin and bleomycin. There is recent evidence that seminomas and Leydig cell tumors express kit (CD117), making the use of a tyrosine kinase inhibitor (such as Palladia™, or Gleevec®) a reasonable treatment option for cases with metastatic disease. The use of metronomic chemotherapy for high-grade seminomas is also a valid treatment option, as one study found that seminomas demonstrated increased angiogenesis.

Prognosis

The prognosis is excellent for nonmetastatic testicular tumors and guarded for metastatic tumors or dogs that have blood dyscrasia secondary to hyperestrogenism. Also, seminomas with high mitotic index and increased numbers of agyrophilic nucleolar organizer regions (AgNORs) had increased risk of metastasis.

Prostate Tumors

Etiology/Pathophysiology

Carcinomas are the most common prostatic tumor, with transitional cell carcinoma and adenocarcinoma being the most frequent types. Other types such as squamous cell carcinoma, undifferentiated carcinoma, and sarcomas are rarely found. In dogs, most prostatic carcinomas are suspected to be ductal or urothelial in origin, rather than acinar, as in humans. The absence of androgen receptors in ductal epithelial cells suggests that canine prostatic carcinoma formation is likely androgen independent. Controversy still exists regarding the effects of castration on the development of canine prostatic carcinoma. Regardless, three studies did reveal that castrated dogs were at increased risk for developing prostatic carcinoma with odds ratios ranging from 3.86 to 4.34.

Epidemiology

Prostate tumors are rare neoplasms in dogs, having a prevalence of less than 1% of all canine cancers. These tumors are extremely uncommon in cats with only a few reported cases.

Signalment

There is no known breed predilection and prostatic carcinoma typically affects older dogs, median age 10 years. Although exceedingly rare, prostatic carcinoma can occur in older cats.

History and Clinical Signs

The most common presenting clinical sign in a dog with a prostate tumor is either tenesmus or dysuria, including hematuria, stranguria or pollakiuria. Older, castrated, male dogs presenting with any of the above clinical signs should be evaluated for urogenital cancer as few other diseases cause such signs. Other possible presenting signs are anorexia, weight loss, acute lameness or back pain which may indicate metastasis to the pelvis or lumbar spine.

In cats, clinical signs vary but include dysuria, urethral obstruction, and obstipation. Physical exam findings and diagnostics are similar to those for prostate tumors in dogs.

Diagnosis

Physical exam findings are variable but the most common abnormality is prostatomegaly that can be palpated as irregular, firm, and painful and/or demonstrates loss of the median raphe. Complete blood count and serum biochemistry rarely reveal any specific changes. Urinalysis often indicates pyuria or bacteriuria as secondary bacterial infection is commonly associated with this neoplasia. Many owners report improvement of clinical signs if treated with antibiotic therapy, but this improvement is often short-lived. Three-view thoracic radiographs are

recommended, although pulmonary metastasis occurs in <10% of dogs at the time of diagnosis. Abdominal radiographs are helpful in identifying prostatomegaly, mineralization of the prostate, sublumbar lymphadenopathy, and/or bony lesions of the lumbar spine or pelvis (typically osteoblastic [proliferative] in nature).

Metastatic, hormone-refractory, androgen-independent prostate cancer in men is similar in biologic behavior to canine prostatic carcinoma. Eighty five to ninety percent of those diagnosed with this form of prostate cancer will have evidence of skeletal metastasis during the course of disease. Skeletal metastasis has been reported to occur in 22% of dogs, with the majority of these lesions found in the axial skeleton.

Abdominal ultrasound is the most useful of all imaging modalities as it can help confirm regional metastasis which occurs in approximately 50% of dogs at presentation. Definitive diagnosis requires cytology or histopathology. Fine needle aspiration, via ultrasound guidance, has been shown to be 80% accurate in confirming a diagnosis of carcinoma. As an alternative, a prostatic wash can be performed. Although less invasive, it is also less sensitive.

In the published feline cases, metastatic disease varied in location, but included pulmonary, pancreatic, renal, and myocardial.

Therapy

There is limited information regarding treatment efficacy for dogs with prostate tumors. Androgen ablation therapy is ineffective in dogs, as tumors arise from androgen-independent regions. For tumors confined to the prostate, total or partial prostatectomy can be considered. Due to persistent incontinence and recurrent urinary tract infections, patient morbidity is high while owner satisfaction is expectedly low. Radiation therapy, an alternate local treatment option, was not found to be useful in one series of dogs which received a palliative protocol. However, a more recent study indicated a 60% response rate and an extended survival time (median survival time 645 days) when intensity-modulated and image-guided radiation therapy (IM/IGRT) were utilized.

Due to the high metastatic rate in dogs, local treatment alone is not effective. Cyclooxygenase (COX) inhibitor therapy is reported to be successful in treating various types of urogenital carcinomas. Two studies indicated that approximately 75–88% of canine prostate carcinomas express COX-2. A previous publication indicated that COX inhibitors were effective in the treatment of canine prostatic carcinoma (MST 6.9 versus 0.7 months). In a separate study, the addition of mitoxantrone chemotherapy to piroxicam did not increase survival.

Palliative irradiation, urethral stenting, laser ablation or cystostomy tube placement can be considered in dogs with urethral obstruction. These options are palliative and may only increase survival time minimally.

Treatment for cats with prostatic carcinoma is unknown. One reported cat underwent a prostatectomy and received doxorubicin (30 mg/m^2) and cyclophosphamide (300 mg/m^2) and was euthanized 10 months later due to recurrent disease.

Prognosis

The overall prognosis for prostate cancer is guarded to grave as this tumor is both locally and distantly aggressive. The rate of metastasis at the time of death is approximately 80%, with the most common sites being the lungs, regional lymph nodes, liver, and bone. Prognostic indicators that have been found to be negatively associated with survival include the presence of metastasis at diagnosis, presence of clinical signs at diagnosis, and the lack of nonsteroidal antiinflammatory drug (NSAID) therapy.

It is difficult to confirm treatment and prognostic information for cats based on the limited reports available. However, it would be reasonable to consider that these tumors have a similar prognosis to their canine counterparts as they also tend to be aggressive.

Penis, Prepuce, and Scrotum Tumors

Etiology/Pathophysiology

Tumors of the penis, prepuce, and scrotum are rare in dogs and even rarer in cats. The most common tumors of the penis are transmissible venereal tumor (TVT) and squamous cell carcinoma (SCC). The prepuce can also be affected by TVT. Most tumors of the prepuce and scrotum are those associated with skin, specifically SCC, melanoma, and mast cell tumor (MCT). Other reported tumors that can affect all three areas include hemangiosarcoma, lymphoma, lipoma, plasmacytoma, soft tissue sarcoma, ossifying fibroma, chondrosarcoma, and osteosarcoma of the os penis.

Epidemiology

Limited information is available for this group of tumors. See the section on epidemiology for transmissible venereal tumors below and the respective chapters for specific tumor types.

Signalment

With the exception of TVT, tumors of the penis, prepuce, and scrotum are generally diagnosed in older dogs.

For TVT, young, sexually active dogs are most commonly affected.

History and Clinical Signs

Presenting signs are dependent on tumor location and include stranguria, hematuria, discharge, foul odor, constant licking, and a large mass.

Diagnosis

Complete staging including abdominal ultrasound to evaluate for regional lymphadenopathy and three-view thoracic radiography is recommended. Fine needle aspiration or preferably biopsy is recommended to obtain a definitive diagnosis.

Therapy

Surgery is the treatment of choice for the majority of tumors in this group. The exception is TVT (see section on TVT below). Penile amputation may be required when tumors are invasive or when extensive prepuce removal is performed. For scrotal tumors, castration with scrotal ablation is recommended. Adjunctive therapy relevant to the tumor type is warranted when metastasis or recurrence occurs.

Prognosis

The reader is encouraged to refer to the specific tumor type chapters for a more in-depth review. Overall, the prognosis for nonmetastatic tumors, that can be completely excised, is good to excellent. However, for metastatic or recurrent tumors the prognosis is guarded to poor. Osteosarcoma of the os penis may have a guarded prognosis as this tumor has the potential to metastasize similar to other axial forms.

Transmissible Venereal Tumor

Etiology/Pathophysiology

Transmissible venereal tumor is often transmitted through coitus but can also spread through close contact such as sniffing or licking of the genitalia. The exact origin of this tumor is unclear but evaluation of antigen expression suggests that TVT expresses similar markers to histiocytes. Canine TVT can be observed in leishmaniotic dogs, and amastigotes can be harbored in canine TVT cells.

Transmissible venereal tumors can affect other members of the canine family such as foxes, coyotes, and wolves. When evaluating the karyotype of TVTs, worldwide, they are similar and are characterized by 59 chromosomes (versus 78 in normal dogs).

Epidemiology

There is a higher prevalence of TVT in warm climates and in rural areas where there are large numbers of free-roaming, reproductively unaltered dogs.

Signalment

Transmissible venereal tumor affects both female and male dogs. There is an increased risk in young, sexually active dogs.

History and Clinical Signs

Transmissible venereal tumor can present as solitary or multiple nodules on the external genitalia that appear as pedunculated or cauliflower-like masses. In males, it usually occurs on the bulbus glandis but can be seen on the penis or prepuce. In female dogs, the lesions develop in or around the vagina. Infected dogs can present with a few weeks (or months) history of bloody discharge, deformed external genitalia, ulceration or swelling of the affected area. Differential diagnosis may include urinary tract infections, prostatitis, other causes of paraphimosis or phimosis or other malignancies (urogenital carcinomas, sarcomas, or other round cell tumors).

Rarely, dogs can have extragenital lesions without a primary lesion. These ulcerative, hemorrhagic lesions can occur in the mouth, nose, eyes or skin caused by biting or rubbing which can predispose the skin to implantation of the TVT.

Diagnosis

Transmissible venereal tumor should be suspected if the geographic location, history, lifestyle, and clinical signs fit the diagnosis. To obtain a definitive diagnosis, either cytologic or histopathologic confirmation is required. Microscopically, the cells are large, discrete (round cells) with abundant blue cytoplasm containing distinct clear vacuoles. Single or multiple nucleoli and mitotic figures may be seen (Figure 147.1).

Transmissible venereal tumors have the immunohistochemical staining characteristics of histiocytes. They stain positive to antibodies against vimentin, lysozyme, macrophage-specific immunostain (ACM)1, and alpha-1-antitrypsin (AAT). Therefore, the use of immunohistochemistry may be helpful in cases where it is difficult to confirm a diagnosis or if there are atypical metastatic sites present.

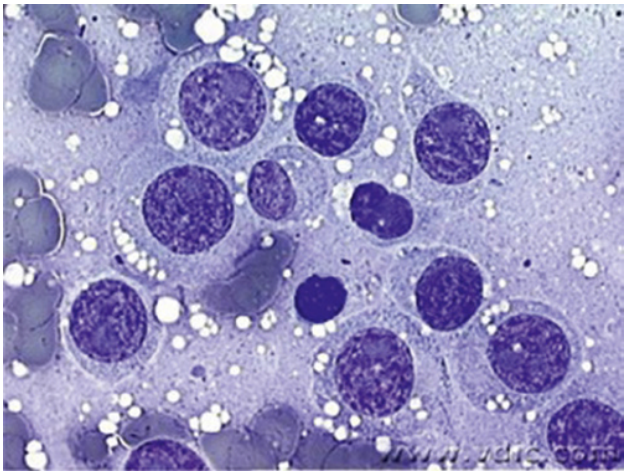

Figure 147.1 Fine needle aspirate of a canine TVT. Note the homogeneous population of discrete round cells with mild anisocytosis and anisokaryosis. The cells have a moderate amount of cytoplasm with multiple discrete clear cytoplasmic vacuoles.

Any dog with suspected TVT should undergo full staging, including urinalysis, as there is evidence that dogs with TVT are at high risk of developing urinary tract infections. Although metastatic disease occurs in less than 10% of reported cases, evaluating for local metastasis with abdominal ultrasound and three-view thoracic radiographs is recommended. A differential for suspected metastasis is transplantation (autologous or allogeneic) of TVT from the primary genital lesion.

Therapy

There are multiple treatment options for TVT. The least invasive, least expensive and most effective option is the use of single-agent vincristine chemotherapy. Administering vincristine at the recommended dose of 0.5–0.7 mg/m^2 IV once weekly for 3–6 treatments elicits a complete response in over 90% of dogs. Other protocols involving cyclophosphamide, vinblastine, doxorubicin, and methotrexate have been used with less success. However, for vincristine-resistant tumors, doxorubicin given at 30 mg/m^2 IV every three weeks can be effective.

Radiation therapy is an effective treatment modality for TVT. Orthovoltage radiation was evaluated in 18 dogs with solitary primary genital and cutaneous lesions. All lesions were treated with a total dose of 10–30 Gy. Seven dogs had a complete response to a single fraction of 10 Gy. The remaining patients required an additional 2–3 fractions to achieve a complete response. In a separate study, 15 dogs with primary genital TVT received cobalt irradiation. A 100% complete response rate was reported.

Surgery can be used in cases of primary or metastatic lesions, but it is not typically recommended as the recurrence rate can be up to 70%.

Lastly, the use of immunotherapy with intralesional bacillus Calmette–Guérin (BCG) has been shown to be effective as a single agent and in combination with vincristine therapy.

Prognosis

The prognosis for TVT is good to excellent as some dogs can experience spontaneous regression. The majority of dogs that receive single-agent vincristine therapy or radiation therapy will be cured of their disease. The prognosis is, however, guarded for dogs that have ocular or central nervous system invasion or evidence of disseminated metastasis. An increase in the AgNOR area in the nucleus was found to be a negative prognostic indicator in dogs with TVT.

Gynecologic Cancers

Trina Hazzah, DVM, DACVIM (Oncology)

VCA West Los Angeles Animal Hospital, Los Angeles, CA, USA

Uterine Tumors

Etiology/Pathophysiology

Uterine cancer is extremely rare in dogs and cats. This is in part because the overwhelming majority of pets are spayed. Leiomyoma is the most common uterine tumor in the dog, followed by leiomyosarcoma. Other types of tumors have been reported such as fibroma, lipoma, hemangiosarcoma, fibrosarcoma, angiolipoleiomyoma, adenoma, adenocarcinoma, and extramedullary plasmacytoma. In women, estrogen is considered to be the primary factor in the development of uterine carcinoma. It is believed that both endogenous and exogenous estrogen can result in endometrial hyperplasia. It also potentiates the transformation of endometrial hyperplasia to endometrial carcinoma. Estrogen is not the underlying hormone responsible for endometrial changes in dogs. In fact, it is progesterone that plays a large role in both neoplastic and nonneoplastic gynecologic diseases of the dog. Dogs develop cystic endometrial hyperplasia which is much less likely to transform into carcinoma.

The most common uterine tumor in the cat is adenocarcinoma which arises from the endometrium. Although much rarer, leiomyoma, leiomyosarcoma, hemangioma, squamous cell carcinoma, and carcinosarcoma have been reported. An association of feline leukemia virus (FeLV) and the development of uterine adenocarcinoma in cats have been reported.

Birt–Hogg–Dubé (BHD) syndrome is a rare inherited condition that occurs in German shepherd dogs resulting from a mutation in the canine orthologue (folliculin) tumor suppresser gene. It manifests in multiple uterine leiomyomas, bilateral renal cystadenocarcinomas, and nodular dermatofibrosis. A similar BHD syndrome has been noted to occur in humans.

Epidemiology

The incidence of uterine tumors is less than 0.5% in dogs and approximately 1% in cats. BHD is inherited through an autosomal dominant pattern.

Signalment

Uterine tumors typically occur in middle-aged to older dogs and cats, but there are reports in dogs under 1 year of age. These tumors are overwhelmingly more common in intact females, but there are reports of uterine stump carcinomas in spayed females. There is no specific breed predilection.

History and Clinical Signs

Most dogs and cats with uterine tumors are asymptomatic. However, purulent to hemorrhagic vaginal discharge, lethargy, anorexia, constipation, and pyometra can occur. Other signs may be associated with the metastatic lesions themselves.

Diagnosis

A minimum database including complete blood count, biochemistry, and urinalysis is recommended for any animal with potential gynecologic cancer. Abdominal radiographs may reveal a mass effect in the caudal abdomen. To thoroughly evaluate the extent of disease or for the presence of regional metastasis, an abdominal ultrasound is required. Although the majority of uterine tumors are benign in the dog, three-view thoracic radiographs should be performed. In cats, thoracic radiographs and abdominal ultrasound are mandatory as malignant uterine tumors are associated with a high

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

metastatic rate (up to 50%). Definitive diagnosis requires histology and is easily obtained at the time of hysterectomy.

Therapy

Ovariohysterectomy is the treatment of choice in all cases of uterine tumors, except in the setting of distant metastasis or carcinomatosis. Surgical excision of any regional metastatic foci is also recommended.

In women, adjunctive chemotherapy has been shown to have a mild to modest benefit for metastatic leiomyosarcomas and carcinosarcomas when compared to surgery or radiation alone. Although there are no veterinary reports on the use of chemotherapy for uterine tumors, it is highly recommended in cases of malignant or metastatic tumors. Based on human data, it would be reasonable to consider chemotherapeutics such as cisplatin, carboplatin, doxorubicin, cyclophosphamide, gemcitabine, and ifosfamide as viable therapeutic options.

A 2007 study evaluated the presence of estrogen and progresterone receptors in smooth muscle genital tumors. Estrogen receptor alpha (ERalpha) was found in 56.3% and progesterone receptor (PR) in 84.4% of canine tumors. This finding makes hormone receptor antagonist therapy a reasonable treatment option.

Prognosis

The prognosis is excellent for dogs and cats with benign tumors following complete ovariohysterectomy. For malignant tumors localized to the uterus, the prognosis can be good as many of these dogs can still be cured with surgery. However, the prognosis is guarded for metastatic tumors. In cats with uterine adenocarcinomas, the prognosis is guarded to poor as they often metastasize.

Vaginal Tumors

Etiology/Pathophysiology

Vaginal tumors are the second most common tumor of the female reproductive system. The most common histologic type is leiomyoma. These tumors, similar to the uterine leiomyomas, are slow growing and do not metastasize. Other less common tumors include fibroma, polyp, lipoma, myxoma, lymphoma, liposarcoma, mast cell tumor, adenocarcinoma, squamous cell carcinoma, fibrosarcoma, leiomyosarcoma, osteosarcoma, hemangiosarcoma, and TVT.

One study found that all pedunculated masses were benign. And of the sessile, broad-based masses, all were malignant (with the majority being TVT).

Feline vaginal tumors are extremely rare, with most being benign.

Epidemiology

In dogs, there is some evidence that vaginal neoplasia may be associated with a history of mammary tumors, ovarian cysts, pyometra or previous treatment with reproductive hormones. One study found that the majority of dogs with vaginal cancer are sexually intact and nulliparous.

Signalment

The mean age for dogs with vaginal cancer is 10.8 years. Although there is no breed predilection, both boxers and poodles have been reported to have an increased risk.

History and Clinical Signs

Common clinical signs reported include purulent to hemorrhagic vaginal discharge, swelling of the vulva or perineal region, a vulvar mass, constant licking of the vulva, dysuria or tenesmus. Tumors typically arise from the vulva, vestibule, or vaginal roof. There is no correlation between the location of the mass and histologic tumor type.

Diagnosis

Definitive diagnosis of malignancy requires histology. However, the presence of a vaginal mass is often easily determined based on history, clinical signs, and physical exam findings (including a digital vaginal exam). For small lesions, vaginoscopy may be required. Full staging is recommended for all animals with vaginal tumors: complete blood count, biochemistry, three-view thoracic radiographs, and an abdominal ultrasound. Paraneoplastic hypercalcemia has been infrequently reported to be associated with older basset hounds with clitoral adenocarcinoma.

Treatment

Surgical excision with dorsal episiotomy is the treatment of choice. Concurrent ovariohysterectomy is also recommended as some malignancies such as leiomyomas may be hormone dependent. For highly invasive vaginal tumors, either subtotal vaginectomy or a complete vulvovaginectomy and perineal urethrostomy can be performed. It is advised that any metastatic foci should be removed at the same time.

Adjunctive radiation therapy and chemotherapy can be considered for animals that have incompletely excised

malignant tumors or metastatic/high-grade tumors, respectively.

The use of carbon dioxide laser ablation in conjunction with doxorubicin chemotherapy(at 30 mg/m^2 intravenously) every four weeks for a total of two treatments has been shown to provide long-term control in one case report of a poodle with vaginal fibrosarcoma.

Another potential treatment is the use of the progesterone receptor antagonist aglepristone, as neoadjuvant therapy prior to surgery for large benign vaginal tumors.

Prognosis

Surgery is often curative for benign tumors and the prognosis is guarded for malignant tumors as they have the potential to metastasize and recur.

Ovarian Tumors

Etiology/Pathophysiology

Ovarian tumors can arise from different locations within the ovary and are classified based on their origin, such as epithelial cells, sex cord stromal elements of the ovary and germ cells. Epithelial tumors are further characterized as adenoma, cystadenoma, adenocarcinoma, and undifferentiated carcinoma. Tumors referred to as sex cord stromal tumors are granulosa cell tumors, luteomas, and thecomas. Although more common in the male, this group also includes Sertoli, Leydig and Sertoli-Leydig cell tumors. Lastly, the germ cell tumors include dysgerminoma, teratocarcinoma, teratoma, and choriocarcinoma. Other rare tumor types include hemangiosarcoma, rhabdomyosarcoma, fibrosarcoma, and carcinosarcoma.

The majority of ovarian tumors, regardless of their histologic subtype, are unilateral. However, adenocarcinomas and mixed sex cord stromal tumors (specifically Sertoli-Leydig cell tumor) can occur bilaterally in about 30% of cases. The rates of occurrence for each type varies depending on the study, but granulosa cell tumors and epithelial tumors account for most ovarian tumors in dogs and granulosa cell tumors are the most common ovarian tumor found in cats.

The overall metastatic rate for ovarian tumors in dogs is approximately 25%, with a higher incidence, approximately 50%, in both adenocarcinomas and teratomas. Sex cord tumors are the only histologic type that has the potential of being hormonally active, as they arise from gonadal tissue of the ovary and can produce steroid hormones.

In cats, the most common ovarian tumor is granulosa cell tumor, followed by dysgerminomas. They are typically unilateral but can be found bilaterally. Similar to dogs, granulosa cell tumors in cats can metastasize and are hormonally active. Although there are few reports of teratomas in cats, they have been noted to occur in young animals and rarely metastasize.

Epidemiology

As ovarian tumors are extremely rare in both dogs and cats, the true prevalence is unknown.

Signalment

The majority of ovarian tumors affect older dogs, with the exception of teratomas. One study found pointers had an increased risk of developing epithelial tumors while English bulldogs were at higher risk for granulosa cell tumors. German shepherds and poodles were also reported to have a higher occurrence of ovarian tumors.

History and Clinical Signs

The clinical signs reported are variable but may include vaginal discharge, distended abdomen, pyometra, and an abnormal estrus cycle. If metastasis occurs, clinical signs may be associated with the location of involvement, such as ascites secondary to tumor effusion. As sex cord tumors can cause hormonal dysfunction, signs associated with excess sex hormones (both estrogen and progesterone) can be observed. Examples of such changes include bilateral alopecia, vulvar enlargement, vaginal bleeding, pyometra, and endometrial hyperplasia. Granulosa cell tumors rarely produce enough sex hormone to cause bone marrow aplasia, but rare examples of sepsis or bleeding secondary to neutropenia and thrombocytopenia have been reported.

Diagnosis

Although the metastatic rate for ovarian tumors is relatively low, it is still recommended that thorough staging is performed including complete blood count, biochemistry, three-view thoracic radiographs, and abdominal ultrasound. An ultrasound is especially important to help evaluate for local metastasis to regional lymph nodes, surrounding organs, and peritoneum. It is not recommended that ultrasound-guided cytology/biopsy be performed. If the tumor is malignant, seeding or translocation of the tumor cells can occur. If histopathology cannot differentiate tumor type, the use of immunohistochemistry may be helpful. HBME-1 (and cytokeratin 7) and inhibin-alpha are useful markers to confirm epithelial and sex cord stromal tumor origin, respectively.

Many dogs with metastatic ovarian carcinoma can present with secondary ascites. One study found that the overall accuracy of using cytology to differentiate ovarian carcinoma effusions from other types is approximately 95%.

Therapy

A complete ovariohysterectomy is the treatment of choice for dogs with ovarian tumors that have no evidence of metastasis and typically results in a cure. There are limited reports of dogs with metastatic tumors. In one report, a dog was treated with cisplatin 50 mg/m^2 intraperitoneally for ovarian carcinomatosis, resulting in long-term control. In humans, platinum drugs, taxanes, and monoclonal antibodies are considered first-line therapies. Based on human research and success with chemotherapy, platinum agents should be considered for metastatic ovarian tumors. In a recent study, cyclooxygenase 2 (COX-2) was found to play a potential role in carcinogenesis and was expressed in 81% of canine ovarian carcinomas. Therefore, the use of NSAID therapy, similar to what has been found in other urogenital tumors, should be considered for ovarian carcinomas.

Prognosis

The prognosis is excellent for solitary ovarian tumors that are completely excised with no evidence of metastasis. If metastatic disease is present, the prognosis is guarded to poor, depending on the response to chemotherapy. The use of platinum drugs and COX-2 inhibitors is recommended.

Treatment and prognosis are similar in cats. Surgery is the treatment of choice, and if metastatic disease is present, carboplatin (intravenous or intraperitoneal) and/or COX-2 inhibitors are recommended.

Mammary Cancer

Julie Bulman-Fleming, DVM, DACVIM (Oncology)

Veterinary Cancer Group, Tustin, CA, USA

Canine Mammary Cancer

Etiology/Pathophysiology

Mammary tumors occur most commonly in intact female dogs and in female dogs spayed later in life. Hormone exposure, primarily during development of the mammary glands, is the most significant risk factor. Increasing age and breed are also consistently reported risk factors. Obesity at 9–12 months of age and diets high in red meat have also been associated with increased risk of tumor development. These factors may influence the level of estrogen and progestin in the body or augment the effect of these hormones on mammary tissue.

Estrogens and progestins stimulate growth and development of mammary tissue and may contribute to tumorigenesis through direct growth factor activity. Secondary increases in growth hormone and insulin-like growth factor 1 may also contribute. In humans, estrogen and progestin also increase DNA and chromosomal damage.

Early ovariohysterectomy is protective against mammary tumor development. Dogs spayed before their first estrus have 0.5% lifetime risk. Dogs spayed before the second estrus have 8% risk and those spayed before the third estrus 26% risk. The benefit of ovariohysterectomy beyond the third heat appears slight, if any, though ovariohysterectomy once a mammary mass has been diagnosed may be of some benefit. The age of first pregnancy and parity does not appear to influence tumor development. Exposure to exogenous progestins and estrogens increases the risk, and has also been linked to tumor development at younger age. Hormone exposure was confirmed or suspected in most male dogs diagnosed with mammary tumors.

The entire mammary chain is exposed to the same hormones and growth factors, which is known as field effect carcinogenesis. As such, dogs are at risk for multiple mammary masses. Up to 66% of dogs have more than one mass. There is histologic and chronologic evidence that mammary masses may progress through benign, *in situ*, and noninvasive stages before developing into invasive carcinoma. Estrogen and progesterone receptor levels appear to decrease as tumors become larger, less differentiated, and more invasive.

Epidemiology

Mammary gland tumors are the most common tumors in intact females, though the overall incidence depends on the population in question. The lifetime risk of intact female dogs has been reported to be as high as 26%. The incidence in North America is lower than many other regions due to the more common practice of early ovariohysterectomy. Evaluation of several European registries showed that mammary tumors account for 50–70% of tumors in intact female dogs. Approximately 1% of mammary tumors occur in males.

Signalment

Mammary masses occur most frequently in older female dogs. The risk increases with age from 7 to 13 years, and dogs with malignant masses tend to be older than those with benign tumors. Increased risk is reported for poodles, Chihuahuas, dachshunds, Yorkshire terriers, Maltese, cocker spaniels, English springer spaniels, Brittany spaniels, German shepherd dogs, German shorthair pointers, English setters, and Doberman pinschers.

History and Clinical Signs

Most dogs with mammary tumors are otherwise healthy. Dogs usually present for a palpable mass or a mammary mass may be an incidental finding. Careful palpation of the other glands, inguinal and axillary

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

nodes is imperative. Some studies have found that the two caudal mammary glands are more commonly affected.

Inflammatory mammary carcinomas account for approximately 8% of mammary masses. Dogs are often systemically ill, with painful, edematous mammary glands. Dogs may also be inappetent, lethargic, and febrile. Inflammatory mammary carcinomas may be misdiagnosed as mastitis, severe dermatitis or vasculitis.

Diagnosis

Evaluation of the mammary chain should be part of a routine examination. The size, mobility, and appearance may increase suspicion for malignancy. A minimum database, including complete blood count, chemistry profile, urinalysis, and thoracic radiographs, should be completed. An abdominal ultrasound to assess visceral lymph nodes is indicated and regional lymph nodes should be aspirated when possible. The lymphatic drainage is unpredictable, but axillary, sternal, and inguinal lymph nodes should be assessed.

Tumor stage has important prognostic and treatment implications, and most clinicians use a modified five-tier World Health Organization (WHO) tumor, node, metastasis (TNM) staging scheme (Table 149.1). The original WHO staging scheme has four stages. Tumor size has been found to be prognostic, and so this delineates the first three stages. The presence of lymph node metastases determines stage 4 disease regardless of tumor size, and dogs with distant metastases have stage 5 disease.

Surgical resection and histopathology provide a definitive diagnosis in most cases. Cytology can be performed if presurgical diagnosis is desired. Cytology has been reported to be 67.5–93% accurate at differentiating benign from malignant masses, with sensitivity of 86–96% and 88–100% specificity for malignancy. Cytologic diagnosis of malignancy also correlated well with survival.

Table 149.1 Canine mammary tumor staging. Modified World Health Organization Tumor, Node, Metastasis (TNM) staging scheme

Stage	Tumor size	Lymph node metastasis	Distant metastasis
1	T1 (T <3 cm)	N0 (none)	M0 (none)
2	T2 (T 3–5 cm)	N0 (none)	M0 (none)
3	T3 (T >5 cm)	N0 (none)	M0 (none)
4	Any T	N1 (positive)	M0 (none)
5	Any T	Any N	M1 (positive)

Forty to fifty percent of canine mammary masses are benign. Both benign and malignant tumors may be simple or complex. Simple tumors are composed of only one cell type whereas complex masses have both luminal and myoepithelial components. In complex carcinomas, the epithelial cells are neoplastic while the myoepithelium is benign.

The most common benign masses include ductal ectasia, lobular and fibroepithelial hyperplasia, adenomatous masses, and benign mixed tumors. Most malignant tumors are carcinomas. Simple mammary carcinomas are most often tubular, tubulopapillary, cystic, papillary, cribriform or solid. Mucinous carcinoma, squamous cell carcinoma, and malignant mixed tumors are less common. A histopathologic grading system for mammary carcinomas exists, and has been found to be prognostic in several studies. Criteria include the extent of tubule formation, nuclear pleomorphism, and mitotic rate. Mammary sarcomas are also reported, with extraskeletal osteosarcoma being most common.

Therapy

Surgery is an integral part of therapy for mammary tumors, with the exception of inflammatory carcinomas and those with widespread metastases. In dogs, it is unclear whether the extent of surgery is prognostic. Most studies suggest that for a single mass, the outcome is the same for mass resection and radical mastectomy as long as excision is complete. However, given the prevalence of multiple tumors, unilateral radical mastectomy has also been advocated. In a 2008 study, 58% of dogs developed a second tumor which would have been prevented by unilateral mastectomy. However, in the same study, had all dogs received unilateral mastectomies, 42% would have had unnecessarily aggressive surgeries. If multiple mammary masses are present, a regional, unilateral or staged bilateral mastectomy is indicated.

One study found that ovariohysterectomy at the time of mass resection or within two years of developing mammary carcinoma improved two-year survival. This may be because tumors in intact females retain some hormone responsiveness. Hormone therapy with agents like tamoxifen (estrogen receptor blocker) is not commonplace, in part because of the ease of sterilization and also because of the significant risk of pyometra in intact females. If the dog is to be spayed at the time of mass removal, ovariohysterectomy should be performed first to avoid tumor seeding.

For large, high-grade, or metastatic tumors, surgery alone is unlikely to be curative. However, the role of chemotherapy for canine mammary carcinoma is unclear. Adequately powered, randomized, controlled trials are lacking. Chemotherapy is often recommended

for masses larger than 3 cm in diameter, when aggressive behavior is predicted histologically, or when metastasis is present. It is also advised for mammary sarcomas.

In a small, nonrandomized clinical trial, adjuvant 5-fluorouracil and cyclophosphamide improved survival. After two years, the median survival time of treated dogs was not reached compared to six-month median survival for those treated with surgery only. A 2012 study evaluating carboplatin alone and in combination with nonsteroidal antiinflammatory agents postoperatively also found significant benefit. A benefit for doxorubicin, docetaxol, and gemcitabine has not been shown. Simon *et al.* (2006) showed a trend towards increased local control and improved survival when doxorubicin or docetaxol was administered postoperatively but the results did not reach statistical significance. Larger, randomized, controlled studies are needed to better evaluate the role of chemotherapy and the most effective agents.

Prognosis

The most significant prognostic factors are tumor size, stage, and histologic grade. Several studies have found that tumors less than 3 cm carry the best prognosis, while others have shown that tumors up to 5 cm carry a similar prognosis. The median survival time for dogs with stage 1 and 2 disease exceeds two years in most studies. One study found that tumor size in the absence of lymph node metastasis was not prognostic. However, 86% of dogs with lymph node metastases had primary tumors larger than 5 cm. Dogs with lymph node and distant metastases generally survive less than six months when treated with surgery alone.

Inflammatory carcinomas and sarcomas carry a poor prognosis. The reported survival time of dogs with inflammatory carcinomas is 25–30 days. The prevalence of metastases is extremely variable between studies, with 8–100% metastases reported at diagnosis. A recent study found improved survival of 183 days when dogs with inflammatory mammary carcinomas were treated with piroxicam.

Feline Mammary Cancer

Etiology/Pathophysiology

Exposure to estrogen and progesterone during mammary development plays the most significant role in tumor development. As in dogs, estrogen and progesterone serve as trophic factors for mammary tissue. Cats spayed before 6 months of age have 91% reduced risk, those spayed before 12 months 86% reduced risk and those spayed between 12 and 24 months have 11% reduction in risk. Ovariohysterectomy later in life has not been found protective. Exposure to exogenous progestins is also associated with increased risk. Female cats exposed to exogenous hormones have 3.4 times the risk of unexposed cats. Over one-third of affected male cats had a known history of progestin exposure. Benign changes are commonly associated with pregnancy, pseudopregnancy, and progestin administration.

Epidemiology

Mammary tumors are the third most common tumor type in female cats, accounting for 12–25% of tumors in female cats in North America. In Europe, the incidence has been reported to be 25–40%. The three main risk factors are hormone exposure, age, and breed, with intact females having seven times the risk of spayed female cats. Eighty to ninety-five percent of feline mammary masses are malignant.

Signalment

Mammary tumors most commonly affect intact females and those spayed as adults. The risk of developing mammary tumors increases from 6 to 14 years of age, with peak incidence at 10–12 years. Male cats account for 1–5% of malignant masses. Siamese cats are at increased risk and also tend to be younger when diagnosed.

History and Clinical Signs

Most cats with mammary tumors present for a palpable mass within the mammary chain and are otherwise healthy. Large, adherent or ulcerated masses may be painful. The caudal glands have been reported to be affected more often although some studies have shown equal occurrence. Multiple masses occur in up to 60% of cats. Inflammatory mammary carcinomas are rare in cats but present with systemic signs and edematous, painful mammae as in the dog.

Diagnosis

As most feline mammary tumors are malignant, initial diagnostic tests should include thorough screening for metastatic disease. This includes a complete blood count, chemistry profile, serum thyroxine level, urinalysis, thoracic radiographs, and abdominal ultrasound. Regional lymph nodes should be aspirated when possible. Lymphatic drainage is unpredictable and so axillary, sternal, and inguinal nodes should be assessed. Cytology may be helpful to rule out cutaneous or lymphoid tumors.

Benign masses do occur in cats, accounting for 10–20% of masses. The most common benign diseases are fibroadenomas, mammary duct ectasia, and fibroadenomatous hyperplasia. Fibroadenomatous hyperplasia usually occurs in young females during pregnancy or pseudopregnancy but can be seen in male or altered cats due to exogenous progestins.

Tubular, papillary, tubulopapillary, cribriform, and solid carcinomas are the most common malignancies. Sixty percent of mammary carcinomas are deemed moderately differentiated, 27.3% are poorly differentiated, and only 12.7% are well differentiated. Feline mammary sarcomas and inflammatory carcinomas have been rarely reported. Metastatic disease occurs in 50–90% of cats, with up to 83% showing lymph node or pulmonary metastasis. Visceral metastasis and carcinomatosis also occur.

Tumor stage has been found to be prognostic. The most commonly used system is a modified WHO four-stage system (Table 149.2). The original staging system was also four tier but criteria included whether a metastatic lymph node was fixed or mobile, which has not been found prognostic.

Therapy

For most solitary tumors, a unilateral radical mastectomy is recommended. For multiple tumors involving both mammary chains, staged bilateral radical mastectomies should be performed. Unlike in dogs, the extent of surgery is prognostic, with cats undergoing radical mastectomies having longer disease-free intervals. One study found a trend towards increased survival, but a more recent report did not show survival advantage. Most mammary carcinomas are estrogen and progesterone receptor negative and so the role of concurrent ovariohysterectomy is unclear. For benign masses, ovariohysterectomy or withdrawal of exogenous hormones can induce regression.

Table 149.2 Feline mammary tumor staging. Modified World Health Organization Tumor, Node, Metastasis (TNM) staging scheme

Stage	Tumor size	Lymph node metastasis	Distant metastasis
1	T1 (T <2 cm)	N0 (none)	M0 (none)
2	T2 (T 2–3 cm)	N0 (none)	M0 (none)
3	T3 (T >3 cm)	Any N	M0 (none)
	Any T	N1 (positive)	M0 (none)
4	Any T	Any N	M1 (positive)

While surgery alone can result in long-term survival for cats with stage 1 or 2 disease, the median survival for cats with more advanced stages is 4–6 months. The benefit of chemotherapy is unproven but is advocated by most clinicians for cats with negative prognostic factors. The use of doxorubicin and cyclophosphamide in the setting of gross disease has been associated with a 45–50% overall response rate. Two studies, which lacked control groups, found no overall benefit to postoperative doxorubicin therapy, but did report survival times for cats with stage 3 tumors which were longer than historical controls. In these reports, cats with stage 3 tumors survived a median of 448 and 460 days. McNeill *et al.* (2009) did not find a benefit of adjuvant doxorubicin chemotherapy over surgery alone. Within the population of cats in the study, 47% had stage 1 tumors which are expected to have long-term survival with or without chemotherapy. The authors comment that the study had 12% power to detect a difference between the groups. Most clinicians advocate chemotherapy for cats with tumors greater than 3 cm diameter, lymphatic invasion or lymph node metastasis.

Prognosis

Median survival time is well correlated with tumor size and stage. Reported survival times for cats with tumors less than 2 cm range from 12 to 54 months. The median survival times for cats with stage 2 disease range between 9-24 months. Cats with tumors larger than 3 cm or more advanced disease survive a median of 4–6 months when treated with surgery only. As noted above, the addition of chemotherapy may improve the outcome for these cats, but clear benefit has not yet been shown.

One study showed that tumor differentiation was also prognostic, with 100% of cats with well-differentiated tumors being alive at one year, 57% with moderately differentiated tumors alive at one year, and no cats with poorly differentiated tumors surviving to one year. As most cats have moderately differentiated tumors, the prognostic benefit of this information is limited. Age, breed, percent necrosis, completeness of surgical excision, proliferative indices, and hormone receptor status may also be prognostic.

Tumors of Bone and Joint

Stephanie L. Shaver, DVM, DACVS[1], William T.N. Culp, VMD, DACVS[1], and Robert B. Rebhun, DVM, PhD, DACVIM (Oncology)[2]

[1] *School of Veterinary Medicine, University of California, Davis, Davis, CA, USA*
[2] *Department of Surgical and Radiological Sciences, University of California, Davis, Davis, CA, USA*

Etiology/Pathophysiology

Primary tumors of bone are most commonly diagnosed in the appendicular skeleton, with osteosarcoma (OSA) being the most common tumor type. Other neoplasms, such as chondrosarcoma (CSA), fibrosarcoma (FSA), hemangiosarcoma (HSA), and histiocytic sarcoma, are less frequently identified. The metaphyseal region of long bones is the typical location for appendicular OSA, with the distal radius and proximal humerus being the two most common sites. The proximal tibia and distal femur may also be affected, with proximal femur, distal tibia, distal humerus, and ulna being less common sites.

While many possible contributing factors have been suggested, the precise etiology of OSA remains unknown. Suspected risk factors include previous radiation therapy, fracture, and metal surgical implants. There is also some evidence that the timing of spay/neuter may affect the incidence of OSA, but a clear causal effect has not been demonstrated.

Osteosarcoma is characterized by proliferation of endosteal cells, which results in the tumor arising within the medullary canal. This is responsible for the typical radiographic appearance of bony lysis and periosteal reaction. Two less common OSA variants, periosteal and parosteal, exist. Periosteal OSA arises from cortical bone but may invade the medullary canal; in contrast, parosteal OSA is characterized by the development of tumor external to the cortex, which does not invade into deeper structures. While extremely rare, parosteal OSA likely represents a less aggressive form of OSA.

Other neoplastic processes that can affect bone include hematopoietic tumors (such as lymphoma, histiocytic sarcoma, or multiple myeloma) and metastasis from a solid tumor. Primary bone tumors such as osteosarcoma often metastasize to other bony sites; however, metastatic bony lesions secondary to other cancers are also common. Many carcinomas, particularly those arising from the urogenital tract, often demonstrate a propensity for bony metastasis. While not absolute, metastases are commonly found in the diaphysis, whereas primary bone tumors generally occupy the metaphyseal region.

Axial skeletal neoplasia may be caused by any of the sarcoma types that affect the appendicular skeleton. OSA remains the most common tumor in axial locations as well, although it only accounts for about 25% of all cases of axial skeletal neoplasia. The mandible and maxilla are the sites most often affected, but other bones of the skull, the scapula, ribs, sternum, vertebrae, and pelvis may also be affected. Multilobular osteochondrosarcoma (MLO, also known as multilobular tumor of bone) typically affects the flat bones of the skull and is a slow-growing, locally invasive tumor. The metastatic propensity of MLO is largely dependent upon grade. In general, mortality from axial skeletal neoplasia occurs from local disease rather than metastasis, likely due to the challenging nature of surgical resection in these areas. Mandibular OSA appears to have a better prognosis than OSA in appendicular or other axial locations. Improved prognosis may result from less aggressive biologic behavior when compared with appendicular sites and from the relative ease of complete surgical excision compared with other axial sites.

Synovial cell sarcoma has been reported to be the most common canine joint tumor; however, other reports also describe a high incidence of histiocytic sarcoma affecting synovial surfaces. These tumors most commonly affect large joints of the appendicular skeleton (e.g., stifle, elbow), and have biologic behavior similar to these tumor types in other locations. Suspicion of a joint tumor

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

should be high for bony lesions where more than one articular surface is involved.

Epidemiology

Large- and giant-breed dogs are most often affected with appendicular OSA, and a genetic component to the disease has long been suspected based on observed breed predilections. It should be noted that while small-breed dogs have a lower likelihood of developing OSA, they are more likely to develop axial OSA than their large-breed counterparts.

Skeletal neoplasia is much less common in the cat, where it is infrequently reported. OSA is the most common bone tumor in cats and, while locally invasive, carries a better prognosis than canine OSA due to the overall lower incidence of metastasis and a protracted course of disease in cats that do develop metastases. Like dogs, appendicular OSA in cats occurs more frequently than axial, but axial OSA is relatively more common compared to the distribution in dogs.

Signalment

Tumors of bone and joints typically affect dogs and cats that are middle aged to older. A bimodal age distribution, however, has been documented for canine OSA, with two specific peaks at 1–2 years and 7–9 years of age. Although the vast majority of dogs with OSA fall within the older group, a young age should not preclude consideration of OSA as a diagnosis.

Large-breed dogs are overrepresented, with breeds such as the Great Dane, Rottweiler, golden retriever, German shepherd, greyhound, Saint Bernard, Irish wolfhound, Scottish deerhound, borzoi, and Doberman pinscher commonly diagnosed with bone tumors. No important sex predilection between male and female dogs exists, but neutered animals are potentially at greater risk.

History and Clinical Signs

Dogs with appendicular bone or joint tumors typically present for evaluation of lameness or swelling of a limb. In many cases, the history may be that of a chronic, progressive lameness that has only been partially responsive to analgesics. An animal may also present with an acute onset of severe, nonweight-bearing lameness, sometimes due to pathologic fracture. It is not uncommon for owners to associate the acute onset with a nontraumatic event such as running, jumping, etc. Axial lesions may go longer without detection, but animals are often evaluated for swelling or mass lesions. Site-specific signs can occur depending on the tumor location and systemic signs such as lethargy or inappetence may occur from paraneoplastic syndromes or simply result from pain associated with the primary or metastatic tumors.

Diagnosis

A complete physical examination should be performed in all cases. Variable degrees of swelling, pain, and instability may be associated with the primary tumor. Each patient should also be carefully assessed for any evidence of metastasis, either to bone or to local lymph nodes. Complete orthopedic and neurologic examinations should be performed, particularly in cases of appendicular neoplasia where amputation may be considered as the surgical treatment of choice. The presence of orthopedic or neurologic co-morbidities does not preclude amputation, but knowledge of these is essential for planning and owner education.

Routine laboratory evaluation by means of complete blood count, chemistry panel, and urinalysis should be performed. These tests serve to evaluate the patient's systemic health prior to anesthesia, surgery, and chemotherapy. In addition, elevated total alkaline phosphatase (ALP) has been shown to be associated with a worse prognosis in canine OSA.

The first step in attaining a bone tumor diagnosis is orthogonal view radiographs of the affected limb or region. OSA has a characteristic mixed osteolytic and osteoproductive appearance, which when combined with a metaphyseal location is highly suggestive of this disease entity (Figure 150.1). As previously mentioned, particular sites are more common for OSA, are often described by the phrase "away from the elbow, towards the knee," with the thoracic limb being more commonly affected. OSA does not generally cross an articular surface; this trait is more characteristic of a primary joint tumor, or fungal or bacterial osteomyelitis. Metastatic lesions are often diaphyseal and predominantly lytic, although a spectrum of lytic versus productive disease is possible with OSA. When radiographs demonstrate an uncharacteristic lesion, other diagnostics, such as culture and biopsy, can be performed to obtain a definitive diagnosis. Radiographs may also be evaluated for the presence or absence of pathologic fracture.

Although classic radiographic findings may be sufficient to proceed with surgical treatment, many cases may benefit from presurgical confirmation of neoplasia and/or tumor type, particularly in patients that live or have a travel history to fungal endemic areas. Ultrasound-guided fine needle aspiration and cytologic evaluation is a relatively noninvasive means of obtaining a diagnosis of

Figure 150.1 Orthogonal view radiographs (cranial-caudal (a), lateral (b)) of the right radius and ulna. An expansile and lytic lesion of the distal radial metaphysis is identified with associated soft tissue swelling. Cytologic aspirate of this lesion was consistent with osteosarcoma.

neoplasia, although differentiation between types of cancer is often not possible with cytology alone. ALP staining of cytologic samples may allow for more conclusive identification of OSA in some cases. When indicated or desired, bone biopsy can be performed which typically results in a specific tumor diagnosis in about 80% of cases.

Bone biopsy may be performed using an incisional technique, Michele trephine, or Jamshidi needle. Jamshidi needles yield a smaller biopsy but provide a diagnosis in the vast majority of cases. Bone biopsies should be planned in order to minimize the size of the surgical site and provide for appropriate tumor excision at the time of definitive surgery. Samples should always be taken from the center of the lesion, as a peripheral biopsy is more likely to yield reactive bone rather than the true disease process. In addition to using the smallest sampling tool thought likely to provide a diagnostic sample, it is also recommended to avoid penetration of both cortices to minimize the likelihood of pathologic fracture.

While micrometastatic disease is thought to be present in nearly all dogs diagnosed with appendicular OSA, gross metastasis is only identified in about 10% of cases at the time of initial diagnosis. Pulmonary and bony metastases occur with approximately equal frequency at the time of initial diagnosis, although metastasis to other locations is possible.

Staging of patients is performed due to its relevance in estimating survival time. Little distinction is made in osteosarcoma regarding histologic grade due to the biologic aggressiveness of these tumors in nearly all cases; however, the presence of gross metastasis (stage III disease) is associated with shorter survival times. Median survival times (MST) in dogs with stage III appendicular OSA are still highly variable, however, and are affected by treatment provided. Grading of non-OSA sarcomas is generally thought to be associated with prognosis, with grade III tumors much more likely to metastasize and associated with a shorter survival time.

Staging in all cases should include three-view thoracic radiographs to evaluate for pulmonary metastasis. Abdominal ultrasound may also be performed to check for metastatic disease, particularly in cases with pelvic limb neoplasia, lymphadenopathy, atypical presentation/clinical findings, or in patients with histiocytic disease. Similarly, lymph node aspirates should be performed when lymphadenopathy is noted on physical examination or imaging studies or if the regional lymph node is readily accessible.

Nuclear scintigraphy, performed with an intravenous injection of technetium-99m, allows for identification of skeletal abnormalities with increased metabolic, particularly osteoblastic, activity. This diagnostic tool is highly sensitive but lacks specificity; areas of increased uptake may be due to neoplastic disease, infection, fracture, or other orthopedic co-morbidities. The input of an experienced radiologist, as well as follow-up radiographs to evaluate abnormal areas, can help to distinguish between these differentials.

Computed tomography (CT) is being increasingly used, both to evaluate for thoracic metastases and for evaluation of the local tumor site. While traditional, high-quality radiography is able to detect pulmonary metastases that are approximately 7–9 mm in size, CT has a reported sensitivity for detection of lesions as small as 1 mm. Despite this improved detection of disease, the clinical relevance of smaller metastatic lesions with regard to survival times is uncertain.

Assessment of the local tumor site in appendicular OSA with CT is generally nonessential when the chosen treatment is amputation. CT may help to evaluate the extent of disease if alternative surgical treatments such as limb-sparing surgery are to be considered. In addition, CT is often highly valuable for surgical planning in cases

of proximal appendicular tumors or disease affecting the axial skeleton. Magnetic resonance imaging (MRI) is generally less useful than CT for imaging bone, making CT the imaging modality of choice in most cases. MRI may be useful, however, in evaluating the local extent of disease prior to limb-sparing surgery, or to assess the proximity of neoplasia to neurovascular structures.

Therapy

Surgical margins around bone and joint tumors generally fall into the categories of wide or radical excision. Wide excision is defined as complete removal of disease with a margin of normal tissue, and radical excision includes the excision of a body part, such as limb amputation for cases of appendicular neoplasia. Limb amputation followed by chemotherapy is the recommended treatment for appendicular OSA, and amputation is often indicated for CSA, FSA, HSA, and for excision of other appendicular tumors in which local excision with adequate margins is not possible (Table 150.1). The decision to pursue limb amputation is typically difficult for owners to make; however, these dogs generally recover well from surgery and owner satisfaction is quite high. Videos of amputee dogs can sometimes be helpful to owners and are now commonly posted for public viewing on numerous websites. Dogs that are obese or have concurrent musculoskeletal or neurologic disease may have a prolonged recovery compared to the average patient and may benefit from physical rehabilitation after surgery.

Tumors of the thoracic limb are preferably treated by forequarter amputation. Forequarter amputation including excision of the scapula is preferred due to the ease of the surgical procedure, the likelihood of wide margins around disease, and improved cosmetic appearance when the scapula is removed, as muscle atrophy over this bone can be unsightly. Tumors of the scapula may be treated by partial or total scapulectomy with preservation of the limb; however, CT is recommended in these cases to ensure adequate margins around the extent of disease. Tumors of the ulna alone may be treated by ulnectomy; CT is again recommended to evaluate local disease for surgical planning.

Pelvic limb tumors are most commonly treated with coxofemoral disarticulation; similarly, this surgical technique is generally preferred over a midshaft femoral amputation due to ease of technique and wider surgical margins. Tumors of the proximal femur may be treated by *en bloc* excision of the acetabulum in addition to amputation or hemipelvectomy. Pelvic tumors can also be treated by partial or total hemipelvectomy. When performing hemipelvectomy, a detailed knowledge of anatomy is important to avoid trauma to intrapelvic structures such as the rectum and urethra. Preoperative CT scan is indicated before hemipelvectomy, and if incomplete or narrow surgical margins are likely, consultation with a radiation oncologist prior to surgery is strongly recommended.

Recovery after amputation surgery is generally rapid, with most dogs ambulating within a few days of surgery. Perioperative analgesia is essential, and may be provided with a wound soaker catheter or with systemically administered medications. Recovery after hemipelvectomy surgery is similar to amputation. Complications of these surgeries include seroma formation and, less commonly dehiscence, hemorrhage, and infection.

Limb-sparing surgery is described for appendicular bone tumors, but appropriate case selection and client education are essential. Limb-spare may be indicated for cases in which the dog is unable to tolerate amputation due to orthopedic or neurologic co-morbidities, or when owners have declined amputation. In general, limb-sparing surgery is considered only for tumors of the

Table 150.1 Treatment options for canine appendicular osteosarcoma

Treatment type	Effectiveness	Other considerations
Amputation + chemotherapy	Gold standard; MST ~1 year	Amputation generally well tolerated
Limb-spare (SRS/SBRT or surgical) + chemotherapy	Comparably effective to amputation + chemotherapy; infection associated with limb spare surgery improves survival	Limited availability due to highly trained personnel required and availability of SRS equipment
Amputation alone	MST <6 months	Death due to progression of metastatic disease
Palliative radiation	Pain relief for 2–3 months	>50% response rate
Aminobisphosphonates (often recommended in conjunction with radiation)	Four months of pain relief with pamidronate in 28% of dogs	Zoledronate more effective, may be cost-prohibitive

MST, median survival time; SRS, stereotactic radiosurgery.

distal radius. The presence of a pathologic fracture is considered a relative contraindication for limb-sparing, as fracture may predispose to spread of tumor cells and subsequent local recurrence. Significant complications associated with limb-sparing surgery include infection, implant failure, and local recurrence. Infection rates associated with limb-sparing surgery are high, and have been described as ranging between 30% and 70%. This high rate of infection is likely due to a variety of factors such as impaired vascular supply, minimal soft tissue coverage, implants, and subsequent delivery of chemotherapeutics. Infection, however, has been associated with a prolonged survival time compared to dogs that do not experience infection; dogs with surgical site infection have been shown to have median survival times approximately twice as long (an average of 250 days longer) as dogs that did not develop postoperative infections. Several different limb-sparing options are available, but a detailed explanation of the many techniques is beyond the scope of this chapter.

Radiation therapy can also be used to treat local disease in canine OSA cases. Full course curative intent radiation therapy is not routinely pursued due to the cost, side-effects to adjacent tissue, and lack of benefit when compared with standard surgical treatment. Developing techniques such as stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT), in which 1 to 5, high dose radiation treatments are delivered to the precise tumor location are showing promise. SRS/SBRT have been shown to have comparable success in some cases when compared to traditional surgical treatment; however, they continue to have limited availability due to the need for specialized equipment and highly trained personnel.

Palliative radiation therapy may also be pursued for pain relief in cases where surgery is not possible or owners do not elect for aggressive therapy. Generally, palliative radiation therapy involves the delivery of several large doses of radiation in 2–4 fractions. Decrease in inflammation, slowing of osteolysis, and reduction in tumor size are all benefits associated with palliative radiation therapy. Over 50% of patients respond to therapy, with onset of pain relief in 1–2 weeks and improvement lasting approximately 2–3 months on average.

While it is reported that only approximately 10% of dogs will have documented metastasis at the time of diagnosis, it should be noted that this number originates from dogs presenting to referral hospitals. It is therefore possible that the incidence in primary care veterinary clinics could be higher since thoracic radiographs are often performed at the time of diagnosis, and referrals are probably less likely in dogs that have detectable metastases. Even though 90% of dogs will have no detectable pulmonary metastasis, with rare exceptions, appendicular OSA in the dog is assumed to be metastatic at the time of diagnosis. The extremely high likelihood of microscopic metastases is supported by studies evaluating survival of dogs undergoing amputation alone. In dogs with OSA that receive amputation alone, the one- and two-year survival rates are only 11.5% and 2% respectively. Systemic therapy to control the outgrowth of micrometastasis is therefore recommended.

Many chemotherapy drugs and combination protocols have been attempted, but a clear benefit of any one particular protocol has not been clearly documented; preferred protocols often vary by doctor or institution. In general, chemotherapy with single-agent carboplatin, doxorubicin or alternating carboplatin and doxorubicin seems currently most favored and generally results in median survival times of 8–12 months. In the authors' opinion, the literature does not provide convincing evidence that any protocol is superior to single-agent therapy with carboplatin. Combined with the fact that carboplatin is generally well tolerated and is not associated with cardiotoxicity, the authors routinely recommend single-agent carboplatin. Additional prospective studies are needed to determine whether either of these protocols is superior and to determine the optimal number of doses. Cisplatin has shown significant efficacy and is considered standard of care for human osteosarcoma, but technical aspects and toxicity associated with administration coupled with the potential for renal toxicity have made this protocol less often utilized in veterinary patients. The administration of chemotherapy in the face of gross metastasis is generally unrewarding, with median survival times most often ranging from 30 to 90 days. Preliminary data support further studies to examine the potential of toceranib phosphate (Palladia™) to slow disease progression but no definitive conclusions can be made to date.

Multiple immunotherapy agents have shown some efficacy either alone or in combination with chemotherapy. These include liposomal muramyl tripeptide phosphatidyl ethanolamine (LMTPPE) and various delivery methods of interleukin (IL)-2. However, these agents are not commercially available and therefore are not routinely used.

Aminobisphosphonates (ABPs) are a group of synthetic analogs of organic pyrophosphate which possesses multiple potential benefits for patients with bone tumors or bony metastasis. Generally, this class of drugs is considered palliative in that they can induce apoptosis of osteoclasts (inhibiting bone osteolysis), reduce pain, improve quality of life, and may delay progression of bony metastasis. In addition, *in vitro* studies have found that this class also exhibits direct cytotoxic effects on osteosarcoma cell lines. While oral ABP formulations are available, this route of administration does not reach

levels believed to be required for the beneficial effects of ABPs against neoplastic bony lesions. Pamidronate is the most commonly used ABP in veterinary medicine as it is the most reasonably priced. Infusions of pamidronate were shown to be well tolerated in dogs and resulted in increased tumor bone mineral density and pain reduction for four months in 28% of dogs with osteosarcoma. When used in combination with palliative radiation therapy, pamidronate also appeared to improve limb function when compared with radiation therapy alone. Another ABP, zoledronate, is much more expensive at this time; zoledronate appears superior to pamidronate in that 50% of dogs achieved pain alleviation for greater than four months in one study.

Prognosis

For dogs with appendicular osteosarcoma that are treated with amputation alone, the MST is less than six months. Amputation followed with chemotherapy significantly improves prognosis, with MST approximately twice as long and between 25% and 62% of dogs alive at one year. Longer survival times are associated with periosteal or parosteal OSA, small stature, and dogs developing surgical site infections after a limb-sparing surgery. Negative prognostic indicators include elevated serum ALP, dogs developing OSA when they are less than 5 years old, metastatic disease (bone, lymph node or lung), increased tumor necrosis, proximal humeral location, and larger tumor size. Amputation for cats with appendicular osteosarcoma is often curative, although metastasis can occur.

Chondrosarcoma has better survival times compared to OSA, with histologic grade the most important prognostic factor. After amputation alone, dogs with grade I CSA had a MST of six years, grade II MST approximately half as long, and grade III CSA only associated with a MST of 0.9 years. Metastatic rate was similarly dependent upon grade, with 0%, 31%, and 50% of grade I, II, and III dogs developing pulmonary metastasis. Prognosis for appendicular HSA is less favorable than other diseases, due to the extremely high metastatic potential.

Variable prognoses have been described for axial OSA based on location and type of treatment. Overall, small dogs have a more favorable prognosis than large dogs, irrespective of location. Mandibular OSA has a better prognosis than other locations; when complete surgical margins are achieved after surgical excision, a 70% one-year survival rate is reported. Negative prognostic indicators include incomplete surgical resection, larger dogs, elevated ALP, and large tumors. Maxillary OSA has a reported MST of approximately five months.

As with appendicular tumors, CSA of the axial skeleton has a significantly better prognosis than OSA. Nasal CSA has a low metastatic rate and reported MST of 210–580 days. Rib CSA treated with surgical excision has a MST of 1080 days. Grade, location, and completeness of surgical excision have all been noted as possible prognostic indicators; however, only small case numbers have been evaluated. Similarly, MLO has moderate metastatic potential but improved overall survival times when compared to OSA. Mandibular location, low histologic grade, and complete surgical excision were positive prognostic factors. MST after surgery ranges from 630 to 797 days, with median time to metastasis between 420 and 542 days.

Prognosis associated with joint tumors is variable depending on type of tumor and whether complete excision is possible. Synovial cell sarcomas treated with complete excision may have a MST of greater than two years with surgery alone. Histiocytic disease typically exhibits a much more aggressive clinical course.

Soft Tissue Sarcomas

Lauren Askin Quarterman, DVM, DACVR (Radiation Oncology)

PetCure Oncology, San Jose, California

Etiology/Pathophysiology

Soft tissue sarcomas (STS) are a group of tumors that arise from mesenchymal tissues. Tumors within this group tend to have different morphologic and histologic features, but the biologic behavior is similar; therefore, they are often treated as one. Several important biologic features have been described:

- ability to arise from any anatomic site
- appear pseudoencapsulated but tend to infiltrate through and along fascial planes
- metastasize hematogenously in up to 20% cases, but regional lymph node metastasis is unusual
- local recurrence after conservative surgery is common
- gross tumors generally have a poor response to chemotherapy and radiation therapy.

Not all lesions arising from the subcutaneous space are malignant, and many are often benign or inflammatory. Though histologic distinction is not clinically important in the treatment of these tumors, the nomenclature is determined by the connective tissue (muscle, adipose, fascial, fibrous, and neurovascular) from which they arise. Tumors classified as STS include fibrosarcoma, peripheral nerve sheath tumor, myxosarcoma, liposarcoma, undifferentiated sarcoma, and malignant fibrous histiocytoma. Soft tissue tumors such as osteosarcoma, chondrosarcoma, hemangiosarcoma, rhabdomyosarcoma, histiocytic sarcoma, nerve root/brachial plexus, oral sarcomas, and synovial cell sarcoma are not classified as STS as they have a higher propensity for metastasis and/or local recurrence.

Epidemiology

Soft tissue sarcomas comprise approximately 15% of all skin and subcutaneous tumors in dogs and 7–9% in cats. In dogs, sarcomas have been associated with radiation, trauma, foreign bodies, implants, and the parasite *Spirocerca lupi*. In cats, three different types of sarcomas are seen: vaccine-associated sarcomas (also referred to as injection site sarcomas), viral-induced sarcomas, and nonviral nonvaccine sarcomas.

Vaccine-associated sarcomas have been shown to be linked to the administration of inactivated vaccines, such as feline leukemia virus (FeLV) and rabies. The development of sarcomas at sites of vaccine administration with FeLV or rabies is believed to be between 1/1000 to 1/10 000 cases. Some reports have shown an increased risk with increasing number of vaccinations and with repeated vaccination at the same site. The time to tumor development at the site of vaccination has been reported to be four weeks to 10 years but most commonly occurs between two and 10 months post vaccination. The majority of injection site sarcomas in cats arise from vaccines, but it is important to keep in mind that there have been reports of tumor development at the site of lufenuron and microchip injections. It is hypothesized that the formation of these tumors is related to inflammation created secondary to the injection. This is supported by the similar histologic appearance of injection site sarcomas to tumors arising in the eyes of cats after trauma.

Viral-induced sarcomas are rare. Typically, these multicentric tumors are seen in young cats that are positive for FeLV. FeLV can serve as a natural vector and transduce nonviral genetic elements from cat cellular DNA. This can result in the formation of a recombinant virus, termed feline sarcoma virus (FeSV), which exhibits altered oncogenicity. FeSV has been isolated from naturally occurring fibrosarcomas of FeLV-infected cats, supporting the theory that FeSV can cause the transformation of cells and induce sarcoma formation in FeLV-positive cats.

Signalment

Soft tissue sarcomas tend to occur in middle-aged to older dogs and cats. No specific breed or sex predilection has been identified but medium and large-breed dogs seem to be overrepresented.

History and Clinical Signs

Soft tissue sarcomas present as firm, fixed, often slow-growing masses most commonly affecting the trunk, extremities, or oral cavity. Many times, they are initially noted when they are small but go untreated as they are assumed to be benign. The skin overlying these tumors is often moveable. When tumors are small, they are nonpainful but as they grow, they invade into the tissues which can result in the tumor becoming fixed or ulcerated and infected. Clinical signs manifested from the tumor are dependent on the site from which it originates; for example, tumors on a limb may result in lameness.

Diagnosis

A fine needle aspirate (FNA) is always warranted on detection of any new mass or lesion. Cytology can be beneficial in helping to rule out cysts or other tumor types (mast cell tumors), but it is always important to keep in mind that cytology is not sufficient for a definitive diagnosis of a STS. These tumors do not readily exfoliate and can contain areas of inflammation and necrosis. The presence of inflammatory cells and necrosis in the absence of neoplastic cells on cytology does not rule out a STS. A study conducted on FNAs of 40 STSs reported that only 62.5% of the cases yielded an accurate diagnosis, while 15% were incorrectly diagnosed.

Biopsy and histopathology are needed for a definitive diagnosis of a STS. There are two types of tumor biopsy commonly employed: pretreatment and posttreatment biopsy. Pretreatment biopsy is the preferred method and includes needle core (Tru-Cut), wedge or incisional, and punch biopsy. All biopsies should be positioned so that the biopsy tract can be included in the curative intent treatment field. Posttreatment biopsy refers to an excisional biopsy, where the diagnosis is made after removal of the gross tumor. Often, this method is attractive to pet owners as it allows for treatment and diagnosis in one step but unfortunately, posttreatment biopsies are rarely curative. An excisional biopsy should only be performed when it is possible to take a 2–3 cm margin around the tumor and even then it may not be necessary as lesions may prove to be benign.

Once a diagnosis of STS has been made, it is important to determine the clinical stage or extent of disease. Knowledge of the clinical stage will help determine the appropriate treatment. Diagnostic tests that should be performed prior to beginning definitive treatment include three-view thoracic radiographs, as the lungs are the most common site of metastasis. Careful palpation of regional lymph nodes with FNA or biopsy if accessible and/or abnormal. Careful palpation of the mass is necessary to determine tumor size and fixation to surrounding tissues. Advanced imaging with the use of computed tomography (CT) or magnetic resonance imaging (MRI) can be helpful to evaluate the extent and invasiveness of larger tumors, tumors in the head or neck, or tumors within a body cavity.

Therapy

Dogs

Surgery

Local tumor control accomplished with wide, surgical excision is considered the treatment of choice, and advances in reconstructive techniques have significantly expanded surgical options for aggressive resection with good functional and cosmetic outcomes.

The surgical approach is classified according to the extent of the wound margins as intracapsular (when the tumor is surgically penetrated); marginal (when the tumor is excised just outside, or at, the pseudocapsule); wide (when a portion of normal tissue is left around the tumor); and radical (when an entire anatomic segment is removed, for example, amputation). The minimum recommended margins for gross surgical resection are 3 cm lateral to the tumor and one fascial plane deep. However, if the tumor is attached to the muscle or fascial layer, the entire layer may be compromised and should not be considered a clean margin. Additionally, adipose and connective tissue are not tumor barriers. Biopsy tracts and any areas of fixation to surrounding tissue require *en bloc* resection with the tumor, as these areas are considered contaminated.

Soft tissue sarcomas are typically surrounded by a pseudocapsule, which allows the tumor to be "shelled out" and submitted for histologic evaluation. Unfortunately, this type of marginal excision commonly results in tumor cells extending to the edges of the resected tissue. Any surgical procedure involving margins less than 3 cm and one fascial plane deep must be considered an incomplete excision even if no macroscopic tumor is evident after removal.

Histopathology of the tumor and surrounding tissue following surgery is important as it provides surgical

margins and tumor grade. Both are necessary in determining whether further treatment, including additional surgery or radiation therapy, is necessary. Following removal of the tumor, surgical margins should be clearly marked on the specimen and completeness of excision should be evaluated. The resected tumor should be pinned out to the original dimensions to prevent shrinkage during formalin fixation. The following terminology is commonly used when evaluating surgical margins and considering additional treatment:

- *incomplete margins* – neoplastic cells are continuous with at least one surgical margin in any plane
- *narrow margins* – distance between surgically created tissue edge and neoplastic cells is less than 5 mm
- *adequate margins* – distance between surgically created tissue edge and neoplastic cells is ≥ 5 mm and <10 mm
- *ideal margins* – distance between surgically created tissue edge and neoplastic cells is at least ≥ 10 mm.

Marginal and incomplete resection is associated with a higher risk of local recurrence (26–60%). Further, dogs with incomplete margins are 10.5 times more likely to develop local recurrence than dogs with complete margins. Studies have also shown that the first surgery provides the best opportunity for local tumor control. Subsequent surgeries increase morbidity, treatment costs, and the risk of further local recurrences, while decreasing survival time. If a second surgery is performed after inadequate resection, a margin of healthy tissue of 3 cm in all directions surrounding the scar is recommended, including the removal of normal-appearing subcutaneous fat and underlying fascia. In a study evaluating scar reexcisions, local recurrence was reported in 15% of dogs and residual tumor was identified in 22% of the resected scars.

Prior to the routine availability of radiation treatment, radical and often disfiguring surgery was the mainstay of treatment and resulted in one-year control rates of 70–80%. Although STS have historically been considered radiation resistant compared to other tumor types, the multimodality approach of combining surgery with radiation has been proven to help prevent local recurrence.

Surgery and Radiation Therapy

The sequencing of radiation and surgery is based on multiple factors and should be determined on an individual basis. There are several advantages and disadvantages to both preoperative and postoperative radiation therapy. The rationale for administering postoperative radiation therapy is that the radiation kills or prevents the multiplication of any microscopic tumor cells left behind. Some advantages of postoperative radiation include the following:

- wound complications are rare in tissues that are irradiated after the first inflammatory phase of wound healing
- removal of a larger tumor with necrotic regions or infections may make the patient and patient's family more comfortable
- postoperative treatment planning may be simpler than preoperative planning in patients in which the size or shape of a tumor creates difficulty in achieving a uniform dose distribution.

Disadvantages of postoperative radiation include increased radiation field size, damage to vasculature, that may lead to local tissue hypoxia which decreases the effectiveness of radiation, and potential delays if post-surgical wound complications occur. Postoperative radiation is generally started within 7–14 days after surgery.

The rationale behind preoperative radiation therapy is to decrease the number of tumor cells, thus reducing contamination of the surgical site. Advantages include a smaller radiation field, reduction in the size of the tumor, making surgical excision with wide margins less difficult, and undisturbed tumor bed and blood supply, which increases the effectiveness of radiation. Disadvantages include the possibility of poor or delayed wound healing in the irradiated field.

Radiation therapy is commonly used as an adjunct to surgery. Radiation seems to have the greatest efficacy when it is used to treat remaining microscopic disease following surgical cytoreduction and is less effective when used to treat bulky, gross disease. Marginal surgical resection combined with radiation therapy is an attractive alternative to limb amputation for a STS on an extremity. It can also be used following a planned marginal resection when wide surgical resection is not possible, such as with tumors of the head or neck. In these cases, removal of all grossly visible tumor is advised. Radiopaque clips are often placed during surgery to mark the lateral, proximal, and distal extent of the tumor to aid in radiation planning.

Several studies have evaluated radiation therapy for incompletely excised soft tissue sarcomas in dogs. They have shown that similar local control and survival rates are attained with a better functional and cosmetic outcome by performing marginal surgical excisions plus adjuvant radiotherapy compared to radical surgery alone. A prospective study evaluated 48 dogs with soft tissue sarcomas treated with surgery to decrease tumor size to <3 cm. This was followed by conventionally fractionated, full course radiation therapy to a total dose of 63 Gy. The result was a five-year survival rate of 76% and a recurrence rate of 16%. The median time to recurrence

was 23.3 months. Another study evaluating 35 dogs with soft tissue sarcomas that were excised to microscopic disease followed by daily radiation to a total dose of 42–57 Gy reported an overall median survival of 61.7 months.

Interestingly, a recent study evaluated intentional marginal excision of canine STS of the limb followed by a coarsely fractionated radiation protocol consisting of four, once weekly, 8–9 Gy fractions. Fifty-six dogs were included. The results compared favorably to studies using more fractionated "definitive" protocols, as the one-, two-, and three-year disease-free intervals were 82%, 74%, and 70%, respectively, with a local recurrence rate of 18%. The main disadvantages of using coarsely fractionated protocols are reduced efficacy and the increased risk of late radiation toxicity, which may be significant and include bone necrosis and radiation-induced tumors at the site. In the study, the risk of developing late radiation side-effects was low when the fraction size did not exceed 8 Gy.

Radiation Therapy

If surgical excision of a soft tissue sarcoma is impossible because of tumor location or size, radiation therapy can be applied; however, measurable and bulky tumors tend to have a poor long-term response to primary radiotherapy. Tumor control with conventional doses of radiation alone (40–48 Gy) are difficult to obtain because of their low growth fraction, relatively long doubling time, and tendency to develop hypoxic regions within the tumor parenchyma. Reported one-year control rates are 30% at 35 Gy (10 × 3.5 Gy), 35% at 40 Gy (10 × 4 Gy), 48% at 45 Gy (10 × 4.5 Gy) and 67% at 50 Gy (10 × 5 Gy). At two years, control rates vary from 12% at 40 Gy to 33% at 50 Gy.

As a single modality, radiation has generally been considered palliative for STS with control defined as a slowly regressing or stable tumor mass. The goal of palliative or coarsely fractionated radiation therapy is to alleviate pain, swelling, and inflammation associated with the tumor, in the hope of improving quality of life. Typical palliative protocols involve fewer fractions of larger radiation doses (4–10 Gy), often given on a weekly basis. The delivery of a small fraction size once per week is unlikely to lead to a durable response because tumor cells have a significant amount of time to repair damage and proliferate between treatments. Therefore, larger doses of radiation are often delivered to optimize killing of tumor cells, with the increased risk of late radiation toxicity accepted as part of the treatment. Since palliative radiation therapy is administered to improve quality of life, not to prolong it, patients likely will not live long enough to experience permanent late effects. A study evaluating nonresectable STS treated with a palliative protocol (3 × 8 Gy) reported stable disease in 87% of the tumors treated with a median time to progression of 8.7 months.

As an alternative to once weekly fractionation, a retrospective study evaluated a palliative radiation protocol consisting of 4 Gy fractions given over five consecutive days. In this study, 10 soft tissue sarcomas were treated. A measurable overall response rate of 80% was reported, with tumor control achieved in 100% of patients and a median progression-free survival of 5.7 months. With this protocol, the risk for late side-effects is about half that of the traditional 8 Gy × 4 fraction protocol.

Many advancements have been made in the field of radiation oncology, and with these advancements and improved technology, stereotactic radiation can now be used to treat STSs. Stereotactic radiation consists of high doses of radiation precisely targeted at the tumor with rapid dose fall-off outside the tumor to help spare normal tissues and limit side-effects. Stereotactic protocols generally consist of 1–3 fractions of radiation given on a consecutive-day basis. The goal of stereotactic radiation is to deliver an ablative dose of radiation to the tumor and achieve long-term control of the disease. Currently, there are no published veterinary studies on stereotactic radiation and STS, but it is expected that this will be a very viable treatment option for nonresectable STS.

Chemotherapy

Adjuvant chemotherapy at times is useful in the treatment of STS. It is best utilized when combined with radiation therapy and/or surgery. Chemotherapy alone does not seem to be effective, with the exception of providing palliation in some cases. Doxorubicin-based protocols, either alone or in combination with cyclophosphamide, have shown the most promise with an overall response rate of 23%.

Despite the fact that STS are slow to metastasize, the metastatic rate for cutaneous STS is grade dependent and varies from less than 15% (grade I and II) to 41% (grade III). Due to the higher metastatic rate of grade III soft tissue sarcomas, postoperative chemotherapy should be considered as it may prevent or delay metastasis. Single-agent doxorubicin, mitoxantrone, or combination protocols are most commonly used.

Metronomic chemotherapy (continuous administration of chemotherapy drugs at doses that are significantly lower than conventional maximally tolerated dose therapy) has been evaluated in canine STS. A retrospective study evaluated 85 dogs with incompletely resected STSs. Thirty dogs received continuous cyclophosphamide (10 mg/m^2) and standard-dose piroxicam therapy (0.3 mg/kg). Fifty-five control dogs did not receive additional therapy. When comparing these two groups, treated dogs had a disease-free interval of 13.7 months which was significantly longer compared to 7.0 months

for untreated dogs. Another study evaluated low-dose cyclophosphamide and its effects on T-regulatory cells and tumor angiogenesis in dogs with STS. This study found that dogs receiving 15 mg/m^2/day of cyclophosphamide had significant decreases in the number and percent of T-regulatory cells as well as microvessel density, further supporting that metronomic therapy may provide antitumor effects.

Cats

Surgery and Radiation Therapy

Injection-associated sarcomas are poorly encapsulated tumors with extension and infiltration along fascial planes. Surgically, 3 cm margins laterally and one fascial plane deep to tumor have been utilized for the treatment of vaccine-associated sarcoma. However, this is not adequate considering the reported high rates of local recurrence which range from 35% to 59%. In response to this, surgical margins of >3 cm laterally and two fascial planes deep to the tumor, along with partial scapulectomy, osteotomy of spinous processes or hemipelvectomy when indicated, are now recommended. Despite attempting aggressive surgical margins, complete resection is achieved in less than 50% of cats, and overall one- and two-year disease-free intervals are only 35% and 9%. A retrospective study evaluated radical excision for treatment of 91 STSs. Radical excision was defined as 5 cm of tissue beyond the palpable edges of the tumor and two fascial planes or bone deep to the tumor. With this approach, surgery resulted in complete margins in 97% of cases and a local recurrence rate of 14%.

Due to the high rate of local recurrence following wide surgical resection, full-course radiation is considered essential in the management of cats with vaccine-associated sarcomas. The timing of the radiation therapy is controversial, and there are pros and cons to preoperative versus postoperative approaches. The time to recurrence when the combination of surgery and radiation therapy is used ranges from 13.5 months to 19.5 months. In studies investigating preoperative radiation therapy, complete resection significantly improved time to local recurrence with a disease-free interval for completely excised tumors of 33 months versus 10 months for incompletely excised tumors. Unfortunately, even with combination therapy, recurrence rates still range from 40% to 45%.

Chemotherapy

The most common chemotherapy drugs used to treat vaccine-associated sarcomas are doxorubicin, carboplatin, and cyclophosphamide. Postoperative chemotherapy has been shown to have only a minimal effect on survival in cats treated with curative-intent surgery and radiation therapy. Chemotherapy, however, may have beneficial effects on local tumor control. The effect of doxorubicin alone was evaluated in 12 nonresectable vaccine-associated sarcomas. An initial reduction of >50% in tumor volume was seen in 50% of the animals. Unfortunately, the response was not durable, and all cats showed progressive disease. However, the median overall survival was significantly longer for cats that did respond. More recently, tyrosine kinase inhibitors have been shown to block the PDGF/PDGF receptor signaling pathway in vaccine-associated cell lines and to inhibit vaccine-associated growth in a murine model. These drugs are currently being evaluated for treatment of these tumors.

Prognosis

Dogs

The overall prognosis for dogs with STS is good, but the range of biologic behavior for these tumors can be broad. The median survival time for dogs ranges from 3.9 years following surgery alone to 6.2 years with surgery and adjunctive radiation. Overall, up to 33% of dogs eventually die of tumor-related causes.

Research has identified valuable prognostic information including histologic grade, mitotic index, and completeness of surgical margins. A complete histologic margin predicts nonrecurrence and recurrence appears to increase with grade. The metastatic rate for dogs with grade I or grade II is less than 15% compared to 41% for grade III STS. High mitotic index (>9 mitotic figures per 10 high-power fields) is prognostic for recurrence, metastais, and survival. Other factors, including markers of cellular proliferation, tumor dimension, tumor location, histologic type, invasiveness, and cytogenetic profile, may be useful indicators of prognosis but presently require further investigation.

Cats

The prognosis for vaccine-associated sarcomas treated with surgery alone, using traditional recommendations of 3 cm margins and one fascial plane deep to the tumor bed, is poor. Multimodal treatment (extensive surgery, radiotherapy, chemotherapy) is recommended and the use of sophisticated imaging techniques can improve diagnosis and help in surgical planning. The combination of radiation therapy either pre- or postoperatively has improved the disease-free interval and overall survival time in cats with vaccine-associated sarcomas. Median survival time with combination therapy is 23 months compared to 19 months with surgery alone.

Vaccine-associated sarcomas are graded from I (least) to III (most aggressive) depending on mitotic index, differentiation, and necrosis. Approximately 15–24% of vaccine-associated sarcomas will metastasize to the lungs or other sites, and evidence has suggested that a higher grade is associated with an increased risk of metastasis. In cats, it appears that completeness of excision is one of the most important prognostic factors. Hence, it is very important that everything is done to ensure the greatest possibility of obtaining complete margins when recommending treatment for these tumors in cats.

Etiology and Pathophysiology

Etiology

Hemangiosarcoma (HSA) is a malignant cancer of vascular endothelial cells. Although ionizing radiation has been associated with cutaneous HSA, there is no clear etiology for the visceral and subcutaneous forms. Vascular endothelial growth factor (VEGF) and other growth factors such as basic fibroblast growth factor (bFGF) and angiopoietin-1 are found in above normal levels in hemangiosarcoma. It is therefore hypothesized that dysregulation of angiogenesis may play a key role. Experimentally, it has been shown that overexpression of VEGF can lead to malignant transformation of vascular endothelial cells.

In humans, this disease is known as angiosarcoma and has been related to arsenicals, vinyl chloride exposure, and androgens as well as radiation exposure. These may induce a mutation in the von Hippel–Lindau tumor suppressor gene leading to an increased synthesis of hypoxia-inducible factor-1 (a transcription factor for angiogenic proteins such as VEGF). Mutations in other tumor suppressor genes such as p53 and PTEN have also been found but studies are limited.

The etiology of dermal hemangiosarcoma differs from visceral, myocardial, and other less common primary forms. Dogs with repeated, prolonged exposure to direct ionizing ultraviolet (UV) radiation have been documented to have an increased risk. The predisposition for dogs to develop dermal HSA regionally on the ventral abdomen supports solar induction, as well as field cancerization (a term used to describe the increased risk for regional tumor development after exposure to carcinogens).

Pathophysiology

Location

Hemangiosarcoma as a primary tumor has been reported to arise in the liver, kidney, bladder, prostate, peritoneum, lung, right auricle, muscle, bone, oral cavity, central nervous system (CNS) and integument, but can arise from any vascular site in the body. In the dog, the spleen is the most commonly affected organ (28–50%), followed by the right atrium and auricle (3–50%) and skin/subcutaneous tissue (13–14%). Multiple unrelated primary tumors can occur as has been speculated in dogs with concurrent splenic and myocardial forms.

Dermal hemangiosarcoma is a much less aggressive disease than visceral hemangiosarcoma. It has been proposed that there are two dermal forms: the solar-induced form, affecting thin-coat predisposed breeds with a good prognosis, and a nonsolar-induced, more aggressive form seen in nonventral locations in thicker coated, non-predisposed breeds. Dermal hemangiosarcoma (both solar and nonsolar) has a low metastatic rate. Common sites of metastasis include lungs, oral or nasal tissue, bone, heart, and CNS. The solar-induced form historically carries the best prognosis. Hypodermal (subcutaneous) HSA is characterized as being aggressive with higher local tumor invasion and a higher metastatic rate than dermal forms.

Hemangiosarcoma is much less common in cats than in dogs. In contrast to dogs, integumentary HSA (subcutaneous and dermal) is more common than the visceral or myocardial form. Seventy-seven percent of all reported feline cases arise from the integument. The most common locations in decreasing order are head/face, pinna, and ventral abdomen/inguinal region.

Metastasis

With few exceptions, hemangiosarcoma is a highly metastatic malignancy. The multistep process involved in metastasis is shared by all solid tumors and includes the creation of new blood vessels (angiogenesis), mobility and invasion into surrounding tissue, embolism into circulation, evasion of host immune defenses, lodging into capillary beds, and extravasation into a new environment. A detailed description of this cascade is beyond the scope of this chapter.

Due to its intimate relationship with blood vessels, HSA is readily able to mobilize and metastasize. The most common route is via the vascular system but spread can occur by tumor seeding onto the local organ parenchyma and within body cavities after rupture.

Although the metastatic rate of hemangiosarcoma is regarded as high, the rate can vary depending on site of origin. The visceral and myocardial forms of HSA are characterized by an extremely high metastatic rate (80–90%) to local (liver, omentum, other intraabdominal organs) as well as distant locations (lungs, CNS). Other less common primary sites such as renal, retroperitoneal, and lingual demonstrate metastatic rates of 75%, 88%, and 45% respectively. Primary integumentary forms have a metastatic rate of 30% for dermal, 35–50% for subcutaneous, and 75–90% for intramuscular locations.

Epidemiology

Hemangiosarcoma accounts for 2–5% of cancers in the dog, and between 0.5% and 2% in the cat. It is more common in the dog than in any other species, and has an extremely high mortality. The dermal forms represents <1% of all skin tumors in dogs and cats. Breeds such as whippets, Italian greyhounds, greyhounds, English pointers, Dalmations, and Staffordshire terriers are at higher risk due to their thin coat and light complexion. Lightly pigmented cats do not carry the same risk for dermal HSA as dogs. However, they are prone to other solar-induced neoplasms such as squamous cell carcinoma. For dermal forms, there are no other known risk factors in the dog and cat. The strong breed association with the visceral and myocardial forms suggests an inherited predisposition for dogs. There is no known predisposition for cats.

Signalment

Dog

Hemangiosarcoma can arise in any breed at any age. The visceral and myocardial forms predominantly affect larger, middle-aged to geriatric dogs such as golden retrievers, Labrador retrievers, and German shepherds. Dermal hemangiosarcoma is most common in older dogs, median age 9 years. Dogs predisposed include thin-coated, lightly pigmented breeds. Hypodermal HSA appears in 9–10-year-old dogs, with no sex or breed predilection. Primary renal and retroperitoneal hemangiosarcoma are extremely rare. The median age for both forms is 10 years, with larger nonspecific breeds most commonly affected. With the renal form, there appears to be a predilection for males. Other primary sites such as the tongue have no specific sex, breed or age predilection.

Cat

The mean age for cats with HSA is 10 years. There is no sex or breed predilection in this species.

History and Clinical Signs

Dog

Visceral Nonmyocardial

Dogs with the visceral form of hemangiosarcoma can present with a variety of symptoms, ranging from lethargy to acute death from hemorrhagic shock. The most common presenting complaints are weakness, lethargy, collapse, and gastrointestinal changes such as anorexia, vomiting, and diarrhea.

Patients often present with pale mucous membranes, delayed capillary refill time, tachycardia and/or arrhythmias, poor pulse quality, and a palpable fluid wave in the abdomen. If no rupture has occurred, findings may be limited to a large cranial abdominal mass or organomegaly.

Myocardial

Dogs with primary myocardial hemangiosarcoma present with symptoms of pericardial effusion such as exercise intolerance, collapse, arrhythmias, and dyspnea. They are at a higher risk for acute death due to the added danger of tamponade. Physical exam findings may include extreme weakness, tachycardia, muffled heart sounds, and pulsus paradoxus.

Integument

Dogs with dermal HSA are often asymptomatic. Symptoms of the hypodermal and intramuscular forms vary greatly. Most patients present for lameness, pain, bruising, swelling or a palpable mass that can range from firm to soft and fluctuant. All forms of integument hemangiosarcoma can demonstrate ulceration.

Compared to dermal HSA which has a predisposition for the ventral abdomen, subcutaneous and intramuscular HSA have no predilection for location.

Uncommon Primary Locations

Unlike the above forms, renal hemangiosarcoma may carry a more prolonged history of vague symptoms, with a delay of 1–2 months between onset of clinical signs and diagnosis. Some dogs will have hemoperitoneum. The majority present with stage I disease (nonrupture, localized). Presenting complaints include lethargy, anorexia, and abdominal pain. The left kidney is more commonly affected.

Clinical signs of retroperitoneal HSA are similar to patients with the renal form. However, time to diagnosis is often shorter as acute hemorrhage is more common.

Dogs with HSA arising from the tongue may be asymptomatic. Diagnosis often occurs as an incidental finding identified during routine physical exam or dental prophylaxis. One-third of these dogs will have clinical signs related to an oral mass, including bleeding from the mouth, difficulty swallowing or difficulty eating. Lesions on physical exam are small (<2 cm) and commonly located on the ventral surface but can arise from the dorsal aspect as well. Up to one-quarter of dogs can have multiple lingual tumors.

Cat

Due to the most common location being the integument, most symptoms include a red or bruised raised swelling or mass. However, for visceral and myocardial forms, similar symptoms as seen in the dog can be expected.

Diagnosis

Complete blood count (CBC), serum biochemistry, urinalysis (UA), abdominal ultrasound, echocardiogram, three-view thoracic radiographs, and coagulation testing are recommended for most forms of HSA. With the myocardial form or if an arrhythmia is present, an electrocardiogram (ECG) should also be pursued. The exception to the above is with the dermal form. Because of the lower metastatic rate, abdominal ultrasound, echocardiogram and ECG may not be necessary. The reader is cautioned to approach each patient on an individual basis.

A high level of suspicion for HSA can be formulated based on ultrasonography findings (70% of splenic masses will be malignant and approximately 70% of those will be HSA). Additionally, HSA often, but not always, appears hypoechoic, cavitated, and nonhomogeneous. Nonetheless, caution must be exercised as other nonmalignant lesions such as hematoma or hemangioma may have a similar appearance.

Effusions are typically serosanguinous to hemorrhagic and samples characteristically lack clot formation.

Hematologic abnormalities may include anemia, thrombocytopenia, schistocytes, acanthocytes, prolonged prothrombin time, prolonged activated partial thromboplastin time, and increased fibrin degradation products. Approximately 50% of all dogs with splenic hemangiosarcoma meet disseminated intravascular coagulation (DIC) criteria.

Dogs with myocardial hemangiosarcoma may demonstrate a decreased amplitude of the QRS complex and electrical alternans on ECG. A visible tumor can be detected with echocardiography in 65–90% of cases.

With renal hemangiosarcoma, over half of patients are anemic. Patients may present with hematuria, proteinuria, hypoproteinemia, and thrombocytopenia. Ultrasonography often reveals a unilaterally, irregular, enlarged kidney.

With all forms, cytologic or histologic analysis is required for a definitive diagnosis. Ultrasound-guided fine needle aspiration for visceral forms can be attempted but is associated with a significant risk of hemorrhage and low sensitivity (38%). Therefore, most cases will require surgical biopsy. If necessary, immunochemical analysis for factor VIII-related antigen (von Willebrand factor), CD31, CD34, and vimentin can be performed.

In cats, full testing, including abdominal ultrasound, three-view thoracic radiographs, CBC, serum biochemistry and UA, is recommended regardless of primary location. Echocardiography in cats may not be warranted as cardiac HSA is extremely uncommon. The value of this and other diagnostics should be determined on a case-by-case basis.

Staging System

Staging describes the severity of cancer based on its size, local behavior, and presence of metastasis. This information is utilized in treatment planning and in assessing prognosis. Unfortunately, no standard staging system has been established for the cat. For the dog, a modified World Health Organization (WHO) tumor, node, metastasis (TNM) system is commonly used (Table 152.1). In this classification, there are three established stages. For visceral HSA, stage I (T0 or T1, N0, M0) describes a tumor <5 cm in diameter or microscopic with no evidence of nodal or distant metastasis and no evidence of rupture. Stage II (T1 or T2, N0 or N1, M0) describes no invasion into adjacent structures with or without tumor capsule rupture, no measurable distant metastasis with or without regional lymph node involvement.

Table 152.1 Modified World Health Organization TNM staging system

Stage	0	I	II	III
T = primary tumor	No evidence of tumor	Tumor less than 5 cm; confined to primary site	Tumor 5 cm or greater or ruptured; invading subcutaneous tissue	Tumor invading adjacent structures, including muscle
N = lymph nodes	No lymph node involvement	Regional lymph node involvement	Distant lymph node involvement	
M = metastasis	No distant metastasis	Distant metastasis		

Table 152.2 Chemotherapeutics commonly used for the treatment of hemangiosarcoma

Drug	Dose	Frequency/days given (every 3 weeks = 1 cycle)	Use	Route	Unique side-effects
Doxorubicin	30 mg/m^2	Every 2–3 weeks (day 1 and day 14 or 21)	Single agent or combined with cyclophosphamide +/- vincristine	Intravenous	Cardiotoxicity
Vincristine	0.75 mg/m^2	Days 8 and 15	Combined with doxorubicin	Intravenous	
Cyclophosphamide	100 mg/m^2	Day 1 (when with vincristine and doxorubicin), days 3–6 (with doxorubicin alone)	Combined with doxorubicin alone or vincristine and doxorubicin	Intravenous or oral	Sterile hemorrhagic cystitis
Dacarbazine	800 mg/m^2	Day 1 (same day as doxorubicin)	With doxorubicin	Intravenous (constant rate infusion)	
Temozolomide	100–125 mg/m^2	Days 1–5	With doxorubicin	Oral	

Stage III (T2 or T3, N1 or N2, M1) describes a tumor invading adjacent structures, lymph node involvement (regional or distant), and/or distant metastasis.

When applied to the integumentary system, the TNM classification can be utilized with the following additional location-specific parameters: stage I, tumor confined to the dermis; stage II, tumor extends into subcutaneous tissue, rupture not a consideration; stage III, muscular invasion has occurred.

Therapy

Surgery

Regardless of species and primary location, surgery along with adjunctive doxorubicin-based chemotherapy (Table 152.2) is the treatment of choice. Notable exceptions include small dermal lesions (stage I) and conjunctival forms; these presentations may not require adjunctive chemotherapy as they carry a much lower risk of metastasis.

Surgical mass removal is vital to minimize the risk of fatal hemorrhage with splenic hemanigosarcoma. Intraoperatively, arrhythmias are common, so continuous ECG monitoring for a minimum of 24 hours postoperatively is recommended. Ventricular tachycardia, sustained tachycardia (180 beats per minute) with paroxysmal runs of ventricular premature complexes (VPCs) or patients that are symptomatic for ventricular arrhythmias can be treated with lidocaine boluses or constant rate infusions. Most arrhythmias will resolve within 24–48 hours.

Patients with splenic hemangiosarcoma commonly have evidence of liver metastasis at the time of diagnosis. However, all hepatic nodules identified at surgery should not be assumed to be malignant as benign conditions such as nodular hyperplasia are also commonly found in the aged animal. It is necessary to perform a biopsy of any suspicious lesion when removing an abdominal mass.

Surgical excision of myocardial HSA is rarely performed. Tumors in this location are a significant technical challenge and are seldom completely removed. For most patients, laparoscopic or open thorax pericardiectomy may be the only surgical option. Pericardiectomy may provide palliation and short-term survival gains as it minimizes risk of pericardial tamponade. Owners should be warned about sudden death from tamponade if removal or pericardectomy is not pursued.

Complete surgical excision of dermal hemangiosarcoma is strongly recommended. If the mass is small and no evidence of subcutaneous invasion is found, adjunctive chemotherapy may not be warranted as the risk of metastasis for this form is low.

Unlike dermal tumors, where surgical excision alone may be adequate, hypodermal and intramuscular tumors require multimodal therapy. HSA in this location is associated with a high local recurrence and metastatic rate. Therefore, wide surgical excision (3 cm minimum margin) +/- adjunctive radiotherapy is recommended. To address the risk of metastasis, systemic chemotherapy (doxorubicin based) is always recommended.

In cats, complete histopathologic excision with wide surgical margins is likewise recommended for all dermal forms of hemangiosarcoma. As in dogs, subcutaneous and other nondermal hemangiosarcoma forms have a higher risk of metastasis. Hence adjunctive chemotherapy should be considered.

Doxorubicin-Based Chemotherapy

Doxorubicin is the most active chemotherapeutic for hemangiosarcoma. It can be used alone or as part of a multiple agent protocol (see Table 152.2). Regardless of which is utilized, chemotherapy is regarded as well tolerated by most animals. Gastrointestinal toxicity (vomiting, diarrhea, anorexia) is often self-limiting and is seen in up to 20% of patients, but requires hospitalization far less often. Like most chemotherapeutics, the most common hematologic side-effects are neutropenia and thrombocytopenia, and, less likely, anemia. Doxorubicin-based protocols that incorporate dacarbazine result in a response rate of 47% but have more significant hematologic and gastrointestinal side-effects. Oral temozolomide in place of dacarbazine has recently been evaluated. The response rate was found to be similar but with less hematologic toxicity.

Doxorubicin, like all anthracyclines, is cardiotoxic. An irreversible, dilated type cardiomyopathy can occur at cumulative doses at or above 180–240 mg/m^2. A more cardioprotective anthracycline is epirubicin. Adverse cardiac effects can be seen with its use but at doses more than double that of doxorubicin. In one study, it was shown to be equally effective as doxorubicin, but more gastrointestinal side-effects (vomiting, diarrhea) occurred. Other formulations of doxorubicin such as pegylated, liposome-encapsulated (PL-DOX) are available. Encapsulation into liposomes leads to decreased cardiotoxicity and decreased drug uptake by phagocytes, thereby prolonging exposure to the drug. Comparison of response and survival time between pegylated and nonpegylated forms has revealed no differences. Of unique concern, PL-DOX may induce palmar-plantar erythrodysesthesia (PPES), a painful desquamation dermatitis. Adjunctive therapy with pyridoxine may minimize symptoms and lessen risk.

Other notable toxicities of anthracyclines include anaphylactic type reactions during infusion and tissue necrosis if extravasated. Proper administration requires accurate intravenous catheter placement, patient sedation when appropriate, and avoiding bolus administration.

In the cat, adjunctive chemotherapy with a doxorubicin-based protocol is recommended following surgical excision for all forms of HSA except small dermal lesions. Single-agent doxorubicin dosed at 25 mg/m^2 every three weeks, or a combination protocol with cyclophosphamide and vincristine, should be considered.

Immunotherapy

Immunotherapy modifies a biologic response by enhancing a preexisting immune response, inducing an immune response or suppressing an immune response. When given in conjunction with chemotherapy, immunomodulatory agents may enhance efficacy and improve prognosis. One such immunomodulatory agent is muramyl tripeptide-phosphatidylethanolamine (L-MTP-PE), a lipophilic derivative of muramyl dipeptide (MDP), a molecule resembling the cell wall of bacteria. L-MTP-PE stimulates cells of macrophage lineage to become tumoricidal. When a doxorubicin-based protocol was used in conjunction with L-MTP-PE (given twice weekly for eight weeks), the median survival time was significantly improved (277 days versus 143 days with chemotherapy alone). L-MTP-PE is not presently available in the United States.

Antiangiogenic Therapy

Angiogenesis is a normal process involved in fetal development, wound healing, and the female reproductive cycle. In health, it is controlled by inhibitory regulators. In the cancer patient, this process becomes abnormally activated and unregulated and is involved in tumor growth and metastasis.

Newer cancer treatment strategies focus on the inhibition of angiogenesis. Growth factors monitor and activate endothelial cell growth and development. As examples, VEGF and bFGF act directly on endothelial cells; Transforming growth factor (TGF) and platelet-derived growth factor (PDGF) attract and activate inflammatory cells and connective tissue, which thereby promotes angiogenesis. Antiangiogenic agents are directed towards inhibition of one or more growth factors or their receptors, thereby preventing further angiogenesis, growth and metastasis of a tumor.

Angiogenesis inhibitors are an attractive antineoplastic treatment as they are not limited to cytotoxic therapy and may be more acceptable and tolerable by both the owner and the patient. Further, they do not induce multidrug resistance as they do not target tumor cells directly.

Metronomic Chemotherapy

Metronomic or continuous low-dose oral chemotherapy has been demonstrated to have antiangiogenic and immune-modulating effects. Its use has been shown to improve survival in dogs undergoing splenectomy. Cyclophosphamide, the most commonly prescribed, also suppresses T-regulatory cells, thereby improving host antineoplastic immune function. In one study, cyclophosphamide (12.5–25 mg/m^2 PO) and etoposide (50 mg/m^2 PO) were administered daily on alternating three-week cycles with piroxicam (0.3 mg/kg/day PO). Results revealed a median survival of 178 days, which was significantly better than historical controls undergoing surgery alone. Although low doses of chemotherapy are used, owner compliance and care are required to minimize risks for sterile hemorrhagic cystitis.

To date, very few metronomic protocols have been evaluated in patients with hemangiosarcoma. Further studies need to be done to determine efficacious drugs, dosages, and timing.

Tyrosine Kinase Inhibitors

Palladia™ (toceranib phosphate) is a receptor tyrosine kinase inhibitor that affects the activities of multiple receptors, including VEGF and PDGF-alpha. Similar to metronomic chemotherapy, it also has immunomodulatory effects against myeloid-derived suppressor cells. Masitinib mesylate (Masivet®), another receptor tyrosine kinase inhibitor approved for use in dogs in Europe, was shown to decrease T-regulatory lymphocytes in the bloodstream of dogs and was well tolerated when combined with a metronomic dosage of cyclophosphamide. However, neither Palladia nor Masivet has been shown to lead to survival benefits for HSA. Imatinib mesylate (Gleevec®), a human receptor tyrosine kinase inhibitor, has been shown to induce apoptosis in hemangiosarcoma cell lines with a dose-dependent killing effect *in vitro*. It is associated with hepatotoxicity in the dog and for most, is cost-prohibitive.

Other Agents

Interferons are cytokines that have been used for antiangiogenic therapy in humans; interferon-alpha 2a inhibits angiogenesis by suppressing bFGF and VEGF production. Daily injections are required, making it less practical for the veterinary patient. Neutralizing antibodies may also eventually be produced, making the use of escalating doses necessary.

Matrix metalloproteinases (MMPs) are another potential target for therapy. These enzymes degrade components of the extracellular matrix, and play an important role in wound healing and tissue remodeling. In the cancer patient, MMPs are involved in tumor invasion, proliferation, and fostering a local environment to enhance tumor growth. Minocycline is a synthetic agent that inhibits MMPs. However, its use has not been shown to significantly prolong survival in dogs with HSA when combined with a doxorubicin-containing protocol.

Complementary Treatment

Nutraceuticals or homeopathic remedies have been explored as adjuncts to standard therapy for hemangiosarcoma in an effort to improve quality of life. Yun-Zhi PSP is the active ingredient in I'm-Yunity (an extract of *Coriolus versicolor* mushroom). The median time to develop metastasis or progression of metastasis was delayed in dogs receiving 100 mg/kg/day. Yunnan Baiyao is a neutraceutical/homeopathic Chinese powder that anecdotally has been shown to promote coagulation, and help prevent intraabdominal and myocardial hemorrhage. The definitive benefit of its use in dogs with hemangiosarcoma has yet to be determined.

Prognosis

Visceral and Myocardial Forms

The long-term prognosis is grave for dogs with the visceral form of hemangiosarcoma. The median survival time (MST) with surgery alone is approximately 72 days. With adjunctive chemotherapy, the median survival time is 6 months (one-year survival 6%). Stage has been shown to be prognostic. Dogs with a stage III presentation have an anticipated MST of three months in spite of standard therapy. Death is typically due to resistant metastatic disease or hemorrhage.

The prognosis for dogs with myocardial HSA is likewise grave. Although survival may be similar to those with the visceral form, a poorer outcome is more typical (MST 4 months) as many do not undergo cytoreductive surgery. In one study, the MST for dogs that had pericardectomy alone was one month.

Both renal and lingual forms are exceptions. With treatment, renal hemangiosarcoma has a MST of nine months, with an approximately 30% one-year survival. Dogs with lingual hemangiosarcoma (grade I and II) have an expected MST of 553 days. Local recurrence following therapy for the lingual form is common.

Integument

Dermal hemangiosarcoma is associated with the best prognosis. A MST of 2.5–3 years (one year 79%, two year 60% MST) can be anticipated. Prognostic factors include breed, tumor location, presence of solar actinic changes, and invasiveness. Predisposed breeds have a decreased risk for developing metastasis, and have a longer survival time (MST 1570 vs 593 days). Sun-exposed locations have a better prognosis and an increased overall survival rate (1085 days vs 539 days for tumors of other locations). Additionally, dogs with solar changes on histology such as solar elastosis, superficial dermal fibrosis, and epidermal dysplasia have an increased overall survival compared to those without solar changes (MST 1549 vs 545 days respectively). Of importance to note is that over 75% of dogs with dermal HSA will develop additional tumors in the same region of skin over time (usually predisposed breeds with the solar-induced form on their ventral abdomen).

The prognosis for dermal hemangiosarcoma is significantly more guarded if invasion into the subcutis or muscle has occurred. With surgery alone, MST is 172 days for stage II and 307 days for stage III disease. One study found the prognosis for dogs with stage II tumors was improved with the addition of chemotherapy (MST 1189 days) but the prognosis for stage III tumors remained similar (MST 273 days). Most dogs with stage III HSA (intramuscular) will die of metastatic disease prior to local recurrence.

Cat

In cats, similarl to dogs, location is a good predictor of survival. Subcutaneous tumors had a longer MST than visceral tumors, and dermal tumors had a longer MST than subcutaneous tumors. Higher mitotic indices (>3/10) were linked to shorter survival.

Melanoma

Philip J. Bergman, DVM, PhD, DACVIM (Oncology)

Katonah-Bedford Veterinary Center, Bedford, Hills, NY, USA

Etiology/Pathophysiology/Epidemiology

Melanoma is a relatively common tumor of dogs, especially in those with significant levels of skin pigmentation. Melanomas in cats are relatively rare. The most common location for canine melanoma is the haired skin, where they grossly appear to be small brown to black masses, but can also appear as large, flat, and/or wrinkled masses. Primary melanomas also can occur in the oral cavity, nailbed, footpad, eye, gastrointestinal tract, or mucocutaneous junction. Ocular melanomas of dogs and cats represent a distinct clinical syndrome and will be discussed elsewhere. Metastatic sites for canine malignant melanoma (CMM) can be varied, including local draining lymph nodes, the lungs, liver, meninges, adrenals, etc.

Melanoma arises from melanocytes, the cells which generate pigment through the melanosome by a number of melanosomal glycoproteins. In humans, cutaneous melanoma can arise due to mutations induced by repeated, intense exposure to ultraviolet light (for example, frequent tanning or working outdoors). Melanoma is currently the most rapidly increasing incident human cancer. Significant recent research into the etiology of human melanoma suggests multiple causes which are independent of the aforementioned UV-associated mutagenesis. Since most breeds of dogs have a hair coat, which affords them protection from sunlight, UV-associated melanoma is a less likely primary causative agent in the dog. However, pigment cells divide every time there is injury to the skin, or if there is constant trauma (for example, areas where dogs scratch or lick). Nevertheless, risk factors for canine melanoma are not well established.

Signalment

The most common oral malignancy in the dog is melanoma. Oral malignant melanoma is most commonly diagnosed in Scottish terriers, golden retrievers, poodles, and dachshunds. Oral melanoma is primarily a disease of older dogs without gender predilection, but may be seen in younger dogs. Additional oral tumor differentials include squamous cell carcinoma, fibrosarcoma, epulides/odontogenic tumors, osteosarcoma, and others. Melanomas in the oral cavities of dogs are found in the following locations in order of decreasing frequency: gingiva, lips, tongue, and hard palate. Feline melanoma is relatively rare, but appears to be malignant in most cases.

Diagnosis/Pathology/Molecular Biology

Melanomas can be difficult to diagnose pathologically in some situations, especially anaplastic amelanotic melanomas which can masquerade as soft tissue sarcomas. Numerous investigators have attempted to increase the precision of identification of melanomas predominantly through immunohistochemical (IHC) means. This may be accomplished through the use of multiple IHC assays on suspected melanoma tissue or through the use of an IHC cocktail of antibodies. The use of PNL2 and tyrosinase, beyond the typical use of Melan A and S100, appears to hold particular promise.

The molecular characterization of canine and feline melanomas is not as well defined as it is in humans. BRAF is a member of the MAPK signaling pathway, which is commonly mutated in human cutaneous melanoma, but infrequently mutated in oral mucosal

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

melanoma. Interestingly, BRAF mutations are also uncommon in canine oral malignant melanoma, suggesting that certain canine and/or feline malignancies can have similar molecular signatures in addition to their already well-known clinical similarities in the context of resistance to chemotherapy and/or radiation, prognosis, and similar variable peculiar sites of metastatic propensity. A number of other investigators have reported a variety of molecular abnormalities and/or associations in canine and feline melanoma.

Staging

The staging of dogs with melanoma is relatively straightforward. A minimum database should include a thorough history and physical exam, complete blood count and platelet count, biochemical profile, urinalysis, three-view thoracic radiographs and local lymph node aspiration with cytology to determine whether lymphadenomegaly is present or not. Williams and Packer reported that local nodes from dogs with oral melanoma have ~70% metastasis when lymphadenomegaly was present, but more importantly, ~40% had metastasis when no lymphadenomegaly was present. Abdominal ultrasound should be considered in cases with moderate to high metastatic potential such as the oral cavity, feet or mucosal surface of the lips, as melanoma may metastasize to the abdominal lymph nodes, liver, adrenal glands, and other sites.

The use of sentinel lymph node mapping and lymphadenectomy is of diagnostic, prognostic and clinical benefit in human melanoma. Relatively few investigations have been reported to date for sentinel lymph node mapping and/or excision for dogs with malignancies and this author strongly encourages additional investigation in this area. Furthermore, the use of novel staging modalities such as gallium citrate scintigraphy is also encouraged.

Therapy

Surgery

Surgery is the most effective local treatment modality for melanoma. Incisional biopsy is an important part of the diagnostic work-up based on the clinical, therapeutic, and prognostic heterogeneity of tumors on the differential diagnosis list. In cases for which cytology results from draining lymph nodes are equivocal, lymph nodes should be surgically excised and submitted for pathologic examination as this outcome holds prognostic and therapeutic importance.

Cutaneous melanocytomas are often completely excised with 1 cm lateral skin and one fascial plane deep margins. In contrast, partial mandibulectomy and maxillectomy are typically required for complete removal of oral melanomas arising from the gingiva or from other oral mucosa in close proximity to bone. Imaging via computed tomography (CT) or magnetic resonance imaging (MRI) can be helpful for delineation of tumor extent/invasiveness and/or involvement of regional lymph nodes. Melanomas in mucosal areas not adjacent to bone such as tongue, lip or buccal mucosa may be amenable to excision of the soft tissues only. Local recurrence rates vary from ~20% to 50% following mandibulectomy and maxillectomy, respectively. Quality of life is typically very good to excellent and most dogs are eating in the first day or two following mandibulectomy or maxillectomy, with high owner satisfaction rates. The combination of surgery and radiation plus adjuvant therapy should be considered in those patients with tumors that are not amenable to clean margin resection.

Radiation Therapy

Radiation therapy can play an integral role in the treatment of a subset of canine and feline melanomas. Radiation therapy is unfortunately ineffective at controlling distant metastasis and therefore should be used for local tumor control when definitive local therapy via surgical removal is incomplete or not possible. Melanoma has historically been believed to be a relatively radioresistant tumor type. Therefore, most radiation protocols used in dogs and cats have utilized higher doses per fraction. Protocols with fewer treatments ("hypofractionated") have less cost, reduced emotional and time commitment for owners, and fewer anesthetic episodes with generally less severe acute side-effects when compared to full-length normally fractionated protocols. A 2–3 cm margin around the tumor is typical for most radiation plans with considerations for irradiation of the local draining lymph node.

The overall response rate to radiation for canine OMM is generally 80–90% with approximately 60% complete response and 25% partial responses. Progression-free median survival times with radiation are typically 5–8 months with high recurrence rates. Median survival times range from approximately five to 12 months. Dogs with less advanced, incompletely resected oral melanoma (majority were stage I with some stage II) that were treated with either carboplatin or cisplatin given once weekly before radiation therapy had a median survival time of approximately 12 months. The median survival time for five cats with oral malignant melanoma treated with radiation therapy and a variety of other adjuvant therapies was only 146 days.

Chemotherapy

Other modalities reported for local tumor control as case reports and/or case series have included intralesional cisplatin implants, intralesional bleomycin with electronic pulsing and many others, but widespread use has not been reported to date.

In dogs with melanoma in anatomic sites predicted to have a moderate to high metastatic rate, or dogs with cutaneous melanoma with a high tumor score and/or increased proliferation index through increased Ki-67 expression, the use of systemic therapies is warranted due to the high risk for metastasis. Rassnick and colleagues reported an overall response rate of 28% using carboplatin for dogs with malignant melanoma. Unfortunately, only one dog had a minimally durable complete response (~150 days), and the rest were nondurable partial responses. Similarly, Boria *et al*. reported an 18% response rate and median survival time of 119 days with cisplatin and piroxicam in canine oral melanoma. Other reports using single-agent dacarbazine, melphalan or doxorubicin suggest poor or absent activity. More recently, and importantly, three studies suggest that chemotherapy plays an insignificant role in the adjuvant treatment of canine melanoma, whereas one study suggests it may provide benefit.

While it can be argued that the studies performed to date to evaluate the activity of chemotherapy in an adjuvant setting for canine melanoma have been suboptimal for a variety of reasons, the extensive human literature suggests that melanoma is an extremely chemotherapy-resistant tumor. It is clear that new approaches to the systemic treatment of this disease are desperately needed.

One potential therapeutic avenue which has not been significantly reported to date in canine or feline melanoma is the use of COX-2 inhibitors. A number of authors have investigated the expression of COX-2 in canine melanoma and have found positive correlations of COX-2 expression to proliferation and survival. Further studies investigating the clinical responsiveness of canine melanoma to COX-2 inhibitors (and potential correlation to COX-2 expression) are encouraged.

Immunotherapy

Immunotherapy represents one potential logical systemic therapeutic strategy for melanoma. A variety of immunotherapeutic strategies for the treatment of human melanoma have been reported, with typically poor outcomes due to a lack of breaking innate or acquired immune tolerance to the tumor. Immunotherapy targets and strategies to date in canine melanoma have used autologous tumor cell vaccines (with or without transfection with immunostimulatory cytokines and/or melanosomal differentiation antigens), allogeneic tumor cell vaccines transfected with interleukin (IL)-2 or granulocyte macrophage-colony stimulating factor (GM-CSF), liposomal-encapsulated nonspecific immunostimulators (e.g., L-MTP-PE), topical imiquimod, intralesional Fas ligand DNA, siRNA (small interfering) against the survivin and/or Bcl-2 genes, bacterial superantigen approaches with GM-CSF or IL-2 as immune adjuvants, pegylated tumor necrosis factor (TNF)-alpha, suicide gene therapy, adenovector CD40 ligand and, lastly, canine dendritic cell vaccines loaded with melanosomal differentiation antigens.

Although these approaches have produced some clinical antitumor responses, the methodologies for the generation of these products can be expensive, time consuming, sometimes dependent on patient tumor samples being established into cell lines, and fraught with the difficulties of consistency, reproducibility, and other quality control issues. Furthermore, we are just beginning to more fully understand the native immune dysregulation potentially induced by the malignancy through increased T-regulatory (Treg) cells, which suppress antitumor responses.

The advent of DNA vaccination circumvents many of the previously encountered hurdles in vaccine development. DNA is relatively inexpensive and simple to purify in large quantities. The antigen of interest is cloned into a bacterial expression plasmid with a constitutively active promoter. The plasmid is introduced into the skin or muscle with an intradermal or intramuscular injection. Once in the skin or muscle, professional antigen-presenting cells, particularly dendritic cells, are able to present the transcribed and translated antigen in the proper context of major histocompatibility complex and co-stimulatory molecules. Although DNA vaccines have induced immune responses to viral proteins, vaccinating against tissue specific self-proteins on cancer cells is clearly a more difficult problem. One way to induce immunity against a tissue-specific differentiation antigen on cancer cells is to vaccinate with xenogeneic (different species) antigen or DNA that is homologous to the cancer antigen. As outlined in cartoon form in Figure 153.1, vaccination with DNA encoding cancer differentiation antigens is ineffective when self-DNA is used, but tumor immunity can be induced by DNA from another species.

Tyrosinase is a melanosomal glycoprotein, essential in melanin synthesis and routinely found to be overexpressed in a wide variety of melanomas across species. Immunization with xenogeneic human DNA encoding tyrosinase family proteins induced antibodies and cytotoxic T cells against syngeneic B16 melanoma cells in C57BL/6 mice, but immunization with mouse tyrosinase-related DNA did not induce detectable immunity. In particular, xenogeneic DNA vaccination induced tumor protection from syngeneic melanoma challenge and autoimmune hypopigmentation. Thus, xenogeneic DNA vaccination could break tolerance

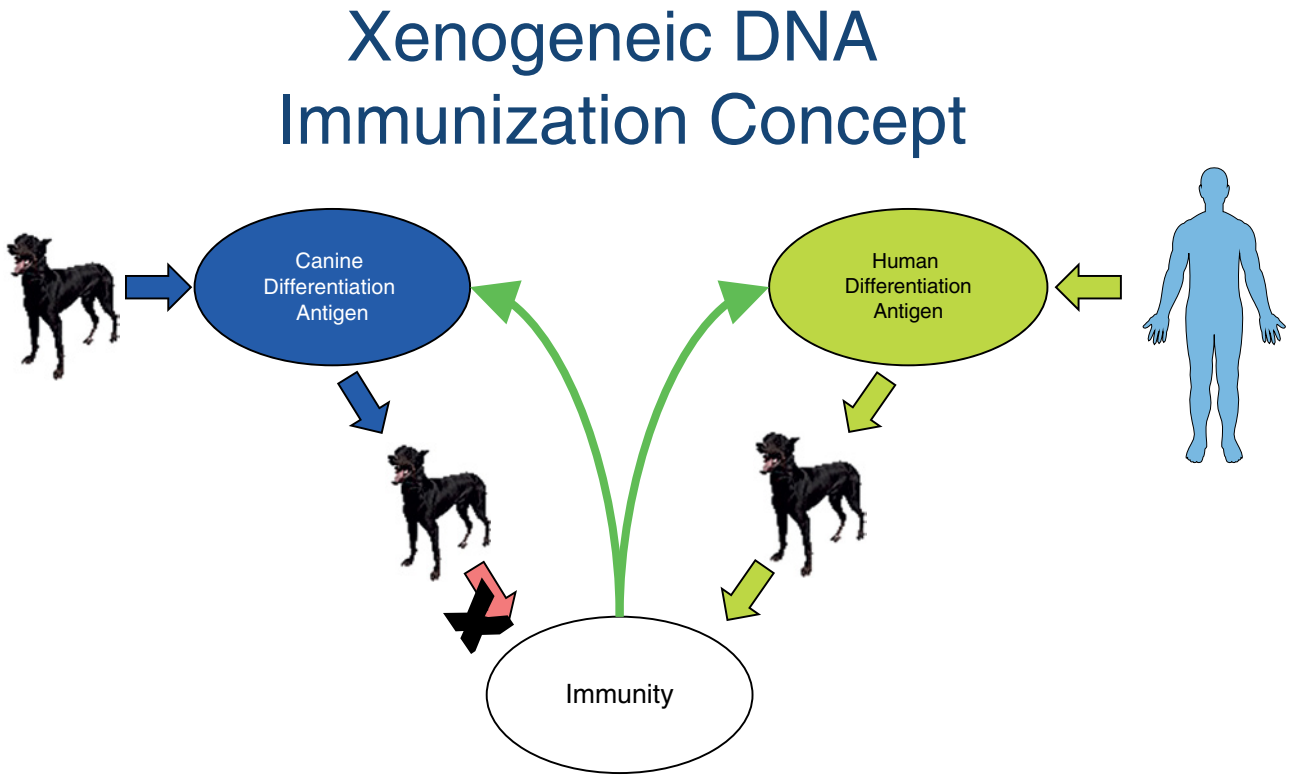

Figure 153.1 Xenogeneic DNA immunization concept.

against a self-tumor differentiation antigen, inducing antibody, T cell, and antitumor responses.

Dogs with stage I–III locoregionally controlled malignant melanoma receiving the xenogeneic melanoma vaccine have a Kaplan–Meier (KM) median survival time (MST) of >1075 days (median not yet reached) whereas those dogs with stage I–III CMM without local tumor control given the same vaccination have a KM MST of 553 days. Dogs which received the xenogeneic melanoma vaccine with stage I, II, III, and IV CMM had KM MSTs of >939 days (median not reached with 92.8% survival), >908 days (median not reached, 79% alive at one year, 63% alive at two years), >1646 days (median not reached, 77%, 65%, 57% alive at one, two, and three years), and 239 days (40.5% and 18.8% alive at one and two years), respectively.

The results of these trials demonstrate that xenogeneic DNA vaccination in CMM:

- is safe
- induces a specific antityrosinase immune response in some dogs
- potentially therapeutic in stage II–III locoregional controlled disease
- is an attractive candidate for further evaluation in an adjunct, minimal residual disease Phase II setting.

Based on these studies, a multiinstitutional safety and efficacy trial for USDA licensure in dogs with locally controlled stage II–III oral melanoma was initiated in 2006 with granting of conditional licensure in 2007, which represented the first US governmental regulatory agency approval of a vaccine to treat cancer across species. Results of this licensure trial documented a statistically significant improvement in survival for vaccinates versus controls and full licensure for the HuTyr-based canine melanoma vaccine from USDA-CVB was received in 2009 (Oncept™, Merial, Inc.).

We have also investigated the efficacy of local tumor control and use of xenogeneic DNA vaccination in dogs with digit malignant melanoma. These investigations led to the development of a canine digit melanoma staging scheme and found an improvement in survival compared to historical outcomes with digit amputation only. We also documented a decreased prognosis for dogs with advanced stage disease and/or increased time from digit amputation to the start of vaccination. Phillips and co-investigators have also recently reported the use of Oncept in horses and determined the safety and optimal use of the needle-free delivery device into the pectoral region in addition to documenting antigen-specific humoral responses after vaccination in all horses.

Human Melanoma Immunotherapy

A similar approach has been used in human patients with metastatic melanoma in the minimal residual disease setting. Although no clinical response data are available since these patients did not have measurable disease, several Phase I trials of xenogeneic DNA vaccines have been completed. Across studies of tyrosinase and gp100 DNA immunization, approximately 40% of patients develop quantifiable CD8+ T cell responses to the target antigen.

Two exciting new approaches which appear to confer a survival benefit in human metastatic melanoma are the use of the anti-CTLA-4 antibody ipilimumab (Yervoy^{TM}, Bristol-Myers Squibb) and the selective BRAF inhibitors vemurafenib (Zelboraf^{TM}, Genetech) and dabrafenib (GSK2118436, GlaxoSmithKline), in patients who are BRAF V600 mutation positive. As a small subset of dogs with malignant melanoma have exon 11 KIT gene mutations, the more routine use of KIT testing by polymerase chain reaction (PCR) of CMM and subsequent use of c-kit small molecule inhibitors (particularly in dogs with advanced stage disease and/or lack of response to Oncept) should be considered.

Canine malignant melanoma strongly appears to be a more clinically faithful therapeutic model for human melanoma when compared to more traditional mouse systems, as both human and canine diseases are chemoresistant, radioresistant, share similar peculiar metastatic phenotypes/site selectivity, and occur spontaneously in an outbred, immunocompetent scenario. It is hoped that in the future, this same vaccine may also play a role in the treatment of melanoma in other species (e.g., horses, cats, humans, etc.) due to its xenogeneic origins, and in melanoma prevention once the genetic determinants of melanoma risk in dogs are further defined.

Prognosis

Melanomas in dogs have extremely diverse biologic behaviors, depending on a large variety of factors. A thorough understanding of these factors helps the clinician to delineate in advance the appropriate staging, prognosis, and treatment options. The primary factors which determine the biologic behavior of an oral melanoma in a dog are site, size, stage, and histologic parameters. Unfortunately, even with a comprehensive understanding of all these factors, there are melanomas which have an unreliable biologic behavior; hence the need for additional research into this relatively common, heterogeneous, but frequently extremely malignant tumor. On divergent ends of the spectrum would be a 0.5 cm haired-skin melanocytoma, which is highly likely to be cured with simple surgical extirpation, in comparison to a 5 cm high-grade malignant oral melanoma with a poor to grave prognosis.

Similar to the development of a rational staging, prognostic and therapeutic plan for any tumor, two primary questions must be answered: what is the local invasiveness of the tumor and what is the metastatic propensity? The answers to these questions will ultimately determine the prognosis and appropriate therapies.

Anatomic Site

The anatomic site of melanoma is highly, though not completely, predictive of local invasiveness and metastatic propensity. Melanomas involving the haired skin which are not in proximity to mucosal margins often behave in a benign manner. Surgical extirpation through a lumpectomy is often curative, but histopathologic examination is imperative for delineation of margins as well as a description of cytologic features. The use of Ki67 IHC has been reported to more reliably predict potential malignant behavior compared to classic histology for cutaneous melanoma.

Oral and/or mucosal melanoma has been considered an extremely malignant tumor with a high degree of local invasiveness and high metastatic propensity. This biologic behavior is similar to the typically grave prognosis associated with human oral and/or mucosal melanoma. Two recent studies have called the veterinary portion of this dogma into question and suggest benign oral melanomas can occur more frequently than previously published. Caution is necessary when assessing histopathologic descriptions suggesting a benign course for oral melanoma as this author has seen approximately 25 dogs over the last 10 years presenting with florid systemic metastases with an original histopathologic report suggesting an expectation for a benign clinical course based on a high degree of differentiation. Similar to cutaneous melanoma, Ki67 appears to have prognostic import in canine oral melanoma.

Anatomic sites of intermediate prognostic significance between generally benign-acting haired-skin melanomas compared to often malignant and metastatic oral/mucosal melanomas in dogs include melanomas of the digit and footpad. Dogs with melanoma of the digits without lymph node or further metastasis treated with digit amputation are reported to have median survival times of ~12 months, with 42–57% alive at one year and 11-13% alive at two years. Unfortunately, metastasis from digit melanoma at presentation is reported to be ~30–40%, and the aforementioned outcomes with

surgery alone suggest that subsequent distant metastasis is common even when no metastasis is found at presentation or digit amputation. The prognosis for dogs with melanoma of the footpad has not been thoroughly established; this author has found this anatomic site to be anecdotally similar in metastatic propensity and prognosis to digit melanoma. Interestingly, human acral lentiginous melanoma (plantar surface of the foot, palms of the hand and digit) has an increased propensity for metastasis, suggesting further similarities between human and canine melanoma.

The most thorough review of prognostic factors in canine melanocytic neoplasms was published by Smedley *et al*. This review took a regimented, systematic approach to analyze published reports to date in order to identify those factors which appear to be repeatable and statistically defendable, while also identifying areas where additional work is necessary due to incomplete data.

Size and Stage

For dogs with oral melanoma, primary tumor size has been found to be extremely prognostic. The WHO staging scheme for dogs with oral melanoma is based on size and metastasis and is summarized in Box 153.1.

MacEwen and colleagues reported MST for dogs with oral melanoma treated with surgery to be approximately 17–18, 5–6, and three months with stage I, II, and III disease, respectively. More recent reports suggest that stage I oral melanoma treated with standardized therapies including surgery, radiation and/or chemotherapy has a MST of approximately 12–14 months, with most dogs dying of distant metastatic disease, not local recurrence. Other investigators have found dogs with stage I oral melanoma to have median progression-free survival times of 19 months, similar to the original MacEwen *et al*. report.

Box 153.1 TNM staging system

T = Primary tumor

T1 Tumor <2 cm in diameter
T2 Tumor 2–4 cm in diameter
T3 Tumor > 4 cm in diameter

N = Regional lymph nodes

N0 No evidence of regional node involvement
N1 Histologic/cytologic evidence of regional node involvement
N2 Fixed nodes

M = Metastasis

M0 No evidence of distant metastasis
M1 Evidence of distant metastasis
Stage I T1 N0 M0
Stage II T2 N0 M0
Stage III T2 N1 M0 or T3 N0 M0
Stage IV Any T, Any N and M1

Nonmelanoma Skin Cancers

Barbara E. Kitchell, DVM, PhD, DACVIM (Oncology)

VCA Veterinary Care Animal Hospital and Referral Center, Albuquerque, NM, USA

Etiology/Pathophysiology

The skin is the largest organ in the body, and has a complex tissue structure made up of many cell types. Any of these cell types could give rise to a tumor. Some cells are more commonly affected by malignant transformation than others.

The skin is composed of layers, referred to as the epidermis and dermis. The epidermis contains stratified epithelium, while the dermis is largely composed of connective tissue, including collagen, extracellular matrix, fibrocytes, and fibroblasts. Within the dermis also reside adnexal structures such as sebaceous or eccrine glands, and the various cells that make up the hair follicles. Below the dermis, subcutaneous tissues largely contain adipocytes. Interspersed throughout the complex organ we call skin are cells of the immune system, which are present as either transient or permanent residents (lymphoid cells, macrophages, mast cells, Langerhans dendritic cells). Panniculus skeletal muscle, neurons and associated peripheral nerve sheath cells, vascular epithelium and hemangiopericytes, and the specialized neuroendocrine cells we know as melanocytes are all important to normal skin structure.

Thus, the number of potential histopathologic diagnoses for tumors of the skin is quite expansive. Skin tumors are generally classified as being of epithelial, mesenchymal, melanotic, or round cell type. Mesenchymal, melanotic, mast cell tumors, and cutaneous lymphoma will be discussed in other chapters.

The functions of this complex organ are also varied, and include prevention of water and electrolyte loss, thermoregulation, respiration, and sensory perception. A critical skin function is to provide a physical barrier to environmental insults, whether mechanical, chemical, osmotic, thermal, or microbiologic. As the front line of defense against environmental insults, the skin's most important defensive mechanism is its self-renewal and repair functions, which are dependent on the presence of both lineage-committed replicating cells and pluripotent stem cells. These replicating cells are subject to mutation as a consequence of repeated noxious environmental exposures, which may ultimately result in carcinogenesis.

Epidemiology

All cancers arise as a consequence of genetic predispositions and environmental exposures to carcinogens. The skin is at particular risk for environmental injury. As a tissue with cells that continuously replicate or that can be recruited to replicate, mutagenic induction followed by tumor cell promotion through repeated rounds of cell replication result in skin tumors of various kinds. Thus, cutaneous tumors are the most common type of neoplasia in both humans and dogs, although fortunately not all skin tumors are malignant.

Genetic contributions to skin carcinogenesis are evidenced by human familial hereditary syndromes, as well as by canine breed predispositions to specific tumor types. The skin is the most prevalent location for tumors in dogs, with an estimated 20–30% of these lesions being malignant. It is estimated that 25% of tumors of cats arise in the skin, and that 50–65% of these lesions are malignant. Excluding the common basal cell tumor of cats, which is generally benign, the incidence of malignancy in feline cutaneous tumors is estimated to be 70–80%. The estimated annual incidence of skin tumors in dogs and cats is 90.4 and 34.7 per 100 000 animals at risk, respectively, while for humans the annual incidence is reportedly 5.2/100 000 people at risk. Nonmelanoma cutaneous tumors are the most common malignant neoplasms affecting people in the United States, but fortunately are not the most fatal types of malignancy.

In dogs and cats, basal cell tumors (also called trichoblastomas), epitheliomas, sebaceous adenomas, epidermal inclusion and other cysts, lipomas, and papillomas are the most prevalent benign tumors noted. Mast cell tumor is the most common malignant skin tumor in the dog, and is discussed in Chapter 155.

Trichoblastomas, which are more commonly still termed basal cell tumors, are the most common skin tumors of cats; approximately 15–26% of all skin tumors in cats are of this histology. Less than 10% of basal cell tumors in cats are malignant in behavior. When malignant, these lesions display a striking tendency toward lymphatic metastasis, which can result in a "chain of pearls" nodular progression up the draining lymphatics to the local lymph node. In dogs, poodles and setters are predisposed to basal cell lesions, which may be described by their histologic subtypes of ribbon, medusoid, trabecular, spindle, granular cell, and clear cell types. These lesions are now believed to arise from the germinal cells of the hair follicles, and are generally benign in behavior.

Dogs are commonly affected by benign tumors of glandular origin in the skin, although this is a rare occurrence in cats. Sebaceous hyperplasia, sebaceous adenoma, and sebaceous epitheliomas are very common in dogs. These lesions are most commonly benign and are rarely diagnosed as sebaceous gland carcinomas, which are generally locally aggressive and rarely metastatic. Benign lesions are often seen in female dogs (especially hyperplasia), with peak incidence in dogs 7–13 years of age. Miniature schnauzers, beagles, poodles, and cocker spaniels are breeds at increased risk, as are Nordic breeds, coonhounds, and terriers.

Apocrine gland adenomas and carcinomas arise from sweat glands in both dogs and cats. These lesions are rarely malignant but can be aggressive when transformed to carcinomas. Feline apocrine gland carcinoma lesions are seen primarily on the head, while benign lesions may be present on the head, limbs or abdomen of older cats. The front legs are the most common sites for canine apocrine gland carcinomas, with golden retrievers and coonhounds being predisposed breeds. Lesions are locally invasive with a predisposition to lymphatic spreading. Apocrine gland adenocarcinomas of the anal sac are discussed elsewhere.

Eccrine gland adenomas and carcinomas arise from specialized sweat glands of the footpads in dogs and cats and are exceedingly rare lesions.

Squamous cell carcinoma is common in both dogs and cats. This tumor of the skin is frequently caused by chronic ultraviolet light exposure in animals with white or fair skin and scant hair or fur covering. As sunlight is most damaging close to the equator and at high altitudes, these geographic regions of the globe have the highest incidence rates of cutaneous squamous cell carcinoma in both people and animals. Lifestyle and behavior contribute to sun exposure in all species of animals. Thus, white cats living largely outdoors are particularly vulnerable to cutaneous squamous cell carcinoma in sun-exposed areas of their head, including ear tips, nasal planum, lower eyelids, and the scantly furred preauricular area of the skin located between the ears and eyes on the lateral forehead. Siamese and other color-point breeds of cats are protected from cutaneous squamous cell formation by the pigment that is present in the exact facial areas that put white cats at risk. Similarly, dogs are most affected in areas of glabrous (nonhaired) skin that receive excessive sunlight exposure. This can occur when dogs "sunbathe" by lying on their back or sides in full sun. Outdoor dogs with no pigment in glabrous skin regions are most at risk. Thus, Dalmatians, pointers, pit bulls, bull terriers, and other dogs with white or pale skin on the ventral abdomen, prepuce, and medial thighs may suffer actinic dermal injury that can ultimately transition to squamous cell carcinoma. Dermal hemangioma and hemangiosarcoma lesions may similarly arise in areas of excessive ultraviolet light exposure.

In addition to physical carcinogenesis from ultraviolet light exposure, there is also a viral etiopathogenesis associated with causation of cutaneous squamous cell carcinoma. Papillomavirus infection in cats may cause the feline equivalent of a human syndrome called Bowen disease, which is a term used to identify multicentric cutaneous squamous cell carcinoma *in situ*. This form of squamous cell carcinoma occurs most frequently in haired skin and has no predilection to arise in nonpigmented areas of the body. These lesions can be seen as crusty, scabbed dermal lesions of the head, neck or trunk of affected cats. Papillomavirus is also associated with the development of feline fibropapillomas called feline sarcoids. Interestingly, cats have been found to be susceptible to human papillomaviruses 5, 21, and 38, which were discovered by polymerase chain reaction (PCR) analysis of papilloma lesions in several cats.

Dogs also harbor papillomaviruses, which may be involved in the causation of oral, footpad, and cutaneous papillomas, and potentially even in squamous cell carcinomas. These lesions are particularly observed in dogs that are immunocompromised.

Breed association is noted in dogs affected by tumors of adnexal skin structures. Infundibular keratinizing acanthomas are common benign tumors of dogs. Synonyms for these tumors include intracutaneous keratinizing epitheliomas, keratoacanthomas, and intracutaneous cornifying epitheliomas. Breeds at risk for these benign lesions include Norwegian elkhounds and other Nordic breeds, German and Belgian shepherd dogs, various terriers, and the Lhasa apso. These lesions are benign and generally cured by local excision, although they are frequently seen as multiple lesions.

Trichoepitheliomas are tumors that demonstrate differentiation into elements of the hair follicle, and are seen on the limbs, neck, and back of bassett hounds, coonhounds, setters, and English springer spaniels. These are rarely malignant, and are referred to as malignant trichoepitheliomas or metrical carcinomas in those rare cases.

Pilomatricomas are tumors of hair matrix cells, and are also benign in general. Kerry blue, soft-coated wheaten, and Airedale terriers are the most affected, as are standard poodles, bichon frise, old English sheepdogs, and bouviers des Flandres. These lesions may ulcerate and ossify. While these lesions are rarely malignant, they are reported to be highly metastatic when malignant transformation occurs.

Neuroendocrine tumors of the skin are referred to as Merkel cell tumors. They are thought to arise from mechanoreceptors in the skin, and are also rare in dogs and cats. While these tend to be highly malignant in humans, they are more benign in dogs.

Ear canal tumors can be classed with skin tumors as a continuous cutaneous organ. Most commonly seen are ceruminous gland adenomas and carcinomas. Ceruminous glands are modified apocrine glands localized to the ear canal. Other tumors of the ear canal include squamous cell carcinomas, basal cell carcinomas, mast cell tumors, histiocytomas, sebaceous gland tumors, plasma cell tumors, melanomas, and various sarcomas. Benign polyps arising in the ear canal are also noted, particularly in young cats.

Signalment

Most cutaneous tumors arise in aged animals, as it can take a lifetime of exposure to environmental carcinogens, coupled with geriatric waning of immune surveillance, to allow tumors to manifest. Occasionally skin tumors will arise in younger animals, particularly in cats affected by retroviruses or feline papillomavirus. There is generally no sex predisposition in the development of skin cancer. Many specific histologic types of skin cancer, particularly those arising in adnexal structures, are breed associated, as described in the section on epidemiology.

History and Clinical Signs

In most cases, the first sign of skin tumor development is the presence of a mass. Masses may be indolent in their growth pattern or may be rapidly progressive. Skin tumors are generally nonpainful, unless infection or inflammation occurs. Basal cell tumors tend to be slowly growing or static in growth pattern, and may be alopecic, ulcerated, and of blue-black or pink color. Cysts and sebaceous adenoma lesions may rupture or become infected, and thus may wax and wane in size. In many cases, owners assume that squamous cell carcinoma on the nose of a cat is a result of an infected fight wound. In these cases, there is a wound that fails to heal properly, and is intermittently scabbed or open and bleeding. Similarly, dermal hemangiosarcomas arise in areas of actinic injury, with a clinical appearance of small red spots or "blood blister" lesions that may bleed or become invasive.

Diagnosis

Diagnosis of skin tumors is by cytology or biopsy. Because these patients are often older, a minimum database (complete blood count, serum chemistry panel, and urinalysis) is helpful in anesthetic planning. However, skin tumors are not typically associated with paraneoplastic syndromes that could be detected on bloodwork. Interestingly, humans affected by squamous cell carcinoma may have hyperglobulinemia that is of polyclonal nature and directed against specific cytokeratins. Hyperglobulinemia may be noted in cats with sunlight-induced squamous cell carcinoma as well, although it is clinically insignificant.

The method of biopsy is determined by size and location of the lesion. Small superficial lesions may be best managed by excisional biopsy, which can be both diagnostic and therapeutic. Larger lesions may require incisional biopsy to allow for surgical or radiation treatment planning. Advanced local imaging with computed tomography (CT) or magnetic resonance imaging (MRI) may be helpful in determining the full extent of the lesion to be addressed.

Carcinomas of the skin may merit clinical staging with lymph node aspiration cytology or lymph node biopsy and thoracic radiographs. Abdominal staging may be considered in cases with malignant lesions on the caudal portion of the body, where lymphatic spread to intrapelvic or intraabdominal node sites may occur. Lymphadenomegaly should be investigated with cytology or biopsy. Pulmonary metastasis is rarely seen in dogs with skin cancer, although squamous cell carcinoma (SCC), malignant pilomatricomas, sebaceous gland carcinomas, apocrine gland carcinomas, and neuroendocrine carcinomas have the potential to metastasize.

Ear canal tumors often cause pain, malodorous discharge, difficulty opening the mouth and neurologic signs such as facial palsy and vestibular signs. These signs may lead to delayed diagnosis of tumor, as patients may undergo protracted periods of treatment of suspected otitis before biopsy diagnosis is obtained.

Ear canal tumors often require advanced imaging studies to determine operability and extent of surgery necessary, or to plan for radiotherapy adjunctively or as primary treatment of nonresectable, invasive lesions.

Therapy

Most skin tumors are best addressed by local surgical excision. Benign lesions of the skin can be excised with modest margins to affect a cure in most cases. Surgical excision allows for accurate diagnosis, histologic grading, and surgical margin assessment, which can guide further adjunctive therapy if necessary. However, surgery can be disfiguring, particularly when the lesion arises on the head and face. Squamous cell carcinoma of the ear tips can be managed by pinna amputation in cats. Nasal planum resection can also be curative in cats, although surgery of SCC of the nasal planum in dogs is often unsuccessful in controlling local disease. Surgery is always the best primary modality for treatment of any cancer, but owners may balk at the degree of disfigurement the dog or cat experiences with nasal planum resection.

Serial resection of squamous cell carcinoma or hemangiosarcoma, while still small, dermal and arising on glabrous skin, is recommended for dogs with field carcinogenesis from sunlight exposure. Highly invasive or large field lesions of the ventral abdomen, prepuce, and medial thighs of such dogs may be less amenable to surgical excision. In these cases, radiation therapy delivered to the local tumor site, or tumor site plus regional nodes, may be curative. Radiation therapy for skin tumors may involve traditional fractionated megavoltage irradiation with curative intent, or may be delivered as palliative fractionated therapy. Superficial radiation, such as delivered through topical plesiotherapy using a strontium-90 probe, is highly effective for small, noninvasive lesions. Photodynamic therapy utilizing laser light to activate photosensitizing agents is a common treatment for human skin cancer patients, although the technology is less readily available to veterinary medicine.

Ear canal tumors generally require surgical excision, which may entail vertical canal ablation in the case of superficial benign tumors, but more likely requires a more aggressive surgical approach with total ear canal ablation and lateral bulla osteotomy. Extensive surgery was associated with long median survivals in both dogs and cats (>36 months and 50.3 months, respectively). Mitotic rate was prognostic for a series of ear canal tumors, with a mitotic index of 2 or less being more favorable. Radiation therapy may be required for patients with incompletely resected tumors of the ear canal, regardless of histologic type of tumor.

Topical 5% fluorouracil cream may be applied to superficial squamous or basal cell lesions in dogs, as is the common practice in human dermatologic oncology. This agent is applied topically twice daily by gloved finger or cotton swab applicator for 3–6 weeks. Significant local irritation and inflammation are seen as part of the therapeutic response. Dogs should be prevented access to the treated site, as licking the topical cream can be harmful to oral mucosa and may be toxic systemically. Critically, fluorouracil should *never* be applied to cats, as even topical application can result in lethal neurotoxicity in this species.

Topical immunotherapy for superficial squamous cell carcinomas may be attempted. Imiquimod 5% cream is a nonspecific active immunotherapeutic agent that induces a strong macrophagic response when topically applied. This immunostimulant causes inflamed, crusted and scabbed lesions to arise in the treated area, which is the basis of the therapeutic effect. Imiquimod is applied topically to superficial lesions once daily, or in sensitive cases three times weekly, for 3–6 weeks.

Intralesional therapy with chemotherapy in sesame oil or purified bovine collagen matrix for depot delivery has also been described in the literature. Agents such as carboplatin, cisplatin, bleomycin, and fluorouracil have all been introduced intratumorally with sometimes striking results.

Systemic therapy with retinoic acid derivatives such as 13-cis-retinoic acid or isotretinoin has been attempted as a cellular differentiation or cytotoxic strategy in canine and feline skin tumors, particularly squamous cell and infundibular keratinizing acanthoma (keratoacanthoma). Retinoid therapy has been reported in the literature to have mixed success.

The use of COX-2 inhibitors has shown modest efficacy in treatment of squamous cell carcinomas of the oral cavity, and thus may be helpful in cutaneous SCC treatment as well. The COX-2 inhibitor nonsteroidal antiinflammatory drugs (NSAIDs) have both antiangiogenic and immunomodulatory effects, and are generally helpful in pain control for veterinary patients. Similarly, the newer class of agents called receptor tyrosine kinase inhibitors (toceranib, masitinib, imatinib) are inhibitors of cell signaling. These agents are promiscuous receptor signaling blockers and may modulate tumor regression through inhibition of vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) receptors, thus acting as antiangiogenic agents. The therapeutic concept referred to as metronomic chemotherapy employs smaller daily or alternate-day dosing of NSAIDs, low-dose cytotoxic agents such as cyclophosphamide, chlorambucil, or lomustine, often combined

with receptor tyrosine kinase inhibitors, to inhibit normal stromal cells that support neoplastic growth. Little information is currently available about the use of daily, low-dose combination metronomic chemotherapy in canine and feline skin or ear canal tumors.

Papilloma lesions may be addressed through the creation of an autologous vaccine. This approach is best used in dogs with multicentric papillomas, as is sometimes seen in dogs that have been heavily immunosuppressed in the transplant or autoimmune disease setting, or in dogs with immunosuppression from T-zone lymphoma. In this approach, 1–3 g of papilloma tissue are harvested from the dog and macerated in a tissue grinder or mortar and pestle along with 10 mL of sterile 0.9% saline. To this mixture is added 1 mL of neutral buffered formalin, which inactivates live virus as well as altering the structure of viral oncoproteins to facilitate immune recognition. The mixture is refrigerated for three days, and then sieved through sterile cheesecloth or a large-gauge filter to remove residual particulate material. The resultant autologous vaccine can be stored in the refrigerator in 1 mL sterile aliquots for future treatment. An immune adjuvant such as Immunocidin® (*Corynebacterium parvum* derivative), squalene, or BCG is added before injection into the residual papilloma lesions. This treatment can be repeated at weekly intervals until lesion regression is noted. There is no literature regarding use of commercial papillomavirus-preventive vaccines in the therapeutic setting.

Systemic chemotherapy or local electrochemotherapy has been attempted for aggressive or metastatic dermal carcinomas. Relatively few agents have been used in this setting, and results are generally anecdotal and not well documented. Cisplatin, carboplatin, bleomycin, actinomycin D, and mitoxantrone have all been used sporadically, with modest response rates noted in the literature. Local drug delivery enhanced by electrochemotherapy may increase the local efficacy of these cytotoxic agents.

Prognosis

The prognosis for patients with localized tumors of the skin, adnexal structures, or ear canals is generally highly favorable. Many lesions are benign and early detection is possible because of the superficial location of the tumors, and ear canal tumors are frequently localized to within the cartilaginous structures of the ear canal, which facilitates complete resection. Thus, most dogs and cats affected by skin or ear canal tumors are cured by surgical excision alone. Exceptions are noted in cases of malignant skin neoplasia, particularly when metastasis to nodes or distant sites is observed. Radiation therapy can be helpful for large or nodally involved lesions, as described earlier.

The most common aggressive skin tumors discussed here are squamous cell carcinomas, which have median survivals of 1–2 years with aggressive surgery and/or radiation therapy in both dogs and cats. The exception to this observed survival rate is in the case of nasal planum squamous cell carcinomas in dogs, which are both locally aggressive and metastatic to regional nodes, and have a poorer overall outcome despite aggressive therapy.

Mast Cell Neoplasia

Zachary M. Wright, DVM, DACVIM (Oncology)

VCA Animal Diagnostic Clinic, Dallas, TX, USA

Etiology/Pathophysiology

Mast cells are part of the normal canine, feline, and human immune system. They primarily exist throughout the skin, lungs, and intestinal tract but are rarely found within peripheral blood.

Mast cells arise from pluripotent hematopoietic stem cells of the bone marrow. Once mature, their cytoplasm contains a large amount of metachromatic granules. These granules contain a variety of substances including histamine, serotonin, platelet activating factor, eosinophilic chemotactic factor, and heparin, among others. In addition, mast cells produce a variety of cytokines that include interleukin (IL)-1, IL-3, IL-4, IL-5, IL-6, and tumor necrosis factor (TNF)-alpha.

The etiology for canine mast cell tumor development is unknown partially because there is no clear human model to provide key predictors.

Canine Mast Cell Neoplasia

Epidemiology

Canine mast cell tumor (MCT) is the most common skin tumor in dogs, representing upwards of 15–20% of all skin tumors. They are one of the most common tumors seen in practice.

Signalment

Mast cell tumor development has clear breed predispositions that include most brachycephalic breeds (boxer, Boston terrier, and pug), Labrador and golden retrievers, pit bull terriers, and shar-peis. There is no reported sex predilection and the mean age of diagnosis is 8.2 years. Clinically, all breeds are capable of developing MCT. While tumors are more often noted in middle-aged to older dogs, the author has seen numerous cases of MCT in juveniles less than 1 year of age.

History and Clinical Signs

Most dogs with a MCT present with a single dermal lesion. Twenty percent of all dogs, and specifically breeds that are predisposed, may present with multiple tumors. The history may include a nonpainful mass that increases and decreases in size. Physical manipulation of the tumor can result in a rapid increase in size due to traumatic local release of histamine (degranulation). Darier's sign is the dermatologic description of wheal formation, local erythema, and/or bruising secondary to manipulation of the tumor. Most MCTs are clinically quiescent and are discovered on routine physical exam by the veterinarian or owner.

Mast cell tumors occur predominantly in the dermis and are most commonly noted on the trunk and limbs. A less commonly noted form, at mucocutaneous sites (mouth, nasal planum, perirectal region), tends to have a more aggressive clinical behavior (Figure 155.1). Additionally, a lesser percentage of MCTs occur in the subcutaneous tissue and many have a clinical appearance consistent with a lipoma.

Primary visceral mastocytosis is a very rare condition in dogs. The disease has a predisposition for the intestinal tract in older (>8 years) miniature-breed dogs. Two independent studies have identified the Maltese breed as having a predisposition to the intestinal form. Clinical signs are typical of most primary gastrointestinal pathology.

Diagnosis

Cytology of the lesion is diagnostic for a MCT. Because of the clinical inefficiency and additional cost, premedication with an antihistamine prior to fine needle aspiration of a simple dermal mass less than 5 cm in

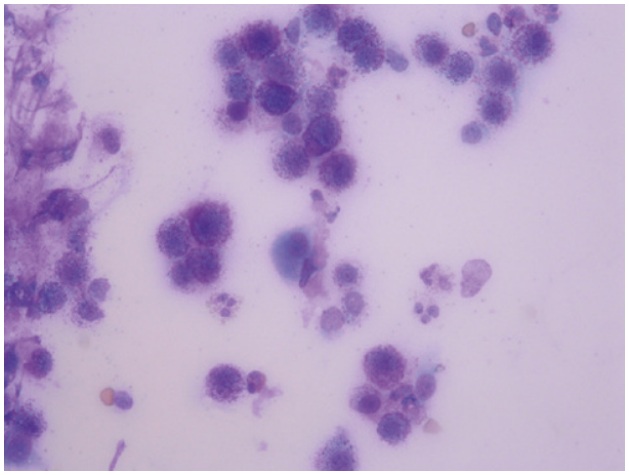

Figure 155.2 Mast cells seen at 40× with varying amounts of metachromatic granules throughout the cytoplasm.

diameter is not indicated. While Darier's sign may develop, significant systemic histamine effects are highly unlikely with simple dermal lesions. Cytology of larger masses, or more vascular organs like lymph node and spleen, does justify systemic protection with antihistamines.

Mast cells are mononuclear round cells with a significant amount of cytoplasm containing metachromatic granules. For comparison, mast cells range in size between a neutrophil and macrophage. Diff-Quik staining techniques are usually adequate in accentuating the diagnostic granules (Figure 155.2). When collecting samples, it is important to save an unstained slide for alternative staining techniques (i.e., Wright's) if mast cells are suspected but granules are not identified with Diff-Quik stain. Without appropriate staining, these poorly granulated

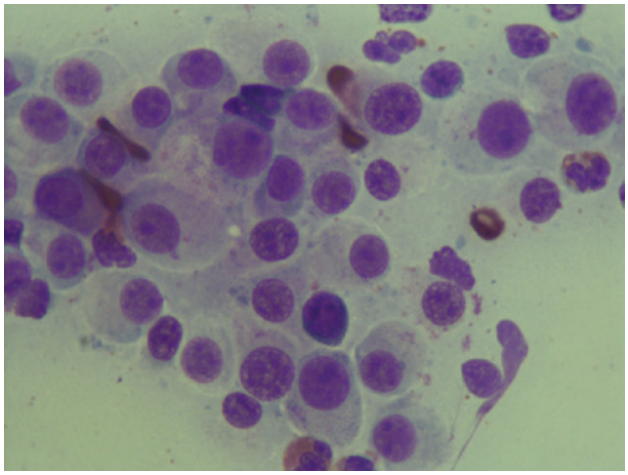

Figure 155.3 A population of Diff-Quik stained round cells at 40×. Notice the lack of consistent granules and cellular atypia (multiple nucleoli, varying N:C ratio, etc.). Alternative cytologic staining techniques (Wright's) are more adept at identifying the granules in high-grade MCT.

tumors may result in a cytologic diagnosis of "round cell tumor" (Figure 155.3). It is important to remember that cytology is ineffective in grading a MCT but the level of cellular pleomorphism may provide clues to the biologic behavior of a tumor.

Staging is important as both prognosis and treatment options are intimately dependent on it (Box 155.1). Initial staging of a MCT is dependent on physical exam findings. Close attention should be paid to the regional draining lymph nodes and organomegaly (hepatic and/or splenic).

Regional lymph nodes, regardless of size, should be cytologically evaluated for metastasis. The determination of lymph node metastasis via cytology is very sensitive but has a low specificity due to the inability to distinguish normal, responsive mast cells from malignant cells. Metastasis can be accurately confirmed if mast cells are the predominant cell type. Additionally, most pathologists will declare a node metastatic if the mast cells are noted in clumps or sheets and/or have marked cellular atypia. Biopsy or removal of the lymph node is recommended if there is an increase in the numbers of well-granulated mast cells but no other signs supportive of metastasis. Recent evidence supports that dogs with no metastasis to regional nodes had a 0% chance of distant metastasis.

Abdominal ultrasound is recommended for dogs with a high-grade MCT or proven lymph node metastasis. While a full abdominal ultrasound is encouraged, focus should rest on the liver, spleen, and lymph nodes (mesenteric, medial iliac, and sublumbar nodes). All abnormal lesions of the liver and spleen should be cytologically evaluated. Two independent studies confirmed that cytology of ultrasonographically normal

Box 155.1 Staging for mast cell tumors

WHO clinical staging system for canine mast cell tumors

Stage 0: Microscopic incomplete excision of any dermal MCT with no evidence of regional nodal or distant metastasis

Stage 1: A single MCT confined to the dermis with no evidence of regional nodal or distant metastasis

a) no clinical signs
b) clinical signs

Stage 2: A single MCT confined to the dermis with regional lymph node metastasis

a) no clinical signs
b) clinical signs

Stage 3: Multiple dermal MCT, any tumor invading local tissue with or without regional nodal metastasis

a) no clinical signs
b) clinical signs

Stage 4: Any MCT with confirmed distant metastasis

Modified WHO clinical staging criteria for canine mast cell tumors

Stage –1: Single MCT completely removed and no evidence of regional nodal metastasis
Stage 0: Microscopic incomplete excision of a single MCT with no evidence of regional nodal metastasis
Stage 1: A single MCT completely removed
Stage 2: Microscopic incomplete excision of a single MCT
Stage 3: A single MCT completely removed with positive regional node metastasis *in situ*
Stage 4: Microscopic incomplete excision of a single MCT with positive regional node metastasis *in situ*
Stage 5: MCT recurrence or positive distant metastasis

liver and spleen does not influence treatment or survival estimates.

While historically pursued, bone marrow aspiration for staging may no longer be indicated for a patient diagnosed with their first MCT or with no clinical evidence of lymph node metastasis. For these dogs, the incidence of bone marrow involvement is low (2.8%). This low yield, combined with cost, invasiveness of the procedure, and ability to prove distant metastasis on more routine testing (abdominal ultrasound), suggests that bone marrow aspiration may not be necessary for every patient. However, bone marrow metastasis/distant metastasis is a significant prognostic indicator and dogs with a recurrent MCT or which develop subsequent MCTs may have a higher incidence (18.7%).

Pulmonary metastasis is rare and sporadically reported for MCT. Consequently, thoracic radiography is not considered part of routine staging but may be helpful in assessing concomitant disease processes (cardiovascular, respiratory, etc.).

The most important prognostic indicator is the grading scheme. Tumor grade is determined by histopathologic features. Incisional biopsy is rarely recommended for a MCT due to the diagnostic capability of cytology and the increased potential for wound dehiscence secondary to both histamine and heparin release from the remaining tumor cells. If cytology is nondiagnostic, incisional biopsy should be minimal in size and in an area of minimal inflammation or necrosis. The incisional site should be easily excised in its entirety when the mass is removed. Overall, excisional biopsy is superior for both diagnostic and therapeutic purposes.

The Patnaik grading scheme is the most well known and used in pathology reports. Tumors are divided into three grades (I, II, and III). Grade I tumors have an indolent behavior with a metastatic potential of near 10%. Grade III MCTs are exceptionally aggressive with a metastatic rate of 80%. Grade II MCTs are by far the most common diagnosis. These tumors can behave similarly to both grade I and III and have a metastatic potential near 20%. Clinically, this grading scheme is very helpful for grade I and III lesions, but less predictive for grade II tumors.

As the vast majority of MCTs are in the grade II category, many clinicians struggle with interpretation and prognosis. Consequently, a recent collaboration of pathologists and oncologists proposed a new grading scheme. Kiupel *et al.* offered a two-tiered system composed of a low-grade and high-grade MCT. First, this study found an improved interpathologist agreement compared to the Patnaik scheme. Second, distinction between the two grades is based on a scoring system that evaluates mitotic index, karyomegaly, multinucleated cells, and bizarre nuclei. It is imperative to always request a microscopic description with mast cell histopathology as these characteristics are evaluated by that grading scheme. Low-grade MCTs (the majority of previously diagnosed grade I and IIs) have minimal metastatic potential and a median survival time of greater than two years. High-grade MCTs have a median survival time of less than four months due to the metastatic behavior of these tumors. To further aid clinical decisions, many diagnostic labs have started to report both grading systems in their histopathology reports.

Attempts have been made to link histologically determined cellular proliferation markers to MCT prognosis and clinical behavior. Proliferating cell nuclear antigen (PCNA), argyrophilic nucleolar organizing region-associated proteins (AgNORs), and the proliferation protein Ki-67 have all been evaluated with mixed results. Mitotic index has been repeatedly shown to have the most prognostic value and is required as part of the initial histopathology report. Tumors with a mitotic index of >5/10 hpf should be treated prognostically as high-grade MCTs.

Evaluation of c-kit mutation has prognostic utility but only when closely linked to histopathologic grade. More importantly, the presence of c-kit overexpression or mutation indicates a tumor that is more likely to be responsive to the new tyrosine kinase inhibitor class of drugs.

Therapy

The systemic toxicity of a MCT often requires treatment. Histamine is the compound found in mast cell granules that results in the most significant clinical changes. Activation of histamine receptors (H1 and H2) can lead to toxicity. Severe anaphylactic reactions are a result of systemic H1 receptor activation and can be treated with diphenhydramine and corticosteroids. In times of crisis, intravenous use of steroids is recommended. As a vasoactive molecule, histamine may also lead to marked hypotension which could require both colloidal and crystalloid support. H2 is more responsible for stimulation of gastric acid. Excessive H2 activation can lead to gastric ulceration and clinical side-effects that include anorexia, nausea, hematemesis, and melena. Routine H2 receptor antagonists such as famotidine and ranitidine can be effective but proton pump inhibitors (omeprazole) appear to be more potent at reducing gastric acid production and aiding healing of ulcers.

Currently, the author only recommends oral preventive diphenhydramine and famotidine (at routine dosing) for patients with documented MCT metastasis or tumor volumes greater than 5 cm in diameter.

Various components within mast cell granules are also responsible for delays in wound healing. This phenomenon is most commonly appreciated during incisional biopsy techniques. Wound failure is often noted within the first 3–5 days postoperatively.

Heparin is also released from mast cell granules. Coagulopathies are rare with MCTs as evidence suggests there is less heparin in malignant MCTs than in normal mast cells. Clinically, increased bleeding at the surgical site of a MCT is the most common coagulopathy noted.

Surgical removal of all MCTs is considered standard of care. Surgical removal of the lesion should include at least 2 cm of healthy tissue lateral to the lesion and one fascial plane deep to the tumor. Prior to pathology submission, it is recommended to mark margins with either suture or ink. Histopathology reports should comment on the surgical margins.

Many tumors are large or in too difficult of a location for a reasonable expectation of complete removal. A short trial (10–14 days) of antiinflammatory prednisone (1 mg/kg/day) can often result in significant tumor reduction. A recent study found that 70% of all MCTs treated with presurgical prednisone responded to therapy. The median reduction in tumor diameter was 45% with a median total tumor volume reduction of 80%. Tyrosine kinase inhibitors are also used to reduce tumor volume for surgery in situations where prednisone does not result in a significant response. When surgically amendable, these medications are not selected as the primary treatment due to their possible toxicities and cost (Figure 155.4).

For low-grade (both Kiupel grade I and the majority of Patnaik grade II) MCTs with no evidence of metastasis, complete surgical removal is considered curative and no adjuvant therapy is indicated.

Often, clinicians must determine treatment plans based on narrow tumor-free margins of 1–5 mm. Tissue specimens will constrict during processing. Adjuvant treatment is indicated if surgery is incomplete and tumor cells extend to the surgical margins. There are no clear guidelines for "narrow" surgical margins (1–5 mm) and each case should be evaluated uniquely. The author is usually more aggressive in adjuvant treatment recommendations for tumors with ≤1 mm clean margins as they have a higher potential to reoccur.

Numerous studies have suggested that there is a subset population (20–70%) of cutaneous MCTs that do not reoccur when tumor cells extend to the surgical margins. Theories include the lack of tumor volume resulting in a decrease in progrowth cancer signaling. The small tumor volume may also be amenable to self immune defense. Additionally, there is some belief that the peripheral mast cells in a tumor are normal mast cells that respond to chemotactic factors released by the tumor. When the tumor is removed and the signals are interrupted, the normal mast cells vacate the area.

Currently, there is no way to determine which low-grade MCT will reoccur. Thus, all incomplete excisions should be treated the same. An additional surgery is the ideal treatment and should be considered if there is adequate local skin for wound closure. For incompletely removed low-grade tumors that cannot be excised, radiation offers a 90% curative outcome. Radiation protocols usually entail a total of 45–55 Gy dispersed evenly over 18–22 total fractions or treatments. Although not evaluated in this adjuvant setting, hypofractionated radiation may also offer added benefit over monitoring alone.

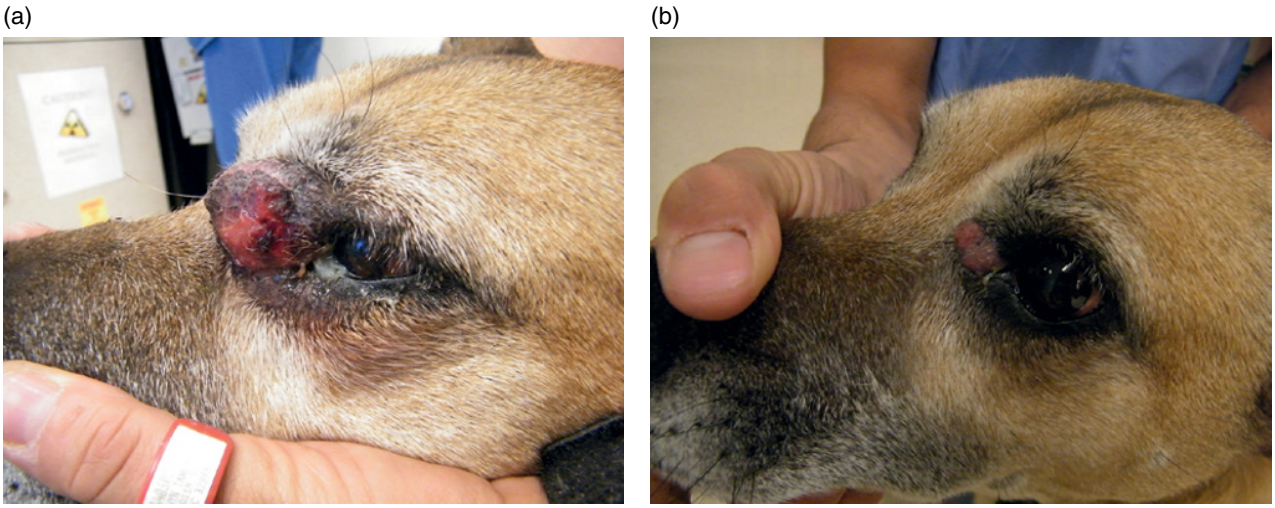

Figure 155.4 (a) A female mixed-breed dog at initial presentation with a MCT of the medial aspect of the upper eyelid. Enucleation of the eye was initially recommended. (b) The same patient after one month of tyrosine kinase therapy. Surgical margins were achieved with aggressive local excision without enucleation.

Either surgical removal or radiation of the draining lymph nodes should be considered for cases where regional node metastasis is confirmed (stage III).

There are a variety of chemotherapy treatment options for a MCT. The European consensus statement on MCTs indicates that chemotherapy is used to treat metastatic disease to either regional lymph nodes or distantly; when radiation or surgery are not available or possible; and as a neoadjuvant to reduce tumor burden prior to more traditional surgery or radiation. It is important to understand that chemotherapy does not offer the same curative results as radiation or surgery and should not be used as a convenient alternative to these modalities.

Prednisone has the longest history of use against MCTs. It is unclear if the effects of prednisone are truly cytotoxic or simply aid in reducing peritumoral edema and inflammation secondary to histamine release. A popular theory suggests that glucocorticoids block stem cell factor release from regional epithelial cells and fibroblasts. Stem cell factor is a known activating protein of the KIT pathway which is often mutated in MCTs. Antiinflammatory dosing of prednisone at 1 mg/kg/day is considered sufficient for MCTs. Immunosuppressive doses have not been found to be more effective and only increase the risk and severity of prednisone-induced side-effects.

Traditional chemotherapy options include the vinca alkaloids vinblastine and vinorelbine, the alkylating agent lomustine, and a taxane, paclitaxel. Both lomustine and vinblastine have an overall response rate of 40–50%. Recently, the drugs were combined with prednisone (Tables 155.1 and 155.2) and achieved an overall response

Table 155.1 CVP combination protocol as initially noted in Rassnick *et al*.

Week	Protocol
Week 1	Prednisone 2 mg/kg/day Lomustine 70 mg/m^2 PO
Week 3	Prednisone 1 mg/kg/day Vinblastine 3.5 mg/m^2 IV†
Week 5	Prednisone 1 mg/kg every other day until week 24 Lomustine 70 mg/m^2 PO
Week 7	Vinblastine 3.5 mg/m^2 IV
Week 9	Lomustine 70 mg/m^2 PO
Week 12	Vinblastine 3.5 mg/m^2 IV
Week 15	Lomustine 70 mg/m^2 PO
Week 18	Vinblastine 3.5 mg/m^2 IV
Week 21	Lomustine 70 mg/m^2 PO
Week 24	Vinblastine 3.5 mg/m^2 IV Taper off prednisone over 4 weeks

IV, intravenous; PO, by mouth (*per os*).

Table 155.2 Alternating lomustine and vinblastine protocol as initially noted in Cooper *et al*.

Week	Protocol
Week 1	Lomustine 60 mg/m^2 PO
Week 3	Vinblastine 2.0 mg/m^2 IV
Repeat for 4-6 cycles pending response	

IV, intravenous; PO, by mouth (*per os*).

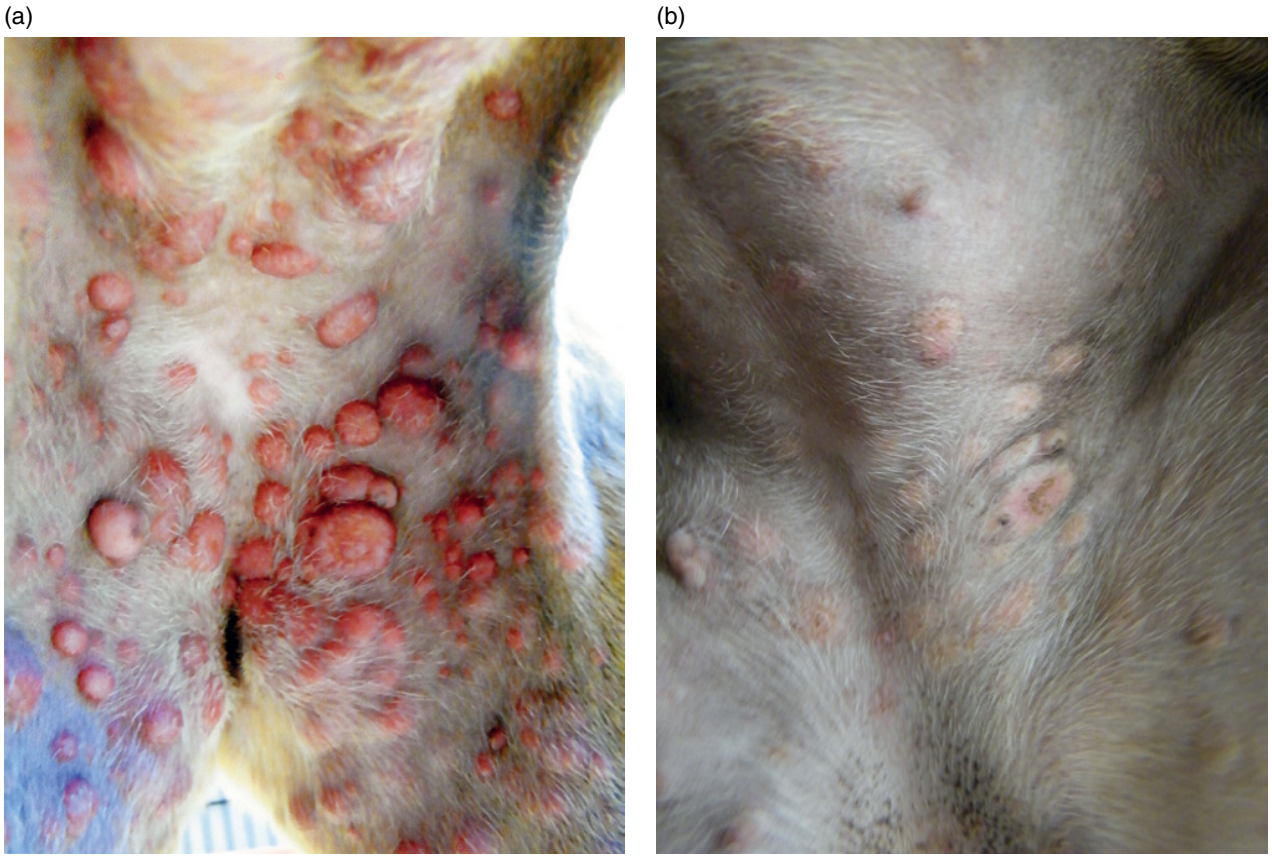

Figure 155.5 (a) A female boxer at presentation with over 300 dermal MCTs. (b) The same patient after two weeks of tyrosine kinase therapy.

of 65%. The micellar prepared paclitaxel has shown promise against MCTs but is not yet commercially available. The current formulation of paclitaxel (suspended in cremophor) has a marked increased risk of anaphylaxis during administration.

The tyrosine kinase receptor KIT is mutated and/or overexpressed in up to 40% of MCTs. These tandem duplication mutations at the juxtamembrane coding region result in the malignant behavior of cellular proliferation, adhesion, migration, and maturation. Consequently, KIT mutations have been found more commonly in higher grade MCTs.

Recent advancements in MCT treatments have led to the development of tyrosine kinase inhibitors. These drugs block the effects of mutated KIT receptors through competitive inhibition. Toceranib phosphate (Palladia™, Zoetis) is the first FDA-approved treatment for canine MCTs. It is labeled for the treatment of recurrent or nonsurgical high-grade mast cell tumors. Additionally, masitinib (Kinavet®, AB Science) achieved European regulatory approval under similar label guidelines but recently lost licensure by the FDA and is no longer available for use in the United States.

The reported efficacy of Palladia is near 40% (Figure 155.5). Palladia may be used for all grades of MCT but is more effective against MCTs with the known KIT mutation. The labeled dose of 3.25 mg/kg every other day results in significant gastrointestinal toxicity, myalgias, and neutropenia. Most clinical oncologists now prefer a lower dose of 2.5–2.75 mg/kg on a Monday-Wednesday-Friday treatment schedule. Oral famotidine and sucralfate may eliminate low-grade nausea or anorexia. Diarrhea is routinely treated with standard doses of loperamide. Protracted or severe clinical signs require a temporary discontinuation (drug holiday) of the medication until clinical improvement. Routine complete blood counts are recommended over the first six weeks of therapy. Therafter, a complete blood count chemistry panel and urinalysis are recommended approximately once every six weeks for patients that remain on tyrosine kinase inhibitors. Mild (grade I and II) neutropenias are commonly noted and do not require additional therapy or dosing alterations. However, patients should be monitored for progression. Idiosyncratic elevations in liver enzymes, hypertension and protein-losing nephropathies are also reported.

Adjuvant therapy with vinblastine/lomustine or Palladia for high-grade MCT is recommended even if the mass has been completely excised. Most adjuvant treatment protocols strive for 3–6 months of therapy, depending on tumor response and the patient's tolerance. In the adjuvant setting, chemotherapy results in median overall survival times of 11–16 months.

Prognosis

Multiple factors have prognostic value for canine MCTs. A subset of tumors have a more aggressive behavior based on their anatomic location. MCTs of the inguinal region (groin, perivulvar, scrotal, perianal) have historically been regarded as having greater metastatic potential. Newer information has revealed that survival is dependent on histologic grade. However, dogs with MCTs in these locations, specifically preputial and scrotal, have a decreased disease-free interval as both local recurrence and the development of subsequent MCTs are common. The biologic behavior of tumors in these areas is still debated so it is reasonable to use caution and proceed with routine MCT staging and more routine follow-up regardless of grade.

Mucocutaneous MCT (muzzle, vulva, sclera, etc.) and oral locations (tongue, palate) have a greater metastatic potential regardless of grade and should be aggressively staged at the time of cytologic diagnosis.

Mast cell tumors are the third most common tumor of the canine nailbed and have a more aggressive behavior compared to a traditional cutaneous MCT. Finally, primary visceral mastocytosis should be considered a highly aggressive neoplasm which is a terminal condition for most dogs.

As previously stated, histopathologic grading offers the most accurate prognosis. The majority of grade I (Patnaik) or low-grade (Kiupel) tumors are cured with complete excision. Less than 10% of grade I MCTs are reported to metastasize, with a median survival time of greater than two years. Alternatively, over 80% of grade III MCTs will metastasize and the median survival for high-grade MCT is less than four months.

Various proliferation markers may be used for additional prognostic information. Dogs with a Ki-67 index of <1.8 had a median survival time that was not reached within the time frame of the study and suggested a curative outcome. Those with a Ki-67 >1.8 had a median survival time of 9.7 months. While increases in both AgNORs and PCNA repeatedly support more aggressive tumors, they appear to only be prognostically valuable in conjunction with tumor grade. When evaluated independently of grade, both indices are ineffective in determining prognosis.

Feline Mast Cell Tumors

Epidemiology

Feline MCTs represent the second most common skin tumor in the cat. A genetic correlation has been linked to young Siamese cats. In addition, cats may develop both a visceral form of MCT that primarily originates in the spleen and a primary intestinal form.

Signalment

Cutaneous forms of feline MCTs are most commonly found in cats 10 years of age, with no reported gender predilection. Siamese less than 4 years of age are reported to be predisposed to the less common histiocytic form of cutaneous MCT. Visceral (both spleen and intestinal involvement) forms more commonly occur in older cats.

History and Clinical Signs

The majority of cutaneous lesions occur on the head and neck but can occur throughout the body. The most common presentation is a red, raised dermal lesion. As in the canine form, MCTs can appear with many other cutaneous manifestations including ulcerations, plaques, etc. (Figure 155.6).

Both abdominal forms of MCT result in a systemically ill patient. Vomiting, lethargy, and weight loss are most commonly noted. Splenomegaly can be severe on abdominal palpation while an intestinal mass is not always detected.

Diagnosis

Cytology is an appropriate diagnostic tool for both cutaneous and visceral lesions. Because of the incidence of

Figure 155.6 A clinically aggressive feline MCT. Note the change in coloration and ulceration throughout the lesion as well as the bruising at the base of the mass.

visceral mastocytosis associated with splenomegaly, the author strongly suggests the use of systemic antihistamines prior to cytology of an enlarged spleen. It is equally important to have corticosteroids readily available in case the cytology procedure results in an acute anaphylactic reaction. It is not necessary to premedicate all cats prior to cytology of an intestinal lesion. However, evidence of mast cells on the cytology sample justifies administration of antihistamines at that time.

An abdominal ultrasound is recommended for visceral mastocytosis. Additionally, mastocytemia is often noted on routine complete blood counts and can be isolated within the buffy coat.

Due to the low risk of metastasis, routine presurgical staging for skin tumors may not be indicated unless the patient has a clinical presentation (rapidly growing tumor) that supports a more aggressive phenotype. However, visceral and intestinal MCT should undergo complete staging with abdominal ultrasound, cytology of the liver and spleen, thoracic radiographs, minimum database bloodwork, buffy coat and potentially bone marrow aspiration.

Therapy

Cutaneous lesions that are <1 cm in diameter can be removed with routine excision. As their behavior is different from that of canine MCT, surgical margins of 2 cm are not indicated in cats. Routine "lumpectomy" or excisional biopsy margins are appropriate. If a minimal surgery is attempted, it is important to allow room for a second, wider surgery, should histopathology indicate a more aggressive lesion. For the clinically low-grade (dermal, <1 cm) tumors, local plesiotherapy with strontium-90 radiation probes offers the same curative outcome and can be used in areas where routine removal is unattainable.

Both intestinal and splenic (or true visceral) mastocytosis require abdominal exploratory surgery. Systemic therapy with antihistamines and corticosteroids is rarely effective at resolving clinical signs. Splenectomy is the treatment of choice for cats with the splenic form. Within reason, this procedure is still clinically applicable in the face of mild to moderate distant metastasis as splenectomy results in significant reduction in tumor burden and histamine release. However, splenectomy itself can be a life-threatening procedure due to the massive histamine release caused during splenic manipulation. It is recommended to premedicate all cats with appropriate dosing of diphenhydramine, famotidine, and dexamethasone preoperatively. Additionally, the spleen should be handled gently during vascular ligation and gently lifted out of the abdomen via a generous abdominal incision.

The visceral form is rarely cured with splenectomy so adjuvant treatment is recommended. Currently, there is no one accepted standard chemotherapy protocol for use in cats. Single-agent lomustine has been evaluated at a dose of 50–60 mg/m^2 (author's note: 10 mg/cat is considered an acceptable lomustine dose) with a reported overall response rate of 50%, with neutropenia and thrombocytopenia the most common and significant toxicities. Due to the variation in clinical picture, accurate survival times have not yet been determined.

Sixty-seven percent of feline MCTs are noted to have a c-kit mutation. At the time of publication, there are no published clinical data on the efficacy of tyrosine kinase inhibitors against feline MCTs. Masitinib has been evaluated in cats in a Phase I trial. The results indicate the drug is well tolerated at 12.5 mg/kg once a day with proteinuria noted as the most significant side-effect. Based on the tolerability of the medication and the proven c-kit mutation, use of tyrosine kinase inhibitor therapy in felines, in similar clinical situations as described in canines, appears reasonable.

If possible, intestinal resection with 5–10 cm margins should be considered for patients with the intestinal form. Unlike the splenic form, the presence of metastasis is much more clinically relevant as it will alter the prognosis significantly.

Prognosis

Neither the Patnaik nor Kiupel grading scheme is appropriate for feline cutaneous tumors. MCTs are labeled as either the more common mastocytic form or the histiocytic form. The latter type is often found in juvenile Siamese cats. The mastocytic form is then subtyped into either compact or diffuse. Compact mastocytic (more commonly referred to as well-differentiated) MCT represents 50–90% of all cutaneous MCTs in cats. The behavior of these lesions is benign and excisional biopsy may be all that is required for the majority of patients. The diffuse mastocytic form has a behavior similar to canine MCT. Thus, additional wide surgical margins and routine staging are indicated.

Splenectomy as a single treatment modality for the visceral form will result in a median survival time of 12–18 months. As previously stated, evidence of metastasis in other organs (lungs, liver, etc.) does not eliminate splenectomy as a surgical option due to the significant reduction in tumor burden and resulting improved clinical outcome. However, in the face of severe multifocal disease, splenectomy alone should not be considered.

The primary intestinal form historically caried the most guarded prognosis (4–6 weeks survival). However, more recent studies indicate that the prognosis may be far better (median survival time 531 days).

Apheresis in Companion Animals

Steven Suter, VMD, MS, PhD, DACVIM (Oncology)

Canine Bone Marrow Transplant Unit, NC State University College of Veterinary Medicine, Raleigh, NC, USA

Apheresis, which in Greek means "a taking away," is an extracorporeal therapy that has been an important part of physician-based medicine since the early 1970s. With the development of sophisticated cell separator machines and the commercial availability of human cytokines, centrifugal apheresis is an essential component in the treatment of a wide variety of human diseases, including cancer. Fortunately, with the availability of used, human cell separator machines to veterinarians employed at both academic institutions and high-end specialty practices, centrifugal apheresis is beginning to be recognized as a valuable tool in the treatment of a variety of canine diseases. This review will discuss how cell separators (also called apheresis machines) work, briefly discuss physician-based applications of apheresis, and review the current state of companion animal apheresis.

Cell Separator Machines

All cell separator machines, regardless of the manufacturer, are designed to separate specific blood components, most often based on cell density centrifugation. Therefore, an integral component of all machines is a large-scale centrifuge that is able to continuously separate blood into various fractions, including white blood cells (WBCs), platelets, and serum using continuous flow centrifugation (CFC). This means the blood can be collected into the machine, centrifuged, and returned to the patient simultaneously. The component of interest is typically pumped into a separate collection bag while the rest of the unused blood components are returned to the patient. Therefore, patients undergoing apheresis typically have a catheter placed in each leg or a dual-lumen catheter placed in one leg that allows blood to enter into the machine and pump the uncollected portions of the blood back into the patient. Because an anticoagulant, such as ACD-A, is added to the blood after it leaves the patient and before it enters the machine, apheresis patients actually experience very little loss of blood volume during the procedure.

The most popular cell collectors for physician-based medicine are the COBE® Spectra and Spectra Optia® apheresis systems manufactured by TerumoBCT (formerly CaridianBCT) and CS-3000 Plus and Amicus™ apheresis systems manufactured by Fresenius Kabi (formerly Fenwal, Inc). Other popular machines, due to their small size and portability, are the Haemonetics® MCS®+8150 Multicomponent Collection System (red blood cells and plasma only) and the MCS®+9000 Mobile Platelet Collection System.

Physician-Based Applications of Apheresis

The most widely used application of cell separator machines in physician-based medicine is the collection of platelets (plateletpheresis) for use in cancer patients receiving chemotherapy, radiation treatments, or bone marrow transplants, as well as patients with aplastic anemia and blood coagulation disorders. It takes approximately five whole units of blood to harvest the amount of platelets that can obtained from one 90-minute plateletpheresis. Therefore, one unit of platelets harvested using plateletpheresis can be used to treat 2–3 patients (www.redcrossblood.org/donating-blood/types-donations/platelet-donation). Plateletpheresis is considered absolutely safe with the most common side-effect being a tingling sensation in the lips due to transient hypocalcemia that is treated with calcium-containing antacid tablets.

Therapeutic plasma exchange (TPE), a form of plasmapheresis, is a procedure where the cell separator machine separates and removes the patient's plasma which is then replaced with either donated plasma or a protein solution such as 5% human albumin. TPE is typically used to remove disease-causing antibodies that cause a variety of immune-mediated diseases, including Guillain–Barré syndrome, chronic inflammatory demyelinating polyneuropathy (CIDP), and myasthenia gravis. It can also be used to treat thrombotic thrombocytopenia purpura (TTP) patients in an effort to reduce the thickness of the blood. TPE can also be used to remove large amounts of medication if the need arises.

Low-density lipoprotein (LDL) apheresis removes LDL cholesterol from the blood of patients with hypercholesterolemia using two specific types of apheresis machines approved by the US Food and Drug Administration (FDA). The Liposorber uses a filter covered with dextran that binds LDL cholesterol and removes it from the circulation. Another machine, called HELP, uses heparin to bind and remove LDL cholesterol. Since hypercholesterolemia is usually caused by the combination of mutations in a variety of genes (especially LDLRAP1) and lifestyle choices, treatment using LDL apheresis is usually life-long.

Photopheresis is a very specialized type of apheresis where the harvested white blood cells are exposed to a photoactive drug called methoxsalen which renders them sensitive to ultraviolet (UV) light. The cells are then exposed to UV light inside the machine and returned to the patient. This procedure can improve the symptoms of certain conditions such as graft versus host disease (GVHD), cutaneous T cell lymphoma, or organ transplant rejection, although it is currently not known exactly how photophoresis works. The length and number of procedures needed to provide benefit are highly variable.

Leukapheresis is used to remove extra white blood cells from the blood in patients with diseases that can cause very high white blood cell counts, including acute lymphoblastic and acute myeloblastic leukemias. Leukapheresis in these patients can significantly decrease blood viscosity and also decrease the chance of acute tumor lysis syndrome in patients starting induction chemotherapy.

Peripheral blood stem cell collections are used to harvest monocytes from patients after some type of blood cell mobilization, such as G-CSF (Neupogen) administration. A small percentage of the harvested monocytes (~1–4%) are CD34+ progenitor cells that can lead to complete hematologic reconstitution after some type of myeloablative therapy (such as total body irradiation or high-dose chemotherapy). This procedure is used to collect CD34+ progenitor cells for their use in both autologous and allogeneic bone marrow transplants when treating patients with lymphoma, leukemia, and multiple myeloma. The cells can also be used to treat other conditions including myelodysplastic syndromes and childhood neuroblastoma.

Companion Animal Apheresis

Plasmapheresis (the separation of plasma from blood to be used in primary and supportive disease management) is the most commonly reported apheresis procedure in the veterinary literature. In horses, plasmapheresis has been explored using continuous-flow cell separator machines based on data showing that plasma harvested from equine blood using fast erythrocyte sedimentation contains a high number of erythrocytes that could cause recipient sensitization and evidence that bacterial contamination can occur using an open collection system. In two studies, Feige *et al*. found that automated plasmapheresis using a Blutz separator AS 104 (Fresenius, Stans, Switzerland) was the method of choice when compared to whole-blood collection followed by either centrifugation or gravity sedimentation and that the plasmapheresis procedure itself was very well tolerated by the donor horses. To this author's knowledge, the use of TPE to treat equine patients with immune-mediated diseases has not been reported.

Canine plasmapheresis has also been reported using both membrane filtration and continuous-flow centrifugation. Bartges *et al*. used discontinuous membrane filtration plasmapheresis (Therapore, Therapeutic Apheresis Systems, Sarns/3M, Ann Arbor, MI) twice, in conjunction with corticosteroids, to treat a dog with acquired myasthenia gravis, which dropped the AchR antibody titer by ~70%. Crump and Seshadri used continuous membrane filtration (Prisma CRRT and TPE Control Unit, Gambro Inc., Lakewood, CO) to treat a dog with immune-mediated hemolytic anemia. In both reports, plasmapheresis was performed safely with minimal side-effects and the dogs responded clinically.

Canine TPE has also been reported, although the majority of studies were performed in the 1980s. Matus *et al*. used a cell separator (IBM 2997 cell separator, IBM Corp., Princetown, NJ) to treat three dogs with an IgA monoclonal gammopathy and secondary hyperviscosity. In all three dogs, one total plasma volume was removed and replaced with lactated Ringer's solution (LRS) and all three dogs responded clinically within 24 hourrs of treatment. This same group also treated one dog with systemic lupus erythematosus using a

combination of plasmapheresis and immunoabsorption. Plasmapheresis was performed eight times over a period of 45 days using the same cell separator and the harvested product was then passed over a column loaded with *Staphylococcus* purified protein A/SSPA, which binds canine IgG classes of antibodies. This dog also responded well clinically. Based on this case report, Matus *et al*. then treated five dogs with systemic lupus and two dogs with immune-mediated hemolytic anemia using plasmapheresis alone, using the same IBM cell separator. One total plasma volume was removed and replaced with LRS and all dogs responded clinically within 24 hourrs of the procedure.

Dogs have been undergoing leukapheresis in a research setting since 1967, although the collection of large amounts of cells needed for routine clinical use using CFC was not possible until the cloning and large-scale production of recombinant hematopoietic cytokines in the 1990s and the development of highly automated computer-controlled cell separators soon thereafter. Although there is a large body of research literature utilizing dogs as a preclinical model to develop leukapheresis techniques to collect a sufficient number of peripheral blood CD34+ cells to allow complete hematologic reconstitution following myeloablative therapy, the use of leukapheresis in the veterinary clinical setting is still in its infancy.

In 2006, Lupu *et al*. reported the use of a COBE Spectra cell separator to harvest enough peripheral blood CD34+ progenitor cells (>5 × 10^6/kg) for use in an allogeneic bone marrow transplant setting. Their choice of cell separator was based on the experience of the group at the Fred Hutchinson Cancer Research Center which showed that automated apheresis using a COBE Spectra machine developed for humans could also be used in dogs. Our group at North Carolina State University also found that an adequate number of peripheral blood progenitor cells could be safely harvested from dogs using a Fresenius Kabi CS-3000 Plus cell separator. We also showed that the CD34+ component of the harvest product was adequate to achieve complete hematopoietic reconstitution following lethal total body irradiation.

Finally, since all cell separator machines are designed for adult humans and their use in small children and dogs can be challenging, our group showed, similar to human pediatric data, that apheresis using a COBE Spectra cell separator can be safely performed in dogs weighing <14 kg if appropriate machine priming techniques are utilized. The smallest dog on which our group has performed apheresis on weighed 4.6 kg (unpublished data). This combination of older and more recent data clearly shows that canine leukapheresis is safe in a clinical setting and the procedure can harvest an adequate amount of hematopoietic progenitor cells for use in the canine bone marrow transplant setting.

Leukapheresis Followed by Bone Marrow Transplantation

Early research, performed mainly at the Fred Hutchinson Research Center, proved that canine peripheral blood CD34+ progenitor cells harvested using human cell separators could lead to complete hematologic reconstitution following lethal myeloablative therapy. Further work showed that dogs with lymphoma could be successfully treated in both an autologous and allogeneic bone marrow transplant setting with long-term survivals longer than chemotherapy alone.

More recently, our group at North Carolina State University used a combination of total body irradiation and autologous peripheral blood CD34+ progenitor cells, harvested using either a CS-3000 Plus or COBE Spectra cell separator, to treat dogs with high-grade B and T cell lymphoma. Five of 15 (33%) dogs with B cell lymphoma transplanted while in remission for their disease remained alive >2 years (median overall survival 524 days), while two of 13 (15%) dogs with T cell lymphoma transplanted while in remission for their disease remained alive >2 years (median overall survival 240 days). Importantly, when we transplanted dogs with B cell lymphoma who were not in clinical remission, their median disease-free intervals were significantly shorter than those who were in remission (52 days vs 456 days). In dogs with T cell lymphoma, although a smaller percentage of dogs were alive >2 years compared with the B cell lymphoma dogs, the median overall survival from the time of diagnosis to death was 602 days (range 246–928 days), which is significantly longer than when dogs are treated with chemotherapy alone.

Our group has also performed two allogeneic bone marrow transplants using DLA-matched donor peripheral blood CD34+ cells to treat one dog with B cell and one dog with T cell lymphoma (unpublished data). Both dogs underwent complete hematologic reconstitution and achieved full donor engraftment within six weeks of transplant. The dog with B cell lymphoma died of unexplained causes ~6 months post transplant, while the dog with T cell lymphoma remains alive ~22 months post transplant. We also treated a dog with acute large granular lymphocytic leukemia using DLA-matched donor peripheral blood CD34+ cells and this dog remains disease free at ~30 months post transplant. Both autologous and allogeneic bone marrow transplantation as treatments of canine lymphoproliferative disorders are currently offered at North Carolina State University and three private practices in the United States (CA, WA, and OH).

Plateletpheresis

Although, as stated previously, one of the primary uses of cell separator machines in physician-based medicine is plateletpheresis, canine plateletpheresis has been rarely reported and remains an underutilized resource in the clinical veterinary setting. Callan *et al*. used a Terumo COBE Spectra machine to assess the safety and feasibility of plateletpheresis using 14 normal adult dogs. In all cases, a high-quality, leukoreduced ($<1 \times 10^6$ WBCs) platelet concentrate (mean total yield of 3.3×10^{11} platelets) was collected in a mean procedure time of only 105 min. Since citrate-induced hypocalcemia was noted in some dogs, prophylactic IV Ca supplementation was recommended. Appleman *et al*. then extended this work by examining the effects of platelet *in vitro* function and *in vivo* survival using two different methods of cryopreservation (6% DMSO or Thrombosol). Although cryopreserved platelets using either method were not able to mimic fresh platelets in terms of *in vivo* platelet recovery, the authors concluded that both cryopreserved products could be considered for dogs with acute, life-threatening bleeding when fresh platelet products are not available.

Conclusion

Although cell separator machines are used daily in physician-based medicine to treat a wide variety of diseases, their use in veterinary-based medicine remains largely unexplored. Recent studies show that dogs can tolerate apheresis using human cell separator machines and that specific blood components can be harvested in a clinical veterinary setting. Moreover, it is clear that animals with a variety of diseases, including cancer, can achieve positive clinical outcomes when treated with cell separator harvest products. As such, apheresis in veterinary medicine remains a largely untapped resource that should expand in the future as more veterinarians become aware of the technology and more machines become available to our profession.

Section 12

Skin and Ear Diseases

157

Approach to the Patient with Dermatologic Disease

Lisa V. Reiter, DVM, DACVD

McKeever Dermatology Clinics, Eden Prairie, and Inver Grove Heights, MN, USA

Skin and ear diseases are among the most common reasons why clients seek veterinary consultation. Not only are diseases such as hypersensitivity disorders and skin and otic infections very common, the skin is the most accessible organ of the body, making it readily visible to owners. Thus, owners can easily detect abnormalities in the appearance, odor, and feel of the skin and haircoat, as well as appreciate how the disease is impacting their pet's quality of life along with their own. Because dermatologic problems are usually multifactorial, chronic, recurrent and noncurable, and often involve several dermatoses occurring simultaneously, owners and veterinarians alike can easily become overwhelmed.

It is the goal of this chapter to make the diagnosis and management of dermatologic disease more rewarding by guiding veterinarians toward a more methodical and efficient approach to the dermatologic patient. This will be accomplished by emphasizing the recognition of crucial lesions and their distribution, and assimilating these findings and other physical exam abnormalities with the history such that a comprehensive list of systematized differential diagnoses will be formulated and the most appropriate diagnostic tests selected. Finally, the chapter will end with a discussion of the common diagnostic tests utilized in the dermatologic patient, including indications, techniques, and interpretation.

History

Despite its complexity, the skin has limited means by which it "reacts" to indicate the presence of an underlying disease process, and because numerous skin diseases will manifest clinically in a similar way, the patient history is vital. Not uncommonly, obtaining a thorough and complete history will take longer than the examination itself. This process can be expedited by having a history form or questionnaire made available to the client to be completed either in the reception area or, ideally, emailed or mailed to the client prior to the consultation. There are several examples of dermatologic history forms available from multiple textbooks (included in the Further Reading section at the end of this chapter), online through the Veterinary Information Network (www.vin.com), and through various veterinary pharmaceutical companies. These forms can be adapted and modified to the clinician's own preferences.

The previously completed dermatology history form can be quickly reviewed with the client before or during the consultation, which decreases the time needed to extract a good history, and should begin with the client's primary complaint. Neglecting this can quickly result in a dissatisfied, "unheard" client, especially when the veterinarian's concerns do not immediately reflect the primary concerns of the client. Addressing the chief complaint will often result in an immediate list of differential diagnoses aimed at identifying the etiology of the underlying disease process. During review of the dermatologic history form, additional questions can be asked or posed in different ways to help extract pertinent information that pertains to specific problems. This is an art and takes practice!

The patient's signalment can further assist with formulating and ranking differential diagnoses, as there are some skin diseases that are more likely to occur in specific age ranges, sexes (including neuter status), and in certain breeds. The age of onset of the dermatologic disease can be particularly helpful in the very young and very old patient. For instance, younger animals are more commonly afflicted with diseases such as demodicosis, otodectes, and dermatophytosis, as well as congenital and hereditary diseases, whereas middle-aged to older animals are more commonly diagnosed with autoimmune dermatoses, neoplastic conditions,

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

and endocrinopathies. However, most diseases manifest between approximately 1 year and 6–8 years of age where no clear relationship between age and disease exists. The breed of the patient may help with the development of an initial differential diagnosis list. There are some breeds, including those with a specific coat color, that seem to be predisposed to specific dermatologic conditions. In addition, certain diseases are congenital or have an identified heritable basis while others simply occur more frequently in some breeds than in others (Table 157.1).

Occasionally, sex predilections for various diseases exist and can help in formulating and ranking the differentials. For instance, females are anecdotally reported to be more prone to systemic lupus erythematosus. Neuter status should also be taken into consideration. Estrus has been known to exacerbate pruritus in females, and intact males are at increased risk for male feminization syndrome.

The disease history can be further clarified by addressing some key questions including the date of onset (in addition to the age of onset, discussed above), location and appearance of the initial lesions, duration and progression of the disease. The approximate date of onset may help to track seasonality or possibly create a timeline for assessment of a drug- or vaccine-induced cutaneous reaction. Depending on geographic location, disorders such as insect bite hypersensitivities and flea allergy dermatitis tend to occur in the summer. In temperate climates, atopic dermatitis often begins as a seasonal disease, typically worsening in the spring, summer, and/or fall. However, some patients with house dust mite hypersensitivity may worsen in the winter in addition to having year-round pruritus. Canine flank alopecia, also known as seasonal or cyclical flank alopecia, tends to result in cyclical episodes of noninflammatory, nonpruritic alopecia in the winter where a shorter photoperiod induces follicular arrest with resolution occurring in the spring.

Specifying the initial lesion location and pattern of distribution can be extremely helpful in developing a differential diagnosis list, as many diseases have distinct areas of involvement. For instance, pemphigus foliaceus affects the pinnae, dorsal aspect of the muzzle, and the pawpads. Sarcoptic mange tends to affect the pinnal margins, elbows, and tibiotarsal areas. The importance of lesional distribution will be further discussed in the physical exam (PE) section. Questions pertaining to disease duration and progression should include if and how location, appearance, and distribution have changed, whether the onset was acute or slow and insidious, and if the disease is continuous or intermittent (seasonal or nonseasonal). An acute onset of severe pruritus often occurs with sarcoptic mange, and diseases such as pemphigus foliaceus and contact dermatitis tend to erupt rapidly. Cutaneous adverse food reaction may also have a rapid onset, whereas endocrinopathies tend to have a slow onset. A patient with seasonal pruritus would not require a food elimination trial, as adverse food reactions cause year-round signs.

One of the most important historical questions to address is whether or not the disease was precipitated by or associated with pruritus, as this information can rapidly help to generate and shorten the list of differentials. If pruritus preceded the lesions, then allergic or parasitic diseases are most likely. If lesions, such as alopecia, precede the pruritus, endocrinopathies, follicular dysplasias and follicular demodicosis must be explored. If papules, pustules, epidermal collarettes or crusts precede the pruritus, the so-called "rash that itches," pursue bacterial, any nonpruritic dermatoses prone to developing secondary bacterial infection such as endocrinopathies, and sterile pustular diseases (e.g., pemphigus foliaceus). Diseases that are typically or always pruritic include atopic dermatitis, cutaneous adverse food reaction, flea bite allergy, contact hypersensitivity, sarcoptic and notoedric mange, and demodicosis caused by *Demodex gatoi* in cats and *Demodex cornei* in dogs. Variably pruritic conditions include cheyletiellosis, demodicosis caused by *Demodex injai*, *Malassezia* dermatitis, superficial pyoderma, feline dermatophytosis, autoimmune diseases such as pemphigus foliaceus, and epitheliotropic lymphoma. Diseases that are nonpruritic include endocrinopathies, follicular dysplasias, canine dermatophytosis, and demodicosis caused by *Demodex canis* and *Demodex cati*. However, these conditions can be pruritic if accompanied by secondary infection.

Identifying patterns of pruritus is also important for identifying underlying disease triggers. A patient whose pruritus always improves with a change in environment likely has atopic or contact dermatitis. In a patient with nonseasonal pruritus that also has seasonal "flares," adverse food reaction should be explored in addition to atopic dermatitis. A patient that suddenly becomes pruritic after residing at a boarding kennel should be evaluated for sarcoptic mange.

Owners often do not recognize the various manifestations of pruritus, such as licking, biting, chewing, rubbing, rolling, and scooting, and the clinician needs to ask about these variable signs. Therefore, evaluation of pruritus should not stop at asking if the patient "itches." Also, determining the level of pruritus is important in the development of an adequate treatment plan and evaluating the patient's response to treatment. Commonly, owners are asked to rank their pet's level of pruritus on a scale of 0 to 10, with 0 representing no itch at all and 10 being so itchy that the pet cannot sleep at night (and neither can the poor owner!).

Table 157.1 Common skin diseases in various breeds

Breed	Disease
Abyssinian cat	Follicular dysplasia Psychogenic alopecia
Afghan hound	Hypothyroidism
Airedale terrier	Atopic dermatitis Canine flank alopecia Hypothyroidism
Akita	Postclipping alopecia Pemphigus foliaceus Sebaceous adenitis Uveodermatologic syndrome
Alaskan malamute	Alopecia of plush-coated breeds (alopecia X, follicular dysplasia, follicular arrest syndrome) Postclipping alopecia Zinc-responsive dermatosis
American bulldog	Atopic dermatitis Ichthyosis Solar dermatitis
American Staffordshire terrier	Atopic dermatitis Canine flank alopecia Demodicosis Solar dermatitis
American water spaniel	Pattern alopecia
Basset hound	Atopic dermatitis Intertrigo *Malassezia* dermatitis
Beagle	Atopic dermatitis Alopecia areata Demodicosis Hypothyroidism Immunoglobulin (Ig)A deficiency Sebaceous adenitis
Bearded collie	Black hair follicular dysplasia Pemphigus foliaceus Symmetric lupoid onychitis
Beauceron	Epidermolysis bullosa Dermatomyositis
Belgian shepherd dog, Belgian tervuren	Dermatomyositis Sebaceous adenitis Vitiligo
Bengal cat	Ulcerative nasal dermatitis
Bernese mountain dog	Color dilution alopecia Histiocytic sarcoma Systemic histiocytosis
Border collie	ABCB1 genetic mutation Black hair follicular dysplasia
Borzoi	Hypothyroidism
Boston terrier	Atopic dermatitis Demodicosis Pattern alopecia Hyperadrenocorticism Tail and facial fold intertrigo
Bouvier des Flandres	Canine flank alopecia
Boxer	Atopic dermatitis Canine acne Canine flank alopecia Demodicosis Dermoid cyst Food hypersensitivity Hyperadrenocorticism Hypothyroidism Histiocytoma Mast cell tumor Solar dermatitis (white boxers) Sterile granuloma pyogranuloma syndrome Superficial bacterial folliculitis Urticaria
Brittany spaniel	Complement deficiency Discoid lupus erythematosus Hypothyroidism Lip fold intertrigo
Bullmastiff and mastiff	Bacterial folliculitis and furunculosis Vitiligo
Bull terrier	Atopic dermatitis Lethal acrodermatitis Nasal folliculitis and furunculosis Pedal folliculitis and furunculosis Solar dermatitis Zinc-responsive dermatitis
Cairn terrier	Atopic dermatitis Ichthyosis
Cavalier King Charles spaniel	Black hair follicular dysplasia Caudal occipital malformation syndrome Eosinophilic granuloma (oral) Ichthyosis Primary secretory otitis media
Chesapeake Bay retriever	Atopic dermatitis Follicular dysplasia Superficial bacterial folliculitis
Chihuahua	Color dilution alopecia Pattern alopecia Pinnal thrombovascular necrosis
Chow chow	Alopecia of plush-coated dogs (alopecia X, follicular dysplasia, follicular arrest syndrome) Atopic dermatitis Color dilution alopecia Demodicosis Hypothyroidism Pemphigus foliaceus Postclipping alopecia Tyrosinase deficiency Uveodermatologic syndrome

The presence of systemic signs and the pet's general health should be addressed, such as water intake, appetite, vomiting, diarrhea, frequency/number of bowel movements, changes in urination, respiratory changes, lethargy, and body condition changes. General information about the patient's environment and geographic location needs to be considered. Certain diseases are endemic in various regions such as blastomycosis in the Mississippi, Missouri and Ohio river valleys or coccidioidomycosis in the southwestern portion of the United States. For the same reason, travel history should also be obtained. It is pertinent to ask if other animals in the home or the owners themselves are affected. If so, contagious and zoonotic diseases need to be considered.

Other medical problems, vaccine history, lists of previous and current treatments and medications, including topical therapy, flea control products and frequency of administration, need to be addressed, including the responses to these therapies. Reviewing previous medical records can be particularly helpful regarding medication history, as often owners find it difficult to remember all the previous medications, including the ones the patient may be currently taking. Asking owners to bring these medications to the initial consultation can also be helpful in this regard. Any previous medical records should be reviewed to help track episodes of recurrence (is there a seasonality?) and progression of the skin disease, verify client observations, and identify past and current medications, including dose and duration. The response to various treatments can also be extremely helpful in the identification of underlying disease processes. For example, a patient that presents on high doses of glucocorticoids for suspected allergic dermatitis that is still markedly pruritic needs to be evaluated for sarcoptic mange and/or undergo a treatment trial for this disease if the mites cannot be found, as allergic patients tend to be glucocorticoid responsive. When presented with a patient that is on an appropriate dose and duration of antibiotic therapy for superficial pyoderma and is not responding, a skin culture needs to be performed.

Finally, a complete dietary history including vitamins, herbs, and other supplements should be taken. This will be useful if a food elimination trial needs to be performed as well as to assess if the diet is complete and balanced. Poor diets can lead to keratinization disorders, poor haircoat quality, and zinc-responsive dermatosis.

Physical Examination

The patient's weight, rectal temperature, and pulse should be obtained by the veterinary technician or assistant before or during review of the patient history. Every patient examination should be approached in a systematic fashion to ensure a thorough PE. Avoid focusing

solely on the area(s) that the owner mentions or you may miss hidden, subtle lesions that can offer important diagnostic clues pertaining to the underlying disease process. A well-lit room is essential and a hand-held magnifying lens may be useful for close examination of lesions. In some instances, the hair may need to be clipped to allow for proper visualization. Painful or "uncooperative" patients may require sedation.

Many dermatologists prefer to start with the nose and head region and work caudally, including all accompanying mucosal and mucocutaneous surfaces. The interdigital spaces, claws, ungual folds, and pawpads must always be evaluated with the patient either standing or in lateral recumbency. Part the hair or roll the skin into individual folds to separate the hair and allow for easier evaluation of the cutaneous surface and follicular ostia while also noting the haircoat quality, color, and luster. Throughout the evaluation, look for evidence of pruritus, such as excoriations and salivary staining, the latter of which commonly manifests as a brownish-red discoloration of the haircoat. An otoscopic examination should be performed in all patients. Examination findings can be documented using topography maps available at www.vin.com or in the texts listed in the Further Reading section. These maps allow for quick illustration of lesion distribution and character during the initial consultation and subsequent rechecks which assist the clinician in making comparisons regarding disease progression between appointments. The patient should be auscultated, and the lymph nodes and abdomen palpated. These aspects of a general examination are important as they can reveal an underlying systemic disease which may be giving rise to the dermatologic changes. Also, findings on a general PE may dictate or change the choice of drug therapy. For instance, the discovery of a cardiac murmur in a feline patient may prompt the clinician to be more cautious with the administration of injectable glucocorticoids, given that cats are at increased risk of developing congestive heart failure when receiving them, especially methylprednisolone acetate.

During the course of the PE, the clinician must learn to identify the major features of the skin lesions. This will allow the disease to be placed in diagnostic categories that facilitate diagnosis. Most important are the type of lesions (primary or secondary) and lesion distribution (body sites involved). Proper identification of lesions is crucial, as they can be correlated with specific diseases.

Morphology of Lesions

Lesion morphology refers to the categorization of cutaneous lesions as primary, secondary, or either primary or secondary. The ability to accurately identify these lesions as well as having an understanding of their development is critical in refining the list of differentials. Also, knowing how primary lesions typically evolve into secondary lesions gives the clinician a better understanding of disease progression. A primary lesion develops spontaneously and is a reflection of the underlying disease process; thus these lesions are the most important to identify. Secondary lesions evolve from primary lesions or are created by the patient scratching or external forces such as trauma, medications, and infection of primary lesions. Some lesions can be considered primary or secondary. Table 157.2 provides a list and description of basic cutaneous lesion morphology. An accompanying figure is provided for most of these lesions which elaborates on their significance/pathomechanism and provides examples of differentials (Figures 157.1–157.18).

Table 157.2 Terminology used to describe lesion morphology

Lesion	Definition
Primary lesions	
Macule/patch (see Figure 157.1)	Circumscribed, flat, nonpalpable change in skin color <1 cm. If larger, termed a patch
Papule/plaque (see Figure 157.2)	Solid elevation of skin ≤1 cm in diameter. Plaque formed by confluence of papules >1 cm in diameter. Can be follicular or nonfollicular
Vesicle/bulla (see Figure 157.3)	Circumscribed, elevated skin lesion containing fluid ≤1 cm in diameter. If greater than 1 cm, termed a bulla. Can be intraepidermal or subepidermal
Pustule (see Figure 157.4)	A vesicle containing purulent exudate. Can be follicular or nonfollicular
Wheals (see Figure 157.5)	Flat-topped sharply circumscribed elevation of the skin caused by edema. If regionalized or generalized, referred to as angioedema
Nodule/tumor (see Figure 157.6)	Solid or cystic elevation of skin >1 cm in diameter. Tumor if >2 cm in diameter
Secondary lesions	
Epidermal collarette (see Figure 157.7)	Circular lesion with a rim of loosely adhered scale or peeling keratin. Often described as the "footprint" of a pustule or vesicle
Excoriation (see Figure 157.8)	Superficial excavations of the epidermis that may be linear or punctate
Erosion/ulceration (see Figure 157.9)	Superficial epidermal defect that heals without scarring due to trauma or inflammation. If deep enough to affect the dermis, an ulcer occurs and heals with scarring
Scar	Formation of fibrous tissue in place of damaged dermis or subcutaneous tissue

Table 157.2 (Continued)

Lesion	Definition
Fissure (see Figure 157.10)	Linear cleavage in the skin
Lichenification (see Figure 157.11)	Thickening and hardening of the skin characterized by an exaggeration of the superficial skin markings. Commonly hyperpigmented
Callus	Alopecic, thickened, rough, often lichenified plaque
Primary or secondary lesions	
Alopecia (see Figure 157.12)	Partial to complete loss of hair
Scale (see Figure 157.13)	Accumulation of loose fragments of stratum corneum
Crust (see Figure 157.14)	Dried exudates of purulent material, serum or blood on surface of skin
Follicular casts (see Figure 157.15)	Accumulation of follicular and keratinaceous debris that adheres to multiple hair shafts at the level of the follicular ostia
Comedones (see Figure 157.16)	Dilated hair follicles filled with cornified epithelium and debris
Pigmentary abnormalities (see Figures 157.17 and 157.18)	Changes in skin coloration caused by a variety of pigments (typically increased or decreased melanin) including black, blue, gray, tan, brown, as well as red/purple (hemorrhage within skin) and yellow-green (bile pigment)

Distribution of Lesions

In addition to recognizing lesion morphology, the location and distribution must be identified. Lesion distribution refers to whether the lesions are localized, multifocal, regionalized or generalized, bilaterally symmetric versus asymmetric, and identifying the general regions of the patient that are involved. Bilaterally symmetric lesions tend to occur in endocrinopathies, immune-mediated and autoimmune diseases, and can also occur in allergic skin diseases. Asymmetric lesions are often the result of infectious and parasitic disease processes. Certain diseases have predilection sites for various areas of the body and familiarity with these regional characteristics is advantageous in honing the list of differential diagnoses (Table 157.3).

Dermatologic Diagnostic Tests and Techniques

After a list of differential diagnoses has been generated based on a thorough history and PE, diagnostic tests can be employed to further narrow the list of differentials

Figure 157.1 *Macule* – pigment changes occur due to increased or decreased melanin (inflammatory and noninflammatory causes), erythema or local hemorrhage. Other types of macules include purpura, petechiae, and ecchymoses. Differential diagnoses (DDx) – hyperpigmentation (noninflammatory): lentigo, pigmented nevi, endocrinopathies, hormonal diseases, color dilution alopecia and other follicular dysplastic diseases, such as canine flank alopecia. Hyperpigmentation (inflammatory): bacterial or yeast infections, dermatophytosis, parasitic disease, and any disease resulting in pruritus. Depigmentation: vitiligo, uveodermatologic syndrome, mucocutaneous pyoderma, discoid lupus erythematosus. Erythema: inflammation secondary to a variety of underlying causes such as bacterial or yeast infections, dermatophytosis, demodicosis, *Sarcoptes*, vasculitis, erythema multiforme, toxic epidermal necrolysis, pemphigus, cutaneous T cell lymphoma, superficial necrolytic dermatitis (SND), hypersensitivity disorders and solar dermatitis or hemorrhage due to trauma, vasculopathies or coagulopathies. Photograph illustrates lentigo.

Figure 157.2 *Papule* – these palpably solid elevations are usually pink to red in coloration and are caused by a localized inflammatory cellular infiltrate within the dermis, epidermal hyperplasia, and early tissue infiltration of neoplastic cells. DDx – superficial bacterial folliculitis, dermatophytosis, demodicosis, *Sarcoptes*, *Cheyletiella*, insect/arachnid hypersensitivity, contact hypersensitivity, flea allergy dermatitis, atopic dermatitis, immune-mediated disease, and drug reactions. Photograph illustrates papules associated with sarcoptic mange.

Figure 157.3 *Vesicle* – lesions are fragile, transient, and difficult to find given that they develop secondary to inflammation and loss of cutaneous cellular and structural cohesion. DDx – viral infections, irritants, drug reactions, and autoimmune diseases including pemphigus vulgaris, lupus, and subepidermal blistering diseases such as mucous membrane pemphigoid, and epidermolysis bullosa acquisita. Photograph illustrates vesicles on the lower lip margin in a dog with epidermolysis bullosa acquisita. *Source*: Courtesy of Sandra Koch.

Figure 157.4 *Pustule* – lesions arise due to neutrophilic inflammation, occasionally eosinophilic. DDx – superficial bacterial folliculitis, impetigo, dermatophytosis, demodicosis, pemphigus foliaceus, lupus, and subcorneal pustular dermatosis. If eosinophils predominate, consider sterile eosinophilic pustulosis, insect or contact hypersensitivity and ectoparasites. Photograph illustrates pustules associated with superficial bacterial folliculitis.

and/or confirm a specific diagnosis. There are four basic screening tests that every clinician should be adept at and perform often, as they are easy, rapid, and inexpensive to conduct and yield immediate results. This minimum database generally includes cytology, including various techniques of cutaneous cytology and otic cytology, as well as trichography, skin scrapes, and cultures. Other diagnostic tests of importance to the dermatologic patient that will be discussed include

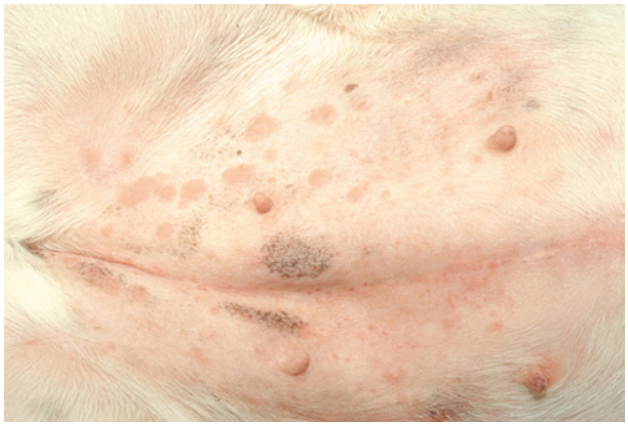

Figure 157.5 *Wheal (hive)* – these edematous lesions typically disappear within minutes to hours. When larger regional areas are involved such as the muzzle or eyelids, this is called angioedema. DDx – vaccine, drug and insect bite reactions, and hypersensitivity disorders. Photograph illustrates urticaria on the abdomen of a dog.

Figure 157.6 *Nodule* – these lesions develop due to an inflammatory or neoplastic cellular infiltrate, or from deposition of metabolic products such as fibrin and crystalline material extending to the dermis and subcutis. There are numerous neoplastic and nonneoplastic causes. Nonneoplastic causes include infectious and noninfectious etiologies. DDx – infectious causes: bacterial infections such as actinomycosis, nocardiosis, feline leprosy, canine leproid granuloma, atypical mycobacteriosis, and bacterial furunculosis. Fungal causes include blastomycosis, cryptococcosis, coccidioidomycosis, sporotrichosis, histoplasmosis, dermatophytic kerion, aspergillosis, phaeohyphomycosis, hyalohyphomycosis, pythiosis, and lagenidiosis. Algal causes include protothecosis. Parasitic and protozoal causes include leishmaniasis, dracunculiasis, *Cuterebra*, and *Neospora*. Noninfectious causes: calcinosis cutis, xanthomas, sterile nodular panniculitis, sterile granulomatous pyogranulomatous syndrome, cutaneous reactive histiocytosis, juvenile cellulitis, foreign body reaction, and eosinophilic granuloma. Photograph illustrates multiple nodules on the muzzle of a dog with sterile granulomatous pyogranulomatous syndrome.

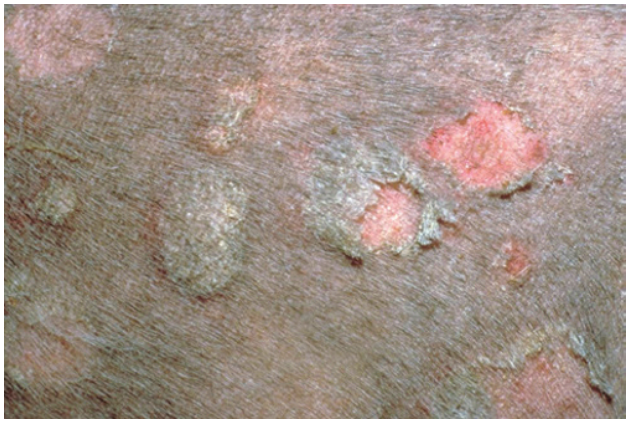

Figure 157.7 *Epidermal collarette* – these are formed from the remnants of a pustule or vesicle after the roof has been lost, or caused by a point source of inflammation, as seen with papules. DDx – superficial bacterial folliculitis most commonly. Fungal infection, immune-mediated dermatoses, contact hypersensitivity, and insect bite reaction are less common causes. Photograph illustrates an epidermal collarette associated with superficial bacterial folliculitis.

Figure 157.8 *Excoriation* – these lesions are self-induced and occur secondary to scratching, biting, and/or rubbing. Usually result from pruritus. Photograph illustrates excoriations and erosions due to scratching and licking on the lateral aspect of the thorax of a cat with adverse food reaction.

therapeutic trials, biopsy and histopathology, and tests of noncutaneous organs.

Screening Tests

Cytology

Cytology is a powerful tool, allowing one to quickly determine whether a lesion is sterile or if infectious organisms and inflammation are present. It allows the clinician to presumptively diagnose a patient with autoimmune diseases, such as pemphigus, when acantholytic cells are observed. Neoplastic processes may also be identified, such as

Figure 157.9 *Erosion/ulceration* – develop due to rapid death and/or loss of keratinocytes as a consequence of self-inflicted trauma or inflammation. An ulcer denotes a deep pathologic process. DDx – autoimmune dermatoses, erythema multiforme, toxic epidermal necrolysis, drug reaction, SND, feline indolent ulcer, deep pyoderma, deep mycoses, vasculitis, neoplasia, chemical/thermal burn. Photograph illustrates an ulcer on the lateral aspect of the thorax of a dog with a cutaneous adverse drug reaction secondary to itraconazole therapy.

Figure 157.10 *Fissure* – lesions may be caused by underlying disease or injury when the skin is thick and then subjected to sudden swelling. DDx – SND, canine distemper, zinc-responsive dermatosis, chronic skin diseases, and keratinization disorders. Photograph illustrates fissures on the metacarpal pawpad of a dog with SND.

cutaneous lymphoma and mast cell tumors. Cytology can be performed in a number of ways depending on the area and the condition of the skin being sampled.

Figure 157.11 *Lichenification* – results from chronic trauma, often due to friction. Lichenification is often accompanied by superficial bacterial folliculitis and/or *Malassezia* dermatitis. DDx – chronic and pruritic dermatopathies, intertrigo, and keratinization disorders. Photograph illustrates the abdomen and inguinal area of a dog with chronic atopic dermatitis.

Figure 157.12 *Alopecia* – may arise from several causes that lead to damage to hairs and/or hair follicles, or result from abnormal hair growth. DDx – primary: endocrinopathies, follicular dysplasia, telogen effluvium, and anagen defluxion. Secondary: pruritus, superficial bacterial folliculitis, dermatophytosis, and demodicosis. Photograph illustrates multiple annular to coalescing areas of alopecia in a beagle with alopecia areata.

Figure 157.13 *Scale* – results from increased production of keratinocytes, such as occurs with abnormalities of keratinization, inflammatory disorders or from increased retention of corneocytes. DDx – primary: ichthyosis, primary idiopathic seborrhea, various follicular dysplasias. Secondary: chronic inflammation or any direct insult to the epidermis such as epidermal infiltration of neoplastic lymphocytes in cutaneous T cell lymphoma. Photograph illustrates large, whitish-gray sheets of scale in a golden retriever with ichthyosis.

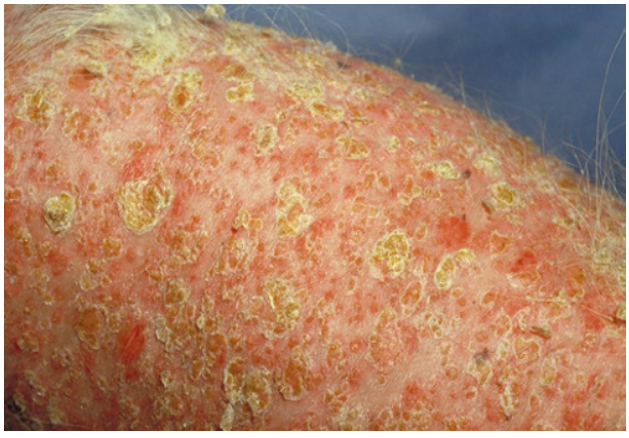

Figure 157.14 *Crust* – forms when purulent exudate, serum, blood, other dried exudates, or cells and/or scales adhere to the skin surface. DDx – primary: SND, vitamin A-responsive dermatitis, zinc-responsive dermatosis, primary idiopathic seborrhea. Secondary: pyoderma, dermatophytosis, pemphigus, and lupus. The coloration, thickness, and adherence of crusts can provide insight as to the underlying disease process. Pyoderma can result in brown-dark red (indicating hemorrhage) or yellow-green crusts. Dark crusts indicate deeper tissue damage or hemorrhage as occurs with traumatic wounds, furunculosis, and vasculitis. Honey-colored crusts usually indicate an infection but also occur with some autoimmune diseases, particularly pemphigus foliaceus. Thick, dry yellowish crusts are more common with scabies and zinc-responsive dermatosis. Tightly adhered crusts are more common in zinc-responsive dermatosis, SND, pemphigus, and some cases of seborrhea. Photograph illustrates the typical honey-colored crusts associated with pemphigus foliaceus.

Figure 157.15 *Follicular casts* – these lesions are composed of a combination of keratin and follicular material that adheres to the hair shaft(s), extending above the surface of the follicular ostia. DDx – primary: sebaceous adenitis, vitamin A-responsive dermatosis, idiopathic seborrhea. Secondary: dermatophytosis and demodicosis. Photograph illustrates clumps of keratosebaceous material adhered to the base of multiple hairs from a dog with sebaceous adenitis.

Figure 157.16 *Comedones* – in general, these lesions may form as a result of primary keratinization disorders or hyperkeratosis due to endocrine abnormalities or inflammation. DDx – primary: endocrinopathies, feline acne, some primary idiopathic seborrheas, congenital hypotrichosis (e.g., Chinese crested dogs), schnauzer comedo syndrome, and vitamin A-responsive dermatosis. Secondary: seborrheic skin disease, application of occlusive greasy medications and administration of systemic or topical corticosteroids, demodicosis and, less commonly, dermatophytosis. Photograph illustrates comedones on the caudolateral aspect of the dorsum of a dog.

Figure 157.17 *Pigmentary abnormalities* – hypopigmentation-hypomelanosis occurs due to a loss of epidermal melanin. DDx – primary: vitiligo. Secondary: common postinflammatory change. Photograph illustrates depigmentation of the nasal planum, rostral muzzle, and lips of a dog with vitiligo.

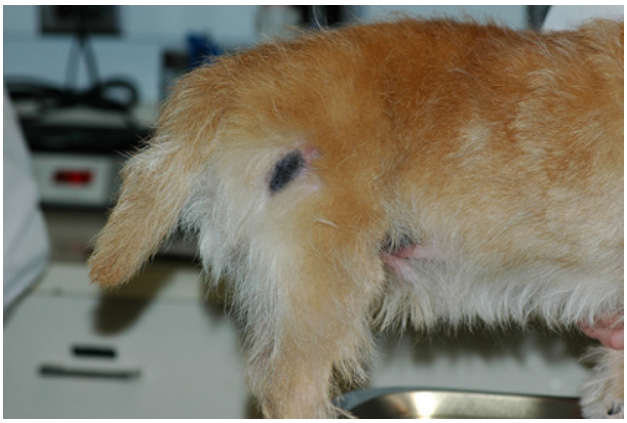

Figure 157.18 *Pigmentary abnormalities* – hyperpigmentation-hypermelanosis occurs with increased epidermal and/or dermal melanin. DDx – primary: endocrinopathies. Secondary: commonly seen in chronic inflammation and as a postinflammatory change associated with a variety of dermatopathies. Photograph illustrates postinflammatory hyperpigmentation in a dog with rabies vaccine-induced alopecia.

Impression Smear

A routine impression smear is one of the most commonly employed dermatologic tests, and an excellent technique to use when pustules, crusts, epidermal collarettes, and draining nodules are present and for moist or greasy areas of the skin. When a pustule is present, gently "open" the pustule by using a 25 gauge needle and pass it in a parallel fashion through the tip of the pustule. Avoid directly "poking" or "sticking" the pustule, as this will artefactually contaminate the specimen with blood and blood-associated leukocytes. When crusts are present, gently remove the crust and sample the contents underneath by pressing the slide gently onto the affected skin. This helps to avoid surface contaminants. When epidermal collarettes are present, rather than

Table 157.3 Regional predilections of skin diseases

sampling the center of the lesion, a more diagnostic sample can be obtained by lifting the scales and crusts from the perimeter and sampling the edge of the lesion as described for crusts.

Once the lesion is prepared for an impression, a glass slide should be gently pressed against the site, heat fixed (either by using a lighter passed under the slide until a light smoky black residue is observed or by using a slide warmer for 20 seconds) or allowed to air-dry, and stained with a modified Wright's stain (e.g., Diff-Quik). Gram stain or new methylene blue can also be used. When using Diff-Quik (which the author prefers), allow the slide to sit in each reagent for approximately 20 seconds. Rinse the slide gently with water after the third solution. The slide should then be air- or blow-dried.

The sample should first be evaluated under the microscope using low-power magnification (×10) to peruse for an infectious versus inflammatory versus neoplastic process. The author finds it easiest to look for acantholytic cells and certain fungal organisms, such as blastomycosis, under the low-power objective, whereas immediate use of the oil immersion objective (×100) may result in the missing of rare organisms or cells. The oil immersion objective is then used (after a drop or two of immersion oil is placed on the slide) to look for organisms and for closer observation and confirmation of inflammatory , neoplastic , and/or acantholytic cells. Draining nodules can also be evaluated by directly pressing the slide to the draining contents and staining as previously described.

Acetate Tape Preparation

This technique is helpful for sampling intertriginous areas, nailfolds, interdigital areas, and dry, scaly, hyperplastic or lichenified skin surfaces. This is the author's preferred technique when *Malassezia* overcolonization or infection is suspected. This test is performed by pressing an approximately 2 cm piece of clear tape sticky side down firmly against the skin several times. The tape is then held at either end and immersed in the No. 3 Diff-Quik stain for 15–20 seconds and then gently rinsed with water to remove excess stain. The tape is allowed to completely air-dry or is blow-dried. A strip of immersion oil is placed on the slide and the tape is placed sticky side down on the strip of oil. Another drop of immersion oil is placed on top of the tape and microscopic evaluation is performed at ×10 and ×100 magnification. A cover slip is not needed.

Surface Skin Scrape

This technique is very useful when evaluating the skin for bacteria and yeast and for sampling areas where an impression smear may be difficult to obtain. However, it is best reserved for sampling affected areas that are greasy, otherwise the sample will not adhere well to the scalpel blade. A No. 10 scalpel blade is used to gently scrape just the surface of the affected area in the direction of the hair growth. It is not necessary to obtain capillary bleeding. Mineral oil is not utilized. The collected material is smeared onto a glass slide and heat fixed, stained, and microscopically evaluated according to the guidelines indicated above for impression smears.

Cotton-Tipped Applicator Smears

Cotton-tipped applicators or swabs are useful for sampling moist lesions and intertriginous areas. The swab is gently rubbed on the surface of the skin and the sample is then rolled onto a glass slide. This technique can also be utilized for hard-to-reach areas where the skin is dry, except that the cotton swab is moistened with saline prior to sampling in order to minimize cell damage during sample collection and preparation. Once the sample is applied to the slide, it is heat fixed, stained, and evaluated as described above for impression smears.

Otic Cytology Otic cytology is also performed using cotton-tipped applicators. Samples are obtained from each external ear canal using a separate cotton swab. A standard system should be used for making slides (i.e., the left ear sample is prepped next to the frosted side of the glass slide and the right ear sample on the other half of the slide). The slide is heat fixed and stained as described above for impression smears. Begin

microscopic evaluation at ×10 and then ×100 magnification. The evaluation of otic cytology is discussed in more detail in Chapter 167.

Fine Needle Aspirate

Fine needle aspirates are best utilized for evaluation of nodular to tumorous lesions. A 20–25 gauge needle attached to a 6–12 cc syringe is used to aspirate the lesion. It is important to release the pressure on the syringe before the needle is withdrawn from the lesion. Once the needle and syringe are removed from the lesion, the needle is detached and the plunger of the syringe is pulled back to draw air into the barrel. The syringe is then reattached to the needle and the contents are expressed onto a slide, gently smeared using a separate clean slide and allowed to air-dry. Alternatively, the fine needle capillary technique can be used. A 22–25 gauge needle is introduced into the lesion by holding onto the hub. Several quick, back-and-forth movements are then made in multiple directions within the lesion, without completely withdrawing the needle, to ensure a representative sample is obtained. The needle is then withdrawn and attached to a syringe (6–12 cc) into which air was already drawn. The plunger is then depressed to expel the material within the needle onto a clean glass slide, spread, and allowed to air-dry.

Following the use of either technique, the slide is then stained with Diff-Quik. Other staining options include gram stain or new methylene blue. Evaluation for microorganisms, such as bacteria, yeast and deep fungal species, and for the overall cell type (i.e., inflammatory or neoplastic) is performed by first evaluating the specimen using the ×10 objective and finally with the high-power objective (×40). The oil immersion objective can also be utilized to evaluate the sample in greater detail.

Trichography (Hair Examination)

Trichography is used for a number of indications. It can be used to detect the presence of parasitic or infectious organisms, such as *Demodex* and dermatophyte arthrospores. Traumatic hair loss due to pruritic behaviors can be confirmed by the presence of hair shafts with blunted tips. When hairs are predominantly found to be in telogen (i.e., resting phase), this may be an indication that an underlying endocrinopathy or follicular arrest may be present. Finally, a presumptive diagnosis of various follicular dysplasias can be made when, for example, marked melanin clumping is present within the hair shafts. The author prefers to gently pluck the hairs using the fingertips so as not to create iatrogenic trauma. The hairs are then placed onto a slide with a drop of mineral oil in an orderly array. A cover slip is placed atop the sample and evaluation is initially performed using ×10 magnification. When aberrant hairs are identified, they can be examined more closely with ×40 magnification.

Skin Scrapes

In general, surface-dwelling mites such as *Sarcoptes*, *Notoedres*, *Cheyletiella*, *D. cornei*, and *D. gatoi* are best procured via superficial skin scrapes, whereas follicular mites, including *D. canis*, *D. cati*, and *D. injai*, require deep skin scrapes for diagnosis.

The superficial skin scrape is performed by applying several drops of mineral oil onto the area to be scraped or onto the chosen skin scraping tool. If necessary, the overlying hair can be shortened with a No. 40 clipper blade to facilitate the scraping procedure, but the clipper blade should not touch the skin surface or any lesions, if present. A No. 10 scalpel blade is used to scrape a large, broad area approximately 10–15 times. Alternatively, a skin scraping spatula (Jorgensen Laboratories, Loveland, CO) can be used. Obtaining capillary bleeding is not necessary, as it is more important to scrape broad, large areas to increase the chances of procuring these difficult-to-find surface-dwelling mites. For scabies, preferred sampling sites include the margins of the pinnae, elbows, and tibiotarsal areas, as these are the most commonly afflicted sites, even if one only identifies mild, subtle lesions. Papules, if present, should also be scraped. The material is then transferred to a glass slide and a cover slip is applied. The sample is then evaluated microscopically with either ×4 (scanning objective) or ×10 magnification in a systematic fashion. The condenser should be lowered to increase contrast and facilitate the finding of mites. Look for all parasitic life stages. The observation of just one egg is considered a positive finding; however, a negative skin scrape does not rule out surface mites. In these cases, when the aforementioned mites are suspected but cannot be confirmed with superficial skin scrapings, a treatment trial may be needed to verify the presence (or absence) of these mites (see Diagnostic Treatment Trials below and see also Chapter 165).

Deep skin scrapes differ from the superficial version in that the sample will be procured from a focal, localized area, squeezing the skin prior to the scrape (and during the scrape if possible) to facilitate extrusion of the mites from the follicles. Several drops of mineral oil are applied either directly to the sample area or to the No. 10 scalpel blade or skin scraping spatula and the skin is scraped in the direction of hair growth until capillary bleeding is evident. Lesions that should be scraped include areas where comedones, erythema, scaling, papules, and pustules are evident. The author finds that comedones are especially important lesions to scrape when follicular demodicosis is suspected. The collected material is then transferred to a glass slide and a cover slip applied and evaluated as described above. If properly performed with

an appropriate number of deep skin scrapes along with the sampling of appropriate lesions, a negative skin scrape can rule out *D. canis* and *D. cati*. However, the diagnosis of pododemodicosis may require biopsy and certain breeds require biopsy to confirm a diagnosis, particularly shar-peis. The identification and treatment of parasitic diseases will be discussed in Chapter 165.

Culture

Bacterial Culture

In this age of methicillin and multidrug resistance, bacterial culture and sensitivity has become a more routinely implemented test in patients with superficial bacterial folliculitis. While performing an aerobic bacterial culture is never contraindicated, there are some instances which make it a necessary test. These include the following:

- poor response and the emergence of new lesions in spite of appropriate antibiotic therapy
- patients with chronic recurrent pyoderma, especially those with a history of multiple courses of antimicrobial therapy
- when rods or unusual organisms are present on cytology
- in cases of deep pyoderma

In cases of superficial bacterial folliculitis, pustules are the ideal lesion to sample; however, epidermal collarettes and crusts can also be sampled. The skin is not cleaned prior to sampling. The pustule is gently lanced with a sterile 25 gauge needle and a mini-tip culturette is touched to the purulent material, taking care to avoid contact with the surrounding nonlesional skin. If crusts are present, the culture should be obtained from underneath the crust. When epidermal collarettes are present, the sample should be obtained from the leading edge where the epithelium is lifted to avoid surface contaminants. The culturette is then placed back into the transport media device and refrigerated until sent overnight to the laboratory. Mini-tip culturettes are commercially available through most microbiology laboratories.

Bacterial cultures of deep infection can vary somewhat depending on the type of lesion being sampled. Fine needle aspiration can be performed to obtain specimens from bullae and dermal or subcutaneous lesions with pockets of fluid. Tissue cultures using sterile technique are best when a nodule, tumor or cellulitis is present. It is also ideal to obtain a tissue culture in the presence of deep infection characterized by exudative draining tracts, rather than merely swabbing any drainage, which will often be contaminated with superficial organisms while deeper organisms may be missed.

The surface should be aseptically prepared by gently swabbing the area with 70% alcohol and can be followed by a rinse with nonpreserved saline. Specimens are obtained via punch biopsy from nonulcerated areas (punch biopsy technique is described in detail below). Local anesthesia is accomplished by infusing 1–2 mL of 2% lidocaine subcutaneously using a 25 gauge needle. Care must be taken not to inject the lidocaine too superficially as it can inhibit microbial growth within the specimen. When in doubt, a ring block may be more appropriate, especially if subcutaneous tissue is also going to be submitted. Sterile instruments should be used as well as gloves. The epidermis is then aseptically removed with a No. 10 surgical scalpel and the remaining deep dermal tissue is used for culture. Removal of the epidermis prevents overgrowth of the tissue culture by surface bacteria that are not relevant to the deep infection. The dermal tissue is placed in a sterile red-top tube with just enough nonbacteriostatic sterile saline to keep the sample moist, and refrigerated and shipped overnight to the laboratory. The tissue sample can be submitted for aerobic, anaerobic, and mycobacteria culture purposes. The laboratory should be notified of the differential diagnoses, as culture media adjustments will be made to facilitate the growth, isolation, and identification of the suspected organisms.

Fungal Culture

Fungal Culture for Deep Mycoses When deep fungal infection is suspected, samples are obtained using the same principles as described above for bacterial cultures of deep infection. Laboratories should be contacted in advance of the differential diagnoses so that modification of culture techniques can be implemented in advance, not only for diagnostic purposes but also because of the human health risks associated with various fungal diseases. Laboratories should also be consulted regarding special requirements for tissue submission. Depending on the suspected organism, additional tests beyond culture may be required, such as polymerase chain reaction (PCR) testing.

Dermatophyte Culture In cases of suspected dermatophytosis, cultures (considered the gold standard for diagnosis) can be performed in hospital using dermatophyte test medium (DTM) or, alternatively, samples may be submitted to a diagnostic laboratory. The clinician should check with their laboratory regarding the preferred means of sample submission. Dermatophyte test medium is most useful because the red color indicator is a helpful diagnostic aid and it also contains inhibitors of bacterial and saprophytic contaminants (e.g., Sab-Duets, Hardy Diagnostics, Santa Maria, CA, USA). Sab-Duets are also popular in that they are double plated: one side contains DTM and the other side contains plain Sabouraud dextrose agar. Dermatophyte test medium may decrease development of conidia, and therefore it is best to perform microscopic identification using the sample plated onto

Sabouraud dextrose agar. The most common dermatophytic agents include *Microsporum canis*, *Microsporum gypseum*, and *Trichophytan mentagrophytes*.

When procuring samples for DTM, hairs should be plucked from within the lesion close to the periphery. A medical-grade plug-in long wave Wood's lamp with magnification can be helpful for identifying fluorescing hairs that can be selected for culture in approximately 50% or more of cases caused by *M. canis* and rarely with *M. gypseum*. The Burton Ultraviolet (Wood's) Exam Light (Philips Burton, Franklin Park, IL, USA) is an excellent model as it provides magnification, and replacement bulbs can be purchased. Medical-grade Wood's lamps do not require a period to warm up, but the room should be darkened and the evaluator allowed to let their eyes adjust for 2–3 minutes. The lamp should be held close to the skin (i.e., 4–10 cm). Infected hair shafts will fluoresce a bright apple green. These are often hiding under crusts, and thus it is important to lift crusts and examine the hairs beneath. Fluorescing hairs are then plucked for culture and can also be evaluated by direct examination to confirm an infection (ectothrix arthroconidia may be observed). Besides directly plucking hairs for culture purposes, the MacKenzie toothbrush technique can be used. Individually packaged toothbrushes can be purchased readily online. This method is especially helpful for sampling poorly circumscribed lesions and nonlesional patients when looking for asymptomatic carriers. A newly unwrapped toothbrush is used to brush the lesions (or the entire patient in asymptomatic animals), and the scales and loose hairs caught in the bristles are gently embedded onto the agar. A sterile needle or hemostat can also be used to remove trapped hair and scale from the toothbrush for placement onto the culture medium.

After inoculation, the culture plate should be placed in a sealable plastic baggie to prevent contamination and dehydration, and put in an incubator. The incubation temperature should be maintained at 75–80 °F and the humidity should be approximately 30%. A digital aquarium thermometer can be used to monitor the temperature, and placing a pan of water in the incubator should be enough to sustain adequate humidity. The plates should be kept away from sunlight or fluorescent light. Cultures should be examined daily and color change (which occurs due to a change in the pH of the media) and colony growth findings must be recorded. Pale, buff-colored to white colonies that simultaneously develop a red ring of color around them as they grow are indicative of dermatophytes. The colonies are typically cottony or velvety and growth will often occur in 4–7 days. A contaminant is likely when there is colony growth and no associated color change of the media or the color change appears more than 10 days after colony growth. Contaminants are also likely when there is a color change but the colony is pigmented. Cultures should be incubated for three weeks before declaring them negative to ensure that there is no late growth of a pathogen.

Cultures grossly suspicious for dermatophyte growth should be evaluated microscopically. The sticky side of clear acetate tape is gently brushed against the colony growing on Sabouraud dextrose agar and placed over several drops of lactophenol cotton blue stain on a glass slide. The sample should sit for 5–10 minutes before examination. This allows for proper absorption of the stain by the spores and thus better visualization. The sample is then ready to be evaluated with the ×10 and ×40 objectives. The macroconidia of *M. canis* are spindle-shaped and have thick, spiny walls that have six or more divisions with a knob at the terminal end. *M. canis* does not produce as many macroconidia as *M. gypseum*, which are thin-walled and ellipsoid with rounded ends having less than six divisions. Microscopic evaluation of *T. mentagrophytes* will typically reveal large numbers of spherical microconidia, rare cigar-shaped macroconidia, and spiral hyphae. The website https://drfungus.org/ contains helpful information regarding the macro- and microscopic evaluation of dermatophytes.

Diagnostic Treatment Trials

Treatment trials are performed often in veterinary dermatology and are used to confirm a suspected diagnosis where the response to therapy is either the only or the best way to diagnose the possible underlying disease. Examples of this include the improvement or elimination of clinical signs with insecticidal therapy in presumptive cases of flea bite hypersensitivity, sarcoptic mange, and *D. gatoi* infestation in cats. In other cases, confirmation of the underlying disease is made when a relapse is observed after discontinuing the trial with subsequent resolution on restarting the trial, as is the case when food elimination trials are performed for diagnosing adverse food reactions. Another example of this concept is the use of glucocorticoids to support a diagnosis of allergic dermatitis when other infectious and parasitic diseases have been ruled out. Further discussion of specific treatment trials can be found in the relevant chapters of this section.

Biopsy and Histopathology

There are several indications for performing skin biopsy early on in the clinical work-up. These include the presence of unusual lesions or lesions that evolve dramatically and/or severely, as in the case of a possible cutaneous adverse drug reaction. Erosive to ulcerative draining dermatoses, especially those that are nodular, also should be biopsied early on. At any point when there is concern of

a life-threatening dermatosis, autoimmune or metabolic disease, or the suspicion of neoplasia, biopsy should be immediately undertaken. Finally, skin biopsies are particularly indicated when a specific condition is suspected and the histopathology is recognized to be diagnostic of that disease. Other less critical reasons for pursuing biopsy include when other tests have not resulted in identification of the condition and when treatment has not resolved the problem. It is important to remember that performing a skin biopsy is never useless. In the best case scenario, it provides a definitive diagnosis, and in the worst case it can rule out other dermatoses and narrow down the category of diseases to be considered. Inform the owner that a precise diagnosis may not be reached but in any case the information obtained will be useful.

In order to maximize results, biopsies must be taken that are representative of the entire disease process. This entails the procurement of spontaneous, primary lesions which generally occur earlier in the course of the disease, along with secondary, more chronic lesions. Therefore, in almost all cases, multiple biopsies should be taken in order to capture the clinical spectrum and evolution of the disease. It is prudent to select lesions that have not been altered by scratching or infection. For depigmenting diseases (e.g., discoid lupus erythematosus), newly depigmented areas are ideal sites for biopsy (e.g., the slate gray areas of the nasal planum rather than the more chronic white/pink or ulcerated areas). When ulcerated areas need to be sampled, biopsy the advancing edge to include some of the epidermis rather than the center of the ulcer. For diseases characterized by alopecia, biopsies should be obtained from the most chronic area of complete alopecia as well as from the junctional and normal areas.

If possible, glucocorticoid therapy should be discontinued 2–3 weeks prior to biopsy. If a long-acting injectable corticosteroid was administered to the patient, it is best to postpone the biopsy for 6–8 weeks, when feasible. Generally, 3–5 biopsies are an acceptable average. When possible, a 6 or 8 mm punch biopsy tool is used. A 3 or 4 mm instrument is used only for difficult-to-biopsy areas (e.g., periocular region, pinnae, nasal planum or footpad). In many cases, punch biopsies can be performed using local anesthesia with 2% lidocaine, with or without sedation. However, when biopsying challenging areas, general anesthesia may be best.

It is helpful to create a small dermatology surgery pack so that all necessary instruments and materials are readily available. Include a No. 10 scalpel blade and handle, straight and curved iris scissors, gauze, Mayo and Metzenbaum scissors, needle and suture, an atraumatic forceps such as a Debakey tissue forceps, and a needle holder. Disposable biopsy punches and 10% formalin-filled vials are readily available in a number of sizes and volumes, respectively.

The biopsy sites must remain perfectly intact and be handled carefully. A scissors or clippers can be used if necessary to gently shorten the overlying hair and improve visualization of the area to be biopsied, taking extreme care not to touch the skin surface or disturb the lesion itself, including crusts. Preliminary scrubbing should never be performed, except in the case of dermal or subcutaneous nodules, where a light prep with 70% alcohol should suffice. An indelible marker is used to circle the lesion and a local anesthetic, such as 2% lidocaine, is injected subcutaneously using a 25 gauge needle and fanning it under the area of the circle. The needle is inserted at the periphery of the site to be biopsied so as not to disturb the lesion itself. Typically 0.5–2.0 mL of anesthetic per site should suffice. The maximum dose of lidocaine that may be administered is 5 mg/kg in dogs and 2.5 mg/kg in cats to avoid adverse effects, such as cardiac arrhythmias. Wait at least five minutes prior to biopsy to allow for optimal analgesic effect.

Center the lesion within the punch biopsy tool and choose a size that minimizes the amount of normal skin margin. However, for vesicles, bullae and pustules, which are fragile and can easily rupture with biopsy, use the largest punch possible or perform an excisional or wedge biopsy. If the procurement of subcutaneous fat is essential to establishing an underlying diagnosis, it may also be pertinent to use an excisional or wedge biopsy technique, and anesthetize the area using a ring block to minimize distortion of the subcutaneous tissue due to local lidocaine infiltration. Rotate the punch biopsy tool in one direction to minimize damaging shearing forces and apply even, continuous pressure until an adequate depth has been obtained to free the tissue down to the subcutaneous fat layer, which should be included in the specimen as it may be important for the accurate assessment and diagnosis of many inflammatory processes. An edge of the subcutaneous fat is gently grasped using an atraumatic tissue forceps to elevate the specimen. The epidermis or dermis should not be grasped, as this could result in a crushing artifact and lead to a nondiagnostic sample. The subcutaneous attachment is then cut. The author prefers a straight or curved iris scissors in most cases. The biopsy sample is then gently blotted to remove excess artefactual blood from the surface.

The sample should be immediately placed in 10% formalin, with a minimum of 10 parts formalin to 1 part tissue required for adequate fixation. Thin samples should be placed, panniculus down, on a small piece of tongue depressor before placement into the fixative to prevent rolling of the specimen, which can make histopathologic evaluation more challenging. Affixed samples must be placed face down into the formalin jar. The

incision is then closed utilizing 1–2 simple interrupted or cruciate sutures.

Provide a thorough history on your biopsy submission form, as well as a description of the physical exam. Preliminary diagnostic tests and their results should also be included if applicable, along with a list of differential diagnoses. Current and past therapy, including response, may also be beneficial. Submission of digital photographs can be very helpful and ideally a dermatohistopathologist should be utilized.

Tests of Noncutaneous Organs

When a dermatopathy is suspected to co-exist with an underlying systemic disease or endocrinopathy, a complete blood count, small animal chemistry profile, and urinalysis may be indicated. These basic tests are also advised to obtain baseline information prior to initiating various treatments. Specific endocrine tests are available for the evaluation of hypothyroidism, hypercortisolism, and sex hormone abnormalities. Various imaging modalities may also be indicated such as radiography and ultrasound. Advanced imaging modalities, including magnetic resonance imaging (MRI) and computed tomography (CT) scans, may also be needed in some cases. The indications and use of these various tests will be elaborated upon in the relevant chapters of this section.

Therapeutic Plan and Client Education

After thorough evaluation, the therapeutic plan most beneficial to the patient can be formulated. Client education is one of the most important aspects of treating the dermatologic patient adequately. Because many skin diseases are controllable but not curable, close communication is essential for a satisfactory long-term result.

Principles of Therapy of Dermatologic Diseases

Sandra N. Koch, DVM, MS, DACVD

College of Veterinary Medicine, University of Minnesota, Minneapolis, MN, USA

This chapter gives a broad overview of a variety of dermatologic therapies and presents the most important general principles that guide their use, including supporting concepts and most common indications. The reader is referred to other chapters in this textbook or reference therapeutic books for details regarding the treatment of various dermatologic diseases using the therapy modalities discussed here.

Topical Therapy

Topical therapy is a useful and versatile treatment modality widely used for skin and otic disorders. Advantages of topical therapy include direct delivery to the target tissue resulting in high drug concentration at the treated site, replacement or reduction of the usage of systemic therapy, avoidance of drug metabolism or gastrointestinal disturbances, lower cost compared to most systemic medications and less probability of causing microbial resistance as seen with systemic antibiotics. On the other hand, topical therapy requires client education for proper use, and can be time-consuming and unpleasant to clients because of staining or greasy preparations.

There are many factors that need to be considered when prescribing topical therapy such as the condition of the skin and ears, the type of lesions present, the need for residual activity, the presence of hair in the area, and the body region and surface area to be treated. Other factors to consider include the active and inactive ingredients (i.e., vehicle) of the medication and administration of adequate drug volume. The vehicle influences treatment effectiveness and may have therapeutic effects; however, it may cause adverse effects such as irritant dermatitis. The ability of the owners to follow instructions and frequency of use should also be considered.

Lastly, there are different formulations or delivery systems available that should be tailored to each patient's needs. These formulations include shampoos, rinses, lotions, powders, creams, ointments, emulsions, sprays, gels, mousses, spot-on solutions, wipes, and ear cleaner solutions. They may have similar active ingredients but their vehicle, efficacy, irritant or cosmetic aspects, ease of administration, and cost will be different according to each formulation and method of application.

Common Formulations of Topical Agents

Shampoos

Medicated shampoos may be effective for cleansing and hydrating the skin, soothing and reducing pruritus, and preventing or treating skin infections. Shampoos may be used for localized or generalized skin disease and may vary in their lathering effect. The type of shampoo and frequency of use are decided on an individual basis according to the skin disorder and ability of the client to bathe their pet. In most shampoo formulations, the active ingredients have limited residual effect; therefore it is generally recommended to keep the shampoo in contact with the skin for 5–10 minutes prior to rinsing. Shampoos are also frequently used as maintenance therapy, such as in allergic animals and those predisposed to skin infections. Different shampoos may be used on an alternating basis or on different parts of the body.

Medicated shampoos are typically classified based on their function, as emollient and moisturizing or hypoallergenic, antipruritic and/or anti–inflammatory, antiseborrheic (keratolytic and/or keratoplastic, and/or degreasing), antibacterial and/or antifungal, and antiparasitic.

Rinses

Rinses are commonly used after shampoos and are available in different forms including those that need to be rinsed off, leave-on formulations that dry on the skin and

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

allow more prolonged effect, and newer formulations such as microemulsion sprays which can work well on large body surfaces without the need for baths. The active ingredients in rinses may vary but they often include moisturizers, antiseborrheic agents, and antimicrobials.

Lotions

Lotions are often used for their cooling, antipruritic, antimicrobial, and drying effects, depending on their inactive agents such as water, alcohol and propylene glycol, and their anti–inflammatory, antipruritic, and antimicrobial active ingredients. They are usually recommended for a determined period of time but may also be used for maintenance.

Creams and Ointments

Creams and ointments lubricate the skin, facilitate hydration of the stratum corneum, help prevent water loss, and form a protective covering increasing the penetration of active ingredients. However, these formulations are contraindicated in exudative areas. They may contain water-washable bases such as polyethylene glycol or hydrophobic oils such as mineral oil. The main disadvantages of these products include their somewhat difficult application to hairy skin, their occlusive properties which can potentially lead to folliculitis, and they can be greasy and messy (ointments). Also, their use is limited to localized and small areas such as the paws, elbows, and nose. They are also often used in ears. Most commonly, these formulations contain antimicrobials, anti–inflammatory, antipruritic, keratolytic, and ultraviolet (UV) radiation-blocking agents. Creams are white and nongreasy and contain preservatives to protect against growth of bacteria and fungi. Ointments are oil based or emulsions of oil and water droplets that do not dissipate well when applied to the skin. They are greasy and clear and do not require preservatives. Ointments are selected when increased absorption, hydration, and occlusion are required.

Gels

Gels do not have a sticky residue and are not messy, compared to creams and ointments. Most commonly, they contain anti–inflammatory, antimicrobial, and keratolytic agents in combination with other inactive agents such as propylene glycol and carboxypolymethylene. They are mostly used for localized treatment or small skin areas.

Sprays

Sprays can be very useful and convenient for the treatment of large body areas when frequent baths are not possible and can also complement the use of medicated shampoos. They may also facilitate treatment of difficult areas such as perianal areas and the interdigital aspects of paws. Sprays may contain emollients, moisturizers, antiseborrheic agents, astringents, anti–inflammatory, antimicrobial, and antiparasitic ingredients. Some animals may not allow their application. Alcohol-containing sprays, which are meant to quickly dry, may be irritating, particularly in acute inflamed skin disorders.

Mousses

Mousses are a new form of topical therapy in veterinary medicine and provide an easy and pleasant way for pet owners to deliver active ingredients to haired and non-haired skin. The product must be applied directly to the skin in order to be effective. Mousses may contain antipruritic, antimicrobial, and antiseborrheic agents.

Spot-On Solutions

Spot-on formulations include flea and tick preventatives, fatty acids, ceramides and keratolytic or antiseborrheic agents. These formulations are usually lipophilic with large molecular weights which slow dermal absorption, lower systemic bioavailability, and provide a large area of distribution.

Wipes

Medicated wipes are very useful for treatment of intertriginous areas such as the interdigital, perianal, perivulvar, facial, and tail skinfolds. They contain antimicrobials or antiseptics and can be used for prevention and treatment of bacterial and yeast skin infections. Alcohol-containing wipes may be irritating, particularly in acute inflamed skin disorders.

Ear Cleaner Solutions

Ear cleaners can be used for the treatment of ear infections, on a maintenance regimen to help prevent infections, and after bathing or swimming to keep the ear canals dry. Ear cleaners are often used in conjunction with topical antibiotics, antifungals, and/or glucocorticoids. The frequency of cleaning varies from once daily to once weekly according to the needs of each patient. It is important to demonstrate the cleaning technique to pet owners to improve compliance and efficacy.

The choice of cleaner depends on the condition of the ears. Ceruminolytic agents help remove dry waxy material by dissolving cerumen and include propylene glycol, mineral and vegetable oils, essential oils, glycerine, and xylene. Astringents work as drying agents, reducing humidity and helping prevent maceration. They are indicated for moist ears and include isopropanol, boric acid, benzoic acid, salicylic acid, acetic acid, and aluminum acetate. Drying agents are typically used after debris or exudate has been removed from the ear canals with a ceruminolytic agent. Surfactants emulsify debris and are good for removing tightly adhered debris and include docusate, calcium sulphosuccinate, and sodium lauryl

sulfate. Antimicrobial agents help remove purulent discharge and treat bacterial and fungal infections; they include chlorhexidine, ethylenediaminetetraacetic acid-tromethamine (Tris-EDTA), monosaccharides, para-chlorometaxylenol (PCMX), and organic acids.

The appropriate use and indications for the various ear cleansing agents will be discussed in more detail in Chapter 167.

Systemic Therapy

Systemic therapy is commonly implemented to treat various dermatoses; however, it requires much knowledge of the patient's medical history, drug pharmacokinetics and pharmacodynamics, potential side-effects, toxicity monitoring guidelines, and potential drug interactions. The veterinarian needs to be familiar with the disease being treated and be aware of all treatment options and decide on the most appropriate therapeutic intervention in order to achieve the best clinical efficacy with the least possible toxicity.

Categories and Indications of Topical and Systemic Therapy

Some of the major categories used in veterinary dermatology include anti–inflammatory, antipruritic, immunosuppressive, antibacterial and antifungal agents, antiparasitics and medications to treat hormonal disorders.

Anti–inflammatory Agents

Topical anti–inflammatory agents include glucocorticoids and essential fatty acids. Topical glucocorticoids may be a useful adjunct to systemic therapy in the treatment of both allergic and autoimmune skin disease. They are often used in pruritic and/or inflammatory skin and otic conditions. Common topical glucocorticoids include betamethasone, hydrocortisone, isoflupredone acetate, fluocinolone, mometasone furoate monohydrate, and triamcinolone acetonide. These products are available in the form of ointments, creams, lotions, gels, wipes, shampoos, rinses, and sprays. Many of the available products are otic preparations containing antimicrobials that are also used extra-label on the skin. Topical essential fatty acids may be used as adjunctive therapy to treat inflammatory dermatoses including atopic dermatitis and sebaceous adenitis, as well as keratinization disorders. They are available in formulations such as spot-on, sprays, shampoos, rinses, and mousses.

Systemic products with anti–inflammatory and/or antipruritic and immunosuppressive effects include glucocorticoids, cyclosporine, oclacitinib maleate, essential fatty acids, pentoxifylline, and a combination of a tetracycline and niacinamide. Systemic glucocorticoid therapy is somewhat arbitrarily divided into anti-inflammatory and immunosuppressive, depending on the dosage used to treat the disease.

There are many indications for the anti–inflammatory effects of glucocorticoids including treatment of pruritic dermatoses such as allergic skin diseases and otitis. Indications for the immunosuppressive effects of glucocorticoids include many autoimmune skin disorders such as the pemphigus complex and various sterile inflammatory dermatoses. Commonly used systemic glucocorticoids include methylprednisolone, prednisone or prednisolone, dexamethasone, and triamcinolone acetonide. The glucocorticoid potency must be chosen based on the disease being treated, its severity, and the patient's overall health. It has been shown that only 21% of orally administered prednisone was present in the blood of cats when compared to prednisolone, suggesting poor prednisone absorption or inadequate conversion into prednisolone in the liver. Therefore, prednisolone should be used in cats instead of prednisone due to potential lack of response to prednisone. Injectable glucocorticoids should be avoided for treatment of chronic skin and ear diseases because this route of administration does not offer any therapeutic benefits over oral administration and is associated with more severe hypothalamic-pituitary-adrenal axis side-effects.

Cyclosporine is a calcineurin inhibitor that is used as an anti–inflammatory or immunosuppressive medication according to the condition being treated and the dose used. It is labeled for the treatment of atopic dermatitis in dogs and cats. Other indications include perianal fistulae in dogs, sebaceous adenitis, autoimmune diseases such as the pemphigus complex (particularly in cats), and various sterile and inflammatory skin disorders. For most treated conditions, cyclosporine may take 4–6 weeks to be effective.

Oclacitinib maleate, a novel immunomodulatory drug, is a selective Janus kinase (JAK) inhibitor, preferentially JAK-1, labeled for the control of pruritus and inflammation associated with canine allergic skin diseases, including atopic dermatitis, in dogs at least 12 months of age. It has a rapid mode of action in most patients, reducing pruritus within 24 hours.

Essential fatty acids are nutritional supplements with anti–inflammatory properties. They may be used concurrently with other medications to treat pruritic and/or inflammatory dermatoses such as atopic dermatitis, sebaceous adenitis, and symmetric onychodystrophy, as well as keratinization disorders. They may also help improve the skin barrier and hair coat quality and ameliorate dry and scaly skin. Omega-3 formulations

(containing eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]) are usually recommended for inflammatory conditions such as allergic skin diseases, while omega-6 or omega-3/omega-6 combination products are typically recommended for keratinization disorders or to improve the skin barrier. There is no current evidence of the ideal formulation, combination, dosage or ratio of essential fatty acids and many different formulations are available. It may take 8–12 weeks for full clinical benefit to be seen.

Pentoxifylline is a methylxanthine derivative with important anti–inflammatory and rheologic properties which results in increased red blood cell pliability, an especially important feature for the treatment of ischemic dermatopathies such as vasculitis. It may be used as an adjunctive or single agent for the treatment of various dermatoses including vaccine-induced dermatopathies, canine familial dermatomyositis, symmetric onychodystrophy, cutaneous vasculitis, and various sterile inflammatory skin diseases. It may take 4–6 weeks for clinical improvement to be seen.

Combinations of a tetracycline and niacinamide have been used to treat a number of immune-mediated diseases such as discoid lupus erythematosus, pemphigus foliaceus, symmetric onychodystrophy, and sterile granulomatous diseases with variable response and a lag period for efficacy of 4–6 weeks.

Antipruritic Agents

Topical antipruritic substances can provide temporary relief and soothing effect for itching and also pain (e.g., lidocaine), and may be used for adjunctive treatment of localized skin conditions including minor skin irritations, allergic or pruritic reactions, acute moist dermatitis, intertrigo, and acral lick dermatitis. These agents include colloidal oatmeal, diphenhydramine hydrochloride (HCl), lidocaine, neutralized zinc and pramoxine HCl, and glucocorticoids (previously discussed). Depending on the product, they are available as powders, solutions, shampoos, lotions, conditioners, rinses, sprays, gels, ointments, and creams.

Systemic antipruritic medications commonly used include antihistamines and glucocorticoids (previously discussed). Antihistamines are usually indicated for the management of histamine-mediated pruritic and allergic skin diseases including urticaria and insect bite hypersensitivity. Despite the frequent use of antihistamines to treat atopic dermatitis, currently there is no conclusive evidence of the efficacy of type 1 antihistamines for treatment of chronic and acute flares of canine atopic dermatitis. The response to any selected antihistamine is generally individualized and unpredictable. Commonly used antihistamines include amitriptyline HCl, diphenhydramine, hydroxyzine HCl or pamoate, chlorpheniramine maleate, and doxepin HCl. Their sedative effect can be beneficial when treating pruritic skin disorders. Although the newer generation antihistamines such as fexofenadine HCl and cetirizine HCl present a more convenient once-daily dosage, there is no current evidence that these antihistamines have superior efficacy compared to the older generation antihistamines. However, their less sedative effect may be a disadvantage for the treatment of pruritic skin disorders. A novel anti-IL31 monoclonal antibody therapy, labeled for the treatment of canine atopic dermatitis, is available for subcutaneous administration, under veterinarian supervision, with 4–8 weeks of efficacy duration.

Immunosuppressive Agents

Topical immunosuppressive agents include tacrolimus and glucocorticoids (previously discussed). Tacrolimus is a calcineurin inhibitor similar to ciclosporin; however, it is available as an ointment and is 100% more potent. It may be beneficial as adjunct therapy for allergic skin diseases, discoid lupus erythematosus, pemphigus erythematosus, localized cutaneous vasculopathies, and perianal fistula.

Systemic immunosuppressive agents are commonly used for the management of immune-mediated skin diseases including autoimmune diseases, such as the pemphigus complex, cutaneous bullous diseases, and various forms of cutaneous lupus erythematosus. These medications include azathioprine, chlorambucil and cyclophosphamide, in addition to glucocorticoids and cyclosporine (previously discussed).

Azathioprine is a derivative of 6-mercaptopurine and is commonly used in conjunction with a glucocorticoid for the first weeks or months as there is a lag period of up to six weeks before its effect can be noted. The use of azathioprine in cats is not recommended because cats are very susceptible to bone marrow suppression when treated with azathioprine.

Chlorambucil and cyclophosphamide are alkylating agents that are more commonly used individually or in conjunction with other drugs such as glucocorticoids. Their lag period for efficacy is usually up to eight weeks.

Antibacterial Agents

Topical antibacterial agents are often used to treat localized bacterial skin infections such as those associated with wounds, acne, perianal dermatitis, pododermatitis, allergic skin diseases, acral lick dermatitis, and otitis externa. They can also be a good adjunct to systemic therapy in severe or generalized cases of bacterial skin infection. These agents include acetic acid, boric acid, bacitracin, benzoyl peroxide, clindamycin, gentamicin,

neomycin, mupirocin, nitrofurazone, silver sulfadiazine, nisin, and enzyme systems. Often, topical antibacterial agents contain glucocorticoids and antifungals which enhance their effect against other organisms and help reduce inflammation and pruritus. Benzoyl peroxide and clindamycin are often efficacious products for acne cases. Mupirocin is particularly effective against *Staphylococcus* infections, including methicillin-resistant bacteria. These products are usually available as creams, ointments, gels, sprays, or wipes and some may also be available in the form of shampoos, such as benzoyl peroxide, and ear solutions, such as acetic and boric acid.

Systemic antibiotics are usually indicated to treat severe and generalized bacterial skin infections including superficial and deep pyodermas and wounds. The use of systemic antibiotics in cases of otitis media remains controversial; however, high doses of antibiotics may be used in combination with topical therapy in selective cases. The most common systemic antibiotics used include amoxicillin-clavulanic acid, cefovecin sodium, cefpodoxime proxetil, cephalexin, clindamycin HCl, potentiated sulfonamides, doxycycline HCl, chloramphenicol, enrofloxacin, and marbofloxacin. Ideally, for recurrent or chronic infections, systemic antibiotic selection should be based on bacterial culture and sensitivity. Broad-spectrum antibiotics such as fluoroquinolones should be avoided empirically and as first-choice agents as they may select for bacterial resistance. Ciprofloxacin has poor and variable oral bioavailability in dogs and cats and should be avoided in these species.

Antifungal Agents

Topical antifungals are usually prescribed for localized fungal infections, otitis externa associated with *Malassezia* infections, or as concurrent therapy with systemic medications for more generalized or severe cases. The most commonly used topical antifungal agents include clotrimazole, miconazole nitrate, nystatin, ketoconazole, posaconazole, terbinafine, and lime sulfur. Some of these products may contain a combination of glucocorticoids and antibiotics which might be beneficial when concurrent bacterial infection and inflammation and/or pruritus are present. These agents are usually available as creams, ointments, gels, solutions, shampoos, rinses, and wipes.

Systemic antifungals are usually indicated for extensive or severe superficial, subcutaneous and systemic or deep fungal infections including dermatophytosis, *Malassezia* dermatitis, onychomycosis, candidiasis, sporotrichosis, blastomycosis, cryptococcosis, histoplasmosis, and aspergillosis. Systemic antifungals may also be used in severe otitis externa cases in conjunction with topical therapy. The most commonly used systemic antifungal agents include ketoconazole, itraconazole, fluconazole, terbinafine, and amphotericin B.

Ketoconazole is most commonly used in cases of *Malassezia* dermatitis and dermatophytosis in dogs. It should not be used solely as a first choice for systemic mycosis and should be avoided in cats due to its hepatotoxic effects.

Itraconazole is better tolerated in cats compared to ketoconazole. Itraconazole is also commonly used in systemic infections and *Malassezia* dermatitis, but may be cost-prohibitive in large-breed dogs.

Fluconazole can be used for *Malassezia* dermatitis, but it is mostly useful in systemic infections when brain or ocular penetration is needed.

Terbinafine has been reported to be effective in *Malassezia* dermatitis and can also be used for dermatophytosis and systemic or deep mycoses.

Amphotericin B is mostly indicated for cases of systemic mycosis but potential nephrotoxicity is a limiting factor to its use. Lipid-based formulations are available and are much less nephrotoxic than the traditional (deoxycholate) form.

Antiparasitics

Antiparasitic products are used for prevention of fleas, ticks and lice, and treatment of parasitic diseases such as ear mites, demodicosis, sarcoptic mange, and cheyletiellosis. Most commonly used antiparasitic formulations include collars, sprays, shampoos, dips, spot-on solutions, otic solutions, and ointments.

Amitraz solution diluted and applied as a dip is labeled for the treatment of canine demodicosis. Amitraz should be avoided or used carefully in cats. Rotenone ointment may also be used in localized forms of canine demodicosis. Flea and tick preventatives are available in a variety of combinations and include deltamethrin, imidacloprid, flumethrin, fipronil, (S)-methoprene, dinotefuran, pyriproxyfen, permethrin, spinetoram, moxidectin, and indoxacarb. An imidacloprid and moxidectin combination has also been used successfully for the treatment of sarcoptic mange, cheyletiellosis, and mild cases of demodicosis. Products containing permethrin should not be used in cats due to their sensitivity to this compound. Other pyrethroids should be used carefully and according to label instructions, particularly in small kittens. Lime sulfur dip is effective against canine and feline scabies (*Notoedres*), feline surface demodicosis (*Demodex gatoi*), cheyletiellosis and lice, but it is ineffective against fleas. There are several effective products available for the treatment of ear mites including products containing pyrethrin, ivermectin, milbemycin, selamectin, and thiabendazole.

Systemic antiparasitic agents include ivermectin, doramectin, moxidectin, milbemycin oxime, selamectin,

nitenpyram, lufenuron (+/- milbemycin oxime), spinosad (+/- milbemycin oxime), and the newest class of parasiticides called isoxazolines, which include fluralaner, afoxolaner, sarolaner and lotilaner.

Ivermectin, doramectin, moxidectin, and milbemycin oxime are macrocyclic lactones that have been used successfully to treat diseases caused by *Otodectes*, *Sarcoptes*, *Notoedres*, *Demodex*, and *Cheyletiella* in dogs and cats under numerous extra-label dosage and administration regimens.

Selamectin is also a macrocyclic lactone and is labeled for use in dogs and cats for the prevention and treatment of fleas, ticks and biting lice, and treatment of sarcoptic mange in dogs and otoacariasis in dogs and cats. It has also been used for the treatment of cheyletiellosis with good results.

Nitenpyram is a neonicotinoid labeled for the control and treatment of flea infestation in dogs and cats. Since it is an adulticide, it should be combined with an insect growth regulator.

Lufenuron is a benzoylurea compound that is used as an insect growth regulator for flea control in dogs and cats.

Spinosad stimulates the nicotinic acetylcholine receptor in insects with efficacy against adult fleas in dogs and cats.

Isoxazolines work by selective inhibition of GABA- and glutamate-gated chloride channels, leading to hyperexcitation and death of the flea or tick. They are indicated for the treatment and prevention of adult fleas and tick infestations. Additionally, they have been used successfully extra-label for the treatment of parasitic diseases such as demodicosis, sarcoptic mange, cheyletiellosis, and otodectes in dogs and cats.

Systemic Medications for the Treatment of Hormonal Disorders

Systemic medications commonly used for the treatment of hormonal disorders include mitotane, trilostane, melatonin, and levothyroxine sodium.

Mitotane is an adrenolytic agent that selectively destroys the zonas fasciculata and reticularis of the adrenal cortex, while generally sparing the zona glomerulosa. Mitotane is indicated for the treatment of pituitary-dependent hyperadrenocorticism in dogs and may also be used in cases of adrenal-dependent hyperadrenocorticism; however, the induction dose may be higher and the duration longer compared to pituitary-dependent cases.

Trilostane is an adrenal suppressant that reversibly blocks 3-beta-hydroxysteroid dehydrogenase, an enzyme necessary for steroid synthesis in the adrenal cortex. Trilostane is approved for the treatment of hyperadrenocorticism of pituitary or adrenal origin in dogs and may also be beneficial for the treatment of hyperadrenocorticism in cats and alopecia X or hair cycle arrest in dogs.

Melatonin is a hormone synthesized in the pineal gland used in dogs to treat alopecia X with anecdotal success in 50% of cases. It may take 3–4 months for beneficial effects to be noticed.

Levothyroxine sodium is indicated for the treatment of hypothyroidism in dogs and cats.

Atopic Dermatitis

Alison Diesel, DVM, DACVD

College of Veterinary Medicine and Biomedical Sciences, Texas A&M University, College Station, TX, USA

Etiology/Pathophysiology

In the dog, atopic dermatitis is defined as "a genetically predisposed inflammatory and pruritic allergic skin disease with characteristic clinical features associated with IgE antibodies most commonly directed against environmental allergens." Although the exact pathogenesis of disease development is incompletely understood, current theory supports a multifactorial involvement of genetic predisposition, immunologic dysregulation, and epidermal barrier dysfunction.

During sensitization, it is suspected that epidermal barrier defects allow enhanced contact of allergens with Langerhans cells in the epidermis. These cells capture the allergens and migrate to regional lymph nodes, acting as antigen-presenting cells. In the lymph nodes, Langerhans cells interact with T lymphocytes, creating a skewed distribution and formation of type 2 T helper (Th2) cells. Upon repeated exposure to the allergen, the sensitized Th2 cells produce a variety of inflammatory cytokines which promote production of IgE and infiltration of inflammatory cells into the skin.

Increased levels of interleukin (IL)-4, IL-5, and IL-13 are noted in dogs with atopic dermatitis, along with elevated levels of interferon (INF)-gamma. Recent studies have also documented elevated levels of IL-31 in dogs with atopic dermatitis. This novel cytokine is also produced by Th2 cells and appears to be responsible for much of the pruritus associated with clinical allergic skin disease. In more chronic lesions, the response favors Th1 cytokine production which will contribute to perpetuation of the inflammatory process.

Historically, atopic dermatitis in dogs was believed to be due primarily to immunologic dysregulation and genetic predisposition (as evidenced by the current definition of the disease). However, more recent evidence supports abnormalities in the epidermal barrier which may also influence disease development. Abnormal structure and composition of the stratum corneum intercellular lipid lamellae, altered ceramide content, and abnormal expression of filaggrin (the epidermal filament-associated protein responsible for binding keratin molecules) have been documented in many dogs with atopic dermatitis. Subsequent to these structural abnormalities, increased transepidermal water loss is also noted. The combination of these changes can increase inflammation and severity of disease. Whether these changes are seen in all dogs with atopic dermatitis or only a percentage of patients is currently unknown. There is a similar disease in dogs, termed "atopic-like dermatitis," which manifests with identical history and clinical signs (see below), but in which documentation of IgE involvement cannot be confirmed. Epidermal barrier dysfunction may be a more important contributing factor for disease development in these patients.

In the cat, the etiology and pathogenesis are even less well defined. Although many of the immunologic mechanisms appear to be similar to those seen in the dog, there is a question of the true implication of IgE involvement with disease development. Additionally, epidermal barrier function has not been evaluated in the cat as a contributing factor. For these and other reasons, many prefer to use the term "nonflea nonfood hypersensitivity dermatitis" when discussing atopic dermatitis in cats.

Epidemiology

Atopic dermatitis can present in dogs and cats worldwide, though geographic differences may play a role in the development of disease (e.g., clinical signs may manifest earlier in life in animals in warm weather climates where the level of allergen exposure is rather high), as well as prevalence in that region. A few older studies have

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

reported variable prevalence of the disease, ranging from less than 5% to greater than 25% of the canine population; true prevalence of disease is uncertain. For the past few years, atopic dermatitis (or "skin allergies") has been consistently listed in the top 10 reasons for dogs and cats to be presented to veterinarians in the United States.

Signalment

Depending on literature cited, age of onset may range from 4 months to 7 years, though the majority of dogs and cats with atopic dermatitis will typically start to manifest clinical disease between 6 months and 3 years of age. There does not appear to be consensus on whether the disease is more prevalent in females or males, or whether sex predilection affects disease development. Although any breed of dog may be diagnosed with atopic dermatitis, breed predisposition has been reported due to the genetic component of disease pathogenesis. More commonly affected breeds include but are not limited to Boston terrier, boxer, Chinese shar-pei, Dalmatian, English bulldog, German shepherd, golden retriever, Labrador retriever, pug, and West Highland white terrier dogs. Although genetic involvement has also been noted in cats, no specific breed predispositions have been identified.

History and Clinical Signs

The hallmark of atopic dermatitis in both dogs and cats is pruritus, which will often be reported as mild at first but progresses to become more moderate to severe as the disease advances. Depending on which specific allergens are involved and/or flare factors in the animal's particular environment, pruritus may be present seasonally or nonseasonally. This may also be affected by geographic location; in dogs and cats with historically mild disease, the severity might increase if they move to a warmer climate where allergen load is higher or different from what they were exposed to historically. If concurrent allergic conjunctivitis or rhinitis is present, serous ocular or nasal discharge, sneezing, or congestion, respectively, may also be present with pruritic skin. In cats, feline asthma may also be a concurrent finding.

In early stages of disease, pruritus may present *sine materia*, or without concurrent lesions. More often, though, dogs without secondary bacterial skin infection or yeast overgrowth will present with fairly symmetric, variably erythematous macules and patches (Figure 159.1) or small papular lesions (Figure 159.2). Additionally, signs of self-trauma may be noted in the form of excoriations (often linear), hemorrhagic crusts, self-induced alopecia/barbered hair, hyperpigmentation, and lichenification (Figure 159.3).

Figure 159.1 Moderately erythematous, coalescing macules in the inguinal region of a dog with atopic dermatitis.

Figure 159.2 Pinpoint, faint papules on the sternum of a dog with mild atopic dermatitis.

Uncommonly, urticarial lesions (hives) may be seen in dogs with atopic dermatitis. Salivary staining of the hair is commonly noted, particularly in light-colored dogs, which also supports the presence of pruritus (Figure 159.4).

On close physical examination, the clinician will often find broken pieces of barbered hair stuck between the gingival tissue and dental arcade, another "clue" that pruritus is present. When additional lesions are noted, such as pustules, crusts, or epidermal collarettes, alternative disease entities including parasites (*Demodex*) and

Figure 159.3 Marked lichenification and hyperpigmentation of the periocular skin in a dog with severe atopic dermatitis. Additionally, hemorrhagic crusts and additional hyperpigmentation with associated alopecia can be seen along the dorsal aspect of the muzzle. Facial pruritus was marked in this patient.

Figure 159.4 Salivary staining on the paws of a patient with atopic dermatitis. Moderate erythema can also be appreciated within the interdigital webs of the right front paw.

infections (particularly superficial bacterial pyoderma and dermatophytosis) need to be investigated.

The distribution pattern of lesions and pruritus is most helpful when considering atopic dermatitis. Clinical disease in dogs most commonly affects ventral sparsely haired areas including the abdomen, thorax, inguinal, and axillary folds. Facial distribution including periocular skin and muzzle is also common. The dorsal and ventral interdigital webbing of the paws along with the lower portion of the limbs is often concurrently pruritic; flexural surfaces of the elbows are included in this body region. Otitis externa and perianal pruritus are often reported by owners, and may manifest as head shaking

Figure 159.5 Cat with moderate-to-severe periocular erythema, swelling, and self-induced excoriation from scratching.

or scooting, respectively. In most cases, the dorsal aspect of the dog is spared, unless concurrent flea allergy dermatitis is noted (caudal hind end distribution including rump and tail head). In some dogs, a more widespread distribution of lesions and pruritus is noted. This may be seen more commonly in different breeds including German shepherd, Chinese shar-pei, and West Highland white terrier dogs, which have shown phenotypic diversity compared to other dog breeds with more standard distribution of lesions reflecting atopic dermatitis.

In cats, the distribution pattern and clinical lesions tend to be less consistent. Cats will, however, generally present with one or more cutaneous reaction patterns: cervicofacial dermatitis (head, neck, pinnal pruritus) (Figure 159.5), self-induced noninflammatory alopecia (Figure 159.6), miliary dermatitis (Figure 159.7) and/or eosinophilic skin lesions (i.e., eosinophilic plaque) (Figure 159.8), eosinophilic granuloma, and indolent ulcer (Figure 153.9). None of these reaction patterns, however, are pathognomonic for allergic skin disease in the cat. Other causes of pruritus need to be investigated prior to diagnosing atopic dermatitis. This is especially true for eosinophilic lesions (particularly plaques and indolent ulcers) as these are often manifestations of bacterial pyoderma in the cat.

In people, a phenomenon known as the "atopic march" has been described where the disease starts with atopic dermatitis or eczema and progresses to rhinitis and asthma. Although the "atopic march" has not been

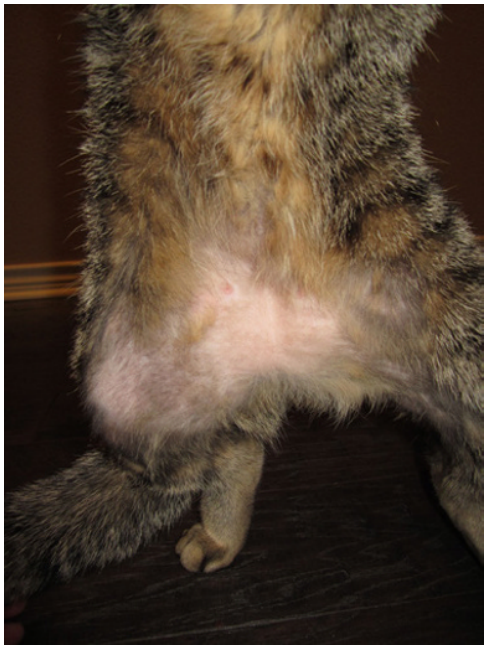

Figure 159.6 Self-induced noninflammatory alopecia on the abdomen of an atopic cat.

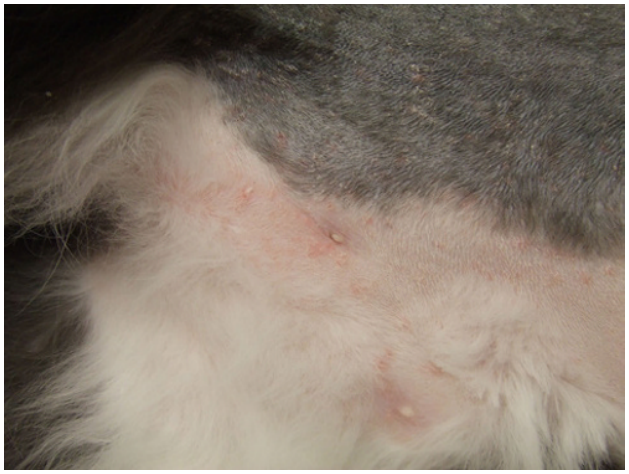

Figure 159.7 Miliary dermatitis lesions (crusted erythematous papules) on the ventrum of an atopic cat. These lesions were readily palpated, but not easily visible until the patient was shaved.

Figure 159.9 Unilateral indolent ulcer on the upper lip of an allergic cat.

reported in dogs, the disease may start off fairly mild with regard to severity of pruritus noted, or be limited to only certain body regions. However, as the dog ages, and particularly if therapeutic intervention is not pursued, the disease will commonly progress. More severe pruritus is generally reported and more body regions become affected over time. Additionally, the seasonality of the disease will often change; what may have begun as very seasonal pruritus will show evidence of extension of season (e.g., signs of atopic dermatitis may have initially been only in the spring, but now extend into the summer and fall) and eventually be present year-round. Seasonal flares or worsening may still, however, be present in these dogs.

Diagnosis

The diagnosis of atopic dermatitis is based on a consistent and fitting history, clinical signs, and exclusion of all other pruritic dermatoses. There is no test which

definitively diagnoses atopic dermatitis (this is true for dogs, cats, horses, and humans); rather, it is a diagnosis of exclusion. This includes ruling out pruritus due to the presence of parasites (fleas, lice, *Sarcoptes*, *Otodectes*, *Cheyletiella*, *Demodex*), infections (staphylococcal pyoderma, *Malassezia* overgrowth, dermatophytosis), flea allergy dermatitis, and cutaneous adverse reaction to food. As pruritus is an additive process, meaning that several contributing factors/diseases can result in the manifestation of pruritus in a given patient, and multiple factors may be present at the same time (e.g., atopic dermatitis with secondary superficial bacterial folliculitis), it is imperative to rule out confounding factors prior to arriving at a diagnosis of atopic dermatitis. Additionally, every patient is slightly different with regard to their "pruritic threshold." Once secondary problems or confounding pruritic dermatoses are identified and addressed, the clinician might note that the patient's baseline level of pruritus is much less severe than what was initially thought.

Recently, a set of criteria has been proposed to aid in the diagnosis of atopic dermatitis in dogs. Granted, the parameters suggested may be seen along with other pruritic skin diseases but if the clinician takes the appropriate steps to rule out parasites and infections, the presence of these criteria strongly supports a clinical diagnosis. The presence of five of the criteria has a specificity of 79% and a sensitivity of 85% to differentiate dogs with atopic dermatitis from those with other chronic and pruritic skin diseases. The presence of a sixth criterion increases specificity to 89%, but sensitivity is decreased to 58%. The criteria (referred to as Favrot's criteria) are as follows:

- Onset of signs before 3 years of age
- Dog living mostly indoors
- Glucocorticoid-responsive pruritus
- Chronic or recurrent yeast infections
- Affected front feet
- Affected ear pinnae
- Nonaffected ear margins
- Nonaffected dorsolumbar area

Once a clinical diagnosis of atopic dermatitis has been made, documentation of IgE involvement may be pursued with either serum or intradermal allergen testing. With allergen serology tests, radioallergosorbent (RAST), enzyme-linked immunosorbent assay (ELISA), or liquid-phase immunoenzymatic assays are used to identify the presence of allergen-specific IgE in the patient's serum via colorimetric, fluorometric, or radiometric analysis. Various commercial laboratories utilize different methodologies for detection of allergen-specific IgE; specificity of the testing reagent (e.g., decreased cross-reactivity with IgG), allergen extracts used, and lack of standardization protocols lead to a great deal of variability between tests. Currently, comparison of tests from different laboratories does not show appreciable correlation.

Intradermal allergen testing is considered to be the "gold standard" for documentation of IgE involvement in atopic dermatitis in the dog. Intradermal injection of various environmental allergens causes mast cell degranulation, extravasation of edema fluid, erythema, and formation of a wheal by IgE binding with sensitized molecules (Figure 159.10). Intradermal testing in cats tends to be more difficult and often frustrating; cats tend to form less distinct wheals and more subtle positive reactions when compared to dogs, although the test can be beneficial in this species as well. This test is best performed by a board-certified veterinary dermatologist; it requires practice with regard to technique and interpretation, and cost of allergen upkeep may be prohibitive for the general practitioner.

It is important to remember that a positive test result must be viewed in light of the animal's history and seasonality of disease. Additionally, these allergy tests can be positive in approximately 50% of animals without a clinical diagnosis of atopic dermatitis so it is imperative that serum and intradermal allergen tests are not used to diagnose disease. Rather, these tests become important considerations if the owner wishes to pursue immunotherapy for their pet (see below). Their importance stems from educated guidance on immunotherapy formulation.

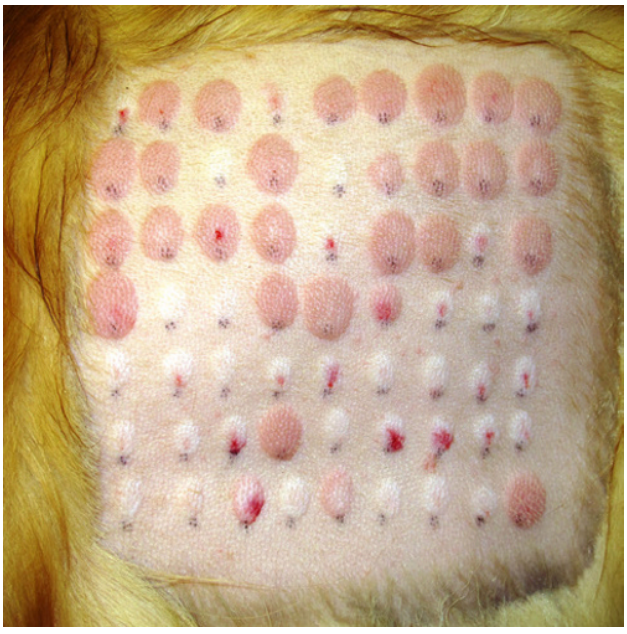

Figure 159.10 Intradermal allergen test showing several positive reactions to various environmental pollens. Positive reactions are demonstrated by the formation of an erythematous wheal.

Several factors can influence the results of allergen testing, including time of year (particularly if seasonal variation is noted), strength of allergens, and significant inflammatory skin disease (either due to atopic dermatitis alone or other concurrent pruritic dermatosis). Additionally, administration of antipruritic pharmacotherapy can dampen or mask "positive" test results. This is especially true for intradermal allergen testing. A recent review proposed optimal and minimal withdrawal times of antipruritic drugs prior to allergen testing. Based on a review of the current literature, antihistamines should be withdrawn for at least seven days, oral and topical glucocorticoids (including otic preparations) for at least 14 days, and a minimum of 28 days for longer-acting injectable glucocorticoids (although many dermatologists recommend at least 4–8 weeks withdrawal) prior to intradermal allergen testing. There was insufficient evidence to make recommendations for medication withdrawal prior to serology allergen testing; these tests may be less influenced by the presence of antipruritic pharmacotherapy but care must be taken with regard to interpretation of results.

Therapy

As with people and other domestic animal species, there is no cure for atopic dermatitis in dogs or cats. However, the disease can be fairly well managed with various therapeutic interventions. Therapy falls into two categories: medical and allergen-specific immunotherapy. Medical therapies aim to primarily address the pruritus and discomfort associated with atopic dermatitis, whereas allergen-specific immunotherapy attempts to "retrain" the immune system, shifting back towards a more "normal" Th1 response as opposed to Th2 dysregulation.

Medical Therapy

With regard to medical therapy for atopic dermatitis, interventions span the spectrum from fairly conservative to more aggressive. Options for conservative therapy include implementation of environmental allergen avoidance, bathing and other topical therapy, antihistamines, and essential fatty acid administration. More potent, "aggressive" medical therapy includes administration of systemic glucocorticoids, ciclosporin, or oclacitinib. Additional/alternative therapies have also been evaluated with variable success.

Avoidance

Avoidance of environmental allergens can be rather difficult, particularly since many dogs and cats with atopic dermatitis show reactions to allergens which cannot easily be avoided or eliminated. Pollens, for example, are essentially impossible to eliminate. Owners will often ask about changing the immediate environment to which the dog or cat is exposed (e.g., removing problematic trees or grasses from the property). However, the spread of aeroallergens can have an approximately 100 mile radius or more, depending on environmental conditions. The statement "if it is not in your own yard, it might be in your neighbor's" holds a large amount of truth.

There is a large market as well for avoidance and reduction of house dust mite allergen (the most common environmental allergen implicated in atopic dermatitis in dogs worldwide). Special air filters, pillow, and mattress covers are designed to reduce the load of house dust mite in the environment, and household cleaning products have been designed to kill and thereby reduce house dust mites in the home. These measures do not completely eliminate allergens from the environment and therefore are insufficient on their own to reduce severity of disease. Decreased exposure, however, may allow for a reduced flare of atopic dermatitis and/or provide benefit as an adjunct intervention with additional therapeutic measures. Additional recommendations for improved allergen avoidance include frequent washing of pet and household bedding, maintained replacement of air filters in the home, avoiding fresh cut grass (for pollen allergens), and frequent bathing.

Bathing and Other Topical Therapy

Along with mechanical removal of environmental allergens, bathing provides additional therapeutic benefit to the atopic dog. Shampoos containing antipruritic ingredients such as colloidal oatmeal, pramoxine (topical analgesic), antihistamine, or glucocorticoids are often recommended as maintenance therapy for the allergic dog; interestingly, however, studies have not documented improvement with any specific ingredient over another. A small study evaluated a lipid and complex sugar-containing shampoo with and without the addition of whirlpool bathing; bathing with the shampoo showed evidence of clinical reduction of pruritus, which was reduced further when a whirlpool was also used. Taken together, the physical act of bathing may be the most important factor for providing relief to the pruritic dog as opposed to a specific ingredient or formulation. The above ingredients, however, are benign and often owners feel their pet experiences more beneficial results when a particular product or ingredient is used.

Bathing is typically recommended once every 1–2 weeks long term. In the face of an allergic flare, more frequent bathing may be beneficial. In dogs where secondary bacterial or yeast skin infections are contributing factors associated with atopic dermatitis, shampoos

containing antiseptic ingredients (e.g., chlorhexidine, miconazole, ketoconazole, ethyl lactate) may be better recommended for maintenance bathing.

Although bathing has historically been considered the "gold standard" adjunct therapy for allergic dogs, newer formulations of products are cropping up with increased frequency. The addition of spray, mousse, and leave-on lotion formulations may increase client compliance due to the decreased effort/time involved in application. These products often are identical to or mimic their shampoo counterparts with regard to active ingredients; depending on the formulation, they may be used to decrease frequency of bathing, or provide longer acting beneficial response after the recommended bath. As many cats are not overly fond of bathing, these alternative formulations may be of added benefit in this species as part of the therapeutic regime.

Application of topical essential fatty acids, lipids, and ceramides has been a newer area of investigation for therapy of canine atopic dermatitis. These products aim to improve the structure and/or function of the epidermal barrier by "normalizing" lipid and ceramide content of the epidermis. Much of the information regarding these therapies has been largely anecdotal; smaller studies indicate that benefits may take several weeks to be apparent (upwards of 12 weeks to see maximal benefit). In the mildly atopic patient, these formulations may be sufficient solely (or with occasional additional conservative therapy) to control disease; however, they are likely to be insufficient on their own to control a more severely affected atopic dog. Their benefit in that case may be as an adjunct therapy, allowing for reduction of more potent therapeutic interventions. As it is still unclear whether all or only some dogs with atopic dermatitis manifest with epidermal barrier dysfunction as part of their clinical disease, the true benefit of these products is largely uncertain.

Particularly when fairly localized pruritus is present in the atopic patient, topical glucocorticoids may provide beneficial results with minimal systemic absorption. These may come in ocular or otic preparations, or in topical lotions, creams, or sprays. The efficacy of various products varies markedly with the potency of the steroid used. Evidence exists in favor of utilization of a 0.0584% hydrocortisone aceponate-containing spray (Cortavance® Virbac, Canada) or 0.025% budesonide-containing leave-on lotion (Barazone®, Dermcare-Vet, Australia) for management of atopic dermatitis in the dog; these products, however, are not necessarily available worldwide (both are currently unavailable in the USA). Depending on formulation and potency of steroid used, side-effects can include some systemic absorption, thinning and decreased elasticity of the skin, phlebectasia, and milia formation.

Similar to topical glucocorticoids, application of topical tacrolimus (Protopic® 0.03% or 0.1% ointment, Astellas Pharma, Illinois, USA) may provide localized control of pruritus in the atopic dog. This calcineurin inhibitor acts similarly to ciclosporin; it more specifically reduces T cell-mediated inflammation without the side-effects of topical glucocorticoid therapy. It does, however, have a much slower onset and may not be beneficial in the face of an acute pruritic flare.

Antihistamines

The benefit of antihistamines in atopic dermatitis is markedly uncertain. As the manifestation of pruritus involves many more inflammatory mediators other than histamine, which may in fact only account for a very small part of itch development in an atopic dog or cat, antihistamine administration by itself may make a negligible difference in the management of the allergic patient. According to a review of the evidence, their benefit has not been convincing, particularly in the case of an acute flare. That said, they may more importantly serve as an adjunct therapeutic intervention, allowing for reduced administration of more potent antipruritic therapy, in particular systemic glucocorticoid administration.

Commonly used antihistamines in the dog include cetirizine (0.5–1 mg/kg PO q24h), hydroxyzine (2 mg/kg PO q12h), diphenhydramine (2.2 mg/kg PO q12h), amitriptyline (1–2 mg/kg PO q12h), chlorpheniramine (0.4 mg/kg PO q8–12h), and loratidine (1 mg/kg PO q12–24h). Additionally, some evidence exists to suggest that fexofenadine (1–2 mg/kg PO q24h) may provide sufficient improvement in pruritus in atopic dogs. In cats, additional options include clemastine (0.25–0.68 mg/kg PO q12h) and cyproheptadine (2 mg/cat PO q12h). It is important to remember that every allergic dog and cat is a bit different; one antihistamine medication may be more effective than another for reduction of pruritus. Serial two-week trials of antihistamine medications may be necessary to arrive at an adequate therapeutic choice.

Essential Fatty Acids and Other Nutritional Supplements

Similar to topical ceramide- and lipid-containing products, systemic administration of essential fatty acids may enhance epidermal barrier function by incorporating more "normal" skin lipids into the epidermis. Although the ideal ratio of omega-3/6 essential fatty acids is unknown, most dermatologists recommend dosing based on eicosapentanoic acid (EPA) and docosahexaenoic acid (DHA). Supplementation of 180 mg/4.5 kg EPA and 120 mg/4.5 kg DHA per day is favored for atopic dermatitis; the daily dose is calculated based on the concentration of EPA and DHA in a particular product. Additional nutritional supplements such as choline,

nicotinamide, histidine, and inositol have been shown to possibly augment barrier function in healthy dogs by increasing production of ceramide skin lipids; whether they have beneficial results in dogs with atopic dermatitis, however, is uncertain. As with some of the other conservative medical therapies, their most important benefit may be in the form of adjunct therapy for the disease, thereby decreasing the need for additional medical interventions.

Glucocorticoids

Glucocorticoids have historically been touted as a mainstay therapy for atopic dermatitis in dogs and cats. Their efficacy in management of pruritus associated with the disease is without question; in fact, excellent response to glucocorticoid therapy can be a key factor in confirming a clinical diagnosis of atopic dermatitis. Strong evidence exists with regard to efficacy, particularly for controlling nonlocalized pruritus associated with atopic dermatitis. Particularly for the acute flare, short-course oral glucocorticoid administration can be highly effective in managing the atopic patient. Recommended dosing for oral glucocorticoids (prednisone, prednisolone, methylprednisolone) is initiation of therapy at 0.5 mg/kg PO q12–24h and then reducing to the lowest possible (ideally alternate-day) dosing which provides sufficient comfort. In cats, it is imperative that either prednisolone or methylprednisolone be prescribed as most cats do not respond as well to the prodrug (prednisone). Additionally, allergic cats often require a higher initial dose (1–2 mg/kg PO q24h) for clinical effect. The use of long-acting injectable glucocorticoids should be avoided for the management of chronic inflammatory diseases such as atopic dermatitis, as they have a much stronger effect on the hypothalamic-pituitary-adrenal axis. Moreover, their antipruritic/antiinflammatory effect is not superior compared to oral short-acting glucocorticoids.

Although highly effective and cost-effective (even for large patients), the side-effects of continued long-term glucocorticoid administration are concerning. Clinicians are encouraged to consider and pursue alternative therapy for atopic dermatitis if glucocorticoid administration is necessary for several months of the year to provide benefit.

Ciclosporin

As with glucocorticoids, there is strong evidence to support ciclosporin administration for management of atopic dermatitis in dogs and cats. This calcineurin inhibitor more specifically targets T cell-mediated inflammation associated with atopic dermatitis. It is important, however, to remember that the modified version of the drug (e.g., Atopica®, Elanco Animal Health, Indiana, USA) must be administered for predicted efficacy. This microemulsion of the parent drug is more predictably absorbed and metabolized in the dog and cat compared to nonmodified formulations.

Dosing is initially recommended to be 5–7 mg/kg PO q24h. Cats, particularly those with indolent ulcers, may require a higher initial dose (7–10 mg/kg PO q24h) to achieve initial beneficial results. When remission is achieved, this dose or frequency of administration may often be decreased while still achieving similar clinical benefit on a long-term basis. Although it is recommended to be given on an empty stomach, administration with food has not been proven to alter clinical improvement. Additionally, drug level monitoring is generally not indicated for the allergic patient; therapeutic drug levels do not typically correlate with clinical improvement. Obtaining ciclosporin drug levels may, however, be beneficial in a dog or cat with a clinical diagnosis of atopic dermatitis that is not responding favorably to therapy.

Compared to glucocorticoids, ciclosporin is generally better tolerated with fewer side-effects, even long term. This is not to say that side-effects do not occur; it is recommended to monitor basic internal health (e.g., complete blood count, serum biochemistry, urinalysis and urine culture and sensitivity) every 6–12 months long term with continued ciclosporin administration. The most commonly reported side-effect is gastrointestinal upset (e.g., vomiting, diarrhea, decreased appetite). These side-effects are typically self-limiting and transient; gastrointestinal upset will typically resolve within 1–2 weeks of initiating therapy. Antinausea medication (e.g., maropitant) may be necessary in the short term to minimize undue patient discomfort.

Other less commonly reported side-effects of ciclosporin include bacterial infections, bone marrow suppression, hirsutism and excessive shedding, gingival hyperplasia, hepatitis, papillomatosis, and seizures. Additionally, in cats, acute and fatal toxoplasmosis has also been documented. It is recommended that cats remain indoors and not be fed a raw diet, be completely restricted with regard to scavenging and hunting, and have serology documenting toxoplasma and feline leukemia virus/feline immunodeficiency virus (FeLV/FIV) status prior to initiating therapy.

Ciclosporin levels in the blood may be influenced by concurrent administration of other medications. Ketoconazole and fluconazole, for example, can increase the circulating ciclosporin levels via competitive binding of the cytochrome P450 enzyme. Although this combination can be clinically useful (e.g., allowing for lowered dose of ciclosporin required to achieve clinical results, thereby decreasing the cost of therapy), it can also increase the chance of side-effects. Care must be taken with other cytochrome P450-associated medications

(e.g., metoclopramide, metronidazole) as concurrent administration may increase side-effects.

As opposed to glucocorticoids, which cause a rapid reduction in pruritus, there is a lag associated with ciclosporin administration and clinical improvement. Maximal benefit is typically noted within about 4–6 weeks. At that time, if the patient is sufficiently comfortable, the medication may be tapered.

Oclacitinib

Oclacitinib (Apoquel® Zoetis, New Jersey, USA) is a novel Janus kinase inhibitor approved for dogs in the USA and Europe to control the pruritus associated with allergic dermatitis in general and, specifically, atopic dermatitis. Oclacitinib rather specifically inhibits production of IL-31 from T cells in the dog.

This targeted therapeutic is similar to other tyrosine kinase molecules which have shown some benefits in the treatment of atopic dermatitis (e.g., masitinib), but the safety profile is markedly enhanced. In a recent study, side-effects were reduced compared to either glucocorticoids or ciclosporin even when the medication was administered long term. Vomiting and diarrhea were the most frequent side-effects reported but were typically transient and self-limiting and did not require additional therapy or withdrawal of medication. Minimal changes were noted on bloodwork and urinalysis, with values remaining typically within the normal range. Decrease in white blood cells was noted in some patients, along with increased cholesterol and lipase in others; however, neither fell outside a normal reference range. Efficacy for control of pruritus associated with atopic dermatitis is considered excellent in most dogs.

Dosing is recommended at 0.4–0.6 mg/kg PO q12h for the first two weeks, and then q24h long term. Increase in pruritus is commonly noted as the frequency of administration is reduced to once daily; however, care should be taken to not administer the dose twice daily longer than the recommended two weeks because of increased risk for concerning, long-term side-effects. The increase in pruritus is likely because the drug has a rather short serum half-life and dividing the once-a-day dose to twice-a-day administration may help control the pruritus flare in some patients. Oclacitinib has a very rapid onset, often markedly decreasing pruritus within the first one to two doses. It has not been extensively evaluated in cats with allergic skin disease and its use in this species is not currently recommended.

Lokivetmab

Lokivetmab (Cytopoint, Zoetis)is the first anti-IL31 monoclonal antibody (mAB) licensed for the treatment of allergic and atopic dermatitis in dogs. The injection is administered subcutaneously at a minimum dose of 2 mg/kg under the direction of the veterinarian. It can provide efficacy within 24 hours and can provide therapy for an average of 4–8 weeks, at which time it may be repeated. This therapy is considered to be safe and is intended for both short- and long-term use. Side effects are minimal; vomiting, diarrhea, injection site discomfort, and lethargy are most commonly reported and tend to be self-limiting in nature. It may be used in dogs of any age, including those with concomitant diseases. There are no drug-drug interactions reported thereby adding to Cytopoint's robust safety profile. As this is a caninized mAB, it should only be administered in dogs.

Miscellaneous Therapies

Many additional therapeutic interventions have been investigated for controlling pruritus associated with atopic dermatitis in the dog. There is some evidence to support administration of recombinant interferons (either recombinant feline INF-omega or recombinant canine INF-gamma); these injections have shown moderate efficacy and a good safety profile in several allergic dogs. However, products are not necessarily available worldwide. Other therapies such as azathioprine, various cyclooxygenase/cyclooxygenase-lipoxygenase inhibitors, and pentoxifylline have been evaluated but have not shown appreciable efficacy in atopic dogs.

Allergen-Specific Immunotherapy

As opposed to addressing strictly the clinical signs associated with atopic dermatitis, allergen-specific immunotherapy aims to address the underlying immunologic dysregulation which is part of the disease pathogenesis. Although the exact mechanism of action is uncertain, successful therapy may lead to a more "normalized" immunologic response to allergen exposure. This was documented in one study where dogs that responded favorably to therapy showed increases in less inflammatory cytokines (IL-10) and regulatory T cells.

Allergen-specific immunotherapy is a "cocktail" of extracts of various environmental allergens based on the results of allergen testing (see above). Although no well-controlled clinical studies have established an ideal treatment protocol, formulation, or administration schedule for immunotherapy, benefits do appear to be noted in some dogs and cats with atopic dermatitis. Efficacy, however, does appear to be less when compared to other options (e.g., glucocorticoids, ciclosporin, oclacitinib). Based on anecdotal reports, approximately 50–75% of dogs and cats with atopic dermatitis show beneficial results with immunotherapy administration. As the therapy aims at changing the underlying immune response, results may take several months to be apparent. Clinical improvements may initially be seen within the first 3–6 months but maximal benefits may not be noted until 12–18 months. Most patients require the addition of

concurrent antipruritic pharmacotherapy during the induction of immunotherapy.

Two formulations currently exist for immunotherapy: subcutaneous injections and sublingual/oral drops. Injections have been available much longer than the oral formulation and so we have much more information regarding their use. Although they are very safe, side-effects may include injection site pruritus, angioedema, or anaphylaxis in a small percentage of patients. Anecdotally, these effects may be more common in toy-breed and very small patients. They are generally well tolerated by cats. Sublingual immunotherapy is a newer option; it is a needle-free way to administer the formulated allergen "cocktail" which may improve client compliance. Although a set protocol has yet to be developed, sublingual immunotherapy is typically administered more frequently (e.g., 1–3 times daily) compared to its injectable counterpart (e.g., q1–3 weeks long term). Although less information is available for the sublingual formulation, trends appear to follow what is seen for immunotherapy injections with regard to time to improvement and percentage of animals experiencing clinical benefit.

There are alternative options for immunotherapy which have been developed more recently. Regional immunotherapy and more generalized formulations eliminate the need for allergen testing prior to formulation. How these less specific options compare to injectable or sublingual allergen-specific immunotherapy has yet to be determined.

Prognosis

Although there is no cure for atopic dermatitis in the dog or cat, the long-term prognosis is considered to be good. Most patients, however, require life-long therapy for the disease and, even with generally good control, flares may periodically occur, necessitating additional therapeutic intervention.

Conclusion

Atopic dermatitis can be extremely frustrating to manage for the practitioner and owner alike. That being said, thorough client education efforts can markedly enhance compliance and, therefore, results long term. It is important to let clients know from the beginning that this is a disease which can be *managed* but never *cured*. Additionally, even with excellent control overall, flares may periodically occur and the animal may still be considered more pruritic than a normal patient. Although we strive for perfection, it is rarely achieved in a dog or cat with atopic dermatitis. Goals for the patient should be to improve their comfort (e.g., reduction of pruritus, decreased frequency of secondary infections) by approximately 80–90% for approximately 80–90% of the time. This may require a combination of therapeutic interventions including bathing/topical therapy along with immunotherapy or various medications. Every patient with atopic dermatitis is different; specific therapy needs to be tailored to the individual based on both patient and client feasibility. Having a client "onboard" with a multimodal approach to atopic dermatitis is imperative for successful management.

Additionally, it is important to remember that rarely does a therapy "stop working" for managing the disease. For example, a dog has been doing fairly well on allergen-specific immunotherapy injections for several months/years and all of a sudden develops moderate to severe pruritus. Prior to jumping to repeating allergen testing/reformulating immunotherapy or abandoning immunotherapy altogether for alternative medications, secondary flare factors such as infections and parasites (particularly fleas and *Sarcoptes*) should be investigated and addressed appropriately. In endemic areas, all patients should be treated year-round with adulticide flea prevention at least every 30 days to minimize the chance of flea infestation leading to an increase in pruritus, thereby exacerbating atopic dermatitis.

Allergic Skin Diseases

Patrick Hensel, Dr. Med.Vet., DACVD

Tierdermatologie, Basel, Switzerland

This chapter includes common allergic skin diseases of dogs and cats with the exception of atopic dermatitis and cutaneous adverse food reactions, which are covered in Chapters 159 and 161, respectively.

Urticaria and Angioedema

Etiology/Pathophysiology

Immunologic and nonimmunologic mechanisms are suspected to be involved in the pathogenesis of urticaria and angioedema, causing degranulation of mast cells or basophils which results in vascular dilation and recruitment of inflammatory cells. The inflammation remains limited to the dermis in patients with urticaria, but it extends to the subcutis with angioedema. While the immunologic process is mediated by a predominantly type I or III hypersensitivity reaction (e.g., allergies), nonimmunologic causes (e.g., heat, cold, stress, chemicals) can also trigger mast cell degranulation (Table 160.1).

A hypersensitivity reaction to an offending substance may not result in clinical signs at the first exposure, but will more likely occur with repeated exposures. Repeated exposures may also potentially result in more severe reactions.

Epidemiology

Urticaria and angioedema are rare in cats and uncommon in dogs and have been associated with various triggering factors as described above.

Signalment

Urticaria and angioedema can occur at any age and affect male and female animals equally. A specific breed predisposition has not been established.

History and Clinical Signs

Urticaria and angioedema typically have an acute onset (minutes to a few hours). Urticaria is characterized by erythematous wheals which are small (1–5 cm in diameter) and present in a multifocal to coalescing pattern (Figure 160.1). They are transient and normally fade within 24 hours but new lesions form as long as the animal remains exposed to the triggering factor. Angioedema presents as a locally extensive and ill-defined swelling of the face and ventral neck due to edema in the deep dermis and subcutaneous tissue (Figure 160.2). In severe cases, serum may leak through the skin. Very rarely and only in severe cases, fever, lethargy, and anorexia may be present. Pruritus may or may not accompany urticaria and angioedema.

Diagnosis

The diagnosis is based on the patient's history, clinical presentation, behavior of the skin lesions, diascopy (blanching) and, if necessary, histopathology. Identifying any triggering factor should be a priority. For this reason, a thorough patient history, including vaccination and any drug exposure, should be recorded. Pyoderma and vasculitis are differential diagnoses consistent with urticaria, but the lesions of those diseases will not blanch on diascopy. Mast cell tumor, cutaneous lymphoma, and amyloidosis should also be considered as differential diagnoses for urticarial lesions. Differential diagnoses consistent with angioedema are cutaneous lymphoma, juvenile cellulitis, mast cell tumor, and infectious cellulitis.

Therapy

The triggering cause should be identified and eliminated to evade symptomatic therapy and prevent recurrences;

Table 160.1 Possible factors for triggering urticaria and angioedema in dogs and cats

Trigger	Remarks
Foods	
Drugs	Penicillin, ampicillin, cephalexin, tetracycline, vitamin K, propylthiouracil, amitraz, ivermectin, moxidectin, vincristine, azathioprine
Vaccines	Panleukopenia, leptospirosis, distemper-hepatitis, rabies, feline leukemia
Insect bites/stings	Bee, hornet, mosquito, black fly, spider, ant
Atopy	Pollen, mold, dust mite
Blood transfusions	
Plants	Nettle, buttercup
Intestinal parasites	Ascarids, hookworms, tapeworms
Infections	Staphylococcal pyoderma, canine distemper
Sunlight	
Excessive heat and cold	
Estrus	
Dermatographism	
Psychogenic factors	
Vasculitis

Figure 160.2 Three-year-old female spayed mastiff with facial angioedema.

however, this may be challenging and not always achievable. In persistent or severe cases, symptomatic therapy is necessary. Epinephrine (0.1–0.5 mL of a 1:1000 solution SC or IM) combined with injectable glucocorticoids and/or antihistamines may be needed for severe cases. For persistent cases of urticaria, oral glucocorticoids (e.g., prednisone/prednisolone at 2 mg/kg/day PO) as well as oral antihistamines (e.g diphenhydramine, hydroxyzine, each at 2.0 mg/kg twice daily) are given. In mild cases, antihistamines are typically used as sole therapy.

Prognosis

If the cause of the disease can be identified and exposure eliminated, the prognosis is considered good.

Allergic Contact Dermatitis

Etiology/Pathophysiology

Allergic contact dermatitis is a type IV hypersensitivity reaction associated with a cell-mediated allergic response to haptens, which are small reactive lipid-soluble molecules. Although an overlap between irritant and allergic contact dermatitis has been reported in regard to cytokine profile and inflammatory cell activation, allergen-specific CD4+ T cells (CCR10+) and some chemokines (e.g., IP-10) seem to be expressed exclusively

in allergic contact dermatitis, which may represent differences in regulatory mechanisms.

Epidemiology

A wide range of allergens, such as various plants (e.g., dandelion, Asian jasmine, cedar mulch), cement, plastic toys and bowls, household cleaners, and topical drugs (e.g., neomycin, propylene glycol), have the potential to trigger contact hypersensitivity. An overlap of contact hypersensitivity with atopic dermatitis (AD) may also exist, since it is suspected that about 20% of dogs with contact hypersensitivity also suffer from AD.

Signalment

Allergic contact dermatitis is considered to be a rare pruritic condition and has no age or gender predisposition. However, some short-haired breeds such as the boxer, pit bull, dachshund, and Boston terrier appear to be affected more frequently.

History and Clinical Signs

Skin lesions typically occur on sites which are sparsely haired and directly exposed to allergens such as the ventral aspects of the neck, chest, abdomen, tail, digital spaces, muzzle, concave aspects of the pinnae, and scrotum (Figure 160.3). Lesions may also develop in haired areas if the sensitizer is in liquid, powder or aerosol form. The skin lesions are characterized by macules, papules, and erythema which may progress in chronic cases and become lichenified, hyperpigmented, and alopecic. Secondary bacterial and yeast infections are commonly present. Excoriations may also occur due to the associated pruritus. As with other hypersensitivity reactions, previous allergen exposure is necessary for the development of sensitization and resultant clinical signs.

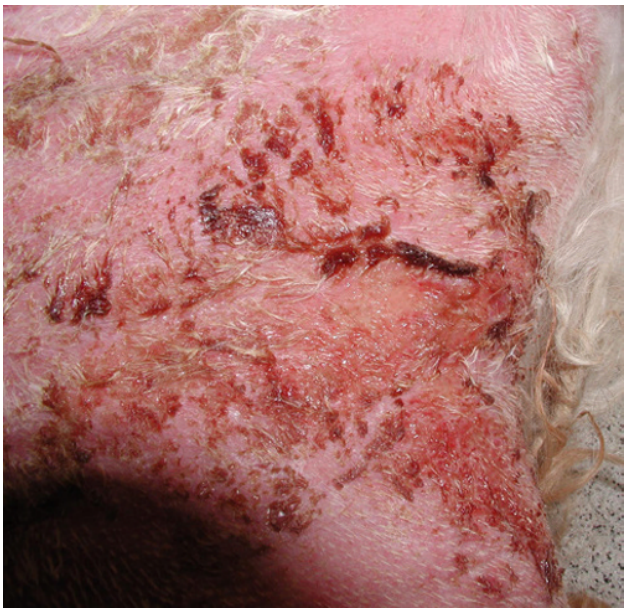

Figure 160.3 Severe contact dermatitis to a plant fertilizer in a 5-year-old golden retriever. Erythema, edema, serosanguinous to purulent exudate, and brownish crusts were present on the ventral abdomen and inner thighs. *Source:* Courtesy of Sheila Torres.

Diagnosis

Allergic contact hypersensitivity is diagnosed based on the patient's history, physical examination findings, resolution of clinical signs after elimination of the offending allergen, provocation of skin lesions with reexposure, and patch testing. The most common differential diagnoses associated with contact hypersensitivity are cutaneous adverse food reaction, atopic dermatitis, scabies, pyoderma, *Malassezia* dermatitis, and insect bite hypersensitivity.

Therapy

The primary goal should be to prevent further exposure to the offending allergen. Symptomatic therapy with glucocorticoids (e.g., prednisone/prednisolone at 0.5–1 mg/kg PO daily) may be attempted where elimination is not feasible; however, response to glucocorticoids occasionally fails. Pentoxifylline (10–30 mg/kg PO 2–3 times daily) has shown some beneficial effect for long-term management and prophylaxis. Patients with a poor response to glucocorticoids may benefit from treatment with ciclosporin (5 mg/kg PO daily).

Prognosis

Prognosis is considered good if the allergen can be eliminated from the patient's environment and good clinical response can be achieved with immunomodulating drugs.

Flea Allergy Dermatitis

Etiology/Pathophysiology

Several allergens responsible for flea allergy dermatitis (FAD) in dogs and cats have been identified in flea saliva. So far, one major allergen, a protein called *Ctef1* from the cat flea *Ctenocephalides felis*, has been associated with flea allergy in dogs.

Epidemiology

The prevalence of FAD varies greatly depending on the climate and geographic location, but it is the most

common hypersensitivity in dogs and cats in flea-endemic areas. Fleas can be a perennial problem in subtropical and tropical climate zones, seasonal in more temperate climate zones, and practically nonexistent in arid, high elevation, or cold climates. Even if fleas are considered to be absent from a particular area, there is a possibility that animal movement or contact may bring fleas into the area.

Signalment

Any dog and cat in a flea-endemic area can become allergic to fleas but no breed or sex predilection has been identified. Although FAD can develop at any age, dogs predisposed to FAD will generally develop clinical signs by 5 years of age.

History and Clinical Signs

The most typical clinical sign associated with fleas is pruritus, but FAD must be differentiated from flea infestation. Clinical signs associated with flea infestation are variable. The pruritus is generally intermittent and an increased number of fleas is common.

The typical predilection sites for FAD in dogs are the lumbosacral area, tail base, and caudomedial thighs, and minimal flea burden is typical. In cats, skin lesions are commonly found on the caudodorsal area, as in dogs, but can also be present on the head and neck. Many dogs and cats suffering from FAD may have concurrent atopic dermatitis and/or cutaneous adverse food reaction which may complicate the clinical presentation and diagnosis.

The most common skin lesions seen in dogs with FAD are erythematous papules and in more severe and chronic cases, self-induced alopecia, lichenification, and seborrhea on the predilection sites (Figure 160.4).

In cats, skin lesions range from miliary dermatitis (crusted papules) to excoriations to self-induced alopecia. Cats also often show skin lesions consistent with eosinophilic granuloma, especially indolent ulcers on the upper lips which can be found in up to 60% of flea-allergic cats (Figure 160.5).

Diagnosis

Any pruritic skin disease should be considered as a potential differential diagnosis for FAD and mainly includes other ectoparasitic disorders, microbial skin infections, or other hypersensitivities. Diagnosis is based on history, clinical signs, and response to therapy. The presence of fleas is not an adequate indicator of FAD and allergy skin testing with flea allergen can show false-negative results. Nevertheless, flea combing should be performed for direct identification of fleas or flea feces.

Figure 160.4 Five-year-old female spayed mixed-breed dog with flea allergy dermatitis exhibiting alopecia, erythema, excoriations, and seborrhea along the caudodorsal aspects of the trunk, tail, and hindlegs.

Figure 160.5 An indolent ulcer in a 4-year-old female spayed domestic shorthair cat with flea allergy dermatitis.

Therapy

The most effective treatment for animals with FAD is avoiding exposure to fleas combined with aggressive flea control. Veterinarians should be aware that none of the current flea preventives have an effective repellent effect. Since fleas in the pupal stage can survive up to 174 days in the environment, it is not unusual for the response to effective flea prevention to take a couple of months. For this reason, it is strongly recommended to maintain regular application of flea products in endemic areas. Fast-acting systemic adulticides are recommended over topically applied flea preventives because they reduce the contact time between the flea and the animal, resulting in faster reduction of irritation and pruritus. Flea preventives with a rapid adulticidal effect act through activation of nicotinic acetylcholine receptors or inhibition of gamma-aminobutyric acid (GABA)-gated chloride channels. Such products are available as oral tablets and topical solutions, and contain either nitenpyram, spinosad, or an isoxazoline (e.g., fluralaner, sarolaner, afoxolaner, lotilaner). Cats are very sensitive to permethrin so parasiticidals containing this product should be avoided in this species.

Despite strict flea prevention and depending on the severity of FAD, dogs and cats may develop episodes of increased pruritus after exposure to a flea. For the symptomatic therapy of pruritus, antiinflammatory dosages of oral glucocorticoids (e.g., prednisone/prednisolone at 0.5–1 mg/kg PO daily) and/or topical therapy (e.g., hydrocortisone aceponate spray [Cortavance®,Virbac], available only in Canada and Europe, or triamcinolone acetonide topical spray [Genesis®, Virbac]) may provide sufficient relief. In dogs, oclacitinib (Apoquel, Zoetis) can be administered at a dose of 0.4-0.6 mg/kg PO BID for up to 2 weeks, then once daily thereafter to alleviate pruritus associated with FAD. Lokivetmab (Cytopoint, Zoetis) is now licensed for the treatment of allergic dermatitis in dogs and, thus, could also be considered as an option for treating pruritus. A minimum dose of 2 mg/kg is administered SC and can be repeated every 4 to 8 weeks as needed. Other important measures include keeping the affected animal indoors and treating all in-contact pets.

Prognosis

Canine and feline FAD tends to worsen with age but with strict flea control, control of other underlying hypersensitivities and other measures which may help to reduce exposure to fleas, the disease can be well controlled.

Cutaneous Adverse Food Reactions

Ralf S. Mueller, Dr. Med.Vet., DACVD, FANZCVSc

Centre for Clinical Veterinary Medicine, Ludwig-Maximilians-University of Munich, Munich, Germany

Etiology/Pathophysiology

Cutaneous adverse food reactions include any skin reactions that are reproducible. Most commonly seen is pruritus, but recurrent pyoderma or edema have also been reported. Food allergy is an immunologically mediated reaction caused by food. Type I hypersensitivity mediated by food-specific IgE antibodies is the most common reaction, but delayed type II (T cell mediated) and type III (where food-specific antibodies and food antigens form complexes) hypersensitivities may also occur.

In veterinary practice, the immunologic basis of food reactions is rarely documented. Thus, technically, the commonly used term "food allergy" is inappropriate, because adverse food reactions may also be nonimmunologically induced (and are then called food intolerances). Food intolerance may be pharmacologic, such as those mediated by pharmacologically active ingredients of the diet (e.g., histamine), toxic (caused by toxins in the food commonly produced by microorganisms in contaminated food stuffs), or metabolic (ingredients in the food are metabolized in the patient to a substance causing the reaction). If none of those mechanisms can be identified, the reaction is idiosyncratic.

However, proving the exact pathogenesis in an individual patient in practice is very difficult. Serum IgE testing for food-specific antibodies in normal dogs without clinical problems is characterized by a high number of false-positive reactions and reliable tests for other types of adverse food reactions are lacking. Thus, in most cases the diagnosis of adverse food reaction is made by response to an elimination diet and deterioration on rechallenge, as described below.

In human medicine, food allergens are typically glycoproteins with molecular weights between 10 and 70 kDa and some typical allergens come from nuts, shellfish, milk, and eggs. In dogs, the most commonly identified food antigens are beef, dairy products, chicken, soy, and wheat – ingredients that are most commonly present in commercial dog foods (Table 161.1). In the cat, beef, dairy, fish, and chicken are the most common reported offending antigens (see Table 161.1).

To what degree related proteins can cause clinical problems via cross-reactivity is not clear. One study evaluating individual rechallenges in dogs with adverse food reactions could not demonstrate evidence of cross-reactivity between, for example, beef and cow's milk. However, a case report of a dog with oral allergy syndrome described cross-reactivity with tomato and cedar pollen. A further *in vitro* study identified bovine IgG as a major antigen in dogs and a potential source of cross-reactivity between beef, cow's milk and potentially mutton (as there is a high homology between bovine and ovine IgG), but whether this is clinically relevant has not been demonstrated convincingly at this point.

History and Clinical Signs

Adverse food reaction is characterized in most cases by a pruritic and nonseasonal dermatitis. The face, feet, ventrum, and perianal area are often affected in the dog (Figure 161.1). Otitis externa is common and may be the only presenting sign in some dogs (Figure 161.2).

The skin may be erythematous; self-trauma quickly leads to alopecia and excoriation and in chronic cases lichenification of affected skin (Figure 161.3).

Papules, pustules, and oily and scaly skin may be due to common secondary infections with bacteria and/or yeast organisms. Concurrent gastrointestinal signs are seen in up to 25% of affected dogs. Beyond vomiting and diarrhea, gastrointestinal signs may include frequent defecation, borborygmi and flatulence, which may in some dogs be the only noncutaneous clinical signs. Recurrent bacterial infection and vasculitis were also reported in

some dogs. In one dog, erythema multiforme was apparently triggered by an adverse food reaction. Concurrent allergic diseases such as atopic dermatitis due to environmental allergens or flea bite hypersensitivity are seen in 20–75% of patients, depending on the study. Gender predispositions have not been reported.

As adverse food reaction and nonseasonal environmentally induced atopic dermatitis have identical cutaneous signs and are often present concurrently, breeds seemingly overrepresented include West Highland white terriers, Labrador and golden retrievers, American cocker and English springer spaniels, Chinese shar-peis,

Figure 161.2 Erythematous otitis externa in an 8-year-old, female spayed golden retriever with adverse food reaction.

Figure 161.3 Ventral lichenification, ulceration, and crusting in a 7-year-old, male castrated schnauzer with adverse food reaction.

and miniature schnauzers. In a recent study from Switzerland, West Highland white terriers, Rhodesian ridgebacks, boxers, and pugs were predisposed.

In cats, all cutaneous reaction patterns associated with flea allergy or environmental allergy can also be due to an adverse food reaction. Food-induced miliary dermatitis, noninflammatory alopecia, eosinophilic granuloma, and head and neck pruritus have all been reported.

Diagnosis

Although serum testing for food allergen-specific IgE is offered in many countries, there is no evidence that this test has any value in the diagnosis of adverse food reactions. In all previous publications, numerous false-positive and false-negative reactions were detected, when comparing test results with clinical rechallenges. In one recent study, false-negative reactions were less likely. However, at this time there is unanimous agreement amongst dermatologists worldwide that the only reliable way to diagnose an adverse food reaction is an elimination diet with food stuffs previously not fed to the patient.

Choice of Elimination Diet

In dogs, one protein source and one carbohydrate source not previously fed will be used exclusively; in cats, feeding only the protein source increases palatibility and compliance. Thus, it is important to obtain a reliable and detailed feeding history for the patient as well as the ingredient lists of commercial foods fed in the past. Ideally, the food should be home-cooked to assure that only the selected food stuffs are used. This is even more important after evidence has been published that many dog foods may include food sources not listed on the label. However, convincing owners to cook for their pets for several weeks may be more difficult nowadays than it used to be half a century ago. In addition, home-cooked diets are rarely balanced, which typically does not lead to clinical problems in adult dogs on a deficient diet for only a short time such as a month or two. However, if home-cooked diets are fed for extended time periods or if the patient is a young dog or cat still growing, care must be taken to seek advice from a nutritionist and balance the diet to avoid nutritional deficiencies.

To what degree cross-reactivities between related allergens (for example, beef and mutton or cow's milk) are clinically relevant in the dog and cat is currently unclear. One study showed *in vitro* evidence of reactivity of most dog sera with specific IgE antibodies against bovine IgG present in cow's milk and lamb and beef extract. Studies evaluating clinical cross-reactivity are rare and so far have not confirmed those findings. The author prefers to use food sources removed as far as possible from the previously fed antigens; for example, animals fed predominantly meat such as beef, mutton or pork will receive poultry proteins such as duck or goose and pets on a predominantly chicken-based food will be recommended goat, buffalo or reindeer.

If owners cannot be convinced to cook for their pets, commercial diets with selected protein and carbohydrate sources are sold by many companies. Furthermore, hydrolyzed diets are also available. These diets contain hydrolyzed proteins and their small sizes make cross-linking of IgE on the surface of inflammatory cells less likely, and thus these diets can be considered truly "hypoallergenic." Hydrolyzed diets and selected protein diets do not lead to remission in all animals with an adverse food reaction and thus are the second best option for diagnosing the condition. The exact reason for this decreased efficacy is not known at this time, but may relate to the presence of a concurrent allergic condition, cross-reactivities or adverse food reactions that are not immune mediated in the first place. However, these diets are often ideally suited for long-term maintenance, once the diagnosis is made and patients have been shown to tolerate them.

If it is not possible for owners to feed a previously unfed protein or carbohydrate source, either because what is available is simply too costly (which may be relevant for owners of large dogs) or because dogs or cats have been fed a wide variety of foods in the past, then it is sensible to choose the food sources the animals have seen the least or only in the more distant past, when clinical signs were not present. In one Dutch study of dogs with an adverse food reaction being fed three commercial protein diets, no dog responded to all of the diets but almost all dogs responded to at least one of them. Thus, performing two or three commercial diet trials in dogs with a suspected adverse food reaction may be useful.

Duration and Execution of the Diet

The ideal duration of an elimination diet is controversial. In a study evaluating the duration until clinical remission in 51 dogs with adverse food reaction, less than a quarter of the dogs responded within the first three weeks, a further half after 4–6 weeks, 10 dogs after 7–8 weeks, and three dogs after 9–10 weeks. However, although the time to complete remission can be extended, most dogs will start improving within the first 6–8 weeks and if a patient shows no clinical improvement on an appropriate elimination diet within that time, the author considers adverse food reaction ruled out. One has to keep in mind that the longer the trial duration, the higher the likelihood for lack of owner compliance.

In most patients, a gradual switch from the original diet to the elimination diet over a few days will help with compliance as well as gastrointestinal complications, particularly in finicky dogs and in cats. In dogs, owners are the limiting factor for most unsuccessful diet trials. However, cats often prove more difficult and due to the threat of hepatic lipidosis after several days of refusing to accept the diet, particularly in obese cats, it is not uncommon to try a number of feeding options before a suitable diet is identified.

The most important detail to relate to the owners is the need for maximal compliance. Even small amounts of food antigens fed infrequently can trigger pruritus and thus mask improvement, so flavored medications or treats such as rawhide, pig's ears, and others must be

avoided during the time of the diet. In particular, dog owners used to giving treats will often only be able to complete a diet trial if suitable alternatives are agreed on prior to starting the diet. For example, jerky of the meat used for the elimination diet can be home-made or acquired in bigger pet stores as chews or treats. Dogs with a high affinity for scavenging need to be kept on the leash and cats with outdoor access are ideally kept indoors. If those restraints are not possible for whatever reason, then an elimination diet trial may still be attempted but the limitation of these more relaxed elimination diets is that a lack of improvement does not rule out adverse food reaction in that patient, although some patients may still improve when the intake of the offending allergen is limited at least to some degree.

Interpretation of the Outcome of an Elimination Diet

If a reevaluation after 6–8 weeks shows no improvement on an appropriate elimination diet and a secondary infection masking the improvement is not present, then adverse food reaction is ruled out and the diet trial does not need to be extended. If, however, there is some improvement seen, then in some patients it may be necessary to continue the trial for up to 12 weeks. Improvement may be due to the elimination diet, concurrent treatments, seasonal changes or other factors, so a rechallenge with the old diet is absolutely necessary for the diagnosis (although some owners will need some convincing) and leads to deterioration of clinical signs within a few days. If after two weeks on the previous diet there is no deterioration of clinical signs, adverse food reaction is ruled out and improvement was due to other factors. As soon as a deterioration is detected, the elimination diet is fed again and if clinical signs improve again (typically much faster than at the initial introduction of the elimination diet), the diagnosis is confirmed.

Subsequently, there are three choices for the client. The easiest is to stay on the elimination diet long term. However, ideally, one food source after another is introduced again gradually for a few days to weeks, depending on the original rechallenge. If a patient deteriorated after two days on the old diet, then sequential rechallenges for four days each should be sufficient. If the original rechallenge led to deterioration after one week, then sequential rechallenges should probably be performed for two weeks each. This way, offending allergens can be identified and this knowledge permits greater flexibility in feeding, although it requires more effort. And lastly, if a home-cooked diet was used for the diagnosis, a commercial diet can be tried based on the feeding history of the patient.

Therapy

Ideally, avoidance of the offending food antigens is the best way to treat adverse food reactions in dogs and cats. If home cooking is used for long-term management, care should be taken to create a well-balanced diet and advice from a veterinary nutritionist may be useful.

However, if avoidance is not possible or if flares due to inadvertent ingestion of antigens are encountered, medical treatment with antiinflammatory drugs also used for environmental atopic dermatitis may be attempted. Glucocorticoids and ciclosporin are efficacious options for dogs and cats suffering from cutaneous adverse food reactions, although anecdotal evidence indicates that higher doses are needed to achieve remission than with atopic dermatitis due to environmental allergens. Oclacitinib (Apoquel; Zoetis) and lokivetmab (Cytopoint; Zoetis) are also licensed for the treatment of allergic dermatitis in dogs and thus are excellent, alternative options for controlling pruritus in canine patients with cutaneous adverse food reaction.

Prognosis

Once the diagnosis is established and offending allergens are identified, the prognosis is excellent, although some rare dogs and cats will develop a reaction against the new food antigens with time and will have to undergo a repeated change in their diet.

Autoimmune and Immune-Mediated Skin Diseases

Nicole A. Heinrich, DVM, DACVD

McKeever Dermatology Clinics, Eden Prairie, MN, USA

Canine Familial Dermatomyositis

Dermatomyositis (DM) is a hereditary, ischemic dermatopathy and myopathy that occurs most commonly in collies, Shetland sheepdogs, Beauceron shepherds, Belgian tervurens, and Portuguese water dogs. Affected dogs generally develop lesions when they are less than 6 months of age, and either sex can be affected.

Dermatomyositis is characterized by nonpruritic alopecia, erythema, scaling, and mild crusting of the face, ears, distal limbs, digits, tail, and bony prominences (Figure 162.1). Additionally, claws may slough and fragment and ulceration may be rarely present in the oral cavity. Skin lesions may vary in severity depending on the individual. The presence and degree of myositis also vary. Clinical signs of myositis include regurgitation associated with megaesophagus, a high-stepping stiff gait, and atrophy of the masticatory muscles and distal limbs.

The diagnosis of DM is made through history, physical examination, and skin biopsy. Punch biopsies should be taken from the center of an alopecic area of skin. Crusted lesions can also be biopsied. The skin should not be scrubbed or clipped prior to procuring the biopsy. Care should be taken to include only abnormal skin in the biopsy. Histopathology will feature changes characteristic of ischemic dermatopathy.

Benign neglect may be an appropriate treatment approach for minimally affected patients. Avoidance of trauma to bony prominences and avoidance of prolonged sun exposure may also be beneficial. Pentoxifylline, prednisone, vitamin E, omega-3 fatty acids, tetracycline with niacinamide, and topical tacrolimus are therapies that may be used either alone or in combination depending on patient response (Table 162.1).

Complications can include secondary pyoderma for those dogs with more significant skin lesions and aspiration pneumonia for those with megaesophagus. Amyloidosis may rarely occur in chronically affected dogs. Minimally affected dogs may experience spontaneous resolution of skin lesions while other dogs may require lifelong therapy.

Erythema Multiforme

Erythema multiforme (EM) is an inflammatory cutaneous reaction pattern of multifactorial etiology, and dogs and cats of any age, breed or sex may be affected. It is characterized by rarely pruritic, sometimes painful, erythematous macules or papules that coalesce and eventually form a clear center and acquire an annular to arciform shape. Additional skin lesions may include plaques, vesicles and bullae, ulcers, and urticaria. Classic target lesions are present in only about one-third of cases. The axillae, groin, mucocutaneous junctions, pinnae, and footpads are most frequently affected. Oral ulceration may be present in some cases. Erythema multiforme can be classified into various categories based upon severity; however, such classifications are beyond the scope of this chapter.

The disease is diagnosed based on history, physical examination, and skin biopsy findings. Punch biopsies should be taken from the center of an erythematous area of skin. The clinician should biopsy affected skin and avoid ulcerated areas as ulcerated skin may yield a nondiagnostic sample. The skin should not be scrubbed or clipped prior to procuring the biopsy. Care should be taken to include only abnormal skin in the biopsy. Histopathology reveals apoptosis of keratinocytes at various levels of the epidermis combined with lymphocyte satellitosis.

Erythema multiforme has a variable appearance, and therefore many potential clinical differentials. Some differential diagnoses include systemic lupus erythematosus, urticaria, superficial pyoderma, dermatophytosis, demodicosis, bullous autoimmune disease, vasculitis

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

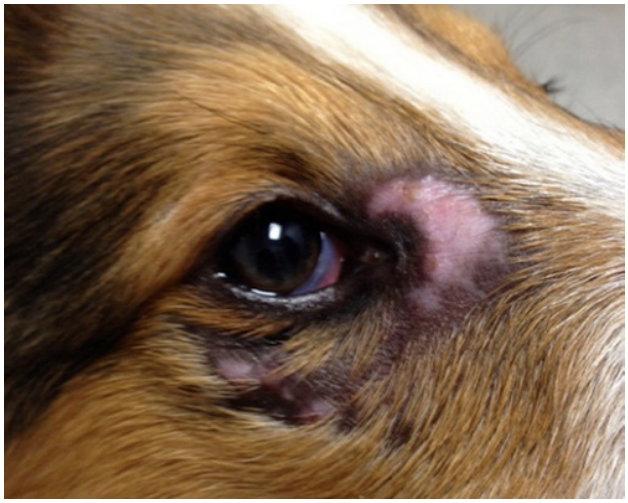

Figure 162.1 Less than 1-year-old, male, intact collie with nonpruritic alopecia associated with dermatomyositis.

and necrotizing dermatoses, superficial necrolytic dermatitis, and zinc-responsive dermatosis.

The identification and removal of the possible underlying cause are important in the management of EM; however, some cases are idiopathic. Triggering causes may include drugs, bacterial infections, *Pneumocystis* pneumonia, parvovirus, food, neoplasia or possibly herpesvirus. Mildly affected individuals may experience resolution of disease without additional therapy. Other patients may need immunosuppressive therapy such as glucocorticoids, azathioprine, ciclosporin, and/or intravenous immunoglobulin therapy (IVIG) (see Table 162.1).

Complications can include secondary pyoderma. The prognosis depends on the severity of the lesions and response to therapy.

Toxic Epidermal Necrolysis

Toxic epidermal necrolysis (TEN) is a severe vesiculobullous disorder affecting the skin and oral mucosa of dogs and cats. Dogs and cats of any age, sex or breed can be affected.

Toxic epidermal necrolysis is characterized by generalized erythematous or purpuric patches, and skin ulceration involving more than 30% of the body. Systemic signs (pyrexia, lethargy, depression, and/or anorexia) typically accompany the skin lesions.

Toxic epidermal necrolysis is often thought of as a severe variation of EM although some clinicians consider the two as separate diseases. It is generally differentiated from EM based on the severity of skin lesions and the percentage of the body that is affected.

The disease is diagnosed based on history, physical examination, and skin biopsy findings. Punch biopsies should be taken from an erythematous area of skin adjacent to an ulcer. The clinician should take care to avoid sampling eroded or ulcerated skin. Ulcerated skin has less diagnostic value. The skin should not be scrubbed or clipped prior to procuring the biopsy. Care should be taken to include only abnormal skin in the biopsy. The histopathology reveals diffuse necrosis of the epidermis with minimal dermal inflammation.

Clinical differential diagnoses include first-degree burn and toxic shock syndrome.

The identification and removal of a possible underlying cause are important in the management of TEN; however, many cases are idiopathic. The most common precipitating factor is drugs. Other less common triggers include vaccination, neoplasia, infections, and pregnancy. Wound care and general supportive care are critical to attempt to prevent sepsis. The use of glucocorticoids is controversial but ciclosporin and IVIG have been used with beneficial results in some cases.

Complications can include severe pyoderma and sepsis. The prognosis is guarded.

Cutaneous Lupus Erythematosus

Discoid Lupus Erythematosus

Discoid lupus erythematosus (DLE) is a fairly common photoaggravated or perhaps even photoinduced, depigmenting autoimmune skin disease. It affects middle-aged dogs, and collies, Shetland sheepdogs, German shepherd dogs, and Siberian huskies are predisposed. One case of generalized DLE has been reported in a Chinese crested dog. DLE has rarely been reported in cats. Sex and age predilections have not been substantiated.

The disease is characterized by depigmentation and loss of cobblestone architecture of the nasal planum (Figure 162.2). Erosions and crusting may also develop. While the nasal planum is most typically affected, lesions may also be found extending proximal to the nasal planum, around the eyes, around the mouth, on the genitals and distal extremities. Oral ulceration may also be present.

Diagnosis is based on history, physical examination, exclusion of systemic involvement, and skin biopsy findings. The clinician should select a site of recent depigmentation for punch biopsy. Lesions with severe crusting, ulceration or scarring should be avoided. The skin should not be scrubbed or clipped prior to procuring the biopsy. Care should be taken to include only abnormal skin in the biopsy. Histopathology reveals lymphocytic interface dermatitis. Direct immunofluorescence can further support the diagnosis.

Table 162.1 Immunosuppressive drug therapy

Drug	Dose	Comments
Pentoxifylline	Dogs: 15–25 mg/kg PO q8–12h	May require 8 weeks for maximum benefit
Tetracycline	Dogs >10 kg receive 500 mg PO q8h Dogs <10 kg receive 250 mg PO q8h	This class of antibiotic combined with niacinamide may require 3 months for maximum benefit
Doxycycline	Dogs: 5–10 mg/kg PO q12h	Can be used when tetracycline is unavailable. Use carefully in dogs with liver disease
Minocycline	Dogs: 5–12.5 mg/kg PO q12h	Can be used when tetracycline or doxycycline is unavailable. May cause more GI upset than other tetracyclines
Niacinamide	Dogs >10 kg receive 500 mg PO q8–12h Dogs <10 kg receive 250 mg PO q8–12h	May cause GI upset
Prednisone Prednisolone Dexamethasone	Dogs: 1–3 mg/kg PO Cats: 2–4 mg/kg PO Dogs: 0.1–0.2 mg/kg PO Cats: 1.5 mg/average sized cat PO	As a general rule, glucocorticoids should be administered q24h until the disease is controlled. Once the disease is controlled, they should be administered q48h or less. A slightly higher dose administered q48h tends to have fewer side-effects than a daily dose, even if the daily dose is lower
Triamcinolone	Dogs: 0.3–1 mg/kg PO Cats: 0.3–1 mg/kg PO	
Methylprednisolone	Dogs: 0.8–2 mg/kg PO or 4 mg/10 lb	
Azathioprine	1.5–2.5 mg/kg PO q24–48h	Dosing q48h reduces side-effects. Monitor CBC/chemistry q2 weeks for initial 3–4 months. May require 2 months for maximum benefit. Do not give to cats
Ciclosporin	Dogs and cats: 5–10 mg/kg PO q24h	Use the modified CSA formulation. CSA blood level monitoring is generally not useful when treating skin disease
Hydroxychloroquine	Dogs: 5 mg/kg PO q24h	
Omega 3 fatty acids	Dogs: 180 mg EPA and 120 mg DHA/10 lb PO q24h	Use as adjunctive therapy. Benefit may not be noted before 8–12 weeks
Vitamin E	Dogs: 200–800 IU PO q24h	Use as adjunctive therapy
Chlorambucil	Dogs and cats: 0.1–0.2 mg/kg PO q24–48h	Monitor CBC/chemistry as for azathioprine
Dapsone	Dogs: 1 mg/kg PO q8h	Monitor CBC/chemistry. Do not give to cats
Tacrolimus 0.1%	Apply topically q12h	
Betamethasone valerate 0.1% Fluocinolone (Synotic®, Zoetis)	Apply topically q12h Apply topically q12h	Topical steroids are useful for focal skin lesions. Dermal atrophy may occur with prolonged use

CBC, complete blood count; CSA, ciclosporin; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; GI, gastrointestinal; IU, international units; PO, by mouth (*per os*).

Differential diagnoses include systemic lupus erythematosus, pemphigus foliaceus, pemphigus erythematosus, vitiligo, trauma, and Vogt–Koyanagi–Harada-like syndrome.

Treatment involves sun avoidance, oral and/or topical glucocorticoids, topical tacrolimus, niacinamide with tetracycline, and ciclosporin (see Table 162.1). These therapies can be used alone or in combination, depending on response to therapy. Complications can include secondary pyoderma.

Prognosis is generally good because DLE is limited to the skin. Chronic, untreated lesions may rarely progress to squamous cell carcinoma.

Exfoliative Cutaneous Lupus Erythematosus

Exfoliative cutaneous lupus erythematosus (ECLE) is an autoimmune disease that affects German shorthaired pointers. The disease occurs in puppies and young adults. Sex predilection has not been noted.

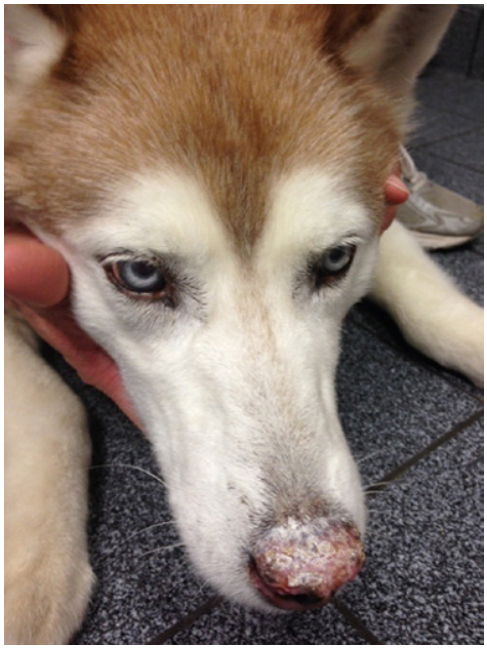

Figure 162.2 Middle-aged, male, neutered Siberian husky with crusting, depigmentation, and loss of cobblestone architecture of the nasal planum associated with discoid lupus erythematosus.

The disease is characterized by widespread scaling, depigmentation, alopecia, ulceration and crusting on the muzzle, pinnae, trunk, and limbs (Figure 162.3). Systemic abnormalities such as lymphadenopathy, intermittent pyrexia, joint pain, infertility, hyperglobulinemia, and thrombocytopenia may also be present. Dogs often assume a hunched stance.

Diagnosis is achieved with history, physical examination, and skin biopsy. The skin should not be clipped or cleaned prior to sampling with a punch biopsy. Multiple specimens should be selected from lesions of varying stages. Histopathology reveals lymphocytic interface dermatitis with marked hyperkeratosis and apoptotic keratinocytes. Destruction of sebaceous glands may also be observed.

Clinical differential diagnoses include primary seborrhea, ichthyosis, and sebaceous adenitis.

Glucocorticoids, ciclosporin, and hydroxychloroquine can temporarily relieve clinical signs (see Table 162.1). Complications may include secondary pyoderma, yeast dermatitis, and otitis.

This disease may wax and wane. Dogs eventually succumb to the disease, but treatment can improve quality of life in some dogs for several months to years.

Vesicular Cutaneous Lupus Erythematosus

Vesicular cutaneous lupus erythematosus (VCLE) is an autoimmune blistering disease that primarily affects middle-aged to older, female Shetland sheepdogs and collies. The disease generally occurs in the spring and summer months, and sparsely haired areas of the skin are most typically affected.

Vesicular cutaneous lupus erythematosus is characterized by transient vesicles that develop into coalescing ulcers with serpiginous borders (Figure 162.4). The abdomen, groin, and axillae are most frequently affected, although lesions may also occur on the mucocutaneous junctions.

Diagnosis is based on history, physical examination, and skin biopsy findings. The skin should not be clipped or cleaned prior to sampling with a punch biopsy. Vesicles or lesional skin adjacent to a fresh ulcer are ideal for sampling. Lesions devoid of epithelium have less

Figure 162.3 One-year-old German shorthaired pointer with exfoliative cutaneous lupus erythematosus. Note the extensive scaling present on the dorsal muzzle, extending to the periocular region and forehead. *Source:* Courtesy of Sheila Torres.

Figure 162.4 Three-year-old collie with vesicular cutaneous lupus. Note the coalescing ulcerative lesions forming a serpiginous pattern. *Source:* Courtesy of Sheila Torres.

diagnostic value. Histopathology reveals interface vacuolation and basal cell apoptosis.

Clinical differential diagnoses include severe erythema multiforme, systemic lupus erythematosus, pemphigus vulgaris, severe dermatomyositis, and bullous pemphigoid.

Treatment involves immunosuppression using glucocorticoids combined with azathioprine or ciclosporin. Pentoxifylline, vitamin E, topical glucocorticoids, or hydroxychloroquine can be used as adjunctive therapy (see Table 162.1). Sun avoidance is potentially important because sun exposure may be part of the disease pathogenesis. Topical and/or oral antibiotics along with general wound care should also be instituted. Complications may include secondary pyoderma and even septicemia. Prognosis is generally good.

Autoimmune Subepidermal Blistering Diseases

This group of diseases is autoimmune in nature and characterized by vesicle formation on various parts of the body. The diagnosis is based on signalment, physical examination, histopathology, and response to therapy. Immunohistochemistry or immunofluorescence is also sometimes required to differentiate among the blistering diseases.

Bulla or vesicles should be sampled via wedge biopsy for diagnostic purposes. If only erosions and ulcers are present, the clinician should obtain a wedge biopsy encompassing both margins of an erosive lesion. It is important to include epidermis in the sample. A biopsy that includes only dermis (e.g., center of an erosion or ulcer) will yield minimal diagnostic information. Samples should be submitted to an experienced dermatohistopathologist to increase the chances of obtaining a definitive diagnosis. Response to therapy and lesion appearance can also guide the diagnosis. Bullous pemphigoid and mucous membrane pemphigoid are fairly glucocorticoid responsive, while epidermolysis bullosa acquisita (EBA) is more glucocorticoid resistant.

The mucous membranes are predominantly affected in mucous membrane pemphigoid. Areas of friction and trauma (i.e., footpads) are predominantly affected in EBA. Vesicular cutaneous lupus erythematosus (discussed above) features extensive abdominal erosions. Bullous pemphigoid and EBA generally feature tense vesicles, while the vesicles of vesicular cutaneous lupus erythematosus are more flaccid.

Bullous Pemphigoid

Bullous pemphigoid (BP) is an autoimmune vesiculobullous disease that more often affects middle-aged dogs. Breed and sex predilections have not been identified.

Initial lesions develop on haired skin and include erythematous macules and patches that progress to turgid vesicles. The lesions evolve to ulcers and crusts. Lesions are not pruritic but can be painful. Pawpads are generally spared and mucosa is less frequently affected than in mucous membrane pemphigoid.

Diagnosis is based on the dermatohistopathologic findings of skin biopsy and immunofluorescence or immunohistochemistry. Refer to the subepidermal blistering diseases introduction for details about biopsy technique and special testing. Histopathology reveals subepidermal bullae.

Clinical differential diagnoses include EBA (although EBA typically features footpad involvement), pemphigus variants, VCLE, and mucous membrane pemphigoid. The presence of nonmucosal involvement is more suggestive of BP than mucous membrane pemphigoid.

Treatment involves topical glucocorticoids, oral glucocorticoids, tetracycline with niacinamide, and/or azathioprine (see Table 162.1). Complications include pyoderma.

Spontaneous remission has been reported although it should be anticipated that life-long therapy could be necessary.

Epidermolysis Bullosa Acquisita

Epidermolysis bullosa acquisita is an autoimmune vesiculobullous disease that affects mostly young adult dogs. Great Danes and male dogs are overrepresented.

Initial lesions include patchy erythema and vesicles of the face, oral cavity, concave pinna, axilla, and groin (Figure 162.5).

Vesicles may be hemorrhagic. Areas of friction tend to have the most obvious lesions. The groin and axilla develop erosions quickly. The oral mucosa and footpads usually feature extensive sloughing. Affected individuals

Figure 162.5 One-year-old Great Dane with epidermolysis bullosa acquisita. Note the ulcers on the buccal mucosa and vesiculation at the lower lip margin. *Source:* Courtesy of Sandra Koch.

may show systemic signs of illness. A localized variant of EBA exists that does not have systemic signs.

Diagnosis is based on the dermatohistopathologic findings of skin or mucosal biopsy and immunofluorescence or immunohistochemistry. Refer to the subepidermal blistering diseases introduction for details about biopsy technique and special testing. Histopathology reveals subepidermal bullae.

Clinical differential diagnoses include bullous pemphigoid, mucous membrane pemphigoid, VCLE, pemphigus vulgaris, severe erythema multiforme, and bullous drug eruptions.

Treatment involves immunosuppressive therapy such as glucocorticoids and azathioprine that can be combined with IVIG in refractory cases (see Table 162.1). Disease complications include lethargy, fever, and sepsis. Anemia and thrombocytopenia were observed in one dog.

Prognosis is guarded to poor because this disease does not respond readily to treatment.

Linear IgA Disease

Linear IgA disease (LAD) is a rare autoimmune disease of dogs. There are no known breed, age or sex predilections. The disease is characterized by ulcerations of the mucous membranes, mucocutaneous junctions, and skin (particularly of the extremities, axillae, groin, and pawpads). The initial lesions are vesicles, but their transient nature means they are rarely observed.

Diagnosis is based on the dermatohistopathologic findings of skin or mucosal biopsy and immunofluorescence or immunohistochemistry. Refer to the subepidermal blistering diseases introduction for details about biopsy technique and special testing. Histopathology reveals subepidermal bullae with mild to moderate inflammation. Clinical differential diagnoses include bullous pemphigoid, mucous membrane pemphigoid, EBA, VCLE, systemic lupus erythematosus, pemphigus vulgaris, severe erythema multiforme, and bullous drug eruptions.

Treatment has not been reported for this rare disease in dogs; however, the same immunomodulatory/immunosuppressive drugs mentioned for the other autoimmune blistering diseases can be tried (see Table 162.1).

Prognosis is guarded due to the paucity of information about this disease in dogs.

Mucous Membrane Pemphigoid

Mucous membrane pemphigoid (MMP) is a rare autoimmune blistering disease of dogs and cats that affects the mucous membranes and adjacent skin. Dogs are affected in adulthood, with no recognized sex predilection. German shepherd dogs may be predisposed.

Lesions are characterized by vesicles that progress to form erosions, ulcers, and crusts. The oral cavity, nasal planum, periocular region, genitalia, footpads, and concave pinnae can be affected. Hypopigmentation and atrophic scarring may occur in some cases. The lesions are nonpruritic, but may be painful. Lymphadenopathy may be present.

Diagnosis is based on the dermatohistopathologic findings of skin or mucosal biopsy and immunofluorescence or immunohistochemistry. Refer to the subepidermal blistering diseases introduction for details about biopsy technique and special testing. Histopathology reveals subepidermal bullae.

Clinical differential diagnoses include bullous pemphigoid, EBA, VCLE, pemphigus vulgaris, erythema multiforme, and bullous drug eruptions. The mucous membranes are markedly affected in MMP. This characteristic can be useful in distinguishing MMP from other blistering diseases.

Treatment involves immunosuppression. Lesions are generally not severe, and tend to respond easily to therapy. Tetracycline and niacinamide should be considered as initial treatment. Glucocorticoids and other immunosuppressants may be considered if the lesions are severe or do not respond readily (see Table 162.1).

Prognosis is good to guarded. Complications include secondary infections of the lesions.

Pemphigus Complex

History, physical examination, impression smears, and histopathology lead to the diagnosis of diseases within the pemphigus complex. The hallmark of diseases in this category is acantholytic keratinocytes (Figure 162.6) and these can be identified on cytology and histology.

Trichophyton mentagrophytes and severe pyoderma are the primary differentials for pemphigus because acantholytic keratinocytes can occur in these conditions as well.

A direct impression smear from under a moist crust or the content of a pustule will reveal numerous nondegenerate neutrophils, acantholytic keratinocytes and sometimes eosinophils. Bacteria may be present if secondary infections occur.

The punch biopsy technique is appropriate for diseases in this category. The skin should not be shaved or cleaned prior to obtaining the biopsy. Crusts should not be removed because they contain acantholytic keratinocytes. With rare exceptions, skin devoid of epithelium should not be biopsied because epithelium is required for a histologic diagnosis. Moist, tightly adhered crusts, pustules, vesicles or the epithelialized edge of an erosion

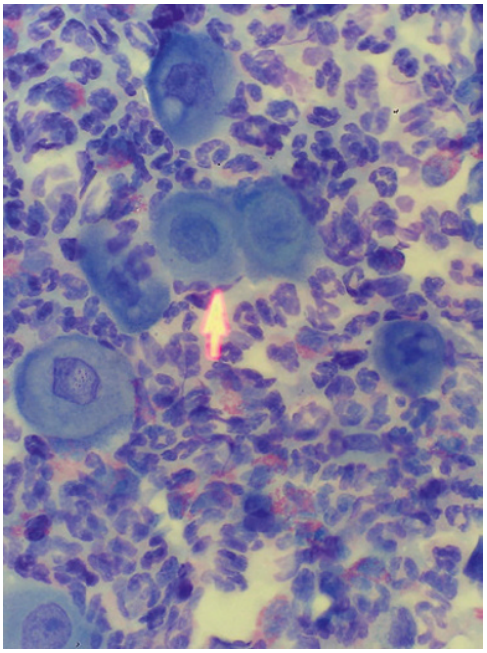

Figure 162.6 Sample collected from a pustule in a case of pemphigus foliaceus. The arrow shows a characteristic acantholytic cell. Also present are large numbers of neutrophils and eosinophils. *Source:* Courtesy of Lisa Reiter.

are the ideal lesions to biopsy. Periodic acid–Schiff (PAS) stain should be requested to evaluate the sample for fungal elements. Immunofluorescence or immunohistochemistry is rarely used to support a diagnosis.

Pemphigus Foliaceus

Pemphigus foliaceus (PF) is a fairly common autoimmune disease that affects many species, including dogs and cats. The disease affects middle-aged to older animals. No sex predilection has been recognized.

Dogs may develop large pustules, erosions and crusts on the face (particularly the periocular region and bridge of the nose), concave aspect of the pinnae, pawpads, and/or trunk (Figure 162.7). Pruritus may or may not be present. Pemphigus foliaceus in cats is characterized by crusting on the pinnae, face, and/or nailfolds. Caseous debris may also be present around the nails (Figure 162.8). Pruritus is usually absent.

The reader is referred to the pemphigus introduction above for details about biopsy technique and special testing. Histopathology reveals broad, subcorneal pustules with acantholytic keratinocytes. Differential diagnoses include superficial pyoderma, pustular dermatophytosis, and drug reactions. Complications include fever, weight loss, lethargy, and anorexia in pets that have widespread lesions. Concurrent dermatophytosis and/or secondary pyoderma may also be present.

Figure 162.7 Cocker spaniel with pemphigus foliaceus. Multifocal to coalescing lesions covered with yellowish crusts localized to the pinna, dorsal aspect of the head and muzzle. Areas of erosion are noted where adherent crusts were removed. *Source:* Courtesy of Sheila Torres.

Figure 162.8 Domestic shorthair cat with caseous debris and erythema of the nailfold associated with pemphigus foliaceus.

Glucocorticoids are generally effective but often need to be combined with azathioprine. Glucocorticoids can also be combined with ciclosporin, chlorambucil, or tetracycline with niacinamide (see Table 162.1).

Topical flea and tick products that contain amitraz have been associated with pemphigus-like disease. The first step in treatment should be to discontinue amitraz-containing flea/tick preventives. Immunosuppressive therapy should then be started.

Prognosis is guarded for pets that do not respond to or cannot tolerate initial therapy with glucocorticoids. Prognosis is good for pets that respond easily to therapy and that can be controlled with low doses of medication.

Pemphigus Erythematosus

Pemphigus erythematosus (PE) is an autoimmune disease with characteristics of pemphigus foliaceus and DLE. Dogs and cats are affected; no breed or sex predilections have been identified.

It is characterized by lesions that are limited to the face and pinnae. Specifically, the nasal planum and sometimes the concave aspect of the ears are affected with pustules, erosions, crusts and sometimes depigmentation. Refer to the pemphigus introduction above for details about biopsy technique and special testing. Histopathology reveals acantholysis and interface dermatitis. Differential diagnoses include dermatophytosis (*Trichophyton mentagrophytes*), DLE, and pemphigus foliaceus. Complications include secondary infections of lesional skin.

Treatment involves immunosuppression with one or a combination of the following: tetracycline/niacinamide, glucocorticoids, azathioprine, ciclosporin, and/or topical tacrolimus (see Table 162.1). Avoidance of intense sun exposure may also be helpful. Prognosis is good. Some cases may be more responsive to therapy than others.

Pemphigus Vegetans

Pemphigus vegetans (PV) is an exceedingly rare autoimmune disease of dogs. Three cases are described in the literature. The disease is characterized by wart-like projections on the pinnae, axillae, and sternum. Additionally, pustules and vesicles may be present on the abdomen and paws, and erosions may be present on mucous membranes. See the pemphigus introduction above for details about biopsy technique and special testing. Histopathology in humans reveals suprabasilar clefting.

Treatment is immunosuppression (see Table 162.1), and prognosis is guarded due to the paucity of information regarding this disease in dogs.

Pemphigus Vulgaris

Pemphigus vulgaris is a rare autoimmune blistering disease of dogs and cats. This disease can occur at any age and male dogs appear to be predisposed but there is no breed predilection.

Characteristic lesions are dramatic and include flaccid vesicles, erosions, and ulcers. Mucosal or mucocutaneous lesions are generally observed first, followed by lesions that may occur on the face and nose (see Figure 162.5). Pressure points, pawpads, and intertriginous areas are also usually affected. Refer to the pemphigus introduction above for details about biopsy technique and special testing. In cases where mucosal erosions predominate, a wedge biopsy encompassing both margins of the lesion may be preferred over a punch biopsy. Histopathology reveals suprabasilar clefting with acantholytic keratinocytes and rounded basal cells.

Differential diagnoses include paraneoplastic pemphigus, mucous membrane pemphigoid, bullous pemphigoid, EBA, erythema multiforme, and epitheliotropic cutaneous lymphoma. Complications include lethargy, anorexia, weight loss, and secondary skin infections.

Treatment involves immunosuppression with glucocorticoids combined with azathioprine or chlorambucil or tetracycline/niacinamide (see Table 162.1). Prognosis is guarded as this disease may be refractory to therapy.

Uveodermatologic Syndrome

Uveodermatologic syndrome or Vogt–Koyanagi–Harada-like syndrome is a rare disease of dogs. The pathomechanism is currently unknown but antibodies directed against melanocytes and pigment-associated proteins have been identified, suggesting that autoimmunity plays a role. There is evidence that genetics participates in disease development in akitas. Uveodermatologic syndrome affects young to middle-aged dogs, and there is no apparent sex predilection. Akitas, Samoyeds, Siberian huskies, Alaskan malamutes, and chow chows are overrepresented, although numerous other breeds have been affected.

The disease is characterized by acute onset of unilateral or bilateral uveitis and concurrent erythema, scaling and depigmentation of the hair, lips, eyelids, nose and occasionally the footpads, scrotum, anus, and hard palate. In most cases, the skin signs are mild with depigmentation being the main lesion. Pruritus may or may not be present.

The diagnosis is based on history, physical (especially ocular) examination, and skin biopsy findings. The clinician should biopsy an area of erythematous and depigmented skin. Histopathology reveals lichenoid granulomatous dermatitis with melanophages. Ocular examination is necessary to diagnose uveitis.

Differential diagnoses include concurrent separate ocular and skin diseases. Uveitis is often an indicator of systemic disease and may be secondary to immune-mediated, infectious, neoplastic, toxic, metabolic, traumatic, or idiopathic processes. Other causes of hair and mucocutaneous skin depigmentation include DLE,

alopecia areata, vitiligo, pemphigus erythematosus, and epitheliotropic cutaneous lymphoma.

Therapy should be directed towards preserving vision. Skin lesions may respond while eye lesions continue to progress. Frequent monitoring of the eyes is important. Topical or intravitreal glucocorticoids, topical cycloplegics, and carbonic anhydrase inhibitors should be instituted along with systemic glucocorticoids combined with azathioprine or ciclosporin (see Table 162.1).

Complications may include secondary glaucoma, cataracts, and blindness. Prognosis is guarded, although better when treatment is instituted early in the disease course. Repigmentation of the skin and hair may or may not occur.

Approach to Alopecia

Linda A. Frank, DVM, MS, DACVD

Department of Small Animal Clinical Sciences, College of Veterinary Medicine, University of Tennessee Institute of Agriculture, Knoxville, TN, USA

Etiology/Pathophysiology

Alopecia or hypotrichosis are common reasons for presentation to a veterinarian. Alopecia implies complete hair loss while hypotrichosis implies thinning of the hair coat. The presentation of alopecia/hypotrichosis may be localized or generalized and focal, patchy or diffuse, depending on disease severity, duration, and the cause of the hair loss. Alopecia may be traumatically induced, with the patient scratching or licking the hair off, or due to hair falling out or failing to regrow following normal shedding.

Trauma-Induced Alopecia

Trauma-induced alopecia is most often secondary to pruritus. Common causes include allergies, ectoparasites, bacterial skin infections, and *Malassezia* dermatitis. Less common causes in older animals include neoplastic diseases such as epitheliotropic lymphoma or mast cell tumor and paraneoplastic syndromes.

Inflammation-Induced Alopecia

Alopecia not associated with trauma may be due to an inflammatory condition, such as pyoderma, follicular demodicosis, dermatophytosis, or sebaceous adenitis (Table 163.1).

Sebaceous adenitis is an immune-mediated destruction of the sebaceous glands and is associated with scaling and alopecia. Breed predilections include the standard poodle, Samoyed, akita, and vizsla. In short-coated dogs, these conditions present as a patchy or "moth-eaten" pattern of alopecia (Figure 163.1).

The lesions might not overtly appear inflammatory; however, the multifocal pattern of the alopecia should make you suspicious of an inflammatory cause. Hairs may epilate easily from the periphery of these inflammatory alopecic sites but not from other locations on the body. While pruritus can be associated with these diseases and may even be directed at the lesions, it is not the cause of the alopecic spots.

Vasculitis from immune-complex deposition secondary to infectious or immune-mediated diseases may cause multifocal alopecia due to local ischemia. Clinically, the lesions may resemble dermatophytosis in that they are circular and alopecic; however, they appear noninflammatory, lacking erythema and crusting with thin rather than thickened skin, unless cutaneous necrosis and ulceration occur (Figure 163.2).

A common example of focal ischemic alopecia is rabies vaccination-induced vasculitis. Vasculitis may also be seen with drug reactions, tick-borne diseases, and systemic lupus erythematosus. Dermatomyositis is an inherited (autosomal dominant with variable penetrance) disorder that primarily affects collies and Shetland sheepdogs. Vasculitis and ischemic dermatitis are thought to be part of the pathogenesis of the disease.

Autoimmune/immune-mediated diseases such as alopecia areata or pseudopelade and neoplastic conditions such as epitheliotropic lymphoma could result in areas of inflammatory alopecia. Alopecia areata is an immune-mediated attack on the hair bulb while pseudopelade is an immune-mediated attack on the follicle wall, resulting in focal to multifocal alopecia. Clinically, the areas of alopecia may not show evidence of erythema, suggesting a noninflammatory mechanism; however, the pattern of alopecia necessitates investigation into inflammatory differentials.

Paraneoplastic alopecia occurs in association with internal neoplasia. This is a presumed inflammatory alopecia although the pathomechanism of the alopecia is unknown. Paraneoplastic alopecia has been described in cats in association with pancreatic and biliary carcinoma. The alopecia is acute and progressive with easy epilation of hair and smooth thin skin.

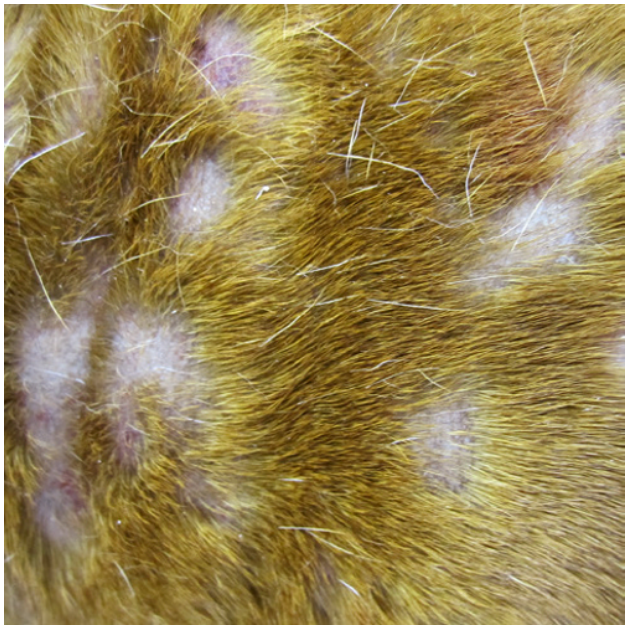

Figure 163.1 A 3-year-old male castrated English bulldog with patchy alopecia of the trunk associated with sebaceous adenitis.

Noninflammatory Alopecia

Alopecia may also occur as a consequence of abnormal hair cycling or hair development. These are grouped under noninflammatory causes of alopecia and include endocrine diseases as well as congenital/hereditary and idiopathic causes of alopecia. To understand these conditions, it is important to understand the hair cycle. Briefly, the anagen phase of the hair cycle is when the hair is actively growing. In most dogs and likely all cats, this is a relatively short phase lasting at most a few months until the hair reaches its maximum length. The length of the anagen phase, and thus the length of hair, is genetically determined and may be of different durations for different regions of the body. From anagen, the hair goes through a short catagen phase in which it reverts into a nongrowing or telogen hair. The hair can remain in telogen for a prolonged period of time before a new cycle is started. For some breeds such as the malamute, this may be a few years. The telogen hairs are well anchored and do not epilate easily. Thus, the presence of telogen hairs is not necessarily pathologic. Dogs that require frequent hair clipping, such as poodles, have a hair cycle more similar to people in that they have a prolonged anagen phase with fewer hairs in telogen at any point in time. These dogs are more likely to develop alopecia from chemotherapeutic agents which inhibit actively dividing cells. Shedding, or exogen, is separate from the hair cycle and is independent of whether a new hair cycle is starting.

Figure 163.2 Adult male castrated toy poodle with focal alopecia secondary to rabies vaccination-induced vasculitis. Dog was referred for nonresponsive dermatophytosis because of the circular lesion.

Alopecia Associated with Abnormal Hair Growth

Abnormalities in hair growth occur during the anagen phase of the hair cycle. There are only a few conditions that fall into this category and they include follicular dysplasias, congenital hypotrichosis, color dilution alopecia, and black hair follicular dysplasia. Follicular dysplasias, where abnormal follicles fail to produce healthy anagen hairs, are most often associated with alopecic breeds (e.g., Chinese crested dog, Mexican hairless dog, and the Sphynx cat) in which the alopecia is a breed characteristic. Congenital hypotrichosis is poorly described in small animals. The hypotrichosis/alopecia occurs either at birth or within the first six months of life and may be associated with other ectodermal defects. Color dilution alopecia and black hair follicular dysplasia are color-restricted alopecias that begin

gradually in the first three years of life (Figure 163.3). The alopecia involves a defect in melanosome migration and/or transfer, which occurs during the anagen phase of the hair cycle.

Alopecia Associated with Hair Cycle Arrest

Alopecia associated with abnormal hair cycling typically occurs because the hairs remain in telogen and a new anagen cycle is not initiated. With time, the telogen hairs are shed but are not replaced, resulting in a diffuse, often symmetric alopecia. Areas of wear such as the neck, pressure points, and tail may become alopecic first as these hairs are removed by friction.

There are many conditions that appear to be associated with hair cycle abnormalities. These include hypercortisolemia, hypothyroidism, hyperestrogenism, alopecia X, patterned alopecia of various breeds, cyclic flank alopecia, postclipping alopecia, and anagen/telogen defluxion. Some of these conditions are associated with a temporary alopecia (postclipping alopecia, anagen/telogen defluxion), some may be seasonal (cyclic flank alopecia), and others are likely permanent with variable response to treatments (alopecia X, patterned alopecia). The cutaneous changes associated with endocrine dermatoses may also occur with other hair cycle abnormalities, including diffuse alopecia often sparing the head and distal extremities, seborrhea, comedones, hyperpigmentation, and cutaneous infections. In addition, many of the histologic characteristics associated with endocrine dermatoses (telogen hairs, follicular keratosis, hyperkeratosis, excess trichilemmal keratinization [flame follicles], thin epidermis, and thin dermis) may also be seen with other hair cycle abnormalities. It is important to realize that, with a few exceptions, histopathology cannot differentiate endocrine diseases from other causes of hair cycle arrest.

Figure 163.3 Neck region of a 9-year-old female spayed gray and white Italian greyhound with long-standing color dilution alopecia. The white hairs are normal. The area which had gray hairs is seborrheic and lichenified.

Specific Noninflammatory Alopecic Disorders

Alopecia X

Alopecia X is a hair cycle arrest that affects primarily plush-coated breeds but also toy and miniature poodles (Table 163.2). It is presumed to be hereditary because of the strong breed predilections although the specific defects or mode of inheritance have yet to be determined. Dogs affected are usually young adults but alopecia X can affect any dog between 1 and 10 years of age. There is no sex or neuter status preference with this condition. Clinically, dogs present with progressive symmetric alopecia that spares the head and distal extremities (Figure 163.4).

The alopecia is often associated with hyperpigmentation of the skin. Because of the similarity of this condition with endocrine dermatoses, it is important to rule those conditions out before a diagnosis of alopecia X can be made. A unique feature of this disease is hair regrowth at the site of biopsy or surgical trauma.

Table 163.2 Common breeds associated with noninflammatory alopecic syndromes (not inclusive)

Alopecia X	Patterned alopecia	Cyclic flank alopecia	Color dilution alopecia	Other
Chow chow	American water spaniel	Airedale	Chihuahua (blue)	Chesapeake Bay retriever
Keeshond	Boston terrier	Boxer	Dachshund (blue)	Labrador retriever (silver)
Malamute	Dachshund	English bulldog	Doberman pinscher (blue and fawn)	Schipperke
Pomeranian	Greyhound	French bulldog	Weimaraner	
Samoyed	Irish water spaniel		Yorkshire terrier	
Siberian husky	Portuguese water dog			
Spitz				
Toy/miniature poodle				

Figure 163.4 Adult male castrated Pomeranian dog with alopecia X. Note that the alopecia spares the head and distal extremities, similar to hypercortisolemia.

Patterned Alopecia

Patterned alopecia is a tardive hypotrichosis that often starts at less than 1 year of age. Many syndromes have been described that are breed restricted. These include pinnal alopecia of dachshunds, ventral and caudal alopecia of dachshunds and Boston terriers (Figure 163.5), alopecia of the ventral neck, flank, and caudal regions of water spaniels, and alopecia of the caudal thighs of greyhounds. The actual mechanism of the alopecia is not known. Because some dogs can regrow normal hair at these sites, it is thought not to be a follicular dysplasia but more likely a hair cycle abnormality, although multiple etiologies are possible. The breed associations suggest a genetic component.

Cyclic Flank Alopecia

Cyclic flank alopecia is a seasonal or cyclic truncal alopecia that usually occurs during or just after short day-length period. The alopecia affects the flanks, lateral thorax, and sometimes caudodorsum and nose bridge (Figure 163.6).

There are often bizarre patterns to the alopecia and the skin may be intensely hyperpigmented. Less common presentations include hypotrichosis and hair pigment changes without overt alopecia, also in strange patterns. The alopecia may not recur each year or in some cases may be permanent. Age of onset is 1.5–4.5 years. Breeds reported to be affected by this condition include boxers, English and French bulldogs, and Airedales (see Table 163.2).

Postclipping Hair Follicle Arrest

Postclipping alopecia or hair follicle arrest refers to failure of hair regrowth following close clipping, usually in preparation for surgery (Figure 163.7).

It may occur more frequently in plush-coated breeds and there are two theories as to why this occurs. The first

Figure 163.5 Patterned alopecia in a young adult female spayed Boston terrier with alopecia of the lateral thorax and ventrum.

Figure 163.6 Alopecia of the lateral thorax and flank in a male castrated boxer with cyclic flank alopecia.

Figure 163.7 Adult male castrated mastiff with postclipping alopecia secondary to receiving an epidural injection.

is that the clipping/surgical preparation causes a hair cycle arrest, possibly because of a temperature change with vasoconstriction to the skin surface. The other theory applies primarily to the plush-coated breeds. It is thought that these dogs may have been clipped during a time when their hair is in a prolonged telogen phase and not able to initiate a new anagen cycle. It is also possible that the clipping uncovered an endocrine or other noninflammatory alopecia condition. The hairs are not cycling because of an underlying disease such as hypercortisolemia or alopecia X but alopecia has not yet occurred. The clipping simply hastened the alopecia. With postclipping hair follicle arrest, the hairs should spontaneously resume normal cycling within 7–30 months, often following a strong stimulus for hair cycling such as shortening day length.

Anagen/Telogen Defluxion

Anagen or telogen defluxion involves hair loss following an illness. Telogen defluxion occurs more commonly in small animals. The illness causes an abrupt cessation of anagen, synchronizing all hairs in telogen. In 1–3 months following the illness, large numbers of telogen hairs are shed synchronously as a new anagen hair cycle begins. Hairs epilate easily during this time. Anagen defluxion occurs more commonly in large animals. The illness causes a generalized disturbance of the anagen stage of the hair cycle resulting in a sudden loss of coat. In contrast to telogen defluxion, hair loss occurs within two days to one week following the illness. In both of these conditions, hairs regrow normally.

Signalment

The breed and age of onset should aid in the initial differential list (see Table 163.1). Congenital/hereditary alopecias are more likely to occur within the first few years of life while endocrine dermatoses and neoplastic diseases occur in middle-aged to older animals. Depending on the trigger, immune-mediated dermatoses can occur within a wide age range and affect many breeds and their crosses.

History and Clinical Signs

When evaluating the dog or cat for alopecia, a thorough history and physical examination are in order. Determining the presence or absence of pruritus and the distribution and pattern of hair loss will help determine the ultimate cause of the alopecia.

Clinically, pruritus-induced alopecias are characterized by broken hairs where the animal has been scratching. Microscopic examination of the tips of the hairs (trichogram) will show a blunted or fractured tip instead of a tapered tip if the animal is inducing the alopecia secondary to trauma. This technique is not helpful if dogs are groomed and clipped regularly, as all of their hairs will be blunted. Evidence of excoriations supporting pruritus may also be observed in the alopecic areas.

Onset of Alopecia

If the onset of alopecia is rapid, infectious or paraneoplastic conditions need to be considered. Also, a recent history of systemic illness could be the cause of a rapid onset of alopecia.

Ease of Epilation

Easy epilation of hairs is more often associated with inflammatory causes of alopecia such as pyoderma, dermatophytosis or demodicosis but can also be seen with conditions that result in rapid progression of alopecia such as anagen/telogen defluxion.

Distribution and Pattern of Alopecia

Distribution and pattern of the alopecia may be key to identifying the underlying diagnosis or formulating your differential diagnosis list but requires careful observation. If the alopecia is color restricted, likely this is color dilution alopecia or black hair follicular dysplasia. If the

alopecia is patchy throughout the coat, an inflammatory cause is likely, whereas if the alopecia is diffuse and symmetric, a noninflammatory cause is more likely.

Diagnosis

Minimum Dermatology Database

A minimum dermatology database consisting of skin scrapings, fungal culture, and surface cytology should be performed on all cases of alopecia. If infections are suspected by clinical presentation (patchy alopecia) or detected by the dermatology database, then treatment should be pursued and alopecia reassessed before further diagnostics are performed.

Trichogram

Trichogram involves the plucking of hairs and examination under the microscope. The tips of the hairs can be examined to determine if the alopecia is traumatically induced (see above). The shafts of the hairs can be examined to look for abnormal clumping of melanin and distortion of the hair shaft, suggestive of color dilution alopecia. This method is not useful for black hair follicular dysplasia, as the hair is too pigmented to allow for this observation. The bulbs of the hairs can be examined for evidence of a preponderance of telogen hairs, which might suggest telogen defluxion when coupled with ease of epilation and supportive history.

Histopathology

Histopathology will help rule out many of the inflammatory causes of alopecia (e.g., folliculitis, sebaceous adenitis, vasculitis, alopecia areata, pseudopelade, neoplasia, or paraneoplastic dermatitis) but, as stated before, it seldom allows differentiation of endocrine diseases from other noninflammatory causes of alopecia such as alopecia X or patterned alopecias. It is helpful to first treat any infections that are identified prior to performing a biopsy as inflammation associated with the infection could mask other causes of alopecia.

Endocrine Testing

If noninflammatory alopecia is first occurring in a middle-aged dog, further investigation into a possible endocrinopathy is warranted. This may include basic bloodwork and urinalysis to screen for abnormalities consistent with an endocrinopathy. However, even if all laboratory parameters are within normal limits, endocrine testing may still be indicated.

Table 163.3 Treatment options for select inflammation-induced alopecic conditions

Disease	Treatment options
Sebaceous adenitis	Vitamin A, synthetic retinoids, ciclosporin, glucocorticoids
Vasculitis	Tetracyclines/niacinamide, pentoxifylline, glucocorticoids
Alopecia areata/ pseudopelade	Glucocorticoids, ciclosporin

Additional Diagnostic Tests

If an older dog or cat first develops alopecia, screening for neoplasia becomes very important. Diagnostics in this case may include basic bloodwork, urinalysis, histopathology, and imaging.

Therapy

Treatment depends on the cause of the alopecia. Table 163.3 lists treatment options for some of the inflammation-induced causes of alopecia.

For many of the noninflammatory causes of alopecia associated with hair cycle arrest (alopecia X, patterned alopecia, cyclic flank alopecia, and postclipping alopecia), melatonin therapy may result in hair regrowth. The recommended dosage is 3 mg q12h for small dogs and 6–12 mg q12h for larger dogs. Side-effects are minimal, with the most common one being sedation. It is possible that melatonin causes insulin resistance so it should be used with caution in diabetic animals. Recently, medroxyprogesterone acetate injections were shown to be marginally effective for treating some Pomeranian dogs with alopecia X.

Prognosis

Alopecia in itself is seldom a life-threatening condition although, in some instances, it may be a cutaneous marker for a systemic disease that could carry a guarded to grave prognosis. Most alopecia caused by pruritus or inflammation can be managed or treated once the underlying cause is identified. If follicular destruction occurs secondary to severe inflammation or ischemia, alopecia could be permanent. In addition, immune-mediated conditions such as alopecia areata and pseudopelade may fail to respond to treatment.

Many congenital/hereditary alopecias have a guarded prognosis for hair regrowth. Once the diagnosis has been determined, it becomes of cosmetic concern only. While some treatments may result in varying degrees of hair regrowth for these individuals, the veterinarian and client must decide if the risks of the treatment are warranted for the disease.

Canine Sterile Papular and Nodular Skin Diseases

Sandra Diaz, DVM, MS, DACVD

Department of Veterinary Clinical Sciences, Ohio State University, Columbus, OH, USA

This chapter will review the etiology, pathogenesis, diagnosis, management, and prognosis of the most common canine sterile papular and nodular dermatoses, including histiocytic disorders, sterile nodular panniculitis, sterile granuloma/pyogranuloma syndrome, and juvenile cellulitis.

Canine Histiocytic Disorders

Canine histiocytic disorders include canine reactive histiocytosis (cutaneous and systemic) and histiocytic sarcoma complex (localized and disseminated histiocytic sarcoma).

Canine Reactive Histiocytosis

Canine reactive histiocytosis includes systemic histiocytosis (SH) and cutaneous histiocytosis (CH). Both forms are characterized by reactive proliferation of activated dermal dendritic cells. They affect mainly the skin and subcutaneous tissue, but in the systemic form other organ systems can be involved, including lymph nodes, eyelids, sclera, nasal cavity, lungs, spleen, and bone marrow.

Cutaneous Histiocytosis

Etiology/Pathophysiology

The etiology and pathogenesis of CH are unknown. Since infectious agents have not been identified and the disease responds to immunosuppressive therapy, immune-dysregulatory mechanisms are likely involved. This disease is characterized by specific morphologic and immunohistochemistry criteria. According to Affolter and Moore, CH originates from CD1+, CD11c+, MHC II+, CD4+, and Thy-1+ (CD90) activated dermal dendritic antigen-presenting cells, admixed with T lymphocytes and neutrophils. The cellular phenotype has become the basis for definitive diagnosis (see diagnosis section below).

Epidemiology

Age at the time of diagnosis ranges from 3 to 9 years and males and females can both be affected, but one study showed male predilection. Collies and Shetland sheepdogs may be predisposed.

Clinical Signs

Cutaneous histiocytosis is characterized by multiple hairless, erythematous dermal to subcutaneous nodules localized predominantly to the face, neck, nasal mucosa, perineum, scrotum, and feet (Figures 164.1 and 164.2). The lesions are not pruritic or painful, but larger lesions may become ulcerated and cause discomfort. The lesions wax and wane, with older lesions spontaneously regressing as new ones form. The disease is usually slowly progressive and, in some cases, may spontaneously resolve.

Diagnosis

The clinical differential diagnoses include other nodular skin diseases such as neoplasia (e.g., multiple cutaneous histiocytomas, mast cell tumors, cutaneous lymphoma), infectious granulomas, sterile nodular panniculitis, and cutaneous sterile granuloma and pyogranuloma syndrome.

Diagnosis is based on the patient's history, clinical signs, cytologic findings, and primarily histopathologic findings. Immunohistochemistry may be required to confirm the diagnosis.

Cytologic examination shows large numbers of histiocytes with abundant cytoplasm; binucleated and multinucleated cells can be seen. Variable numbers of other inflammatory cells can be present.

Figure 164.1 Two-year old Bernese mountain dog with cutaneous histiocytosis. Nodular lesions are present on the lips and planum nasale.

Figure 164.2 Close-up of the lesions on the lips of the dog in Figure 164.1. Note the multiple, crusted, erosive to ulcerative nodules.

Histologically, the skin lesions are characterized by a nodular to diffuse infiltrate that extends from middermis to the subcutaneous tissue. The infiltrate is perivascular and periadnexal. Early lesions have a linear or nodular configuration, but it may become diffuse in chronic cases. The infiltrate can invade the wall of blood vessels, causing focal or multifocal areas of ischemic necrosis. Important differential diagnoses for histopathology include sterile granuloma and pyogranuloma syndrome, multiple cutaneous histiocytomas, and cutaneous lymphoma. Immunohistochemistry may be required to differentiate cutaneous histiocytosis from these conditions.

It is recommended to contact veterinary diagnostic laboratories for availability and tissue submission requirements for immunohistochemistry. Because a limited number of markers are available to be used on formalin fixed specimens, the submission of fresh tissue samples may be necessary. Canine cutaneous histiocytosis has been characterized by proliferation of CD1+, CD11c+, MHC II +, CD4+, and Thy-1+ (CD90) activated dermal dendritic cells.

Therapy

Immunosuppressive drugs have been used with mixed results. Most cases respond completely or partially to immunosuppressive therapy with glucocorticoids, but require long-term or intermittent therapy to induce remission and prevent reoccurrence. Up to 50% of cases respond to prednisone as sole therapy. Azathioprine, ciclosporin, and leflunomide have also been shown to be effective, and can be helpful in cases not responding to glucocorticoid therapy. Tetracycline/niacinamide treatment has been found to be effective as maintenance therapy to avoid recurrence. Since tetracycline has been unavailable in the US market, doxycycline or minocycline can be substituted for tetracycline.

Prognosis

Prognosis is guarded. Up to one-third of patients have reoccurrence of skin lesions and thus long-term therapy is required. Dogs with nasal involvement may be more likely to have recurrence.

Systemic Histiocytosis

Systemic histiocytosis is considered a disseminated form of cutaneous histiocytosis. In addition to the skin and mucocutaneous junctions, lesions may be found in the lungs, spleen, liver, lymph nodes, eyelids, sclera, and bone marrow.

Etiology/Pathophysiology

The etiology and pathogenesis of SH are currently unknown. As for CH, since infectious agents have not been identified and the disease responds to immunosuppressive therapy, immune-dysregulatory mechanisms are likely involved.

Signalment

Systemic histiocytosis was first recognized in Bernese mountain dogs, but since then has been described in several other breeds. In one report including 26 dogs, Bernese mountain dogs were overrepresented (11/26),

followed by Rottweilers (4/26), and golden and Labrador retrievers (3/26). The age at the time of diagnosis varies from 1 to 9 years. Males seem to be more frequently affected in Bernese mountain dogs. No sex predisposition was observed in other breeds.

Clinical Signs

Systemic histiocytosis differs from CH in the extent of lesions present and the multiorgan involvement. Lesions affect the skin, with high prevalence for mucocutaneous junctions; other organs commonly involved include the nasal cavity, eyes, spleen, lymph nodes and testicular tissue. Bone marrow, liver, lungs, and gingiva can also be affected. In a recent study, 2/26 dogs had hypercalcemia. The clinical signs vary depending on the organs affected and extension of the lesions. Anorexia, weight loss, conjunctivitis, and stertorous respiration are commonly seen. The disease waxes and wanes and dogs are asymptomatic between clinical episodes. The clinical episodes can increase in severity and respond less effectively to therapy with chronicity.

Diagnosis

Clinical differential diagnoses include neoplasia, infectious and sterile granulomas, cutaneous histiocytosis, and cutaneous sterile granuloma and pyogranuloma syndrome. The diagnosis is based on history, clinical signs, cytology, histopathology, and ruling out infectious causes.

Cytologic findings are similar to CH, consisting mainly of large numbers of histiocytes, with occasional bi- or multinucleated giant cells. Histopathologic findings are identical to those observed with CH, composed of multifocal nodular infiltrate affecting the deep dermis and subcutaneous tissue. The cellular infiltrate consists mainly of histiocytes, lymphocytes, and neutrophils. The infiltrate is angiocentric and may invade the blood vessels, causing destruction of the vascular wall, thrombosis, and ischemic necrosis. Invasion of the blood vessel wall has been observed more consistently in cases of SH. The infiltrating histiocytes express CD1+, CD11c+, MHC II+, CD4+, and Thy-1+ (CD90), consistent with activated dermal dendritic cells.

Therapy

The clinical signs wax and wane, and some dogs can undergo long periods of remission, but most cases require long-term immunomodulatory therapy. The experimental use of thymosin, which modulates T lymphocyte effector and regulatory function, has shown promising results; however, further use of this treatment has not been documented. Good response has been seen with leflunomide and ciclosporin, both of which have an inhibitory effect on T lymphocytes. The good response to these drugs suggests an important role of T lymphocytes in the pathogenesis of canine reactive histiocytosis. Ocular lesions may be more difficult to treat and often require the use of ophthalmic ciclosporin preparations. The use of high doses of glucocorticoids and cytotoxic agents has shown poor response.

Prognosis

The prognosis is guarded; the clinical course waxes and wanes but it is usually prolonged. Most cases are euthanized due to relapse of clinical signs or poor response to therapy.

Histiocytic Sarcoma Complex

Previously known as malignant histiocytosis, this complex includes localized and disseminated histiocytic sarcoma (HS). Histiocytic sarcoma is a highly aggressive neoplasm. It may develop as a localized tumor or a widely disseminated disease; animals with initially localized disease often develop metastasis. The disease is characterized by infiltration of neoplastic proliferation of cells of the histiocytic lineage, including dendritic antigen-presenting cells and macrophages. The presence of macrophages has been documented only in cases of hemophagocytic HS, in which the histiocytes are markedly erythrophagocytic. Histiocytic sarcoma is highly breed specific, with Bernese mountain dogs, Rottweilers, and flat-coated and golden retrievers having a high prevalence. Immunohistochemistry plays an important role in differentiating histiocytic tumors from other neoplasias with similar histopathologic findings such as lymphoma, poorly differentiated mast cell tumors, and malignant fibrous histiocytoma.

Pathogenesis

Histiocytic sarcomas are characterized by localized or disseminated infiltration of malignant histiocytes. Expected immunohistochemical expression pattern for HS in snap-frozen tissue samples is CD1+, CD4-, CD11c+, CD11d-, MHC II+, ICAM1+, Thy -1+/-. Hemophagocytic HS expresses MHC II, beta-2 integrin, and CD11d. The disease is familial in Bernese mountain dogs in which an oligogenic mode of transmission has been proposed.

Signalment

Histiocytic sarcoma affects mainly Bernese mountain dogs, Rottweilers, flat-coated and golden retrievers with a median age at presentation of 8 years. The tumor has been found to have a male predisposition in Bernese mountain dogs and flat-coated retrievers.

Clinical Signs

Localized HS is reported to be most common in the bone, appendicular joints, and skin. Distant metastasis

to the lungs, lymph nodes, and abdominal viscera has been reported in up to 91% of cases. Affected dogs are usually presented for lameness or a soft tissue swelling. In dogs with disseminated HS, the clinical signs are vague and include anorexia, lethargy, and weight loss. Pulmonary involvement is common and dogs may show evidence of dyspnea at the time of initial presentation. Neurologic abnormalities, including ataxia and paraparesis, are also common. Other organs often affected include the liver and spleen. Although clinicopathologic findings are nonspecific, anemia, thrombocytopenia, and hypoalbuminemia were consistently reported in cases of hemophagocytic HS. Diffuse splenomegaly with ill-defined masses was also consistently present in these cases.

Diagnosis

The diagnosis is based on clinical signs, signalment, and cytologic and histopathologic findings. The main clinical differential diagnoses are other neoplasias and systemic histiocytosis. Both localized and disseminated HS have the potential for highly aggressive behavior so complete staging to determine disease extent is recommended to determine possible treatments and prognosis. Cytologic finding include large round cells with foamy cytoplasm and multinucleated giant cells admixed with spindle-shaped cells. Histopathologically, the tumors are poorly demarcated and the neoplastic infiltrate consists of pleomorphic mononuclear cells and multinucleated giant cells. Phagocytosis of neutrophils and erythrocytes is not uncommon. Marked anisokaryosis and anisocytosis with high mitotic rate are also present. The histopathologic findings and the use of immunohistochemical staining help differentiate these tumors from other round cell tumors.

Recently, a screening program has been proposed for early detection of disseminated HS in Bernese mountain dogs. The program suggests screening of Bernese mountain dogs over 4 years of age every six months, including diagnostic imaging and measurement of ferritin as a blood-borne marker of the disease.

Therapy

For cases of localized HS, improved outcome has been reported with the use of localized therapy, including surgery and radiation therapy. Unfortunately, the rate of metastasis is very high (up to 91%) so the use of adjuvant systemic therapy may be beneficial. The disseminated form of the disease usually has poor sensitivity to chemotherapy. Lomustine, doxorubicin, and vincristine have been used with variable success. The use of bisphosphonates has been proposed to increase the effectiveness of chemotherapy against HS cells. The use of a multiple drug protocol including cyclophosphamide, vincristine, and prednisone has also been reported to induce a temporary response.

Prognosis

In general, the prognosis is poor. Dogs with localized HS receiving aggressive localized treatment and systemic chemotherapy may have a better prognosis with a median survival time of 568 days. The median survival time for dogs with disseminated HS receiving chemotherapy is 106 days. The presence of distant metastasis or disseminated disease worsens the prognosis. Many dogs are euthanized at the time of diagnosis because of poor clinical condition and poor prognosis.

Sterile Nodular Panniculitis

Panniculitis refers to inflammation of the subcutaneous fat and it may be associated with a variety of conditions. Sterile nodular panniculitis (SNP) refers to sterile inflammation of the subcutaneous fat tissue of unknown origin. Clinical signs include single or multiple subcutaneous nodules, intermittent fever, and anorexia.

Concurrent inflammation of the fat in other organs can be seen in cases of SNP. Skin lesions can be solitary or multiple and multiple lesions can be associated with systemic signs including fever, lethargy, and anorexia.

Pathogenesis

Sterile nodular panniculitis has been documented in association with systemic lupus erythematosus, pancreatitis and pancreatic tumors, rheumatoid arthritis, and lymphoplasmacytic colitis. In people, a deficiency of alpha-1-antitrypsin, a protease inhibitor, has been suggested to be a predisposing factor. In dogs, this association has not been made with certainty. In one dog with panniculitis in which alpha-1-antitrypsin was found to be low, a *Bartonella* infection was present, making it difficult to determine the cause. In one retrospective study, 37% (16/43) of the patients had prior surgery with lesions developing at the surgery site.

Signalment

A large retrospective study did not identify any age, breed or sex predilection; however, others suggest 3–5 years as the most common age of onset and dachshunds, miniature poodles, and collies as the breeds at increased risk for SNP. In two studies, the most affected dogs were neutered, suggesting no gender predilection.

Clinical Signs

Clinically, SNP manifests as single or multiple subcutaneous nodules varying in size from a few millimeters to several centimeters in diameter. Lesions can be of normal skin color or be erythematous or bluish in color. Initially, the nodules are firm but they may liquefy and become soft. Some lesions regress while others develop draining tracts and become ulcerated (Figure 164.3).

Well-delineated ulcers are characteristic. Draining lesions discharge an oily, clear to yellowish brown material, which may also be hemorrhagic (Figure 164.4).

Nodules may heal with scarring and are more commonly found on the trunk but can occur anywhere. Fever, lethargy, and anorexia are commonly seen in dogs with multiple lesions; these signs occur simultaneously or just before the beginning of nodule formation. Other systemic signs reported include peripheral lymphadenopathy, joint effusion and pain, vomiting, and abdominal pain.

Figure 164.3 Multifocal areas of ulceration on the lateral thorax of a Labrador retriever with sterile nodular panniculitis.

Figure 164.4 Oily, hemorrhagic discharge from an ulcerated nodule in a Weimaraner with sterile nodular panniculitis. *Source:* Courtesy of Dr Melanie Hnot.

Diagnosis

Sterile nodular panniculitis must be differentiated from other forms of panniculitis and other diseases with similar clinical presentation, including infectious diseases such as bacterial, fungal or mycobacterial infection, sterile granuloma and pyogranuloma syndrome, foreign bodies, injection site reaction, insect bite, drug reaction, and neoplasia. Sterile nodular panniculitis is diagnosed based on the patient's history and clinical signs, exclusion of other causes of panniculitis, and cytologic and histopathologic findings. It can be a cutaneous marker of a concurrent disease process so a systematic diagnostic approach is needed to help identify a possible etiologic factor.

A complete history, physical examination, and minimum database including hemogram, chemistry profile and urinalysis can serve as guides in deciding which additional test(s) will be useful in the diagnosis. In a recent study, neutrophilia, increased alkaline phosphatase (ALP), mild hypoglycemia, and hypoalbuminemia were present in over 50% of cases with systemic involvement. Cytologic evaluation of aspirates from intact lesions can vary in appearance from suppurative to pyogranulomatous or granulomatous with fat droplets or cells present and no microorganisms. Aspirates from deep firm nodules may show spindle cells that resemble neoplastic cells. The definitive diagnosis can be based only on histopathologic findings. Wedge biopsies should be performed to collect samples that include the epidermis, dermis, and subcutaneous tissue. The sample should be collected aseptically if submitted for fungal, bacterial (aerobic/anaerobic), and mycobacteria cultures. Bacterial and fungal cultures of intact nodules yield no growth. Special stains of biopsy samples can be used to help eliminate bacteria and fungi as causative agents. Some organisms are difficult to culture or identify with routine methods, and molecular studies like polymerase chain reaction (PCR) are necessary. This is particularly true for mycobacteria and *Leishmania*.

Therapy

Surgical excision of solitary masses can be curative. Dogs with multiple lesions are treated with immunosuppressive drugs. In dogs, oral prednisone or prednisolone is usually effective at 2 mg/kg/day for two weeks; then, the patient should be reevaluated. If remission is achieved within that time, the dose should be decreased by 25% every seven days until the lowest effective dose is given

every 48 hours. Regression of the lesions may take 2–8 weeks. If remission has not been achieved after four weeks of daily immunosuppressive doses of glucocorticoids, the case may require combination therapy with other immunosuppressive drugs such as azathioprine or ciclosporin. Topical and intralesional corticosteroids have been effective in some cases, and may be the treatment of choice when systemic immunosuppressive therapy is contraindicated. In addition to immunosuppressive treatment, vitamin E and potassium iodide have been recommended, but their efficacy is unknown.

Prognosis

The prognosis is usually good, with most cases showing a good response to treatment. Some cases may require prolonged immunosuppressive therapy.

Sterile Granuloma/Pyogranuloma Syndrome

Sterile granuloma/pyogranuloma syndrome (SGPS) is an uncommon disease presenting clinically with cutaneous papules, nodules or plaques of unknown origin. The lesions may be solitary or multiple, and localized or generalized.

Pathogenesis

Sterile granuloma/pyogranuloma syndrome is an idiopathic canine skin disorder. The pathogenesis is unknown, but the inflammatory nature of the infiltrate, failure to demonstrate infectious agents, and the good to excellent response to immunomodulating drugs support it being an immune-mediated disorder. However, it has been hypothesized that SGPS may be related to an immune response against persistent endogenous or exogenous antigens, such as *Leishmania* spp. or *Mycobacterium* spp. organisms or incomplete clearing of associated antigens, causing a granulomatous/pyogranulomatous inflammatory reaction. The presence of *Leishmania* spp. DNA has been documented in cases of SGPS in Spain and Italy. The finding of antigenic fragments or organisms may become possible as we advance our diagnostic techniques.

Signalment

Sterile granuloma/pyogranuloma syndrome can affect dogs of any age and gender, but in a retrospective study 24/29 cases were male. It is seen more frequently in the Great Dane, boxer, golden retriever, collie, dachshund, English bulldog, and Weimaraner.

Clinical Signs

The clinical signs are characterized by firm, hair-covered to partially alopecic, erythematous papules, nodules, or plaques. Lesions develop more commonly on the head and distal extremities, and less commonly on the pinnae, eyes, trunk, and abdomen. Lesions involving the tongue and prepuce have been seen in individual dogs. In most cases, the lesions are multiple and are not associated with pain or pruritus. Occasionally, draining tracts and ulceration can be observed, especially on lesions localized to the feet (Figure 164.5).

Lymphadenopathy was present in 31% of the cases in a review including 29 dogs. Systemic signs associated with this syndrome have not been reported. The condition may resolve spontaneously or take a waxing and waning course.

Diagnosis

Clinical differential diagnoses include bacterial and fungal infections, foreign bodies, SNP, cutaneous eosinophilic granulomas, and cutaneous neoplasms. Diagnosis of SGPS is based on its clinical appearance, histopathologic findings, and failure to document the presence of microorganisms. Wedge biopsies should be performed to collect samples that include the epidermis, dermis, and subcutaneous tissue. The samples should be collected aseptically if they are being submitted for cultures. Histopathologically, SGPS is characterized by multifocal, nodular to diffuse pyogranulomatous/granulomatous dermal infiltrates. Special stains on biopsy samples are negative. Aerobic and anaerobic bacterial cultures and fungal culture from fresh tissue samples are also negative. Some organisms are difficult to culture or identify with routine methods, and molecular studies such as

Figure 164.5 Partially alopecic, erythematous and ulcerated nodule present in the interdigital space of digits 4 and 5 in a dog with sterile granulomatous pyogranulomatous syndrome. *Source*: Courtesy of Dr Wendy Lorch.

PCR are necessary. This is particularly true for mycobacteria and *Leishmania*.

Therapy

Surgical excision can be curative for solitary nodules or plaques. Systemic treatment is often needed for multiple lesions, including immunosuppressive doses of glucocorticoids or other immunomodulating agents. The use of tetracycline and niacinamide combination was shown to be effective for long-term management in a case of SGPS. A trial with this combination is warranted before more potent immunosuppressive drugs are used. Tetracycline/niacinamide is used at 250 mg of each for dogs less than 10 kg, and 500 mg of each in dogs more than 10 kg q8–12h. If tetracycline is unavailable, doxycycline at 5 mg/kg q12h can be used. If shortage of doxycycline occurs, minocycline can be substituted for doxycycline.

Prednisone or prednisolone can be used at 2.2–4.4 mg/kg q24h PO until resolution of the skin lesions (usually 10–14 days), then the medication can be tapered to the minimal effective dose (see treatment for sterile nodular panniculitis). Most cases require long-term alternate-day glucocorticoid therapy to avoid reoccurrence. Refractory cases may require the addition of other immunomodulating agents like ciclosporin or azathioprine.

Prognosis

The prognosis is good. The condition may resolve spontaneously or take a waxing and waning course. Most cases required prolonged use of immunomodulatory drugs.

Juvenile Cellulitis

Canine juvenile cellulitis, also known as juvenile pyoderma, puppy strangles, or juvenile sterile granulomatous dermatitis and lymphadenitis, is an uncommon lymphocutaneous disease. It is characterized by a sterile granulomatous or pyogranulomatous dermatitis and lymphadenitis and usually affects young puppies.

Pathogenesis

The cause of juvenile cellulitis is unknown. Cytologic examination of aspirates of affected lymph nodes and skin lesions does not reveal infectious agents, and culture results of intact lesions are always negative for bacterial and fungal growth. In addition, the condition responds dramatically to treatment with glucocorticoids, suggesting an immune dysfunction. There may be a heritable component as it has been documented more frequently in certain breeds and within litters. Vaccine reactions have been postulated as the cause of juvenile cellulitis, but the role of vaccine or other viruses in the disease development remains unclear. A nonviral infectious etiology has also been considered but attempts to isolate bacteria and fungi have not been successful.

Signalment

Most cases are young puppies less than 4 months old, with a few reported cases in older dogs. No sex predilection has been reported. Breeds that appear to be predisposed include golden retrievers, dachshunds, Gordon setters, and Weimeraners. Other breeds reported include the Labrador retriever, Siberian husky, miniature poodle, Chesapeake Bay retriever, Lhasa apso, and mixed-breed dogs.

Clinical Signs

Early clinical signs consist of edematous moist dermatitis affecting mainly the eyelids, lips, and muzzle. The affected skin rapidly develops papules and pustules. Lesions are characterized by severe edema, fistulation, and drainage with copious purulent discharge and crust formation. Purulent otitis externa and conjunctivitis are also common; the pinnae are often severely swollen and may develop ulcerative lesions. Affected skin is usually painful. Submandibular and prescapular lymphadenopathy is commonly present. Concurrent neurologic signs and orthopedic problems have been reported preceding or associated with the signs of juvenile cellulitis. The patient may be lethargic and depressed and older dogs may present with more severe systemic signs and pyrexia.

Diagnosis

Clinical differential diagnoses include angioedema in acute cases and as lesions progress; staphylococcal pyoderma, demodicosis, and adverse cutaneous drug reaction should also be considered. Other less likely differential diagnoses include neoplasia (cutaneous lymphoma, mast cell tumor) or infectious causes such as nocardiosis, actinomycosis, mycobacterial infections, and subcutaneous opportunistic mycoses. Diagnosis is often based on characteristic clinical presentation, but can be confirmed by cytologic or histopathologic findings. Tests may include fine needle aspirates of lymph nodes, impression smears or skin scraping, cytology or skin biopsy. Cytology from fine needle aspirates of affected lymph nodes reveals a sterile granulomatous or pyogranulomatous inflammation. Histopathologic findings usually reveal granulomatous or pyogranulomatous dermatitis which may extend into the panniculus.

Furunculosis and suppurative inflammation have also been reported in advanced cases.

Therapy

Treatment consists of immunosuppressive doses of glucocorticoids. Initial treatment should be aggressive, as scarring can be severe if the disease is not controlled quickly. Oral prednisone or prednisolone can be given at 2 mg/kg/day until lesions resolve, usually 2–4 weeks, and then slowly tapered off completely over the next few weeks. Some dogs may respond better to oral dexamethasone at 0.2 mg/kg/day (initial dose). Antibiotics should be given if secondary bacterial infections are present. Oral cephalexin can be given at 25–30 mg/kg q12h for the duration of the corticosteroid treatment. Ciclosporin has also been effective in cases refractory to glucocorticoids. Griseofulvin was used with good results in six puppies at the dose range of 14.2–34 mg/kg q12h. All cases were completely recovered within three weeks. The authors postulated that griseofulvin could induce downregulatory signals within the lesions.

Prognosis

The prognosis is good. Most cases respond well to treatment and relapses are uncommon.

Demodicosis

Canine Demodicosis

Etiology/Pathophysiology

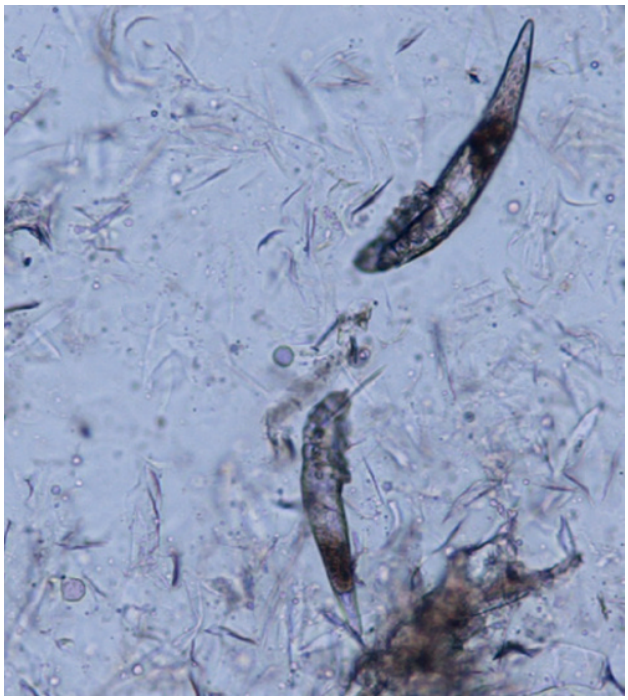
Canine demodicosis is currently known to be caused by three species of mites: *Demodex canis*, *D. injai*, and *D. cornei*. *Demodex canis* and *D. injai* are thought to be two separate species. However, *D. cornei*, a short-bodied mite, is believed to be a morphologic variant of *D. canis*. *Demodex canis* and *D. injai* live within the hair follicles or sebaceous glands, and *D. cornei* lives on the stratum corneum.

Recent studies using real-time polymerase chain reaction (PCR) have validated the widely held belief that all dogs, healthy and diseased, harbor *D. canis* mites in their skin. Puppies are believed to acquire *D. canis* from their mothers at birth. However, the mode of transmission of *D. injai* and *D. cornei* is currently not known.

Demodex canis mites have a life cycle involving four stages. They begin as fusiform eggs. These eggs develop into six-legged larvae, then eight-legged nymphs, followed by the adults. The life cycle of *D. cornei* and *D. injai* has not been investigated but it is likely to mirror the life cycle of *D. canis*. Adult *D. injai* mites are much longer than the *D. canis* species (Figure 165.1). Adult *D. cornei* mites have a short tail (Figure 165.2).

Demodicosis caused by *D. canis* can occur in juvenile (≤18 months) or adult dogs (>4 years). Older dogs that develop demodicosis may have another disease process leading to an immune dysfunction that allows the mites to multiply and cause disease. Some examples include hyperadrenocorticism, hypothyroidism, diabetes mellitus, or malignant neoplasia. Immunosuppressive therapy can also result in a proliferation of mites. This includes topical and oral corticosteroids and oclacitinib maleate (Apoquel® for dogs; Zoetis). Allergic dermatitis is often a concurrent diagnosis. Often, no cause is identified for the development of adult-onset demodicosis. *Demodex injai* has only been reported in adult dogs.

The reason for development of demodicosis in some dogs versus others is not precisely known. We do know that certain breeds develop disease more commonly than others, suggesting the influence of genetics. Breeds more commonly diagnosed with demodicosis caused by *D. canis* include the shih tzu, West Highland white terrier, English bulldog, and Boston terrier. In the author's experience, pit bull terriers and Yorkshire terriers also seem overrepresented. Demodicosis caused by *D. injai* has been noted at greater frequency in terriers and shih tzus.



Other factors suggested to play a role include parasitism, inadequate nutrition, and stress. However, many affected patients do not have these problems. Various *ex vivo* studies have investigated the immune response of dogs with juvenile-onset generalized demodicosis caused by *D. canis*, but a defect has yet to be identified. Nevertheless, the current belief is that these dogs inherit an immune dysfunction of variable severity linked to a subset of T cells capable of recognizing specific mite antigens and keeping the mites in small numbers. This theory, however, needs to be validated. Overexpression of the Toll-like receptor 2 gene may result in the clinical findings associated with demodicosis.

History and Clinical Signs

There are two types of infestations of *Demodex* mites: localized and generalized. The localized variant consists of one or more lesions usually on the face and forelegs. These cases typically self-resolve and affect puppies. An infestation is considered generalized when large body areas, several localized lesions, an entire body region, or two or more paws are affected. This form primarily begins at the puppy stage and may resolve, but typically progresses without treatment as the puppy ages.

Demodex canis infestation can cause a variety of signs. Lesions seen can include alopecia, erythema, scales, papules, and pustules. If hair follicles rupture (i.e., furunculosis), severe inflammation associated with tracts draining serosanguineous to purulent exudate is noted (Figure 165.3).

Lymphadenopathy and/or fever may occur in these cases especially if large areas of the body are affected. Follicular casts and comedones are very typical lesions. Pruritus may or may not be present and is usually noted when secondary infection or seborrhea occurs. Secondary superficial or deep bacterial infection is often present in

Figure 165.2 Adult *Demodex cornei*.

Figure 165.3 Juvenile-onset generalized demodicosis caused by *Demodex canis*. Diffuse alopecia, erythema, and edema are noted. Hemorrhagic crusts on the lateral aspect of the face correspond to areas of furunculosis.

the generalized form of the disease and may aggravate lesions, resulting in crusts, pustules, thickened skin, and hyperpigmentation. Paws rarely are affected alone and lesions can be similar to the ones described. Bullae

and fistulous tracts are also present on paws when furunculosis develops (Figure 165.4).

Demodex cornei mites have been found in demodicosis caused by *D. canis*, suggesting that these mites are a morphologic variant of *D. canis* and not a separate species.

Demodex injai typically manifests with dorsal and occasionally facial seborrhea oleosa (Figure 165.5). In these areas, hypotrichosis is present. Pruritus may also be noted.

Diagnosis

Diagnosis of *D. canis* infestation involves performing multiple deep skin scrapings. As mites live in the hair follicles and sebaceous glands, the lesional area is squeezed before scraping in an attempt to extrude the mites. The scraping should be deep enough that capillary bleeding occurs. Multiple adult mites and/or immature forms are diagnostic. Mites should be easy to find if skin scrapings are performed adequately. If only a few mites are found after multiple skin scrapings in an animal with clinical signs suggestive of demodicosis, consider this finding important. This scenario is typically encountered in cases of juvenile, localized demodicosis.

Figure 165.4 Feet of a dog with juvenile-onset generalized demodicosis caused by *Demodex canis*. Multiple tracts draining serosanguineous exudate correspond to areas of furunculosis.

Figure 165.5 Excessive oil along the dorsum of a West Highland white terrier with demodicosis caused by *Demodex injai*.

Similar technique should be applied when *D. injai* infestation is suspected; however, mites can be harder to find because they are present in small numbers and often in sebaceous glands, making their extrusion difficult. Superficial scrapings should be adequate for *D. cornei* but mites are typically not easy to find.

Trichoscopy may also reveal mites in severe cases of demodicosis caused by *D. canis*. Various hairs are plucked from affected areas, placed in mineral oil on a glass slide and covered with a cover slip before microscopic evaluation. These may or may not be positive in affected dogs. Acetate tape impressions of affected squeezed skin have recently been shown to reveal mites in 100% of samples. Mites can also be found on cytology of exudate collected from draining tract lesions. Mites may also be identified using a zinc sulfate centrifugal fecal flotation technique. It is important to emphasize that sensitivity of these tests is generally lower than that of deep skin scrapes adequately performed. Biopsy may be needed in Chinese shar-peis or dogs with fibrotic lesions especially affecting the paws. Mites can be found in the stratum corneum, hair follicles, and on occasion the sebaceous glands. Inflammation may present as an interface mural folliculitis, nodular dermatitis, or a suppurative folliculitis and furunculosis.

Therapy

Affected dogs should be treated with appropriate systemic antibiotics, if indicated. Supportive care may be needed in severe cases. Underlying disease processes should be addressed. Localized cases are typically self-limiting and resolve without treatment in about 6–8 weeks. Generalized cases should be treated for one month beyond two negative consecutive skin scrapings. Skin scrapings are recommended monthly to assess progress. Numbers of live versus dead mites and their life stages can help assess response to therapy.

The most effective treatments are amitraz, macrocyclic lactones, and isoxazolines. The only treatment currently licensed in the United States is amitraz. Labeled treatment is a 0.025% amitraz (Mitaban®; Zoetis) solution used as a dip every 14 days. Variations of this therapy protocol, such as weekly applications at 0.025%, 0.05%, 0.075% or 0.1%, can be considered for more difficult cases. Removal of follicular debris, crusts, and hair that prevents penetration of the solution into the hair follicle is an important part of this treatment regimen; therefore, medium to long hair coats should be clipped and crusts removed prior to dipping. This chemical is a monoamine oxidase inhibitor as well as an alpha-2-adrenergic agonist. Potential side-effects include lethargy, ataxia, vomiting and diarrhea, polyuria and polydipsia, bradycardia, depression, and hyperglycemia. The person providing treatment should

not directly contact the solution or inhale it. Application in a well-ventilated area is important.

Ivermectin is a therapy that is often very efficacious in treating demodicosis. Herding breeds should be assessed for a mutation of the ABCB1 (formerly MDR1) gene which encodes for the cell membrane transporter P-glycoprotein. This mutation can lead to severe toxicosis with avermectins. Some of the breeds reported to be predisposed to this mutation include collies, border collies, Shetland sheepdogs, Australian shepherds, Old English sheepdogs, white Swiss shepherds, long-haired whippets, McNab, and silken windhound. This mutation is still possible in any dog breed, but less likely. The genetic test for the mutated gene can be done through Washington State University College of Veterinary Medicine.

Possible side-effects associated with ivermectin toxicosis include lethargy, vomiting, diarrhea, anorexia, mydriasis, and ataxia. In severe cases, seizures, coma, and death can result. Side-effects can also occur in dogs that carry a normal ABCB1 gene and are often less severe and may resolve by lowering the dosage. Due to possible side-effects, an incremental dose increase is strongly suggested. The dosage range is 0.3–0.6 mg/kg once a day PO. The author determines dosing by calculating the dose desired in this range and starting at one-third this dose. This is given for one week, followed by two-thirds the final dose for one week, then ending at the final dose desired.

Other macrocyclic lactones that can be used are moxidectin and doramectin. Moxidectin is dosed at 0.2–0.5 mg/kg/day PO. Again, gradual dosing is indicated. Possible side-effects include those listed for ivermectin. Moxidectin is also available as a topical product in combination with imidacloprid (Advantage Multi® for dogs; Bayer). This is an approved European treatment applied weekly for demodicosis. It is labeled for monthly usage in the United States but has shown better results when applied every 1–2 weeks, primarily for juvenile-onset cases and mild forms of demodicosis. Doramectin can be given at 0.6 mg/kg subcutaneously (SC) or PO once a week. The SC administration has resulted in better outcomes.

Milbemycin oxime (Interceptor® for dogs; Elanco) is another efficacious product. This can be used at 0.5 mg/kg PO once daily increasing by 0.5 mg/kg every seven days to a final dosage of 2.0 mg/kg/day. This medication is generally well tolerated. Mild neurologic side-effects have been noted. Breeds that do not tolerate ivermectin, including collies, may tolerate this medication but care is recommended to ensure no adverse side-effects ensue, as neurologic effects are still possible. Ataxia has been noted in dogs homozygous for the ABCB1 gene mutation at a dosage of 1.5 mg/kg/day PO.

The newest available therapies are in the isoxazoline class. These drugs are not labeled for treatment of *Demodex* sp. but have been found to be very efficacious. These include lotilaner (Credelio® for dogs; Elanco) at 20 mg/kg PO, and sarolaner (Simparica® for dogs; Zoetis) given at 2 mg/kg PO. These products are labeled for monthly usage for flea and tick prevention and treatment. Fluralaner (Bravecto® for dogs; Merck) given once at a minimum dosage of 25 mg/kg PO has also been found to be very efficacious at treating demodicosis. This product is labeled for administration every 12 weeks for the prevention and treatment of flea and tick infestations in dogs. Afoxolaner (Nexgard®; Merial) given at the minimum dosage of 2.5 mg/kg PO every 14 days for two months has been found to be very effective. However, only one dose may result in deep negative skin scrapings. It is labeled for monthly usage for flea and tick control and can be used in dogs 8 weeks of age and older, whereas fluralaner and sarolaner can only be used in dogs at least 6 months of age. Lotilaner, like afoxolaner, may be used in dogs as young as 8 weeks of age. These parasiticides act by blocking insect GABA- and glutamate-gated chloride channels and are generally very safe but should be used with caution in dogs with a history of seizures. Possible side-effects include vomiting and diarrhea. Sarolaner may cause tremors, unsteadiness, or seizures. Fluralaner may cause seizures in patients which do not have a history of seizures, but is labeled as safe for use in breeding, pregnant, and lactating dogs, and in those with the ABCB1 gene mutation. Lotilaner may also cause an increase in blood urea nitrogen. Afoxolaner should be used with caution in dogs with a history of seizures.

Females or males that have been treated should be neutered due to the potential for passing the predisposition to develop demodicosis to offspring. In addition, females should be spayed because the stress of a heat cycle or pregnancy could worsen the disease.

Prognosis

Overall, prognosis is good. Recurrence of disease can occur, so following the treatment recommendation of 30 days past two consecutive negative skin scrapings can help prevent recurrences. Life-long therapy may be needed in some cases. Long-term glucocorticoids are not recommended in patients with demodicosis or that have had demodicosis. The author believes that any glucocorticoids or oclacitinib maleate (Apoquel; Zoetis) should be used with great caution. A dog is not considered cured until one year after treatment is completed. With the advent of isoxazolines as maintenance flea and tick preventtives, the likelihood of recurrence or even development of demodicosis will probably diminish.

Feline Demodicosis

Etiology/Pathophysiology

Three species of demodectic mites have been implicated in feline demodicosis. These include *D. cati*, *D. gatoi*, and an uncommon, unnamed, morphologically distinct *Demodex* mite. *Demodex cati* spends its life cycle in the

hair follicles and sebaceous glands. This mite is slightly narrower than *D. canis*. *Demodex gatoi* has a shortened abdomen and spends its life cycle on the epidermal surface. The length of the unnamed mite is between *D. cati* and *D. gatoi*.

Demodicosis due to *D. cati* is typically associated with an underlying disease or immunosuppressive therapy. Concurrent diseases that may be present include feline immunodeficiency virus, feline leukemia virus, diabetes mellitus, squamous cell carcinoma *in situ* or other neoplastic disorders, toxoplasmosis, systemic lupus erythematosus, and hyperadrenocorticism. It has been reported to be more common in the Burmese and Siamese breeds.

Demodex gatoi, unlike *D. cati*, is not generally associated with an underlying disease. However, it has been identified in scrapings along with *D. cati* in cats positive for feline immunodeficiency virus. This mite is more commonly located in certain geographic areas. In the United States, it is more often found in the south, especially in the Gulf of Mexico area.

Little is currently known about the unnamed *Demodex* mite. The published reports have found this mite in cats diagnosed with other concurrent illnesses or had recently recovered from illness.

History and Clinical Signs

Demodex cati can cause either a localized or generalized infestation, both of which are rare. Localized demodicosis is primarily located around areas on the head, including in the ears, causing a ceruminous otitis externa, particularly in feline immunodeficiency virus-positive cats. Pruritus is variable but typically not present. Other signs include alopecia, erythema, and the presence of scales and crusts. Generalized cases often affect the head but lesions are also found elsewhere on the body. Presentation is similar to the localized form, but may include hyperpigmentation.

Demodicosis caused by *D. gatoi* is more common than the disease caused by *D. cati*. It is contagious between cats and pruritic. Clinical signs are typically fitting with the degree of pruritus. Traumatic alopecia often results from the severe pruritus on the sides of the thorax, abdomen, and the medial aspect of the legs. Other signs include erythema, scale, excoriation, and hyperpigmentation. A common clinical presentation is self-induced, clinically noninflammatory, symmetric alopecia (Figure 165.6). Some cats can be asymptomatic carriers.

Diagnosis

Skin scrapings should be performed in cases where feline demodicosis is suspected. Broad, superficial scrapings are performed to detect *D. gatoi* (surface mite), whereas deep skin scrapings must be done to diagnose *D. cati* (follicular). *Demodex gatoi* mites are typically more difficult to find due to their small size and low numbers as cats ingest these mites during grooming. Therefore, scraping areas where the cat cannot groom may increase the chances of finding mites. Fecal flotation may be another means of finding *D. gatoi*. Cellophane tape impressions viewed under the microscope may help to reveal the mites. A negative test does not rule out this infestation so diagnosis in many cases may only be made based on history and response to a therapeutic trial. The unnamed mite has been found via trichoscopy and skin scrapings.

Figure 165.6 Self-induced, clinically noninflammatory, symmetric alopecia on the dorsum and thighs of a cat with demodicosis caused by *Demodex gatoi*.

Therapy

Underlying causes leading to the development of demodicosis caused by *D. cati* should be evaluated. This disease when localized may resolve spontaneously if underlying diseases have been controlled. Amitraz (Mitaban; Zoetis) at concentrations of 0.0125–0.025% applied weekly may help. Cats are sensitive to this product and it is not recommended in cats with diabetes. A generally safe option is lime sulfur applied as a 2–4% solution every week. Unfortunately, therapy may need to be continued long term as relapses are possible. Other treatment options include doramectin administered weekly at 0.6 mg/kg SC and ivermectin at 0.2–0.3 mg/kg PO daily to every other day. Cats should be monitored for side-effects such as neurotoxicity. The off-label use of the oral isoxazoline fluralaner (Bravecto) for the treatment of demodicosis has been reported in cats. A single oral dosage of 28 mg/kg resolved *D. cati* in one case report. No side-effects were noted. Topical fluralaner, which is available for cats, may cause vomiting and diarrhea, decreased appetite, or lethargy. It may also cause alopecia or crusting. While a single topical treatment has been shown to be efficacious for the treatment of *Otodectes cynotis* in cats, there are

currently no studies evaluating it's use in the treatment of feline demodicosis. Independent of the parasiticidal chosen, treatment should be continued for 30 days past two consecutive negative skin scrapings performed 4–6 weeks apart.

Options for *D. gatoi* include the above treatment protocols described for amitraz or lime sulfur dips. Treatment typically is needed for 6–8 weeks. In-contact cats should be treated as well. Application of a moxidectin/imidacloprid (Advantage Multi for cats; BayerDVM) spot-on product every week to two weeks for up to three months has been anecdotally reported to work well in some cases. It has also been shown to be efficacious in one case report, applied weekly for 10 doses. Also, ivermectin at 0.2–0.3 mg/kg PO every 24–48 hours may be effective. The extra-label use of oral fluralaner (Bravecto) at 26–34 mg/kg given once has recently been shown to be another efficacious treatment option.

No specific treatment recommendations exist for the unnamed mite, but concurrent daily ivermectin at 0.3 mg/kg PO and 8 oz/gal of diluted lime sulfur rinses twice weekly for 6–8 weeks has been used. Also, SC ivermectin at 0.6 mg/kg daily for four weeks has been used.

For all types of feline demodicosis, isoxazolines may prove to be efficacious. Also, topical fluralaner may be a viable option as opposed to oral administration. More studies are needed in this area.

Prognosis

The prognosis of feline demodicosis varies, especially in cases of *D. cati* where underlying systemic disease is likely present. Overall, prognosis varies from good to guarded.

Scabies

Canine Scabies

Etiology/Pathophysiology

Sarcoptes scabei var. *canis* causes canine scabies, or sarcoptic mange. This is a highly contagious mite that is transmitted between dogs as well as foxes and coyotes. Fomites can also be a source of transmission. The female burrows into the stratum corneum to lay eggs. The larvae travel to the skin surface and develop into nymphs, which may live on the skin surface or in the molting pocket that may also be inhabited by larvae. The mites prefer areas with less hair, so they are more commonly found on the pinnae, elbows, hocks, and ventrum. They typically live 17–21 days. Depending on the humidity and temperature, females and nymphs can survive 4–21 days away from the host. These mites can cause disease at any time of year. Other animals including cats, humans, and foxes can be affected. Humans are usually only transiently affected.

Description of mite characteristics is important in differentiating canine scabies from the feline Sarcoptidae mite, *Notoedres cati*. *Sarcoptes scabei* mites are ovoid and small, with two anterior pairs of short legs with long unjointed stalks and suckers. There are two pairs of rudimentary posterior legs that do not extend beyond the body wall of the mite (Figure 165.7). The anus is terminal.

Research suggests that young dogs of any breed and of both sexes are more likely to become infested with the mites, suggesting that age-related immunity plays a role in pathogenesis. Nutritional status and oxidative stress also play a role in development of infestation. Specifically, alterations in the oxidant and antioxidant balance and greater apoptosis of peripheral leukocytes may contribute to a dog's susceptibility to infestation.

History and Clinical Signs

Scabies causes an intense pruritus. It is important to question if other pets or humans in the same household are also pruritic as this is a valuable diagnostic clue. However, some dogs can be asymptomatic carriers. As previously mentioned, this mite typically affects specific body regions but any body region can be affected. Corticosteroids may be beneficial in some patients at the beginning of therapy to reduce pruritus.

Early signs include papules and scales. Excoriations may also be present. With chronicity, self-induced alopecia, hyperpigmentation, hyperkeratosis or keratinous crusts, and lichenification may develop. The crusts may become thick and yellow (Figure 165.8). Peripheral lymphadenopathy may be present. Some dogs only develop erythema and excoriations.

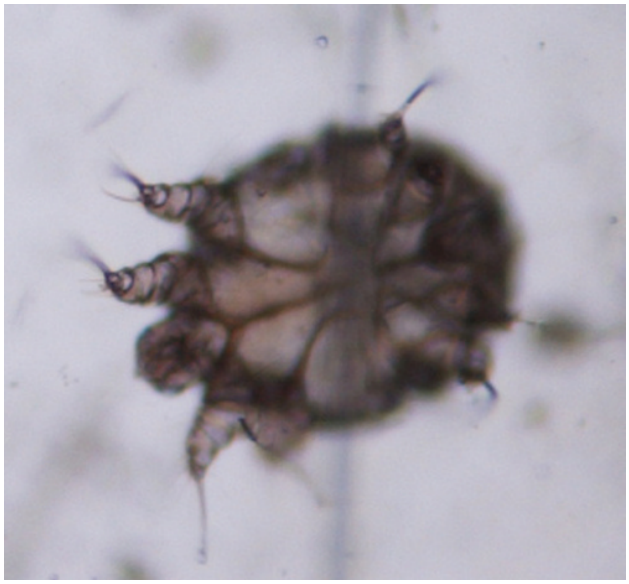

Figure 165.7 Adult *Sarcoptes scabei* var. *canis*.

Figure 165.8 Alopecia and thick yellowish crusts covering the ear margin of a dog with scabies.

Cats that become infested with *Sarcoptes scabei* var. *canis* can develop dermatitis of the face and pinnae. Papules and crusts are present. Dermatitis of the paws as well as claw abnormalities may develop. Some cats may also develop crusting and scaling over the body. Pruritus is a variable finding. Such infestations are uncommon and rare cases have been noted in indoor cats not cohabiting with dogs.

Diagnosis

Infestations with this mite are often diagnosed based on history, clinical signs, and response to therapy. Multiple superficial skin scrapings are required for diagnosis. Unfortunately, as few as 20% of skin scrapings may reveal mites or eggs. Finding even one is diagnostic of canine scabies. It is suggested to scrape the aforementioned areas that are generally affected even in the absence of lesions, as well as areas with papules and yellow crusts. Large numbers of mites are typically found on scrapings from cats infested with *Sarcoptes scabei* var. *canis*.

An additional supportive test is to demonstrate the pinnal-pedal reflex. This test entails scratching the pinnal edge with a resultant ipsilateral leg making a scratching motion. Most dogs with scabies mites have this reflex (sensitivity of 81.8%); however, it can be rarely positive in other diseases (specificity of 93.8%).

Laboratory testing utilizing an enzyme-linked immunosorbent assay (ELISA) is available in certain countries. This test has high specificity and sensitivity, but false-negative results are possible.

Therapy

Affected as well as in-contact dogs should be treated. Area treatments containing pyrethrins, permethrins or a combination of these are available for use in the home environment, keeping in mind that high concentrations of permethrins (>0.1%) are toxic to cats. Discarding bedding is advised. In the United States, a licensed treatment is selamectin (Revolution® for dogs, Zoetis) applied topically every 30 days for two doses; however, for better results most dermatologists recommend administering it every two weeks for 3–4 treatments. Lime sulfur dips at a 2–3% concentration every week for 4–6 weeks is another option. Ivermectin at 0.2–0.4 mg/kg can be given PO every seven days or SC every 14 days for 4–6 weeks. Milbemycin given orally at 2 mg/kg every week for 4–6 treatments has been shown to be effective. An imidacloprid/moxidectin combination product (Advantage Multi) is approved for the treatment of scabies in dogs and is applied topically every 30 days for two doses. Amitraz (Mitaban) solution at 0.025–0.03% applied over the whole body every two weeks for three treatments or weekly for 4–6 treatments should be effective. Fipronil spray applied to the entire body every two weeks for three applications is another treatment option. Doramectin can be given at 0.2–0.6 mg/kg SC every seven days for 4–6 weeks.

Many of these patients have secondary infections which should also be identified and addressed. Isoxazolines have been shown to effectively treat scabies as well. One dose of fluralaner (Bravecto) at a minimum of 25 mg/kg orally or topically has been shown to eliminate scabies mites. Afoxolaner (Nexgard) given at a minimum dosage of 2.5 mg/kg PO for 1–2 monthly doses should also eliminate these mites. Sarolaner (Simparica) can also be used at approximately 2 mg/kg PO for two monthly doses. There are no current publications relating to lotilaner (Credelio) and scabies mites, but the author suspects it, too, would be efficacious at resolving sarcoptic mange. Antiinflammatory doses of corticosteroids given for approximately one week may also help in alleviating the pruritus caused by the mites.

The treatment protocols detailed under "Feline scabies" are also recommended for cats infested with *Sarcoptes scabei* var. *canis*. However, three applications of the moxidectin/imidacloprid (Advantage Multi) compound product applied every two weeks has been shown to be more efficacious in five cats with sarcoptic mange than weekly ivermectin at 0.2 mg/kg SC for four weeks or selamectin (Revolution) administered every two weeks for two treatments.

Prognosis

Most dogs with scabies are cured with treatment. Rare cases have been noted to be refractory to ivermectin and selamectin. The selamectin cases may have been related to poor application on densely coated dogs. In some cases, the author finds it beneficial to keep the patient on monthly selamectin or an isoxazoline (unless it is fluralaner which is given every 3 months) when reinfestation is considered possible.

Feline Scabies

Etiology/Pathophysiology

Feline scabies or notoedric mange is caused by *Notoedres cati*. This mite can also affect foxes, dogs, rabbits, and humans. The lesions on humans are transient. It commonly affects other cats in multiple cat residences as it is very contagious. This mite typically occurs epizootically in endemic areas.

Notoedres cati follows the same life cycle as *Sarcoptes scabei* var. *canis*. Morphologically, it is similar to the canine scabies mite but is smaller, the unjointed stalk is of medium length, more striations are present on the body, and the anus is dorsally oriented.

History and Clinical Signs

Notoedres cati causes intense pruritus predominantly of the facial region. The skin becomes thickened with folds (Figure 165.9). Crusts are yellowish and tightly adherent. Excoriations and partial alopecia may develop. Lesions begin on pinnal edges and spread over the face and neck. The paws and perineum may be affected and peripheral lymphadenopathy may occur.

Diagnosis

Microscopy of superficial skin scrapings of affected cats typically reveals several mites. Diagnosis is also achieved by identifying the eggs or fecal pellets.

Therapy

Affected and in-contact cats should be treated. Safety must be considered in choosing treatments. Weekly 2–3% lime sulfur dips for 4–8 weeks are beneficial. Treatment should continue until negative skin scrapings and resolution of lesions are obtained. Ivermectin at 0.2–0.3 mg/kg may be given PO or SC every 1–2 weeks for 3–4 treatments. Doramectin can also be given at a dose of 0.2–0.3 mg/kg SC once. Selamectin (Revolution) applied topically once or twice every 14–30 days is another option. The moxidectin/imidacloprid (Advantage Multi) topical product has been shown to be effective after one application.

Figure 165.9 Thick crusts on the convex aspect of the pinna of a cat with chronic notoedric mange. *Source:* Courtesy of Dr Clarissa Pimentel de Souza.

Cheyletiellosis

Etiology/Pathophysiology

Cheyletiella, also known as walking dandruff, is a mite that generally results in a dermatitis of varying severity. *Cheyletiella parasitovorax*, *C. blakei*, and *C. yasguri* are the species of most concern in dogs and cats, with *C. yasguri* more likely to be found on dogs and *C. blakei* more likely to be found on cats, although these species are not entirely host specific. All species are contagious, and humans in contact with animals carrying the mite can become transiently affected.

These nonburrowing mites produce ova that attach to the dog or cat hairs. They are large mites that live in the keratin on the surface of the skin. They have four pairs of legs with combs and their mouthparts have characteristic hooks (Figure 165.10).

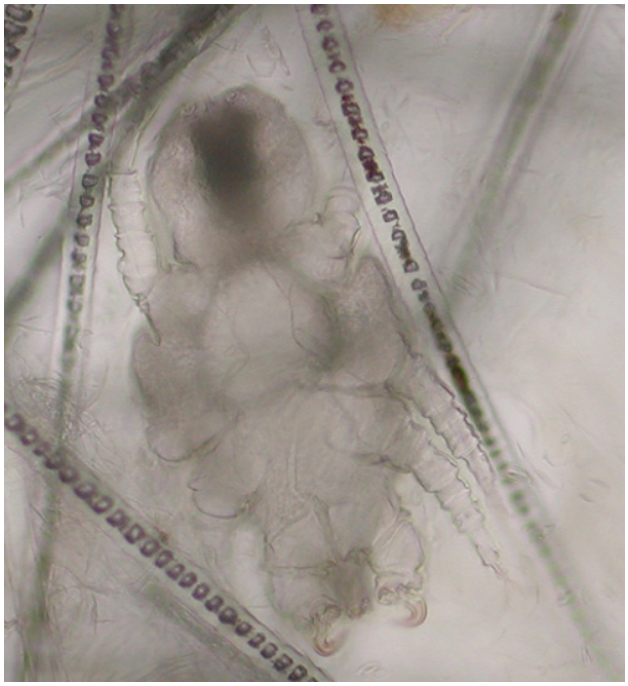

Figure 165.10 *Cheyletiella yasguri* mite; note the characteristic hooks of the accessory mouthparts.

The mites complete their life cycle on the host but mites and eggs attached to the hair shaft can contaminate the environment, creating a source for reinfestation. The adult females can also live off the host for approximately 10 days.

History and Clinical Signs

This mite infestation may result in varying levels of pruritus and severity of clinical signs. Any breed may be affected, but an increased incidence in cocker spaniels and boxers has been anecdotally reported. The resultant dermatitis manifests as dry scales along the dorsum (Figure 165.11). This often worsens over time with hair loss and an increase in pruritus. Cats can also develop miliary dermatitis.

Diagnosis

To diagnose *Cheyletiella*, material is collected from affected areas by acetate tape impressions, flea combings, or superficial skin scrapes. This material can be directly examined by visual inspection (often utilizing a magnifying glass) or using a microscope. If available, evaluate material in a Petri dish in mineral oil utilizing a dissecting microscope. Fecal examinations may also reveal the mite as many pruritic animals will ingest the offending parasite in the process of licking, biting or chewing the affected areas. Two other means of garnering material for examination include a vacuum sample of the affected area or performing a trichoscopy of affected hairs. Some dermatologists find that scraping papules (which are usually rare or absent) and microscopically examining the sample with mineral oil increases the chances of finding the mite. However, none of these diagnostic tests is 100% sensitive so a treatment trial may be necessary to confirm a presumptive diagnosis.

Figure 165.11 Cocker spaniel with cheyletiellosis showing excessive scaling along the dorsum.

Therapy

Fortunately, cheyletiellosis typically responds well to therapy. Options include weekly applications of lime sulfur or amitraz (Mitaban) dips, or pyrethrin shampoos and sprays for 3–4 treatments. However, amitraz and especially permethrins are not generally recommended for cats due to drug sensitivities. Fipronil in the spray form every two weeks for 3–4 treatments or topical concentrated solution every 30 days for three treatments are other options. Selamectin (Revolution) can be applied monthly or every two weeks for 4–6 weeks. Ivermectin at 0.2–0.3 mg/kg can be given PO weekly for 3–6 treatments or by SC injection every 14 days for three treatments. Doramectin is an option at 0.2–0.4 mg/kg SC every seven days for 4–6 weeks. One other treatment is milbemycin oxime (Interceptor) given at 2 mg/kg PO weekly for 3–4 doses. Because this is a highly contagious mite, all animals in the home should be treated.

Lynxacarus radovsky

Etiology/Pathophysiology

This mite, otherwise known as the cat fur mite, is found worldwide, typically in warm humid climates, such as in Australia, Brazil, and Puerto Rico. In the United States, it has been reported in Hawaii, Florida, and Texas. This mite is specific to the cat, but has been found on a dog. Cats acquire this mite through direct contact, but fomites must also be considered.

History and Clinical Signs

Clinical signs include a dull, unkempt coat giving the hair a "salt-and-pepper" appearance (Figure 165.12). Lesions may include alopecia, papules, and crusting and are typically present along the dorsum. Heavily infested cats or those with a long-term infestation can have exfoliative lesions. Pruritus is not typically present and when noted, a search for fleas or other external parasites is warranted.

Diagnosis

Diagnosis of *L. radovsky* infestation is accomplished by identifying the mite with microscopy. Trichoscopy and tape impressions are the ideal diagnostic methods. The

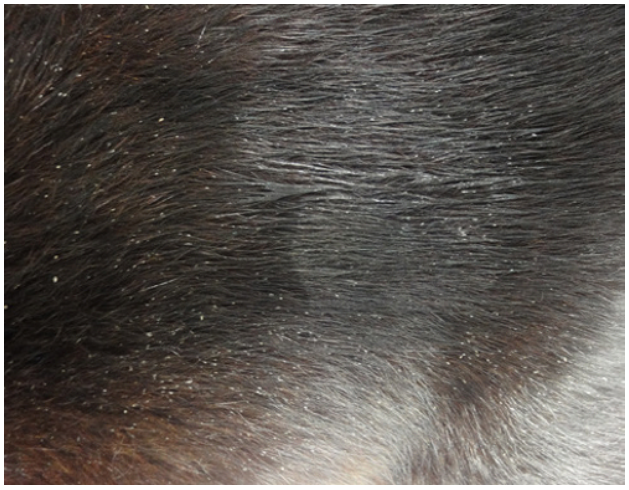

Figure 165.12 Cat with *Lynxacarus radovsky* infestation showing a "salt-and-pepper" hair coat appearance. *Source:* Courtesy of Dr Clarissa Pimentel de Souza.

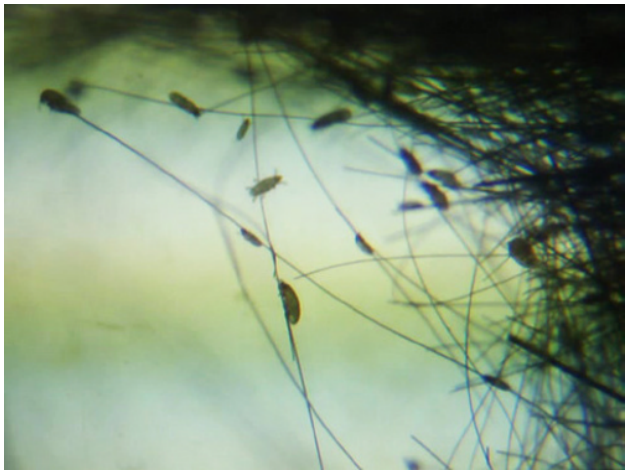

Figure 165.14 Trichoscopy from a cat with *Lynxacarus radovsky* infestation. Note multiple mites attached to the hair shaft. *Source:* Courtesy of Dr Clarissa Pimentel de Souza.

mites have a long body and ventrally oriented head. Sternal extensions attach to the host's hair and the legs have terminal suckers (Figure 165.13). These mites are visualized attached to the hairs (Figure 165.14).

Therapy

Most parasiticidal treatments are effective. More efficacious options include lime sulfur dips or insecticidal sprays such as fipronil, applied weekly to biweekly for 3–4 treatments. Ivermectin or doramectin can also be given at 0.2–0.3 mg/kg SC every 1–2 weeks for 3–4 treatments. Ivermectin can also be given at this dosage orally. Fluralaner (Bravecto) given off-label at a single dosage of 25–50 mg/kg PO or two topical applications of moxidectin/imidacloprid (Advantage Multi for cats) spot-on product two weeks apart has been shown to eradicate the mites. Care must be taken when treating cats with certain parasiticidal topicals, especially those that contain >0.1% permethrin, as this compound is toxic to cats. It is suggested that in-contact cats also be treated.

Figure 165.13 *Lynxacarus radovsky* mite. *Source:* Courtesy of Dr Clarissa Pimentel de Souza.

Dermanyssus gallinae

Etiology/Pathophysiology

This mite primarily affects poultry but is contagious to other animals including dogs, cats, and humans. It is a vector of many significant diseases. Other names are the poultry mite or red mite. These mites spend most of their life span off the fowl host, residing in cracks, crevices, and nests within the poultry house. They feed at night and once fed and engorged, they develop the red coloration. Poultry mites are resilient and can survive up to eight months away from fowl.

History and Clinical Signs

Dogs and cats can be attacked by these mites when in contact with poultry houses or from wild birds that enter and nest in houses. This mite can cause severe pruritus along with papules and crusts. Most cases present with lesions on the limbs and dorsum.

Diagnosis

Finding the mite is best achieved by performing skin scrapings. Mites may also be visualized microscopically on samples collected with cellophane tape impressions.

Therapy

These mites generally respond well to almost all parasiticidal treatments. It is also recommended to treat the surrounding premises to prevent reinfestation.

Pediculosis

Etiology/Pathophysiology

Pediculosis refers to a dermatitis caused by lice. Two types affect dogs, Anoplura, or sucking lice, and Mallophaga, or chewing lice. *Linognathus setosus* is the sucking louse of dogs and *Trichodectes canis* the chewing louse. Cats are parasitized only with a chewing louse, *Felicola subrostratus*. The eggs are deposited on the hairs of the host. The lice typically stay on one host but can be transmitted by close contact. They are species specific. The chewing lice survive primarily on epidermal debris and hair but some species also take blood. The canine chewing louse may carry *Dipylidium caninum*, or tapeworms. Sucking lice solely feed on the blood of the host and can result in severe anemia.

History and Clinical Signs

Pediculosis is relatively uncommon, but more likely to be noted in young and uncared-for animals. Chewing lice on the dog typically affect the dorsum, head, and tail and can cause severe pruritus. In the cat, the face, ears, and back are most commonly affected. Lesions on the dog typically consist of trauma-induced alopecia, seborrhea, and excoriations. Papules and crusts may also be present. Cats can present with no clinical signs or have intense pruritus. The coat may be matted with scale, crust, and alopecia. Sucking lice are primarily present on the pinnae and dorsum, and can result in weakness from the ensuing anemia. Pruritus with resultant excoriations and alopecia may also occur.

Diagnosis

Lice can be distinguished based on the morphology of the head and associated mouthparts. Sucking lice have an elongated, narrow head, whereas chewing lice have a broader head with mouthparts adapted for chewing. They can sometimes be found with direct visualization of the mite or the nit (egg). Microscopy can be utilized to view acetate tape impressions of hair and scale.

Therapy

Treatment should target the affected animals as well as those in contact. Clipping of matted hairs is recommended. Topical sprays and soaks such as lime sulfur can be utilized twice two weeks apart. However, most insecticidal therapies are efficacious. These include but are not limited to ivermectin at 0.2 mg/kg PO or SC twice two weeks apart, selamectin (Revolution) every two weeks for 2–4 treatments, or spot-on fipronil (Frontline®) or spray every two weeks. One application of fipronil or selamectin may work as well for chewing lice. Doramectin can also be used at 0.2–0.4 mg/kg SC weekly for 3–4 weeks. Imidacloprid (Advantage) spot-on alone for one application to treat chewing or sucking lice or the combination with moxidectin (Advantage Multi) applied topically once for chewing lice should be effective. Fluralaner (Bravecto) given once PO has been shown to eliminate *Linognathus setosus*. Appropriate supportive care may be required for anemic animals. Premises should be treated as lice can survive 1–2 days off the host.

Trombiculosis

History and Clinical Signs

Trombiculosis is a dermatitis caused by chigger mites. The larval forms can cause infestation of dogs and cats.

Eutrombicula alfreddugesi, a mite found in the southeast and south central United States, and *Neotrombicula autumnalis*, a mite more commonly found in Europe, are notably orange-red in coloration (Figure 165.15). They typically affect patients in late summer and fall. The larval forms attach to the skin.

Lesions often occur in body regions that contact the ground. However, in cats they are most commonly noted around the eyes, mouth, and base of the pinnae. The larvae pierce the skin and produce pruritic papules and crusts. Scaling and alopecia may also be present. Some animals are asymptomatic.

Walchia americana is a chigger mite that has been reported in cats. It has been found in the southwestern and eastern United States. These mites preferentially affect the ventrum, dorsum, and ears but have been noted on the medial legs and interdigital spaces. Reported lesions include nodules, papules, and wheals with scales and yellow exudate. Swollen paws and cracked claws have been noted.

Straelensia cynotis has been noted on dogs in some European countries. It too causes infestation primarily in

Figure 165.15 *Eutrombicula alfreddugesi* larva. *Source:* Courtesy of Dr Erica Toledo.

late summer and early autumn. This mite is found in the follicular ostia. It causes papules and nodules typically over the dorsum and head. Alopecia, scale, and erythema have been noted. Pruritus appears to be dependent on the presence of secondary infections.

Diagnosis

Diagnosis can be made with visualization of the reddish colored mite attached to the skin. Definitive diagnosis can be made by placing the mites obtained by skin scraping on mineral oil and examining the sample microscopically.

Diagnosis of *Walchia americana* is generally made with skin scrapes. Biopsy can be helpful as well. Unfortunately, skin scrapings are unrewarding with *Straelensia cynotis*. The mite can be found within the hair follicle on biopsy. Also, the histopathology is unique in that it shows a pseudoepitheliomatous follicular hyperplasia and perifollicular mucinosis.

Therapy

Treatment of *Eutrombicula* or *Neotrombicula* usually consists of 1–2 applications of topical parasiticidal agents or dips. Otic products that have parasiticidal properties can also be efficacious. Studied products include 0.25% fipronil spray applied to the entire body monthly for 1–4 months. Another evaluated option is a permethrin-pyriproxyfen topical spray or spot-on for dogs for 1–2 treatments. Systemic glucocorticoids may be indicated to alleviate pruritus and antibiotics may be of benefit if secondary superficial pyoderma is present.

Treatment of *Walchia americana* consists of the same parasiticidal products used for the treatment of *Eutrombicula* and *Neotrombicula*. Treatment of *Straelensia cynotis* has been suggested with macrocyclic lactones or fipronil.

Ticks

Ixodid (hard) ticks and argasid (soft) ticks both can affect cats and dogs. The ixodid ticks, which have a chitinous shield, can serve as vectors of rickettsial, protozoal, and viral diseases. They may also cause a hypersensitivity reaction from their bite, and can sometimes result in tick paralysis. The types of ixodid ticks of importance will not be elaborated on in this section.

Argasid ticks do not have the chitinous shield, or scutum. *Otobius megnini* can inhabit the ear canal in dogs and cats. The larvae and nymphs of this tick can lead to otitis externa. They can cause a severe irritation. Treatment includes manual removal of the ticks. Oil-based ear treatments may smother the tick. Prevention is key to help reinfestation. Many topical and oral parasiticidal treatments offer tick prevention.

Bacterial Pyodermas

Jennifer R. Schissler, DVM, MS, DACVD

College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

Etiology/Pathophysiology

Pyodermas are bacterial infections of the skin and commonly involve coagulase-positive staphylococci. Indeed, staphylococcal pyoderma is one of the most common conditions treated in clinical practice. For this reason, this chapter is focused exclusively on staphylococcal pyodermas. Staphylococcal infection opportunistically arises secondary to dermatologic or systemic diseases that prompt cutaneous physical or immunologic function insults. These may include hypersensitivity, endocrine, conformational, and keratinization disorders, as well as an immunocompromised status. Clinical presentations are diverse, and mimic a multitude of other dermatopathies. In the current era of antimicrobial resistance, optimal outcomes for staphylococcal pyoderma are achieved via correct diagnosis, rational treatment and follow-up, and management of the inciting cause(s).

Staphylococcus pseudintermedius, previously identified as *Staphylococcus intermedius*, is the most common etiologic agent in canine pyoderma. *Staphylococcus aureus*, *Staphylococcus schleiferi* subsp. *coagulans*, and coagulase-negative staphylococci such as *Staphylococcus schleiferi* subsp. *schleiferi* are isolated at a lesser frequency on healthy or inflamed skin.

Staphylococcal pyoderma is less prevalent in cats than dogs. Feline keratinocyte adhesion of *S. aureus* and *S. pseudintermedius* is inferior compared to human and dog keratinocytes, perhaps a reflection of inferior host adaptation. *S. pseudintermedius*, *S. schleiferi*, and *S. aureus* are most frequently isolated; *S. aureus* is isolated at a higher frequency than in dogs.

Pyoderma Classifications and Presentations

Pyodermas are often categorized based on the depth of infection (surface, superficial or deep) and the site involved, particularly when describing a pyoderma that affects a specific body region (e.g., interdigital pyoderma, nasal pyoderma). These categorizations are useful, particularly the depth of infection because it dictates the methods and duration of therapeutic interventions.

Surface Pyodermas

Acute Moist Dermatitis

Acute moist dermatitis, also known as pyotraumatic dermatitis and commonly referred to as a "hot spot," is characterized by the rapid development of a focal, erythematous, erosive, and exudative lesion that develops due to intense pruritus and self-trauma (Figure 166.1).

Acute moist dermatitis is typically initiated by hypersensitivity disorders, including cutaneous adverse food reaction, atopic dermatitis, and flea bite hypersensitivity, or pruritogenic parasitic diseases such as pediculosis, sarcoptic mange, and cheyletiellosis. Surface staphylococcal overgrowth is concurrently present in nearly all cases of acute moist dermatitis. Cytology of exudate obtained via surface impression smear reveals neutrophils and intracellular and extracellular cocci. Superficial bacterial folliculitis lesions (see "Superficial bacterial folliculitis" section below) observed at the periphery of the self-trauma suggest a longer duration of staphylococcal involvement and that the staphylococcal folliculitis itself

Companion website: www.wiley.com/go/bruyette/clinical

Figure 166.1 Acute moist dermatitis in a golden retriever dog with atopic dermatitis and superficial staphylococcal folliculitis.

may be the inciting cause of the acute moist dermatitis. This scenario is termed "pyotraumatic folliculitis."

Patients may present on an emergency basis due to rapid, severe progression. Lesions can be painful. Sedation may be required prior to clipping of the coat for optimal examination and initial topical treatment. A thorough examination of the entire coat and obtaining a detailed history are critical, as diagnosis and appropriate management of the underlying pruritic disease are very important, particularly in recurrent cases.

Initial treatment involves cleansing of the lesion with an antimicrobial. A 2% aluminum acetate solution (Domeboro® solution, Bayer) may be used as a topical nonirritating drying and antimicrobial agent. At-home therapy involves daily application (1–3 times/day) of a topical antimicrobial and/or drying agent; use of a topical anesthetic (e.g., pramoxine, lidocaine) or corticosteroid may be additionally beneficial. Limit daily topical corticosteroid use to no more than one week to avoid cutaneous side-effects, such as demodicosis, comedones, cutaneous atrophy, and ulceration.

Application of an Elizabethan collar or breathable physical barrier is recommended in the first 3–7 days of treatment to prevent self-trauma. Oclacitinib (Apoquel®, Zoetis), lokivetmab (Cytopoint®, Zoetis), or systemic corticosteroid treatment is often required to provide rapid relief of pruritus, and, for severe presentations, may be required for several days before topical therapy is attempted at home. Concurrent systemic antimicrobial therapy is required for pyotraumatic folliculitis (see also "Treatment of pyodermas" section below). The patient should be rechecked in 7–14 days to assess response to antimicrobial and antiinflammatory therapies.

Intertrigo

Increased warmth and humidity of the environment, friction, and the protected cutaneous microenvironments of skinfolds are predisposing factors for staphylococcal intertrigo. The aforementioned factors result in surface maceration of the stratum corneum and bacterial overgrowth, predominantly with staphylococci. Concurrent *Malassezia* overgrowth is common, and gram-negative bacteria may also contribute. It is largely a condition in dogs, particularly in the context of hypersensitivity, and is rare in cats. Intertrigo is typically pruritic. Locations affected include abdominal, inguinal, vulvar, lip, tail, and facial folds, with the latter two locations overrepresented in English bulldogs and pugs. Moist erythematous skin, purulent exudate, and in advanced cases ulcerative dermatitis are observed (Figures 166.2, 166.3, and 166.4).

Cytology of exudate obtained via surface impression smear confirms the presence of cocci and may also involve yeast and rods. Neutrophils are variably present. Topical antimicrobial and drying agents are indicated.

Figure 166.3 Dorsal interdigital moist erythema with *Malassezia* and *Staphylococcus* overgrowth in a 5-year-old Rottweiler with atopic dermatitis.

Figure 166.4 Severe, purulent tail fold intertrigo with mixed bacterial overgrowth and crusting staphylococcal superficial bacterial folliculitis in an English bulldog with atopic dermatitis. Surgery was ultimately required for control of the dermatitis.

Surgical correction of redundant folds may be indicated for severe, recalcitrant presentations.

Superficial Pyodermas

Impetigo

Impetigo, also referred to as "puppy pyoderma," occurs in puppies and juveniles less than 1 year old. It is typified by subcorneal, often grossly large, pustules caused by staphylococci, most commonly *S. pseudintermedius*. The pustules do not necessarily involve the hair follicles and are typically located in the axillary and inguinal areas. The pustules progress to crusts and epidermal collarettes. Patients are not typically pruritic nor painful. Cytology of pustules reveals degenerated neutrophils and intracellular cocci.

Impetigo is often idiopathic in otherwise healthy puppies. It may also occur in immunocompromised patients suffering from parasitic or infectious diseases, or suboptimal nutrition and housing conditions.

Impetigo is expected to self-resolve in otherwise healthy patients. Use of topical antimicrobial therapy may hasten resolution and may be required for resolution in immunocompromised patients. Treatment options include daily to alternate-day shampoo treatment with a nondrying, antimicrobial shampoo including chlorhexidine or ethyl lactate. Alternatively, for focal lesions, consider convenient antimicrobial wipes, sprays, foams, and ointments/creams applied once or twice daily. Continue topical therapies until lesion resolution. For severe cases or cases that do not respond to topical therapy, systemic antibiotics are indicated. Systemic antimicrobial treatment should continue for one week past resolution of lesions. Resolution of lesions is expected to occur within 14 days.

Superficial Bacterial Folliculitis

Superficial bacterial folliculitis is the most common presentation of pyoderma and, as stated previously, opportunistic *S. pseudintermedius* is the most common etiologic agent. Infection of the hair follicle and epidermis produces characteristic follicular-oriented papules, pustules, and epidermal collarettes (Figure 166.5) progressing to crusts, "moth-eaten" alopecia, and hyperpigmentation (Figures 166.6 and 166.7).

In short-coated dogs, well-demarcated areas of raised hair resemble urticaria from afar. Papular crusting dermatitis (i.e., miliary dermatitis) is most frequently observed in cats. Distribution is dependent on cause, and pruritus is variable.

Differential diagnoses for folliculitis include, but are not limited to, dermatophytosis, demodicosis, pemphigus foliaceus, and, in cats, hypersensitivity syndromes. Systemic and topical treatment is indicated for patients

Figure 166.5 Epidermal collarettes with macular erythema and hyperpigmentation on the abdomen of a terrier mix with superficial staphylococcal folliculitis, atopic dermatitis, and iatrogenic hypercortisolism.

Figure 166.6 Well-circumscribed partial alopecia, crusting and moist erythematous skin of the periocular and perioral regions due to superficial staphylococcal folliculitis in a 7-year-old domestic shorthair cat with atopic-like dermatitis.

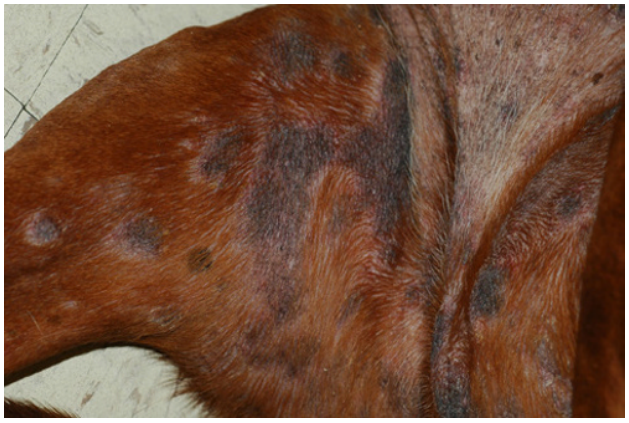

Figure 166.7 Hyperpigmentation and well-circumscribed "moth-eaten" alopecia caused by superficial staphylococcal folliculitis in a 10-year-old redbone coonhound.

with regional or generalized superficial pyoderma. Focal, mild presentations may resolve with daily topical therapy alone.

Diagnosis is achieved via cytology of exudate obtained by rupture of a pustule or avulsion of crusts. The presence of extracellular cocci or phagocytosed cocci confirms the diagnosis. If cytology is negative, culture and/or histopathology are required to make a definitive diagnosis. Superficial pyoderma is commonplace, so it is rational to empirically treat cytology-negative cases of folliculitis to assess for response, particularly if demodicosis and dermatophytosis have been ruled out.

Mucocutaneous Pyoderma

Mucocutaneous pyoderma, a crusting, erosive and depigmenting condition of the canine nasal planum and lip margins, may be an inflammatory response to staphylococci, although the etiopathogenesis remains unknown (Figure 166.8). It may occur alone or in the context of cutaneous hypersensitivity.

Less commonly, lesions may involve the prepuce/vulva, anus, or eyelids. Of note, the German shepherd dog is overrepresented. Differentials for this condition include discoid lupus erythematosus, pemphigus foliaceus, and epitheliotropic lymphoma. Mucocutaneous pyoderma may occur secondary to these conditions, and the histopathologic findings of mucocutaneous pyoderma are similar to that of discoid lupus erythematosus. Thus, diagnosis of mucocutaneous pyoderma is typically made via clinical response to antimicrobial therapy; cytology of exudate may not confirm the presence of cocci. Treatment involves antimicrobial systemic and topical therapy. Empirical or culture-based antimicrobial for a minimum of three weeks prior to biopsy of the aforementioned lesions is recommended to assess for responsiveness and optimize likelihood of a diagnostic biopsy reflective of the primary disease process.

Figure 166.8 Mucocutaneous pyoderma with multifocal labial and perioral depigmentation and erythema with multifocal depigmentation and erosions of the nasal planum in a German shepherd dog.

Canine Chronic, Recurrent Pyoderma

Recurrent pyoderma is characterized by the chronic reemergence of superficial bacterial folliculitis after successful treatment and confirmed clinical and cytologic resolution. This syndrome is most commonly associated with atopic dermatitis, cutaneous adverse food reaction and hypothyroidism, and is typically pruritic when lesions are present. Treatment of this syndrome includes not only topical and/or systemic antimicrobial therapy to treat active infection, but also identification and control of the underlying dermatosis to prevent recurrence.

Patients with idiopathic recurrent pyoderma are euthyroid, fail to respond to a proper elimination diet trial, and have no other signs of atopic or cutaneous disease other than pyoderma typically associated with pruritus. Such patients may be managed via use of frequent application of antimicrobial shampoos, wipes, or sprays to limit chronic use of systemic antibiotics. The immune response to staphylococci, perhaps a true hypersensitivity, may play a role in idiopathic recurrent pyoderma, and in canine patients with atopic dermatitis. Indeed,

subcutaneously injected commercial *S. aureus* phage lysate antigens (Staphage Lysate®, Delmont Laboratories) may be used as maintenance therapy to reduce or eliminate recurrence of pyoderma. This treatment is indicated in patients with idiopathic or atopic recurrent pyoderma cases failing to respond to topical maintenance therapy.

Deep Pyodermas

Generalized Deep Pyoderma

Generalized deep pyoderma arises due to furunculosis (follicular rupture) and foreign body response directed at the liberated hair shafts in the dermis. Lesions include nodules, hemorrhagic bullae, ulcers, draining tracts and crusts with variable pain and pruritus (Figures 166.9 and 166.10).

In cats, deep pyoderma most commonly presents in the context of chin acne. In short-coated breeds with atopic dermatitis or cutaneous adverse food reaction, cystic hemorrhagic, bullous lesions are often observed on the chin and interdigital areas. Staphylococci represent the predominant organism but deep pyoderma may also be accompanied by infection with *Enterococcus*, *Pseudomonas*, and *Proteus* species as well as *Escherichia coli*. Differentials include dimorphic and opportunistic mycoses, pythiosis, lagenidiosis, neoplasia, foreign body, sterile pyogranulomatous dermatitis, and other bacterial etiologies, including species in the genera *Mycobacterium*, *Actinomyces*, and *Nocardia*. Cytologic presence of numerous extracellular cocci or phagocytosed cocci supports the diagnosis. Given the diverse clinical differentials and requirement for prolonged treatment, bacterial culture (aerobic and anaerobic) and sensitivity, fungal culture, and histopathology are recommended for definitive diagnosis and appropriate treatment.

Figure 166.9 Nonblanching, hemorrhagic, nodular, deep staphylococcal pyoderma in a 5-year-old Rottweiler with atopic dermatitis.

Canine Acne

This disease is typified by deep folliculitis and furunculosis affecting the chin and perioral margin, and is a focal form of deep pyoderma. Chin acne usually manifests in young dogs between 3 and 12 months of age although it often persists throughout adulthood and may be complicated by concurrent atopic dermatitis or cutaneous adverse food reaction. Breeds with a short, coarse hair coat are predisposed, including boxers, English and French bulldogs, and Boston terriers.

Lesions consist of papules and nodules that often become erosive and ulcerative with resultant draining tract formation. Hemorrhagic bullae are also common (Figure 166.11).

Demodicosis should be ruled out by performing deep skin scrapes. Juvenile cellulitis is a differential diagnosis; however, classic submandibular lymphadenopathy as well

Figure 166.10 Erythematous nodules with ulcers due to deep *Pseudomonas* pyoderma on the lateral hindlimb of a 3-year-old Rottweiler mix.

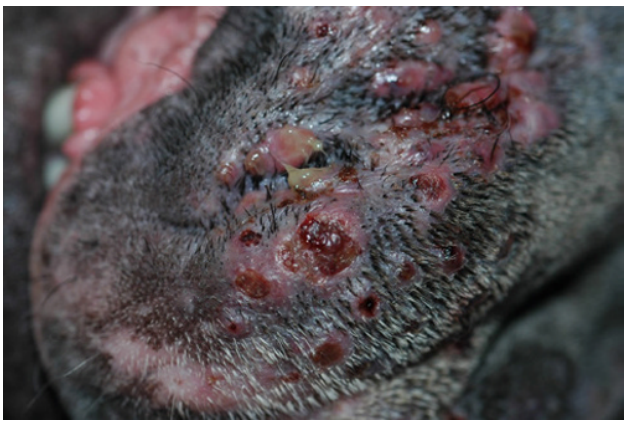

Figure 166.11 Nodular, ulcerative, and purulent deep staphylococcal pyoderma on the chin of a cane corso dog with atopic dermatitis.

as generalized muzzle, periocular, and pinnal involvement clinically differentiate it from chin acne in many cases (see Chapter 164 for a more thorough discussion of juvenile cellulitis). Chin acne is supported by the presence of cocci and a mixed population of inflammatory cells on cytologic evaluation.

Treatment involves systemic antimicrobial therapy, ideally based on aerobic culture and sensitivity testing (see "Treatment of pyodermas" section below), with adjunct topical antimicrobial therapy. Benzoyl peroxide gel, silver sulfadiazine cream, clindamycin cream, and mupirocin (reserved for resistant staphylococcal infections), are often well tolerated when applied to the facial area. Because furunculosis and subsequent deep pyoderma are frequently present, treatment for a minimum of six weeks may be required. Treatment should be continued for two weeks past clinical and palpable resolution.

Figure 166.12 Dorsal interdigital nodule with hemopurulent exudate due to furunculosis and deep staphylococcal pyoderma in a cairn terrier.

Interdigital Pyoderma

Interdigital pyoderma has a diversity of presentations and therefore terms commonly used include canine pododermatitis, pedal folliculitis/furunculosis, and interdigital "cysts." Lesions may include interdigital erythema, salivary staining of hairs, papules, nodules, hemorrhagic bullae, and draining tracts. Clinical signs may include licking and biting of the feet, and lameness. Staphylococci are common bacterial etiologic agents of pododermatitis and infection often occurs concurrently with *Malassezia* and gram-negative bacterial organisms. Interdigital pyoderma is a multifactorial disorder consisting of predisposing abnormal conformation, primary etiologies, and secondary infections that perpetuate the dermatitis.

Abnormal weight bearing as a result of abnormal conformation, musculoskeletal disease, and/or obesity are predisposing factors for the development of interdigital pyoderma. In such cases, rather than generalized interdigital involvement, focal dorsal or ventral dermatitis is often recurrent in one or several interdigital spaces. Short-coated dogs such as Labradors and English bulldogs appear to be predisposed.

Hypersensitivity, autoimmune, and inflammatory conditions are primary etiologies; secondary bacterial and yeast surface overgrowth and/or bacterial folliculitis perpetuate the dermatitis. Occasionally, hypothyroidism and hypercortisolism may result in interdigital bacterial or yeast overgrowth.

A conformation-related disorder involving ventrally oriented cystic follicles, primarily on the forelimbs, has been described. These dilated follicles may be grossly visible as comedones and milia. The cystic follicles rupture in the dermis. The subsequent foreign body response clinically manifests as dorsal interdigital nodules, hemorrhagic bullae, and edema (Figure 166.12). Draining tracts and deep secondary bacterial infection frequently ensue. Treatment of this condition may include multiple carbon dioxide (CO_2) laser ablations of the ventral cystic lesions in addition to antimicrobial therapy as described subsequently in this chapter (see "Treatment of pyodermas").

Diagnosis involves obtaining a thorough history and performing a physical examination to identify possible primary causes. Deep skin scrapes or hair plucks for demodicosis must be performed, as demodicosis may demonstrate all the aforementioned clinical manifestations. In some cases of pododemodicosis, biopsy may be required for diagnosis.

Perform multiple surface cytologic preparations of erythematous interdigital spaces to confirm the presence of bacterial organisms as well as *Malassezia*. Consider aspiration of nodules and hemorrhagic bullae to assess for secondary bacterial infection and other causes of nodular dermatitis, including neoplasia. Consider the possibility of a foreign body, particularly in the context of a solitary nodular lesion with mixed inflammation. Culture and sensitivity of tissue biopsies or aspirates of nodular lesions should ideally be performed with confirmed or suspected bacterial involvement, as such lesions indicate deep pyoderma and require prolonged therapy. Avoid culture of draining tracts as they may not be reflective of the relevant bacterial organisms within the tissue.

Pedal pruritus (licking and biting of the feet) with generalized dorsal or ventral interdigital involvement persisting despite resolution of secondary infection is suggestive of cutaneous adverse food reaction or atopic dermatitis.

Topical antimicrobial therapy is ideal for secondary surface bacterial and yeast overgrowth. Chlorhexidine, benzoyl peroxide, or ethyl lactate-based shampoos may be used as a soak, particularly for painful feet, every 24–48 hours initially. Aluminum acetate solution (Domeboro)

may be similarly used as a foot soak for drying and antimicrobial effects. Antimicrobial wipes and sprays may be considered, but acid- and alcohol-based products should be avoided in erosive and ulcerative presentations (see "Treatment of pyodermas" section for additional treatment recommendations).

Focal nodular staphylococcal or mixed bacterial lesions may be treated with silver sulfadiazine cream, clindamycin ointment, or mupirocin (reserved for resistant staphylococcal infections). Application of dimethyl sulfoxide (DMSO) just before or after application of the topical antimicrobial may improve its penetration and provide additional antiinflammatory effects. Topical corticosteroid treatment (as the sole ingredient or a combination product) may be helpful for additional antiinflammatory benefits, particularly for hypersensitivity. Topical corticosteroids should be avoided in the presence of comedones and milia, as they may exacerbate these lesions. Systemic antimicrobial therapy is indicated for nodules, draining tracts or severe bacterial surface pyoderma (see "Treatment of pyodermas" section). Deep pyoderma (draining nodules, crusts, ulcerations) typically require a minimum of six weeks of systemic antimicrobial therapy, and should be continued four weeks beyond cytologic and clinical resolution (including palpation).

Acral Lick Dermatitis

Although commonly encountered in canine practice, acral lick dermatitis (ALD) is a challenging condition to manage given its multifactorial genesis and chronic nature. Optimal control is achieved via identification and control of contributing factors. Acral lick dermatitis is characterized by repetitive licking, typically of the distal limbs. Lesions, commonly known as lick granulomas, take the form of erosive to ulcerative nodules or plaques with purulent and/or hemorrhagic exudates (Figure 166.13).

Figure 166.13 Acral lick granuloma with erosive surface on the carpus of a 9-year-old Labrador mix; deep staphylococcal pyoderma and atopic dermatitis were contributing factors.

The most common primary factors are atopic dermatitis and cutaneous adverse food reaction, as well as concurrent behavioral etiologies. Importantly, the most common perpetuating factor is secondary deep staphylococcal pyoderma. This must be treated to reduce lesion size and severity. Common bacterial genera concurrently isolated from ALD lesions include *Pseudomonas* and *Enterobacter*. Importantly, methicillin-resistant and multidrug-resistant staphylococcal infections are common in ALD. Cultures obtained from the surface of the lesions do not accurately represent the organisms within the lesion. Thus, tissue biopsy for culture and sensitivity is indicated to select antibiotic therapy, as treatment required is typically in excess of eight weeks.

Methicillin-Resistant and Multidrug-Resistant Staphylococci

Antimicrobial resistance in veterinary medicine has rapidly evolved in recent years from a mere theoretical possibility to an unwelcome reality. Of concern, methicillin-resistant (MR) and multidrug-resistant (MDR) staphylococci pose a risk of difficult-to-treat nosocomial infections and, to a lesser extent, zoonotic infection. To best serve our community and patients in the present era of antimicrobial resistance, critical examination of infection control and antimicrobial prescribing practices as individuals and as a profession is essential.

Methicillin-resistant staphylococci possess the *mecA* genetic element, encoding penicillin binding protein 2a (PBP2a). Beta-lactam antibiotics cannot bind to PBP2a, rendering them ineffective. The *mecA* gene is present within staphylococcal chromosomal cassettes (SCCs) that are also horizontally transferred amongst *Staphylococcus* spp. Staphylococcal chromosomal cassettes may contain other antimicrobial resistance genes, imparting multidrug resistance in nearly all strains of MR staphylococci encountered in veterinary practice. Of note, beta-lactam antimicrobial use selects for survival of MR staphylococci, but does not create, *de novo,* spontaneous resistance.

Cutaneous MR staphylococcal infection and colonization are a worldwide phenomenon, recognized in the dog, cat, horse, cattle, and swine. In years past, MR staphylococcus appeared to be very rare to absent in the canine and feline population but a remarkable increase in frequency of methicillin resistance in the canine and feline population was noted early in the 21st century. The rapid rise of MR staphylococcal infection in veterinary patients is thought to have

occurred via acquisition of the *mecA* gene from human staphylococci and subsequent selection of resistant strains via widespread use of beta-lactam antimicrobials. Methicillin-resistant canine and feline cutaneous infections and colonization have been subsequently reported worldwide, with MR *S. pseudintermedius* most commonly seen. Prevalence varies by geographic location.

Frequent antimicrobial treatment is a risk factor for canine MR staphylococcal pyoderma and carriage of MR staphylococci in healthy dogs and cats. Risk factors associated with MR *S. aureus* infection in the dog and cat include frequent antimicrobial courses, frequent veterinary visits, multiple days of hospitalization, and the presence of surgical implants.

Recognition of Methicillin Resistance

Methicillin-resistant and MDR staphylococcal pyoderma cases do not typically possess unique clinical features. Rather, the first indication of resistance is lack of response to empirical antimicrobial therapy. Therefore, to ensure appropriate response, all patients must be reexamined prior to conclusion of antimicrobial treatment. If resistance is suspected, perform a cytologic evaluation to assess for the presence of cocci, as well as bacterial culture and sensitivity. A sterile needle is used to rupture a pustule or lift the edge of an epidermal collarette or crust to reveal exudate. The sample is collected with a sterile swab. For cases of papular or nodular pyoderma, punch biopsies are recommended for culture.

Although "methicillin resistance" is the accepted term, the more stable oxacillin is used as a surrogate in the laboratory for methicillin susceptibility. Resistance to oxacillin is a strong indicator of *mec*A acquisition and resistance to all beta-lactam antibiotics. Upon interpreting antibiograms, it is important to recognize that oxacillin-resistant staphylococci may show *in vitro* sensitivity to other beta-lactams. Thus, interpretation of staphylococcal antibiograms should first involve noting oxacillin susceptibility, rather than simply searching for reported susceptible antimicrobials. If a bacterial strain is resistant to oxacillin, it should be considered resistant to all beta-lactam antibiotics.

Direct the laboratory to perform extended antimicrobial panels for suspected resistance. Additionally, species identification of staphylococci is useful, as MR *S. aureus* has a more significant zoonotic implication given that it is host-adapted to humans. Methicillin-resistant, coagulase-negative staphylococci, including *S. schleiferi* subsp. *schleiferi*, are clinically significant and should not be disregarded.

Treatment of Pyodermas

Appropriate management of staphylococcal pyoderma is an active area of investigation, which may result in future changes in systemic antimicrobial dose and duration.

Systemic Therapy

Systemic antimicrobial therapy is indicated for regional, generalized or severe superficial bacterial folliculitis, mucocutaneous pyoderma, and forms of deep staphylococcal pyoderma. For milder presentations, expected time of resolution with systemic therapy is 14–28 days. Duration of therapy may be longer and treatment for one week beyond clinical resolution is recommended. For deep pyoderma, treatment may take 6–12 weeks to achieve visual and palpable resolution. For severe presentations of deep pyoderma, consider continuation of antimicrobial therapy four weeks beyond palpable resolution to prevent relapse. Importantly, all patients receiving antimicrobial therapy for staphylococcal pyoderma must be periodically rechecked (every 2–4 weeks) prior to conclusion of antimicrobial treatment to ensure appropriate response.

Empirical and Culture-Based Therapy

Rational antibiotic options for empirical treatment of staphylococcal pyoderma include cephalexin (22–30 mg/kg PO q12h), amoxicillin/clavulanate (13.75 mg/kg PO q12h), cefpodoxime (5–10 mg/kg PO q24h), and cefovecin (8 mg/kg SC q14 days). Lincomycin (15–25 mg/kg PO q12h) and clindamycin (5.5–10 mg/kg PO q12–24h) are considered first-line choices, but their conservation is recommended as some MR and MDR staphylococcal strains retain susceptibility to these antimicrobials. For cases of resistant pyoderma, clindamycin should be used with reservation if the laboratory has not tested for inducible resistance (D-test). This test should be requested if erythromycin resistance is present. If this test is not available and the bacterial strain is resistant to erythromycin but susceptible to clindamycin, do not prescribe the latter.

Culture and sensitivity-based selection of a systemic antimicrobial is indicated for patients that fail to clinically respond to empirical therapy, have evidence of deep pyoderma, or have a chronic history of antimicrobial use with unknown or lackluster response. Empirical treatment is not recommended in these cases as staphylococcal antimicrobial resistance patterns are unpredictable. Dwindling rational systemic treatment options for MDR staphylococcal pyoderma present a global practical challenge. A 2010 study examining 103 isolates of MRSP in North America reported that nearly 90% of isolates were

resistant to ciprofloxacin, clindamycin, erythromycin, and trimethoprim sulfa (TMS); 69.9% were resistant to tetracycline and gentamicin, and 57.3% were resistant to chloramphenicol.

If resistant superficial bacterial folliculitis is present with limited therapeutic options, consider daily topical therapy prior to use of amikacin, rifampin, or chloramphenicol, as this may be sufficient to resolve the problem with minimal risk to the patient. Chloramphenicol may be used with success in resistant cases, but vomiting and diarrhea can be frequent, and transient bone marrow suppression is possible but apparently rare. Reversible weakness (often seen in the hindlimbs) may occur in dogs. Clients must also wear gloves to prevent rare but fatal aplastic anemia of humans. At present, resistance to rifampin is rare. Although it is often stated that a secondary antimicrobial is required with use of rifampin, successful treatment with monotherapy has been documented with *S. aureus* and, therefore, this long-held concept may not apply to treatment of staphylococcal pyoderma. Hepatotoxicity can be life-threatening and biochemistry values must be monitored every seven days during administration. Given the potential for renal failure, amikacin is reserved for patients with severe, deep, resistant pyoderma with no other rational systemic treatment options. When used, frequent urinalysis and monitoring for casts are recommended.

Although susceptibility to vancomycin, linezolid, synercid (quinupristin/dalfopristin), and teicoplanin may be provided in antibiograms, use of these antibiotics is strongly discouraged. These are drugs of last resort used for human MRSA patients with life-threatening infections and selection for further resistance must be avoided.

Topical Therapy

Adjunct topical therapy is indicated in all forms of pyoderma and may be used as the sole treatment for surface pyodermas such as acute moist dermatitis and intertrigo, as well as with superficial pyodermas, including impetigo and superficial bacterial folliculitis. The use of topical therapy may shorten the duration of systemic therapy, and thus reduce antibiotic selective pressures. The choice of topical ingredient(s) and formulation is dependent upon lesion location, distribution, type, and compliance of the client and the animal.

Shampoo therapy is ideally performed 2–3 times weekly as an adjunct for all forms of pyoderma. Active ingredients include chlorhexidine 2–4%, benzoyl peroxide 2.5%, and ethyl lactate 10%. Benzoyl peroxide can be drying and is best used for patients with greasy or purulent dermatitis. A contact time of 5–10 minutes is generally recommended. When instituted as a sole therapy for superficial bacterial folliculitis, daily use is recommended.

Wipes and sprays are convenient for frequent use, and are a convenient sole therapy for intertrigo. These preparations may include acids, such as acetic acid 2% or boric acid 2%, and alcohols for antimicrobial and drying effects. These drying ingredients are particularly helpful for intertrigo, but are painful if applied to ulcerative lesions. Chlorhexidine (2–4%) is commonly found in wipe and spray preparations, and nisin is found in wipe preparations. Of note, chlorhexidine is appropriate for both gram-positive and gram-negative bacteria, whereas nisin is most appropriate for treatment of staphylococci alone. For sole therapy, apply every 12–24 hours; for adjunct therapy, application every 24–72 hours is appropriate.

Hypochlorous acid is available in a convenient, commercial spray formulation (Vetericyn VF®, Innovacyn). It can be used solely once to twice daily for localized superficial and deep pyoderma or as an adjunct to other topical and systemic therapies for more generalized conditions. Hypochlorous acid is the sodium salt of sodium hypochlorite (household bleach). Dilute bleach rinse solutions (0.005–0.01%) are used by human and veterinary dermatologists, particularly for treatment of allergy-induced recurrent and resistant staphylococcal pyoderma. The author uses a dilution of 2 tablespoons of household bleach per gallon of water as a rinse. This effective and affordable therapy can be used after bathing or applied directly to a focal area as frequently as daily as a sole therapy or as infrequent as twice weekly as an adjunct therapy. The patient is patted dry. Note that this solution must be reconstituted daily. It is nonirritating, and there are some data to suggest it is antiinflammatory as well.

Creams, ointments, and gels are most appropriate for focal presentations. Many commercial antibiotic preparations (neomycin, polymyxin B, gentamicin) are available combined with antifungal and corticosteroid ingredients. Concurrent use of a topical corticosteroid may obscure interpretation of antimicrobial response, and chronic use may result in cutaneous atrophy and ulceration. Creams and ointments containing an antimicrobial as the sole ingredient are therefore preferred. Active ingredients include silver sulfadiazine, benzoyl peroxide, fusidic acid, hydrogen peroxide, and mupirocin. Of note, mupirocin ointment should not be used routinely, as mupirocin resistance has been documented, and it is used for decolonization of methicillin-resistant *S. aureus* of humans. For sole therapy, apply every 12–24 hours; for adjunct therapy, application every 48–72 hours is appropriate.

Staphylococcus aureus Phage Lysate Therapy

Subcutaneously injected commercial *S. aureus* phage lysate antigens (Staphage Lysate) may be used as maintenance therapy to reduce or eliminate recurrence of pyoderma in canine patients with idiopathic recurrent pyoderma or atopic dermatitis, and can be used in combination with maintenance topical therapy once active pyoderma has been resolved.

Subcutaneous injection of 0.5 mL is administered twice weekly for a trial period of 10–14 weeks. Topical and/or systemic antimicrobial therapy is required at the initiation of treatment if an active bacterial infection is present. If beneficial, frequency may be tapered to the least frequent administration required to increase the interval between recurrences or prevent recurrences, typically every 7–14 days.

Otitis

Sue Paterson, MA, VetMB, DVD, DECVD, FRCVS

Veterinary Dermatologicals, Altrincham, Cheshire, UK

Otitis Externa

Etiology/Pathophysiology

Otitis externa is inflammation of the external ear canal. The microscopic structure of the external ear canal is similar to that of the interfollicular epidermis of the skin. It is a stratified cornified epithelium with adnexal organs such as hair follicles and their associated sebaceous and ceruminous glands. The epidermis lining the canal is only a few layers thick and is punctuated by hair follicles. Therefore, any disease that affects the skin can also affect the external ear canals. Those diseases that cause otitis externa are referred to as primary causes, the most important of which are listed in Box 167.1.

It is crucially important that the primary cause is identified and managed adequately in all cases of otitis externa. Failure to do so leads to recurrence of the problem and progression of the disease to produce a chronically damaged ear. Primary disease initially causes inflammation within the canal which leads to an increase in epidermal turnover and hyperplasia of the canal wall with narrowing of the lumen. As the disease process progresses, sebaceous glands become hyperplastic, often with dilation of their ducts. This is followed more chronically by dramatic changes in the ceruminous glands and ducts which become enormously enlarged, leading to further loss of lumen diameter. Chronic change drives the disease process once it has been established, causing perpetuation of the otitis. Where this is not resolved, effective therapy is difficult and disease perpetuation or recurrence is inevitable. Where the disease process becomes chronically irreversible, the lumen may be completely obliterated and in some of these cases, ossification of the soft tissue may also take place. Once the damage to the ear has become this extensive, medical therapy is rarely effective. Progressive pathologic changes lead to alterations in the microclimate within the external ear canal, causing an increase in temperature and humidity, surface maceration, and an increase in microbial colonization within the ear (Figure 167.1).

Infection is secondary to the inflammatory process and although effective therapy is essential, if other factors are not managed, recurrence is likely.

Signalment

Age

In young dogs, allergy, especially atopic dermatitis, is the most common trigger of otitis. In cats, especially kittens, *Otodectes cynotis* is more important, accounting for about 80% of all cases of feline otitis externa. Otic demodicosis is an uncommon cause of ear disease in the dog and is very rare in the cat. Juvenile-onset disease is seen in animals less than 3 years of age. Adult-onset disease is seen in those older than 3 years.

Other examples of primary causes affecting young animals include primary idiopathic seborrhea and immune-mediated diseases such as juvenile cellulitis. In older animals, systemic disease such as canine hypothyroidism is important although hepatic, renal, and pancreatic diseases may also predispose animals to otic infection. Rare primary causes for otitis externa that can occur in animals of any age include keratinization disorders such as sebaceous adenitis and autoimmune diseases such as pemphigus foliaceus and discoid lupus erythematosus.

Breed

Primary disease triggered by atopic dermatitis is most commonly seen in the West Highland white terrier, Staffordshire bull terrier, Labrador retriever, German shepherd dog, and boxer. Otitis due to cutaneous adverse food reactions is most common in the Labrador

Box 167.1 Primary causes for otitis externa

Allergy – atopic dermatitis, cutaneous adverse food reaction, contact allergy

Endocrine disease – hypothyroidism (dog), hyperthyroidism (cat), hyperadrenocorticism (dog and cat)

Ectoparasites – *Otodectes cynotis*, *Demodex* spp., *Otobius megnini*

Autoimmune/immune-mediated disease – pemphigus foliaceus, discoid lupus erythematosus, erythema multiforme, juvenile cellulitis, drug reactions, vasulitis

Keratinization disorders – sebaceous adenitis, zinc-responsive dermatosis, primary idiopathic seborrhea

Foreign bodies – grass awns, ceruminoliths (accumulations of cerumen due to failure of epithelial migration)

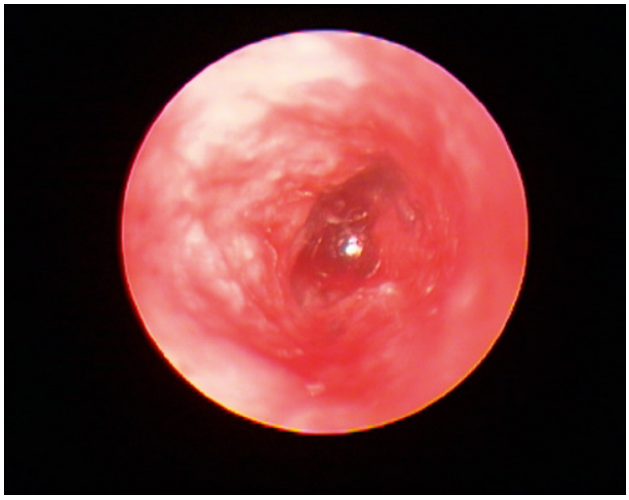

Figure 167.1 Ulcerated ear canal in a case of *Pseudomonas* otitis.

retriever. Juvenile-onset demodicosis is frequently seen in the shih tzu, American Staffordshire terrier, English bulldog, and boxer. Hypothyroidism is commonly recognized in giant breeds such as the dogue de Bordeaux and Newfoundland, as well as hunting dogs such as spaniels and retrievers. Keratinization disorders are often breed linked (e.g., sebaceous adenitis in the akita and standard poodle; primary seborrhea in the cocker spaniel and Persian cat; zinc-responsive disease in the Siberian husky and malamute).

There are many breed characteristics that predispose to the development of disease. Dogs with hairy ear canals, such as the cocker spaniel which has compound hair follicles within its canals, are at increased risk of developing disease. Other dogs with hirsute canals include the poodle and old English sheepdog. Dogs with pendulous pinnae such as spaniels, basset hounds, and bloodhounds are predisposed to disease, as are breeds such as the shar-pei which have narrowed canals.

Box 167.2 Predisposing factors in otitis externa

Conformation of the ear – narrowed canal (shar-pei), hairy external ear canal (spaniels, poodles), hairy concave pinna (spaniels), large pendulous pinnae (basset hounds, bloodhounds)

Inappropriate cleaning, irritant treatment – use of astringent, low-acidity topical products or potent ceruminolytic cleaner when not appropriate

Wetting of the ear – swimming dogs, water-based cleaners, topical medication mixed in water

Obstructive ear disease – polyps, ceruminous gland adenomas, other neoplasia

Box 167.3 Perpetuating factors in otitis externa

Chronic changes – epidermal and glandular hyperplasia, stenosis, failure of epidermal migration, calcification of ear canals, ulceration

Otitis media

History and Clinical Signs

The key aims of history taking are to try to establish the primary cause for the otitis and any predisposing, perpetuating or secondary factors that may be contributing to the disease. Primary causes (see Box 167.1) should be identified in all cases of otitis. Successful management of these triggers is particularly important in chronic disease. Predisposing factors, which are listed in Box 167.2, contribute to ear disease but do not cause it. Perpetuating factors, listed in Box 167.3, and secondary factors which are infections, listed in Table 167.1, are those that drive the process once it has been established. They need to be managed to ensure a complete resolution of disease is achieved without danger of relapse.

In order to identify the primary causes and the other contributory factors, a carefully taken history should include all aspects of the dog's general health and lifestyle. Dogs with atopic dermatitis usually demonstrate a seasonal exacerbation of otitis, pollen-allergic dogs being worse in the spring and summer and house dust mite-allergic dogs being worse in the fall and winter. Allergic dogs that swim commonly develop signs of "swimmer's ear." Hypothyroid dogs may have more generalized systemic signs such as lethargy and a poor exercise tolerance. Where otitis has an acute onset and the disease progresses rapidly to become severe, immune-mediated

Table 167.1 Secondary causes in otitis externa

Infectious organism		Acute disease	Chronic disease
Bacteria (most common isolates)	Gram-positive bacteria	*Staphylococcus* spp. *Streptococcus* spp.	*Enterococcus* spp. *Corynebacteria* spp.
	Gram-negative bacteria	Uncommon	*Pseudomonas* spp. *Proteus* spp. *Escherichia coli*
	Anaerobic bacteria	Uncommon	*Bacteroides* spp.
Yeast (most common isolate)		*Malassezia pachydermatis*	*Malassezia pachydermatis*

disease such as drug eruptions and autoimmune disease should be considered. Contact irritant or hypersensitivity should be considered when signs of otitis become worse after commencement of topical therapy. Contact reactions may be to one of the active ingredients in the topical product such as an antibiotic, antifungal or glucocorticoid, or can be to the vehicle (e.g., propylene glycol).

Examination of each case should include a full physical and dermatologic inspection before examining the pinnae and ear canal. A physical examination may reveal signs, for example of bradycardia in a hypothyroid dog. Accompanying signs of more generalized disease may provide useful clues. Dogs with atopic dermatitis or adverse food reaction may have pedal salivary staining due to foot licking, or recurrent ventral pyoderma. Dogs with endocrine disease may have seborrhea, a poor hair coat or bilaterally symmetric alopecia which typically spares the face and distal extremities. Where keratinization disorders cause otitis, lesions may be more generalized (e.g., diffuse thinning of the coat with prominent follicular casts on hairs in cases of sebaceous adenitis). Dogs that shake their heads or traumatize their pinnae without signs of otitis may be in the early stages of allergy or may have disease that principally affects the pinnae. These diseases include those caused by ectoparasites such as *Sarcoptes scabiei*, *Notoedres cati*, lice and the rabbit flea (*Spilopsyllus cuniculi*), and immune-mediated diseases such as vasculitis and dermatomyositis. The pinna is an excellent area to view primary lesions, which tend to be better preserved at this site due to the difficult accessibility. Pustular lesions on the pinna may be seen with sterile autoimmune disease such as pemphigus foliaceus or, rarely, with pyoderma. Papular eruptions are most commonly seen with ectoparasites, and ulcers with immune-mediated disease such as vasculitis.

Examination of the ear canal may be undertaken with either a hand-held or a video otoscope (Figure 167.2). The latter obviously has the advantage of better illumination and magnification and allows for superior visualization of the canal and tympanic membrane. Assessment of the canal is important to decide which predisposing and perpetuating factors are present. Predisposing factors such as neoplasia, stenosis of the canal, or the presence of a large amount of hair need to be addressed as part of the overall management of the otitis (Figure 167.3).

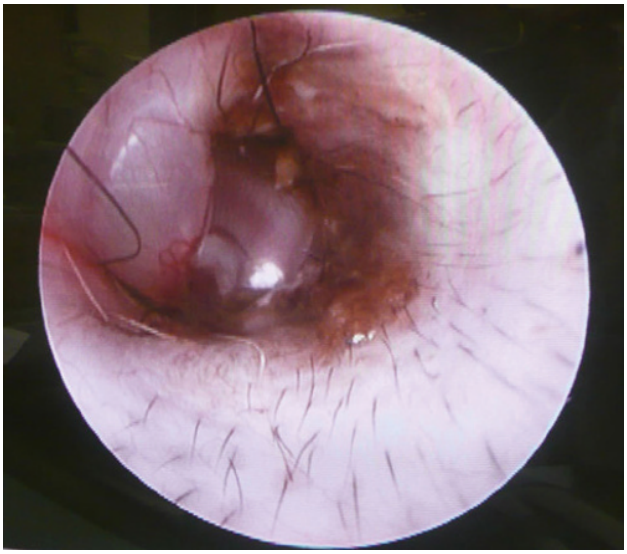

Figure 167.2 Video otoscopic image of the external ear canal and tympanic membrane of a dog.

Identifying and treating perpetuating factors such as chronic changes and otitis media are important to prevent relapse of the otitis. The degree of pathologic change present helps the clinician decide if the otitis can be treated medically or whether surgical intervention is more appropriate. Assessment of the tympanic membrane can help in making a diagnosis of otitis media if the structure is abnormal or ruptured.

Diagnosis

Predisposing and perpetuating factors, and to some degree primary and secondary causes, can be recognized

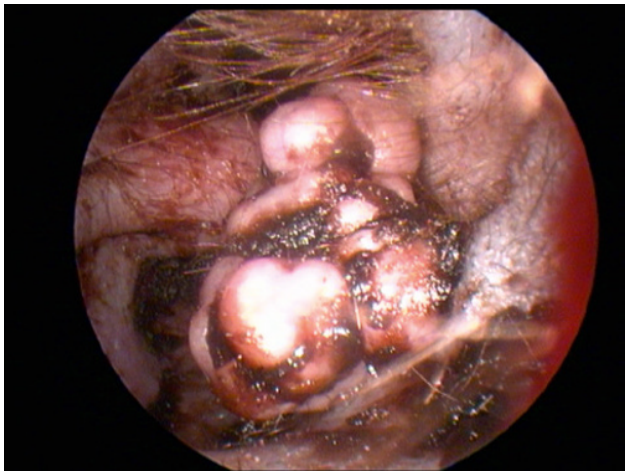

Figure 167.3 Ceruminous gland adenomas in the ear of a dog illustrating a predisposing factor of otitis externa.

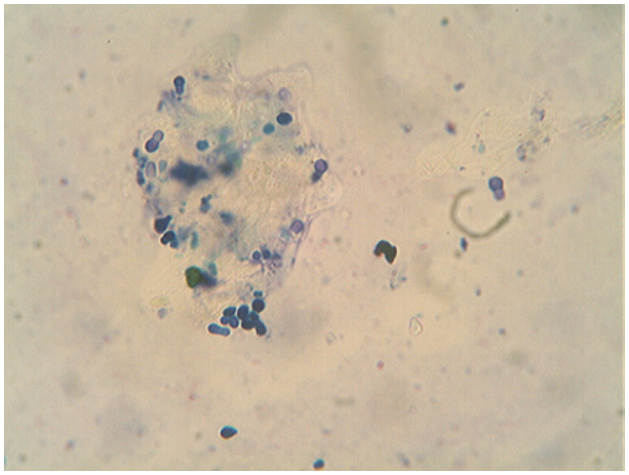

Figure 167.4 Ear cytology stained with Diff-Quik showing *Malassezia* organisms and anucleated squamous epithelial cells.

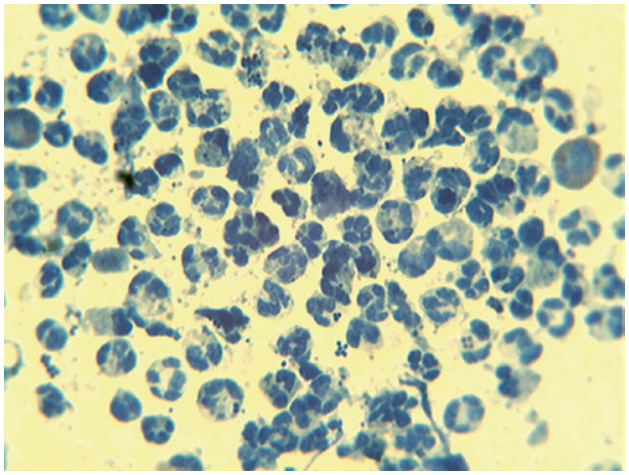

Figure 167.5 Ear cytology stained with Diff-Quik showing degenerate neutrophils and phagocytosed cocci.

by a history and clinical examination. Diagnostic investigations allow a more definitive identification of primary and secondary factors. Where a history suggests a primary cause then appropriate diagnostic tests may include food trials, *in vitro* or *in vivo* allergy tests, ectoparasite assessment, endocrine function tests or skin biopsy. Secondary infection can be identified by cytology of exudate and, where necessary, culture and susceptibility. Samples should be collected, if possible, before cleaning is performed using a shielded cotton swab (sample is taken by inserting the swab down an alcohol-cleaned otoscope cone) from the horizontal canal and rolled onto a clean glass slide. Both unstained (to identify ectoparasites such as *Demodex* spp. and *Otodectes cynotis*) and stained (to identify inflammatory cells, bacteria, and yeast) samples should be examined. Samples to be stained should be heat fixed before staining with a modified Wright's stain such as Diff-Quik (Figures 167.4 and 167.5).

Cytologic findings and interpretation are shown in Table 167.2. Cytology is often all that is needed to institute therapy in otitis externa. However, where rods are found with cocci on cytology (Figure 167.6), where cocci are identified but have failed to respond to rational therapy or where otitis media is suspected, culture and susceptibility is advised as bacterial sensitivity patterns may be unpredictable.

Therapy

Therapy can be divided into two parts; the first is the selection of an appropriate cleaner and the second is dealing with the pathologic process, which may be treating infection and/or reversing pathologic change within the ear canal. Assessment of the otic discharge allows the clinician to select the best cleaning product (Table 167.3).

Where the discharge is thick and waxy (e.g., keratinization disorders, hypothyroidism and *Malassezia* infection) then the cleaner needs to be able to break up the wax (i.e., ceruminolytic activity). Where an inflammatory infiltrate is present and the discharge is more purulent or mucopurulent (e.g., gram-negative infection), then an aqueous-based flush is better.

Examples of agents with good ceruminolytic properties include dioctyl sodium or calcium sulfosuccinate, carbamide peroxide, triethanolamine polypeptide oleate condensate, hexamethyltetracosane, and squalene. Propylene glycol and mineral or vegetable oils are less potent ceruminolytics. Aqueous-based flushing agents include ethylenediamine tetraacetic acid (EDTA)-tris, 0.2% chlorhexidine, and 2% acetic acid. Although the main function of an ear cleaner is to clean, many contain components that have antibacterial or antiyeast activity. Such actives include

Table 167.2 Cytologic findings and interpretation

Finding	Normal ear	Abnormal ear
Cerumen	Low numbers of anucleate corneocytes	Larger numbers of anucleate and nucleated corneocytes
Malassezia	Low numbers adherent to corneocytes	Peanut-shaped organisms >5–10/high power field (hpf) considered significant
Bacteria	Low numbers adherent to corneocytes	Large cocci in pairs, fours or clumps usually *Staphylococci* spp. Smaller cocci in chains usually *Streptococci* spp. Rods cannot be differentiated from each other and may be *Proteus* spp., *Escherichia coli* or *Pseudomonas* spp.
Inflammatory cells	Absent	Neutrophils only in acute disease, neutrophils and macrophages in chronic disease. Neutrophils are seen in all bacterial skin infections, neoplasia, and irritant and allergic dermatitis
Acantholytic cells	Absent	Seen in autoimmune disease (e.g., pemphigus foliaceus)
Neoplastic cells	Absent	Uncommon. Some neoplasms may shed cells into cerumen; fine needle aspirates are more useful
Ectoparasites – *Otodectes cynotis*, *Demodex* spp.	Absent	Eggs, immature stages, and adults can be found in cerumen

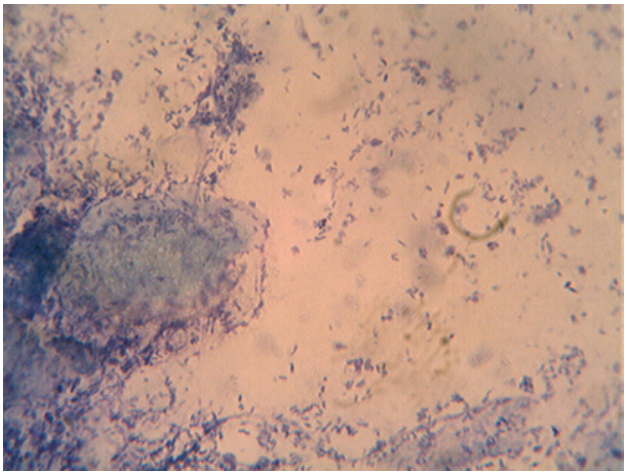

Figure 167.6 Ear cytology stained with Diff-Quik showing numerous rod-shaped bacteria consistent with *Pseudomonas* spp. intermixed with cocci.

EDTA-tris, lactic acid, salicylic acid, isopropyl alcohol, parachlorometaxylenol (PCMX), and microbial adhesion-blocking carbohydrates. EDTA-tris has been shown to have antibacterial potentiating activity and will render bacteria more sensitive to topical antibiotic therapy with aminoglycosides or fluoroquinolones when the ear is presoaked with this product 10 minutes before antibiotic application. The cleaning solution should be used to flood the ear canal and then gently massaged to dissolve debris before an absorbent pad is used to remove excess material.

Antiparasitic agents are found in many different ear preparations. Active ingredients with antiparasitic actions include ivermectin (0.01%), pyrethrins (0.05–0.15%), rotenone (0.12%), piperonyl butoxide (1.5%), milbemycin oxime (0.1%), and thiabendazole (4%). All products have activity against *Otodectes cynotis*. In addition, ivermectin and milbemycin applied topically would be expected to have some activity against *Demodex* spp. Products with generalized effects such as topical selamectin and moxidectin may also be used to treat ear mites. Finally, excellent results have been reported for orally and topically administered, long-acting, systemic parasiticides of the isoxazoline class for the treatment of *O. cynotis* and demodicosis in dogs and cats.

Antibiotic therapy may initially be based on cytology. However, where rods or mixed infection are seen on cytology or where cocci are identified and the case has not responded to previous therapy, culture and susceptibility should be performed. Antibiotics can be considered as first, second or third line for topical therapy of otitis externa and indeed for otitis media (Table 167.4).

Glucocorticoids are useful in the therapy of otitis externa. They reduce swelling, pruritus, inflammation, and glandular secretions. They can also help to open up the ear canal to allow adequate penetration of topical drugs. They may be given systemically or topically (Table 167.5).

The more potent topical steroids, such as mometasone furoate and hydrocortisone aceponate, produce more marked antiinflammatory effects than dexamethasone or betamethasone, which are both more potent than prednisolone.

Antiyeast drugs are rarely needed systemically. The azole antifungals miconazole, clotrimazole, and posaconazole as well as nystatin are available in a range of licensed veterinary ear drops in the United States and Europe.

Table 167.3 Selection of ear cleaner based on the type of discharge present

Type of discharge	Thick and waxy	Moderately waxy/ purulent	Mildly waxy/ purulent	Mucopurulent/ hemorrhagic
Typical findings	Sterile ceruminous otitis	*Malassezia* otitis	Gram-positive otitis	Gram-negative otitis

The waxier the discharge, the greater the ceruminolytic properties of the ear cleaner to emulsify the wax

The more mucopurulent the discharge, the more aqueous the cleaner to break down mucus and flush the ear

Table 167.4 Topical antibiotic therapy for use in otitis externa and media

Order of use	Drug	Indications	Safety in otitis media
First-line drugs	Framycetin	Gram-positive and many gram-negative bacteria	Unsafe
	Neomycin	Gram-positive and some gram-negative bacteria	Unsafe
	Fusidic acid	Gram-positive bacteria	Unsafe
	Florfenicol	Gram positive bacteria	Unsafe
Second-line drugs	Gentamicin (may be used as first line where neomycin unavailable)	Gram-positive and many gram-negative bacteria	Proprietary veterinary products unsafe; aqueous solutions appear safe at 2.0–4.0 mg/mL
	Polymyxin	Excellent Gram-negative activity	Unsafe
	Enrofloxacin Ciprofloxacin Marbofloxacin Orbifloxacin	Fluoroquinolones have excellent Gram-negative and -positive activity. Their use is best reserved for gram-negative infection	Proprietary veterinary products unsafe; aqueous solution mixed with EDTA-tris appears safe. Enrofloxacin used at 0.5–1.0 mg/mL. Marbofloxacin used at 0.1–0.3 mg/mL
	Silver sulfadiazine	Broad spectrum; excellent activity against *Pseudomonas* spp.	Safety of veterinary product unknown; 1% cream mixed with sterile water diluted 1:10 appears safe
Third-line drugs best reserved for severe gram-negative infection on the basis of culture and sensitivity	Amikacin	Resistant gram-negative bacteria	Ototoxic – off-license use of aqueous solution of 30–50 mg/mL
	Tobramycin	Resistant gram-negative bacteria	Ototoxic – off license use of aqueous solution of 8 mg/mL
	Carboxypenicillins	Resistant gram-positive bacteria	Ototoxic – off-license use of aqueous solution of 10 mg/mL

All aqueous solutions constitute off-license use of these drugs.

All therapeutic protocols should include regular follow-up examinations every 7–14 days. Cytology should be performed at each visit and antimicrobial therapy should be continued until a complete clinical and cytologic resolution of the infection has been achieved. Long-term management should include regular ear cleaning with an appropriate product and therapy of the underlying primary cause.

Table 167.5 Systemic glucocorticoid therapy for use in otitis externa and media

Glucocorticoid	Dosage (mg/kg)	Comments
Prednisolone	1.0–2.0 PO q24h	Should be reduced to an alternate-day regime after two weeks then completely tapered
Methylprednisolone	0.8–1.8 PO q24h	
Triamcinolone acetonide	0.1–1.8 PO q24h	
Dexamethasone	0.1–0.2 IV	Given as a single treatment at the time of ear flush; may be repeated at subsequent rechecks after 7–10 days if other glucocorticoids are not being used

PO, by mouth (*per os*).

Otitis Media

Etiology/Pathophysiology

Otitis media is inflammation of the middle ear and is often bacterial in origin. The organisms most commonly isolated are *Staphylococcus pseudintermedius*, *Pseudomonas* spp., *Escherichia coli*, *Proteus* spp., and *Enterococcus faecalis*. Occasionally, *Malassezia pachydermatis* may be involved. In most cases, infectious otitis media is secondary, resulting from a descending infection as an extension of otitis externa, rather than an ascending infection from the oropharynx or a result of hematogenous infection. Other causes of otitis media include primary secretory otitis media (PSOM) principally recognized in the Cavalier King Charles spaniel, foreign bodies, nasopharyngeal polyps seen most commonly in cats and neoplasms such as squamous cell carcinomas and lymphoma.

Secondary otitis media is caused by the drainage of exudate and infectious organisms into the tympanic bulla from the external ear canal. This causes inflammation to the lining epithelium, the mucoperiosteum, which forms a pseudostratified columnar epithelium containing increased numbers of secretory cells and glands. As a result of ongoing inflammation, granulation tissue forms within the bulla. With more chronic disease, this develops into dense connective tissue and, with time, bone spicules may develop within this dense tissue.

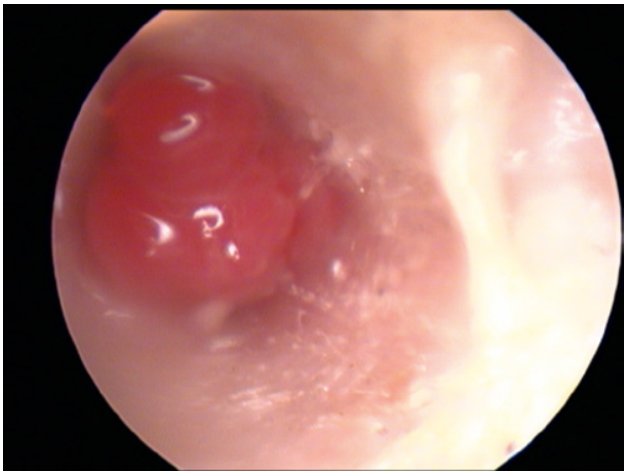

Figure 167.7 Nasopharyngeal polyp in a cat.

Signalment

When otitis media occurs as an extension from otitis externa, it most commonly affects middle-aged or older dogs. Occasionally, younger dogs may be affected. Breeds that are predisposed to otitis externa will also be susceptible to developing otitis media. Nasopharyngeal polyps can be seen in any age of cat, including very young kittens (Figure 167.7).

Primary secretory otitis media can be seen in young to middle-aged Cavalier King Charles spaniels.

History and Clinical Signs

Approximately 50–80% of all dogs with otitis externa of more than six months duration will have otitis media. Owners often report that dogs shake their heads and are reluctant to open their mouths to, for example, carry a ball, yawn, bark or eat hard food. This is generally due to pain in the region of the temporomandibular joint. Owners may complain that their dog's hearing has deteriorated, which may be due to conductive changes in hearing as a result of fluid within the middle ear or cochlear damage if infection has spread to the inner ear. Neurologic signs in the form of ataxia or nystagmus are more suggestive of otitis interna than otitis media. Cranial nerve dysfunction which can be seen with otitis media includes Horner syndrome, especially in cats, facial nerve paralysis and keratoconjunctivitis sicca which can occur due to damage to the parasympathetic innervation of the lacrimal gland.

Diagnosis

The principal steps in diagnosis are otoscopy, myringotomy, and diagnostic imaging. Otoscopy is an insensitive modality for diagnosing otitis media. Where the

Figure 167.8 A swab being passed through a sterile otoscope cone, which guards the swab from discharge and contaminants present in the vertical ear canal during cytologic sampling.

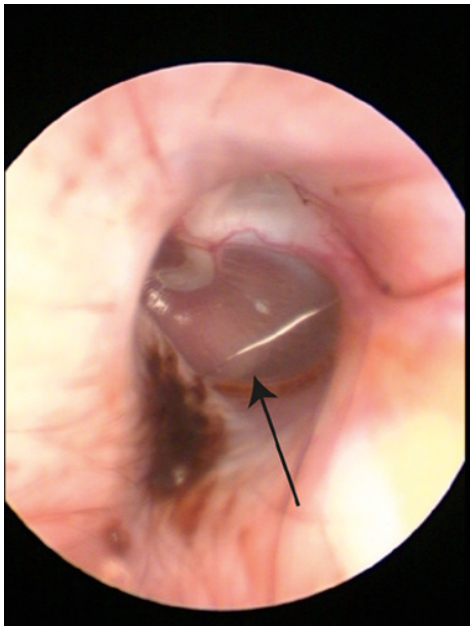

Figure 167.9 Videootoscopic image of a normal tympanic membrane in a dog. Black arrow indicates the recommended site of myringotomy in the caudoventral quadrant of the pars tensa.

tympanic membrane can be visualized and can be seen to be ruptured or intact but abnormal, suggesting previous damage, then a diagnosis of otitis media is possible. If the tympanic membrane is ruptured, samples may be taken from the middle ear. A clean otoscope cone or videootoscope head should be inserted as far into the horizontal canal as possible and a fine catheter or microswab may be inserted through the tube or working channel to "guard" it from discharge in the external canal (Figure 167.8). Material can be gathered onto the swab or suctioned up the catheter to sample the middle ear.

If the tympanic membrane is intact but appears abnormal, it is possible a previous defect in the tympanum has healed in the presence of ongoing otitis media. In these cases, myringotomy should be performed to take samples from the middle ear. Direct visual observation (ideally with a video otoscope) in a carefully cleaned ear canal is important to avoid damage to sensitive structures. The myringotomy should be performed by an experienced clinician using a diode or carbon dioxide (CO_2) laser or manually using a sterile rigid polypropylene catheter cut to an angle of 60°. A small hole made in the pars tensa in the caudoventral quadrant to avoid the pars flaccida and the manubrium of the malleus (Figure 167.9) allows for collection of material from the middle ear, which can be examined cytologically and submitted for culture and sensitivity. Cytology in otitis externa is useful but in otitis media, the presence of mucus from the middle ear can make identification of bacteria difficult. Where cytology reveals signs of an inflammatory infiltrate and infectious organisms, a definitive diagnosis of otitis media can be made. Where cytology is unremarkable, cultures are necessary and are probably best undertaken in all cases.

Advanced imaging is useful in otitis media. Radiography is only diagnostic in chronic disease. The open-mouthed view, which allows for comparison of both sides, and the lateral oblique view provide the most information. Changes on radiography that are consistent with otitis media are increased density of the air-filled bulla, thickening, lysis or irregularity of the tympanic bulla wall, or formation of new bone. Computed tomography (CT) and magnetic resonance imaging (MRI) are more sensitive modalities, picking up subtle changes such as granulation tissue or fluid or mucus within the middle ear.

Therapy

Therapy of otitis media may be divided into several stages:

- flushing the bulla
- infusion of topical medication(s) into the bulla
- reduction of inflammation with glucocorticoids (topical or systemic)
- administration of systemic antibiotics
- reassessment every 7–10 days

Continue therapy until negative cytology and cultures have been achieved and the ear appears clinically normal.

Flushing the bulla is the most important part of treatment. This is best achieved in an anesthetized animal, which should be intubated and the endotracheal cuff fully inflated to avoid the risk of inhalation of any flush solution. An aqueous-based flush helps hydrate the mucous within the bulla and aid removal by suction. Suitable flushes include water, sterile saline, dilute chlorhexidine solution (<0.2%), and EDTA-tris. All have a high degree of middle ear safety. Ceruminolytics are generally not necessary in otitis media due to the nature of the discharge, and only squalene has been shown to be safe in the dog. The cat's middle ear appears to be more sensitive to ototoxic effects and only water, sterile saline, and EDTA-tris are considered safe.

Once the ear has been cleaned, medication can be administered. No medication is licensed for the therapy of otitis media so in each case, a careful assessment should be made of the risks of topical drugs causing signs of ototoxicity versus the benefits in resolving the infection. The safest antibiotics for infusion into the tympanic bulla are aqueous solutions of fluoroquinolones (ciprofloxacin, enrofloxacin, marbofloxacin) and aqueous gentamicin. Other aminoglycosides such as tobramycin and the semisynthetic penicillin ticarcillin have been associated with severe hearing loss when used to treat otitis media. Antifungal drugs that are considered safe are clotrimazole, miconazole, nystatin, and tolnaftate, although the author has seen temporary deafness caused by both clotrimazole and miconazole that resolved when topical medication was withdrawn. Drugs that are infused directly into the bulla are thought to stay trapped within this structure for several days, providing high local levels of the drug.

Therapy with glucocorticoids is important to reduce the inflammation and exudation in middle ear disease and to help reduce the formation of granulation tissue. Many different protocols are available for therapy. The author's preference is to administer intravenous dexamethasone (2 mg/mL) at a dose of 0.1–0.2 mg/kg at the time of the ear flush and then follow with antiinflammatory doses of prednisolone at 1–2 mg/kg daily PO for two weeks. Alternative systemic glucocorticoids are listed in Table 167.5. Aqueous dexamethasone, fluocinolone, and a commercial product containing dimethyl sulfoxide (DMSO) and fluocinolone (Synotic®, Fort Dodge Animal Health) are recognized as having low ototoxic potential and can be infused by catheter into the bulla after flushing.

The use of systemic antibiotics in otitis media is a subject of debate. The levels of systemic antibiotics achieved in the tympanic bulla can never approach the levels achieved by topically administered drugs. However, where topical therapy cannot reach the middle ear due to, for example, stenosis of the external ear canal or where the ear is so severely ulcerated or painful that the dog will not tolerate topical therapy, then systemic medication may be the only option. All oral drugs should be prescribed on the basis of culture and susceptibility. Oral fluoroquinolones are the most appropriate first-line drugs in otitis media; aminoglycosides and ticarcillin-clavulanic acid may be used systemically but only where all other drug options have been explored. Drug doses are found in Table 167.6.

Follow-up appointments are important in otitis media and should be undertaken every 7–10 days. If necessary, the dog should be readmitted to permit further flushing of the tympanic bulla under anesthesia. Topical and systemic therapy may be adjusted on the basis of culture and sensitivity results. Antiinflammatory therapy may be reduced as the disease improves. The author will generally reduce prednisolone to an alternate-day dosage after two weeks and then taper, aiming to withdraw it after a further two weeks. Therapy should be continued until the ear appears clinically, cytologically, and culturally normal. Maintenance therapy should include regular ear cleaning and maintenance of any underlying causes.

Table 167.6 Systemic antibiotic therapy for use in otitis media

Drug	Dosage (mg/kg)	Comments
Difloxacin	5.0–10.0 PO q24h	Higher dose rates constitute off-license usage
Enrofloxacin	5.0–20.0* PO q24h	
Marbofloxacin	2.0–5.0 PO q24h	
Orbifloxacin	5.0–12.5 PO q24h	
Gentamicin	6.0–8.0 SC q24h	Renal function must be assessed (urine analysis and blood samples) before starting and during aminoglycoside therapy
Amikacin	15.0–20.0 SC q24h	
Ticarcillin-clavulanic acid	15.0–25.0 IV q8h	Use can be justified only under exceptional circumstances

* Doses higher than 5.0 mg/kg in cats can cause retinal damage which can lead to blindness.
IV, intravenous; PO, by mouth (*per os*); SC, subcutaneous.

Cutaneous Manifestations of Systemic Disease

Kinga Gortel, DVM, MS, DACVD

Tri Lake Animal Hospital and Referral Centre, Lake Country, BC, Canada

The skin can manifest myriad changes associated with systemic diseases. Some, such as the cutaneous manifestations of hyperadrenocorticism, are so well recognized and characteristic that they provide obvious clues about the underlying etiology. Others are more subtle or rare. In addition to the diseases described in this chapter, the skin can directly exhibit symptoms of bleeding disorders (petechiae, ecchymoses, bruising), icterus, dehydration, and cachexia. Changes in the skin can be a direct result of a multisystemic disorder (e.g., vasculitis affecting multiple organs) or result from disease occurring in another organ (e.g., superficial necrolytic dermatitis associated with liver disease). The skin is an easier site to sample compared to other organs, and skin biopsies (or in some cases cytologic examination or cultures) can be essential to facilitating the diagnosis of the underlying disease.

Although internal diseases are relatively uncommon as a cause of skin disorders, their likelihood increases when certain findings are present. Internal disease is more likely in patients exhibiting unexpected changes in weight, activity level, appetite, thirst, or urine production, and these signs should be investigated as part of the history collection. Patients presenting with skin disease for the first time at an advanced age without a readily identifiable cause also warrant further work-up for internal disease.

Hormonal and Metabolic Disorders Causing Cutaneous Manifestations

Canine and Feline Hypercortisolism

Hypercortisolism (i.e., Cushing disease, Cushing syndrome) is common in dogs and causes both nonspecific and fairly distinct dermatologic changes. The signs are similar whether endogenous or exogenous glucocorticoids are the cause. The most common but nonspecific change occurs in the hair coat, with a lack of luster and density, slower growth, and often a lightening of the color. Hair is progressively lost, resulting in alopecia that spares the head and distal extremities and predominantly affects the trunk, typically in a symmetric pattern. More specific signs include thinning skin and resultant prominent blood vessels, as well as comedones, milia, and calcinosis cutis. Easy bruising, seborrhea, slow wound healing, and striae are also seen. Generalized demodicosis can occur, and iatrogenic or spontaneous hypercortisolism is an important consideration in adult-onset disease. Lesions of superficial bacterial pyoderma are commonly seen in dogs with hypercortisolism.

Naturally occurring and iatrogenic hypercortisolism are rare in cats. Cutaneous signs include alopecia and thin skin. Skin fragility, described below, occurs in over 50% of cases, and may be more common in cats with adrenal neoplasia. A unique finding reported only in iatrogenic hypercortisolism is medial curling of the pinnae.

Calcinosis Cutis

Calcinosis cutis refers to the various forms of calcification of the skin. It most commonly occurs in association with iatrogenic or spontaneous hypercortisolism in dogs. It appears to be more common in large-breed dogs. It is more rarely seen with systemic fungal infections such as blastomycosis, with diabetes mellitus, and with various other diseases. Rarely, calcinosis cutis affecting multiple footpads or the interdigital skin has been seen in dogs and cats in association with chronic renal disease (Figure 168.1). This site is not typically affected in dogs with hypercortisolism, so renal failure should be considered in a patient with calcinosis affecting multiple feet.

Figure 168.1 Calcinosis cutis affecting multiple feet in a young cat with chronic renal disease.

Figure 168.2 Calcinosis cutis. Firm, coalescing erythematous papules on the lateral thorax of a mature bulldog with iatrogenic hypercortisolism.

Calcinosis cutis often starts as erythematous papules that coalesce into very characteristically firm plaques (Figure 168.2). The lesions can ulcerate and become pruritic. The axilla, groin, and dorsal trunk are commonly affected. The diagnosis is made on the basis of characteristic clinical features and histopathology, and investigation for the underlying cause is warranted in all cases.

The treatment of calcinosis cutis relies on identification and removal of the underlying metabolic problem and if this can be achieved, it is associated with a good prognosis. Correction of hypercortisolism usually allows calcinosis cutis to resolve within several months, but some lesions can undergo osseous metaplasia and persist indefinitely.

Figure 168.3 Feline acquired skin fragility in a geriatric cat. Extensive tearing of the very thin skin following minor trauma.

Feline Skin Fragility Syndrome

Feline acquired skin fragility syndrome is a rare condition characterized by extremely thin skin that tears and bruises easily (Figure 168.3). It is associated with spontaneous or iatrogenic hypercortisolism and seems to be more common with adrenal tumors. It can also result from excessive levels of progestational compounds, either administered therapeutically or secreted from adrenal tumors. The syndrome has also been reported in association with diabetes, cholangiohepatitis, hepatic lipidosis, neoplasia (e.g., pancreatic and intestinal carcinoma), and other diseases.

Cats with acquired skin fragility syndrome may present for spontaneous skin tears following minimal handling or trauma. They have extremely fragile, thin skin that tears very easily during restraint. The skin is not hyperextensible and bleeds minimally upon tearing. The diagnosis is usually made by the very characteristic clinical findings, although histopathology is confirmatory. Affected cats have a poor prognosis.

Canine Hypothyroidism

Hypothyroidism is a common endocrine disorder of dogs. Dermatologic changes occur in 60–80% of cases, but can be subtle. Cutaneous signs of hypothyroidism include progressive alopecia in areas of wear, including the dorsal and distal tail ("rat tail" appearance), ventral and lateral trunk, the upper limbs (typically caudal thighs), and often the dorsal aspect of the muzzle. The pattern of alopecia is somewhat different from the classic bilaterally symmetric alopecia sparing the head in hypercortisolism. Some hypothyroid dogs maintain a

normal hair coat. The loss of guard hairs, leaving behind the finer undercoat, can lead to the appearance of a "puppy coat." The hair coat can also lighten due to longer retention of hair and subsequent bleaching. Recurrent pyoderma and otitis externa are common. Pruritus is not a feature of hypothyroidism but can be seen if secondary pyoderma, *Malassezia* dermatitis, or otitis externa are present. Advanced cases can present with thick, puffy skin (myxedema) due to accumulation of dermal glycosaminoglycans. This is a rare manifestation as most hypothyroid dogs are diagnosed and treated before progressing to this stage.

The diagnosis of hypothyroidism relies on history, examination findings, complete blood count and serum biochemistry findings, thyroid hormone (total T4 and free T4) and thyrotropin (TSH) measurements, and occasionally skin biopsies. The total T4 is often assayed in dogs with dermatologic disease. Because it is lowered by multiple nonthyroidal factors (e.g., drugs and severe nonthyroidal illness), it is easy to mistakenly diagnose hypothyroidism using this measurement alone. Confirmatory testing should be performed before initiating treatment. Although a response to thyroid supplementation is sometimes used as a diagnostic tool, treatment with thyroxine can result in temporary improvement of many dermatologic conditions by stimulating hair growth. This can lead to false confirmation of an incorrect diagnosis of hypothyroidism.

Treatment of hypothyroidism is usually very rewarding and most of the cutaneous abnormalities can be corrected. However, during the initial few weeks of therapy, there can be increased scaling as well as profound hair loss as telogen hairs are replaced due to a coordinated initiation of the new hair cycle.

Sex Hormone Dermatoses

These uncommon dermatoses can be associated with gonadal and adrenal disorders. They most often present with truncal alopecia. Hyperestrogenism can occur in intact male dogs with functional testicular tumors (see section on Neoplastic and Paraneoplastic Disorders Affecting the Skin at the end of this chapter), or in intact female dogs with cystic ovaries or, more rarely, with functional ovarian tumors.

Hyperandrogenism in male dogs is rare. It can be idiopathic or associated with testicular neoplasia. In the idiopathic form, young dogs exhibit hypersexual behavior and sometimes aggression, as well as seborrhea oleosa and truncal hair loss. Hyperandrogenism due to testicular neoplasia results in hyperplasia of the circumanal glands and the tail gland, which appear thickened and universally enlarged. Macular hyperpigmentation can also be seen. The diagnosis of these conditions can be made with endocrine testing and ultrasonography.

Superficial Necrolytic Dermatitis

Superficial necrolytic dermatitis, sometimes called hepatocutaneous syndrome, is most often seen in dogs with a characteristic idiopathic hepatopathy. It can also be seen with anticonvulsant medications and pancreatic tumors. Superficial necrolytic dermatitis has been rarely reported in cats. This condition is described in detail in Chapter 169.

Xanthomas

Xanthomas are rare granulomatous skin lesions that occur in association with an abnormality in lipid metabolism. Most have been associated with diabetes mellitus or with the feeding of high-fat foods. An underlying hereditary defect of lipid metabolism has also been reported. The lesions occur most commonly on the head (particularly the preauricular area or ears), distal limbs, and bony prominences, and consist of small white or yellow papules, nodules, or plaques. Histopathology is needed to make the diagnosis.

The treatment of xanthomas relies on the correction of the underlying metabolic problem and if this can be accomplished, the prognosis is favorable. Xanthomas in cats with idiopathic hypertriglyceridemia can undergo regression with a low-fat diet.

Amyloidosis

Amyloidosis refers to a diverse group of diseases featuring the extracellular deposition of protein fibrils with characteristic staining properties (amyloid). In dogs and cats, most cases of amyloidosis show systemic involvement, affecting the kidneys and less commonly other organs. Skin lesions are seen in some patients. Amyloidosis can also be limited to the skin. In this form, dermal or subcutaneous nodules can be seen anywhere, but most commonly on the ear. Purpuric macules have also been reported. The diagnosis is made by histopathology. Solitary nodules can be excised but no effective treatment is reported for more widespread lesions.

Other hormonal disorders that can sometimes cause cutaneous manifestations include the most common endocrine diseases of the cat. Diabetic cats sometimes develop seborrheic skin disease, thin skin, and alopecia. Hyperthyroid cats can exhibit an increased rate of claw growth, excessive shedding and matting, alopecia due to excessive grooming, and occasionally other changes.

Although pruritus is a well-documented complication of hepatobiliary disease in humans, it is not typically

recognized in companion animals. One case report described pruritus in a puppy with a portosystemic shunt whose pruritus resolved upon correction of the vascular abnormality.

Systemic Infectious Disease Causing Cutaneous Manifestations

Feline Herpesviral Dermatitis

Feline herpesvirus-1 (FHV-1) can cause a characteristic facial dermatitis in cats. The condition is most common in adult cats, and not all cases exhibit the ocular or respiratory signs typical of this viral infection. There can be a recent history of an upper respiratory tract infection in the weeks preceding development of the lesions in some cats. The lesions consist of inflamed and often ulcerated areas near the nares. They most often affect the nasal planum, dorsal aspect of the muzzle, and periocular skin (Figures 168.4 and 168.5). The lesions do not appear pruritic even though eosinophils typically predominate. The clinical appearance and eosinophilic inflammation can lead to an inappropriate diagnosis of an eosinophilic plaque or mosquito bite hypersensitivity, with inappropriate treatment using corticosteroids, which can lead to marked worsening of the disease.

The diagnosis of feline herpesviral dermatitis is made by the fairly striking clinical appearance of the facial form, histopathology, and either immunohistochemistry or polymerase chain reaction (PCR) testing for FHV-1 on biopsy samples. Viral inclusion bodies are difficult to find on histopathology, so this condition should be considered in biopsies consistent with eosinophilic plaques located on the face.

Figure 168.4 Feline herpesviral dermatitis and rhinitis in an adult cat. Small crusts and a loss of the cobblestone architecture of the nasal planum are seen.

Treatment of FHV-1 infection with oral famciclovir is effective for cutaneous, ocular, and respiratory symptoms. It can be more effective than other therapeutic strategies. The drug appears to be well tolerated in cats but there is some uncertainty about the dose and duration of treatment, with recent recommendations reflecting higher doses than had been used previously. In some cats, the skin lesions can become recurrent or chronic.

Feline Leukemia Virus and Feline Immunodeficiency Virus Infection

Feline leukemia virus (FeLV) usually causes skin lesions by its immunosuppressive actions, although it can also induce skin tumors. The cutaneous symptoms are quite nonspecific. Affected cats are susceptible to a number of secondary infections including recurrent abscesses, pyoderma, dermatophytosis, demodicosis, and paronychia. Multiple cutaneous horns of the footpads are sometimes seen in cats infected with FeLV. Giant cell dermatosis is a histologically unique and rare manifestation causing pruritus and crusting of the face and often other areas of skin. Although feline immunodeficiency virus (FIV) is more commonly associated with recurrent or chronic oral disease, some cats also exhibit skin infections. The signs of these two immunosuppressive viral diseases are very similar. The diagnosis is made by serologic testing.

Canine Distemper

Canine distemper virus infection in dogs can be manifested by a combination of respiratory, ocular, gastrointestinal, neurologic, and cutaneous signs that

Figure 168.5 Feline herpesviral dermatitis in an adult cat. Extensive unilateral eosinophil-rich ulceration is present on the face.

appear simultaneously or sequentially. The classic but uncommon cutaneous manifestation of canine distemper is "hard pad disease" – footpad and nasal hyperkeratosis. The footpads are thickened, fissured, and unusually hard. The centers of the footpads can feel surprisingly hard even when they appear minimally affected. Widespread impetigo can also be seen in puppies. The diagnosis is often made on the basis of clinical signs in a dog with an inadequate vaccination history. Histopathology and immunohistochemistry on affected skin can also be useful to confirm the diagnosis.

Systemic Mycoses

Cutaneous lesions consisting of papules, nodules, ulcers, abscesses, and draining tracts are seen in many systemic mycoses. They are seen most commonly in blastomycosis (20–50% of cases) and feline cryptococcosis (40%), and result from hematogenous spread of the fungus to the skin. Sporotrichosis is generally transmitted by cutaneous inoculation of fungal spores, in most cases resulting in cutaneous or cutaneous lymphatic signs. However, cats with sporotrichosis have a high frequency of upper respiratory and lung lesions, suggesting that the inhalatory mode of infection also plays a role in this species, and the hematogenous route is important in the cutaneous dissemination of the disease.

Nasal mycotic rhinitis in dogs (most commonly aspergillosis) is usually associated with profuse mucopurulent nasal discharge and can cause crusting and ulceration of the nasal planum (Figure 168.6). Depigmentation of the nasal planum ventral to the nares is a characteristic finding.

Figure 168.6 Mild nasal mycotic rhinitis in a mature dog with nasal aspergillosis.

The ideal diagnostic method for systemic or localized mycoses is identification of the fungal organism by cytologic and histopathologic examination of affected tissues. Serology is useful as a noninvasive diagnostic test for cryptococcosis and can also be used to monitor response to therapy. A sensitive urine or serum antigen test is currently available for the diagnosis of blastomycosis when organisms are not found on cytology or histopathology. Sampling of the affected tissue for a definitive mycotic rhinitis typically requires rhinoscopy.

Leishmaniasis

Leishmania organisms are protozoa of several species that cause a spectrum of clinical disease in dogs and other mammals, including cats. Leishmaniasis varies in its clinical presentation from focal to generalized cutaneous disease to disseminated internal disease. The severity varies from asymptomatic to fatal. *Leishmania* protozoa are usually vector borne by sandflies, but vertical transmission and direct horizontal transmission are likely important in certain populations of dogs. Leishmaniasis has a worldwide distribution but is endemic in parts of Europe (most commonly in the Mediterranean basin) and South and Central America. It was considered to be of minimal importance in North America until the early 2000s, when *Leishmania* was found in multiple foxhound kennels.

Leishmaniasis in dogs most frequently combines cutaneous and internal disease. The most common sign is a nonpruritic exfoliative dermatitis with alopecia that is generalized but most pronounced on the head (Figure 168.7). A characteristic feature is adherent silvery-white scale. Mucocutaneous ulcerations, alopecia, and erythema can also be seen. Less commonly, nodular skin disease is present.

The diagnosis of leishmaniasis can be made by cytology (from skin, lymph nodes, bone marrow aspirates), histopathology, PCR testing of blood and other tissues, and antibody serology testing.

Lagenidiosis

Lagenidiosis is a rare disease caused by a fungus-like, aquatic, "water mold" oomycete of the genus *Lagenidia*. It occurs most often in dogs living in the southeastern United States and has been reported in cats. The disease is sometimes limited to the skin and local lymph nodes, but often also causes lesions at distant sites, including the great blood vessels, respiratory tract, and mediastinum. The systemic form is universally fatal. The diagnosis is made by histopathology, which is similar to histopathology from tissues originating from dogs with pythiosis or

Figure 168.7 Two-year-old boxer with visceral leishmaniasis caused by *Leishmania chagasi*. The skin lesions are generalized and characterized by erythema and thick scales adhered to the skin surface and hair shafts. *Source:* Courtesy of Dr Romeika Reis Lima.

zygomycosis. More specific tests include serology for anti-*Lagenidium* antibodies, culture, and PCR testing.

The prognosis for dogs with systemic lagenidiosis is grave. For dogs with only cutaneous lesions, aggressive resection can be curative and amputation can be considered for those with distal limb lesions affecting one leg. Radiography of the thorax and ultrasonography of the abdomen is recommended prior to surgery because of the frequency of systemic dissemination. Medical therapy with antifungal drugs is typically ineffective alone but has been described as an adjunct to surgical resection.

Many other infectious diseases can present with cutaneous manifestations. This list includes canine herpesvirus infection, pseudorabies, feline infectious peritonitis, feline calicivirus infection, toxoplasmosis, neosporosis, brucellosis, pythiosis, entomophthoromycosis, and rickettsial and ehrlichial infections in dogs.

Nutritional Disorders Causing Cutaneous Manifestations

Zinc-Responsive Dermatosis

Zinc-responsive dermatosis is an uncommon skin disease in dogs. It includes syndromes caused by nutrient deficiency, nutrient imbalances, and the inability to absorb or utilize zinc. Absolute nutritional zinc deficiency is unlikely in a patient eating a well-balanced diet. Relative deficiencies can be seen in dogs when zinc absorption is impaired by excessive amounts of other nutrients.

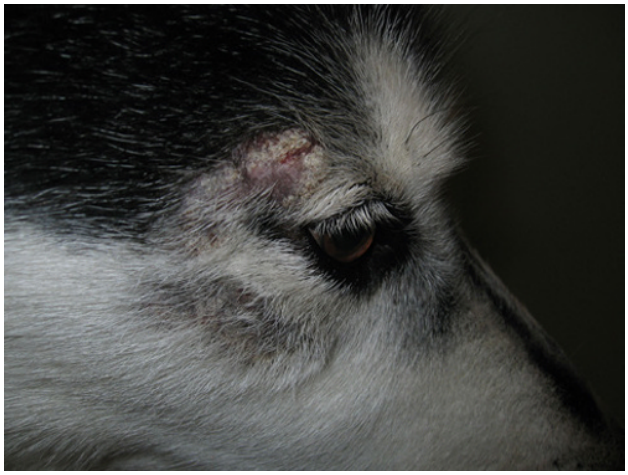

Figure 168.8 Zinc-responsive dermatosis (syndrome I) in an adult Siberian husky. Crusting, erythema, alopecia, and hyperpigmentation of the periocular skin are present.

Syndrome I zinc-responsive dermatosis occurs in dogs eating a well-balanced diet and has been reported most commonly in Siberian huskies and Alaskan malamutes. A more severe form has been reported in a litter of pharaoh hounds. Skin lesions usually begin in early adulthood and consist of early erythema followed by crusting, scaling, lichenification, and alopecia. The distribution is typically around the mouth, chin, eyes, and ears (Figure 168.8). An inability to absorb zinc from the gastrointestinal tract has been shown in some malamutes.

Syndrome II zinc-responsive dermatosis has been reported predominantly in large-breed puppies or young adult dogs eating diets deficient in zinc or diets that interfere with zinc absorption (e.g., excessively high in calcium, other minerals and vitamins, or phytates). Dogs with this syndrome have extensive crusting and fissuring of the footpads and nasal planum, and generalized crusting plaques. Very similar but more severe clinical signs have been seen in generic dog food dermatosis, which was seen in North American in the 1980s but was virtually eliminated with the reformulation of these foods. In this syndrome, a deficiency of multiple nutrients is likely and more severe systemic signs are present.

The diagnosis of zinc-responsive dermatoses is made by clinical signs, dietary history, and histopathologic findings.

The treatment of syndrome I zinc-responsive dermatosis consists of oral zinc supplementation. Most cases respond well within 4–6 weeks, but require ongoing

treatment to maintain remission. Zinc methionine is a commonly used veterinary preparation. The dose of elemental zinc is 2–3 mg/kg per day. The addition of low-dose corticosteroids has also been reported to benefit patients not responding adequately to zinc supplementation. The intravenous administration of zinc sulfate has been described in patients with a poor response. Young dogs with syndrome II zinc-responsive dermatosis show a dramatic response to zinc and dietary correction, but do not require lifelong supplementation.

Feline Pansteatitis

This rare condition has been reported in cats eating diets high in polyunsaturated fatty acids (PUFAs) such as red tuna, without adequate vitamin E consumption. PUFAs increase oxidative stress through free radical production. Affected cats show inflammation and necrosis of subcutaneous and intraabdominal fat resulting in firm, painful nodules. They are often lethargic, anorexic, febrile, and painful with movement and palpation.

The diagnosis is made by histopathology coupled with a suggestive dietary history. Vitamin E supplementation and a dietary change can be used, but the prognosis for severe cases is poor.

Immune-Mediated Systemic Diseases Causing Cutaneous Manifestations

Panniculitis

Panniculitis in dogs and cats can be due to myriad etiologic factors, such as infectious agents, drug reactions, and immune-mediated diseases (systemic lupus erythematosus, polyarthritis, or others). Patients with panniculitis should be evaluated for pancreatic disease, as panniculitis has been associated with pancreatitis and pancreatic tumors. The reader is referred to Chapter 164 for a more detailed discussion of panniculitis.

Systemic Lupus Erythematosus (SLE)

This multisystem autoimmune disease shows highly variable signs affecting various organs. It is rare in dogs and very rare in cats. Circulating autoantibodies directed against a wide variety of tissue antigens are present. The estimated frequency of skin lesions is 20–50% of affected dogs and cats. The lesions can consist of mild alopecic scarring, scaling, and crusting, to widespread ulcers involving the skin and oral mucosa. Lesions of the nasal planum more typically seen with discoid lupus erythematosus may be present. Some patients exhibit lesions in hairless areas exposed to light. In addition to skin disease, other manifestations include polyarthritis, hematologic changes, protein-losing nephropathy, and other signs. German shepherd dogs are predisposed to SLE.

The diagnosis of SLE can be difficult. Criteria for the diagnosis of canine SLE include the presence of a positive antinuclear antibody (ANA) titer as well as a number of other clinical and laboratory findings. The reader is referred to other sections within this book for a more thorough discussion of these criteria. Skin biopsies can be helpful but although the classic changes of SLE are quite suggestive, the histopathologic findings in SLE are variable. Direct immunofluorescence or immunohistochemistry can be used to demonstrate immunoglobulin and complement at the dermoepidermal junction.

The prognosis for dogs with SLE is guarded, but some patients can be controlled effectively for years. The disease is highly variable in its severity, which can also wax and wane. Corticosteroids are used most often, frequently with the addition of steroid-sparing agents.

Vascular Diseases

A variety of diseases affecting the cutaneous blood vessels can result in skin lesions. Vasculitis refers to vascular diseases in which blood vessels appear to be the target of an inflammatory response. Although many cases are idiopathic, vasculitis can be initiated by myriad factors including drugs, rabies vaccination, infectious diseases, and food allergy. Thus, the term *vasculitis* describes a cutaneous reaction pattern rather than an etiologic diagnosis.

Lesions are often found on the pinnal apex. The footpads are also commonly affected with central or marginal ulcers. More widespread lesions can also be seen, consisting of purpura, erythematous plaques, hemorrhagic bullae, and ulcers. The skin is often the only organ affected but in some cases, other organs are concurrently affected. For example, cutaneous and renal vasculopathy of greyhounds is associated with renal disease.

Canine Uveodermatologic Syndrome

This rare syndrome consists of granulomatous uveitis and concurrent depigmenting dermatitis. A genetic basis is present, with akita dogs reported most frequently. The uveitis is usually bilateral and acute in onset, with the skin lesions occurring later in most cases. Depigmentation is seen on the skin of the nasal planum, lips, eyelids, and occasionally elsewhere. The diagnosis can be made tentatively based on the unique combination of clinical signs, and definitely using skin biopsies.

Other systemic diseases with an immune-mediated etiology that cause cutaneous lesions include erythema

multiforme, toxic epidermal necrolysis, cryoglobulinemia and cryofibrinogenemia, graft-versus-host disease, acute eosinophilic dermatitis (Wells-like syndrome), acute neutrophilic dermatitis (Sweet-like syndrome), familial canine dermatomyositis, and hypereosinophilic syndrome.

Neurologic Disorders Causing Cutaneous Manifestations

Canine Chiari-Like Malformation

Canine Chiari-like malformation has been reported most frequently in young Cavalier King Charles spaniels. It can be found in other breeds, and brachycephalic small-breed dogs are predisposed to the condition. Chiari-like malformation is a developmental abnormality leading to hypoplasia of the occipital bone and thus a reduced volume of the caudal fossa, the part of the skull that accommodates the cerebellum and brainstem. The cerebellum variably herniates through the foramen magnum, crowding the spinal cord and altering the flow of cerebral spinal fluid in that region with resultant syrinx formation. It is easily mistaken for a dermatologic condition, as it often causes persistent unilateral or bilateral scratching at the cervical and shoulder regions. A characteristic feature is that some dogs do not actually make contact with the skin when exhibiting the scratching. The presence of pruritus in this area, particularly if it is unilateral and not accompanied by skin lesions, should increase the suspicion of canine Chiari-like malformation. Neck pain is a common feature and is found in most affected dogs on physical examination.

The diagnosis can be made by the very characteristic clinical signs in a predisposed breed, but definitive diagnosis requires magnetic resonance imaging (MRI). The reader is referred to the neurology section for a more comprehensive discussion of Chiari-like malformation.

Sensory Neuropathies

Both inherited and acquired sensory neuropathies can result in cutaneous manifestations. A sensory neuropathy of English pointers, German short-haired pointers, English springer spaniels, and French spaniels results in severe paw licking and chewing progressing to further mutilation of the limbs and autoamputation. This condition has also been reported in one miniature pinscher. Canine ganglioradiculitis is an inflammatory disease of the cranial and spinal ganglia and nerve roots. Affected dogs develop sensory deficits and mutilation/hyperesthesia. Cauda equina syndrome can cause lumbosacral hyperesthesia, pruritus, and/or self-inflicted lesions of the hindlimb(s).

Neoplastic and Paraneoplastic Disorders Affecting the Skin

Male Feminizing Syndrome Secondary to Testicular Neoplasia

Dermatologic manifestations of canine testicular tumors are rarely encountered in parts of the world where neutering is common. Male feminization occurs most often with Sertoli cell tumors, affecting 24–57% of dogs with these tumors. Cryptorchid testes are at greatly increased risk for development of neoplasia. The syndrome is thought to be related to estrogen secretion from the tumor, but other factors may play a role as elevated estrogen levels are not always found. Bilaterally symmetric alopecia beginning in the perineal, inguinal, and flank regions is most common in affected dogs. Seborrhea, comedones, and hyperpigmentation of the skin, particularly in the inguinal and perianal areas, can also be seen in more advanced cases. Gynecomastia, nipple enlargement, and a pendulous prepuce can be present. A characteristic clinical feature is linear preputial dermatosis: a line of erythema with variable hyperpigmentation or comedones extending from the opening of the prepuce along its ventral aspect to the scrotum. Affected male dogs may attract other male dogs.

The tumor may be palpable in the affected testicle, and the nonneoplastic testicle can atrophy. However, testicular palpation is not universally abnormal and is not possible in cryptorchid dogs. Affected dogs can also exhibit myelosuppression. Approximately 20% of these tumors are malignant and roughly 10% will metastasize to the lungs and abdominal lymph nodes.

Although skin histopathology, estrogen levels (particularly estradiol-17-beta), ultrasonography and sometimes general bloodwork can be suggestive, the constellation of characteristic clinical signs, histologic confirmation of testicular neoplasia, and response to castration are diagnostic for the syndrome.

Feline Paraneoplastic Exfoliative Dermatitis

Feline exfoliative dermatitis is a paraneoplastic syndrome seen in old and middle-aged cats with thymomas. Skin lesions usually precede systemic signs such as dyspnea and weight loss. Affected cats show generalized erythema and severe scaling, often beginning on the head and neck but progressing to widespread lesions. The scales can become quite large, sometimes in excess of 1 cm in diameter. Alopecia is a common finding. Some patients also exhibit crusting, and brown keratosebaceous material can be present around the eyes and mouth, in the ear canals, and in the interdigital spaces. Pruritus is absent to mild unless secondary infections are

present. Secondary *Malassezia* dermatitis and bacterial overgrowth can occur.

The pathogenesis of the cutaneous syndrome is not well understood, but is thought to be a cell-mediated immunologic reaction secondary to the underlying thymoma. A mediastinal mass can be detected in most patients by radiography or ultrasonography and fine needle aspirates can be diagnostic. Surgical removal of the thymoma induces regression of the skin lesions. Median overall survival time after surgery in one small study was 1825 days, with a three-year chance of survival of 74%.

Feline Paraneoplastic Alopecia

Feline paraneoplastic alopecia is a highly visually distinct, bilaterally symmetric progressive alopecia in which the skin appears unusually thin and shiny (Figure 168.9).

The majority of affected patients are older cats with pancreatic carcinoma, but the condition has also been reported with biliary carcinoma. The pathogenesis of the cutaneous lesions is poorly understood but is thought to be induced by the cytokine milieu released by the tumor. The alopecia typically begins on the ventral abdomen and thorax, with progression to the head and medial extremities. The hair epilates easily, revealing smooth, shiny, glistening skin that is not fragile. Some affected cats have scaly or fissured footpads that can be painful. The condition is not always pruritic but affected cats may groom excessively, especially if the skin disease is complicated by secondary *Malassezia* dermatitis. The onset is typically quite acute and rapidly progressive. Affected cats are systemically ill and exhibit weight loss.

The clinical appearance is visually striking and distinctive. Histopathology confirms the diagnosis. Routine hematology and serum biochemical profiles are typically not helpful. Ultrasonography can be useful in finding the underlying neoplasm, but often fails to reveal a mass. Unfortunately, this disease carries a poor to grave prognosis as many tumors are not resectable and metastasis is common.

Figure 168.9 Feline paraneoplastic alopecia in an adult cat with pancreatic carcinoma. *Source:* Courtesy of Dr Edward Clark.

Nodular Dermatofibrosis

Nodular dermatofibrosis is a syndrome of multiple cutaneous nodules of collagenous origin occurring in conjunction with renal cystadenocarcinomas or cystadenomas in dogs. This syndrome most commonly occurs in German shepherd dogs and their crosses, and the renal disease is almost always bilateral. The disease is typically diagnosed in middle age. In addition to the renal tumors, intact females can develop uterine leiomyomas. In the German shepherd dog, an autosomal dominant mode of inheritance is suspected. Molecular studies have suggested that nodular dermatofibrosis is not a paraneoplastic syndrome but a genetic disease linked to a mutation in the gene encoding folliculin. It is analogous to Birt–Hogg–Dubé syndrome in humans. Rarely, nodular dermatofibrosis has been found in other breeds in the absence of internal tumors.

Nodules are typically most numerous on the head and limbs, including the feet, but can occur on other areas of the skin, generally in a symmetric fashion. They are firm, localized in the dermis or subcutaneous layer, mobile, and covered by intact epidermis that can sometimes ulcerate, causing lameness. The nodules range in size but can be up to 5 cm in some cases. The disease has a protracted clinical course, with the appearance of renal failure or metastasis occurring months or more often years from the time that the lesions are first noticed. The mean time from first observation of nodular dermatofibrosis to death is about 2.5 years.

The diagnosis of nodular dermatofibrosis is generally made by histopathology of the skin masses combined with abdominal ultrasonography. When skin biopsies are collected, the presence of multiple lesions and the suspicion of this condition should be conveyed to the pathologist.

There are currently no reported effective treatment options and because bilateral renal disease is virtually always present, surgery is not an option. The cutaneous nodules should be monitored and excised if they become ulcerated or infected leading to patient discomfort or if they disturb patient mobility due to their size or location. It is important to relay the fairly slow progression of the disease to owners of affected dogs.

Feline "Lung-Digit" Syndrome

Feline "lung-digit syndrome" describes an unusual pattern of metastasis that is seen with various types of

primary lung tumors, particularly bronchial and bronchoalveolar adenocarcinoma. This syndrome warrants mention because affected cats are most often presented for their skin disease rather than for pulmonary disease. Multiple digits on multiple feet are commonly involved. The most commonly recognized clinical signs on presentation include swelling of the distal digits, ulceration of the skin of the digit or nailfold, purulent discharge, as well as constant extrusion, deviation, or loss of the nail.

The diagnosis is made by radiography of the digits, which reveals osteolysis of the third phalanx, by thoracic radiography, and by digital biopsy. Clinical signs and radiography can provide a high index of suspicion for "lung-digit" syndrome. The prognosis for affected cats is grave, with a median survival time of 67 days after presentation in one study.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a very rare blistering disease involving the skin, mucocutaneous junctions, and mucosal surfaces. It has been reported in two dogs, one in association with thymic lymphoma and one with splenic spindle cell sarcoma. Only one case has been reported in a cat, in association with lymphocytic thymoma. Autoantibodies develop as a result of the neoplastic process which targets epithelial adhesion molecules, mainly of the plakin family, leading to loss of cellular cohesion.

Clinically, the disease is severe and very similar to pemphigus vulgaris in which vesicobullous and erosive to ulcerative lesions predominate in the skin and mucosal surfaces. Histologically, it bears some of the same features of pemphigus vulgaris but also features of erythema multiforme and the diagnosis is made on the basis of skin biopsies and investigation for underlying neoplasia.

Other cancers are sometimes associated with skin lesions. Superficial necrolytic dermatitis, although most commonly associated with liver disease, has also been found in dogs with pancreatic glucagonoma, in a cat with a pancreatic tumor, and recently in a cat with primary hepatic neuroendocrine carcinoma. One of the underlying causes for generalized adult-onset demodicosis is neoplasia, particularly indolent lymphoma.

Superficial Necrolytic Dermatitis

Mitchell D. Song, DVM, DACVD

VETMED Specialty Referral and 24-Hour Emergency Care Veterinary Hospital, Phoenix, AZ, USA

Etiology/Pathophysiology

Superficial necrolytic dermatitis (SND), also known as hepatocutaneous syndrome and metabolic epidermal necrosis, is an uncommon, generally fatal, crusting and scaling skin disease, which is similar to necrolytic migratory erythema in humans. It has been described in dogs, cats, and black rhinoceroses. For the purposes of this chapter, the remaining discussion will be confined to the disease in dogs.

Superficial necrolytic dermatitis is an external manifestation of an internal disease, most commonly advanced hepatopathy, but it has also been associated with glucagonoma, ingestion of mycotoxins or long-term phenobarbital and phenytoin treatments. There is a recent case report describing SND associated with an insulin- and glucagon-producing pancreatic carcinoma. Diabetes mellitus can be a complication of this disease.

The exact etiopathogenesis of SND is currently unknown. Several studies investigating the serum amino acid profile of dogs with SND have found profound hypoaminoacidemia, indicating that this may participate in the development of skin lesions because amino acids are necessary to maintain cellular integrity in the epidermis. In one study, glutamic acid, phenylalanine, tryptophan, and ornithine were not significantly different but all other amino acids were 60% or less than the mean reference values for normal dogs. In 72% of the dogs studied, either glutamine or arginine was the most diminished plasma amino acid. Deficiencies in cutaneous essential fatty acids, zinc, and biotin have also been suggested to play a role in skin lesion development.

Signalment

Superficial necrolytic dermatitis is a disease of older dogs, with an average age of 10 years. Currently, there are not enough reported cases to enable accurate determination of breed or sex predilection, though one paper reported a predilection towards Shih tzus.

Clinical Signs

Skin lesions are mostly associated with those areas on the body where trauma naturally occurs, including the footpads, muzzle, and mucocutaneous junctions (periocular, perioral, anal and genital regions). It is not uncommon for lesions to also develop on the elbows, hocks, and margins of the pinnae. The development of cutaneous lesions is often the reason for owners to seek veterinary advice. The footpads typically become thickened, crusted, and fissured which often leads to pain and lameness (Figure 169.1). The elbows, hocks, and prepuce may be alopecic, erosive to ulcerated, erythematous, crusty, and scaly (Figure 169.2).

Secondary bacterial and fungal (often yeast) infections occur frequently and aggravate the cutaneous lesions associated with SND.

In cases where there is severe liver disease, dogs may have jaundice of the sclera and/or mucous membranes. In cases associated with diabetes, dogs may be polydipsic and polyuric.

There are many laboratory abnormalities associated with SND, which may vary according to the individual case and underlying disease. Those that have been reported include mild to severe normocytic, normochromic, nonregenerative anemia, microcytosis, hyperglycemia, glucosuria, and possibly ketonuria if the patient has developed diabetes mellitus. Urine amino acids including lysine, proline and 1-methylhistidine are increased. Increases in liver enzymes, hypoalbuminemia, decreases in creatinine and phosphorus, and increases in cholesterol and triglycerides have also been reported. It should be noted that there is no clinical

correlation between the severity of the liver pathology and the severity of the skin lesions.

Diagnosis

Skin biopsies of early lesions display very characteristic histologic changes. The epidermis has moderate to severe parakeratotic hyperkeratosis and acanthosis. There is both intercellular and intracellular edema with keratinocyte vacuolation in the upper half of the epidermis, which results in significant epidermal pallor. There is basilar epidermal hyperplasia. Because of the eosinophilic superficial keratin accumulation coupled with central pallor and basilar hyperplasia which stains deep blue, skin biopsies taken from early lesions display a striking "red" (eosinophilic), "white" (central pallor), and "blue" (basophilic basilar hyperplasia) pattern. Biopsy tissues taken from chronic lesions often lose the central pallor which could result in an erroneous diagnosis of zinc-responsive dermatosis. Epidermal pustulation, cleft formation, necrosis, erosions, and ulcers may also be seen. In the dermis, there may be a mild superficial perivascular lymphoplasmacytic infiltrate, edema with vascular ectasia, and congestion.

Abdominal ultrasound of dogs with hepatic disease and SND reveals a liver with a slightly irregular surface. There are variable sized hyperechoic regions (strands) present diffusely throughout the parenchyma. The strands encompass round to oval hypoechoic areas. The result is a "Swiss cheese" or "honeycomb" appearance to the liver. Biopsies taken from the liver display a vacuolar hepatopathy with parenchymal collapse. Pancreatic tumors may be visualized with ultrasound; however, if not visualized and the liver ultrasound is normal, glucagon levels should be assayed to rule out a glucagonoma.

Therapy

Treatment for dogs with SND is usually short-lived and largely unrewarding. Most cases are fatal, with life expectancy ranging from 1.7 to 6.4 months. One reported case survived for 32 months before being euthanized.

Treatment should initially be directed at stabilizing dogs with diabetes. Surgical resection can be beneficial in cases associated with glucagonomas but it is important to keep in mind that glucagonomas typically metastasize rapidly, so the improvement post surgery may be temporary. In one reported case, metastasis precluded surgery, and the dog was treated with subcutaneous octreotide (2 µg/kg twice daily), a somatostatin analog that inhibits glucagon release. Skin lesions and systemic signs improved within five days. The dosage was increased to nearly 3 µg/kg twice daily and all clinical signs improved further within 10 days. Anorexia was the main side-effect. The dose (1–3.4 µg/kg) and frequency of administration (2–3 times daily) of the octreotide injections were adjusted to maintain disease control with minimal side-effects. The dog was later euthanized due to progressive metastatic disease. In another case report, adipose tissue-derived mesenchymal stem cells were infused in addition to intravenous amino acids, 46 times over a 30 month period. Survival time was increased to 32 months after diagnosis.

Many dogs with liver disease have been treated with amino acids, either intravenously or orally. Amino acid solutions which have been used include Aminosyn® 10% solution (Abbott Laboratories), Procalamine® (B. Braun Medical Inc.) and Travasol® 8.5% amino acid injection (Baxter Healthcare) though no particular product has

been especially more beneficial than any other. Because of the hyperosmolarity of the solutions, they should be administered via a central venous catheter over an extended period of time (6–12h) and are repeated every 1–2 weeks until improvement is noted. The infusions are then repeated as necessary to help control relapses. Various doses have been suggested including 25 mL/kg or 500 mL per dog. Some dermatologists advocate administering the infusions three days in a row followed by once- to twice-weekly treatments thereafter and repeating as signs relapse. Clinical improvement may be noted within 5–10 days. If there is minimal to no response after four or more infusions, the therapy is unlikely to be of benefit to the patient. One dog was reported to survive for 24 months but was also treated with intravenous lipid infusions (Intralipid®, Baxter Healthcare) at 1.4 g/kg every 6.5 weeks. In that dog, it was proposed that the addition of the lipids was responsible for the extended survival time.

Oral supplementation with egg whites (cooked), zinc (e.g., zinc methionine 2 mg/kg PO q24h), powdered amino acid commercial supplements, and essential fatty acids has been used and may be of some benefit though all efficacy so far has been anecdotal.

Many dogs are treated with corticosteroids but this practice should be discouraged. The beneficial effects and improvement of clinical signs are short-lived and the corticosteroid may increase the patient's risk for developing diabetes mellitus. Secondary bacterial and/or fungal infections should be treated with appropriate antibiotics or antimycotics.

Prognosis

The prognosis is grave, with most dogs dying or being euthanized within a few months after the beginning of clinical signs.

Sebaceous Adenitis

Etiology/Pathophysiology

Sebaceous adenitis (SA), also referred to as granulomatous SA, is an uncommon dermatosis that occurs in dogs and rarely in cats. The cause and pathogenesis of SA currently remain unknown, but several etiologic speculations exist, including an immune-mediated disorder targeting the sebaceous gland, a primary keratinization disorder that obstructs the sebaceous gland duct leading to inflammation and ultimately glandular destruction, a developmental, genetically inherited defect resulting in an inflammatory reaction directed against the sebaceous gland and, lastly, aberrant lipid metabolism and/or storage that eventually leads to sebaceous gland destruction.

Despite our lack of understanding of the pathomechanism, the endresult is inflammation and obliteration of the sebaceous glands, which normally produce and cover the skin with a protective layer of sebum. Sebum is instrumental in maintaining epidermal moisture and hydration and also has antimicrobial properties. Thus, a predisposition to secondary bacterial and/or *Malassezia* overgrowth or infection develops. Otitis may also occur. In addition, the inflammation that targets the sebaceous glands ultimately affects the hair follicles, which leads to abnormal changes in the quality of the hair coat, and eventually hair loss.

A genetic predisposition to develop the disease is known in some breeds. In standard poodles and akitas, the disease is inherited as an autosomal recessive trait. The mode of inheritance in the Havanese is currently being investigated.

Signalment

Most commonly, SA tends to afflict young adult to middle-aged dogs, but dogs of any age may be affected. The disease appears to be slightly more common in males. Sebaceous adenitis has been reported in over 50 breeds of dogs although specific breeds have been overrepresented including standard poodles, vizslas, akitas, springer spaniels, German shepherd dogs and their crossbreeds, Samoyeds, and Havanese. Possible increased frequency exists in chow chows, dachshunds, beagles, Lhasa apsos, miniature pinschers, and retrievers.

History and Clinical Signs

The cutaneous changes of SA generally include varying degrees of alopecia, hyperkeratosis, and excessive scaling, with follicular casts (i.e., scales surround a single hair or group of hairs) being a consistent feature. However, the clinical presentation is somewhat dependent on hair coat type and breed. In general, short-coated breeds seem to differ clinically from long-coated breeds. In short-coated breeds such as viszlas and dachshunds, the disease is manifested by symmetric to asymmetric, "moth-eaten," annular to coalescing and serpiginous to rarely diffuse areas of alopecia with fine, white scaling affecting the head, pinnae, neck, and trunk. Follicular casts are subtle and hairs are easily epilated. Pruritus is typically absent. In long-coated breeds, such as the standard poodle, the lesion distribution and lack of pruritus are similar to those of short-coated breeds, but diffuse alopecia is more common and obvious follicular casting is present. The hairs are often dull and brittle and may lose their typical architecture (i.e., the classic curly hair coat of the poodle becomes wavy or straight). The hair may also become lighter or darker in color. Groups of hairs surrounded by scales (i.e., follicular casts) are easily epilated (Figure 170.1).

Commonly, the lesions initially affect the head, pinnae, and neck and progress caudally to the dorsal and lateral

Figure 170.1 Examples of follicular casts from an adult black standard poodle. Groups of hairs are ensheathed at their base by keratosebaceous debris.

Figure 170.2 Dorsum of an adult male castrated standard poodle with a notably darker, wavy to straight hair coat in those areas afflicted by SA. Scales and follicular casts are also present.

aspects of the trunk (Figure 170.2). In chronic cases, the lesions may extend to the legs and tail. Secondary bacterial folliculitis and *Malassezia* dermatitis are common. As excessive scale accumulates in the ear canal and aural orifice, otitis externa may occur. In some cases, otitis and excessive otic scale may be the sole manifestation of SA, as is commonly observed in the Havanese. This has also been reported in the vizsla, although the pinnal lesions were erosive to ulcerative (Figure 170.3).

When secondary infections are present, pruritus tends to intensify. Sebaceous adenitis in the akita may manifest in a more severe form with accompanying systemic signs such as fever, lethargy, and inappetence, which may result

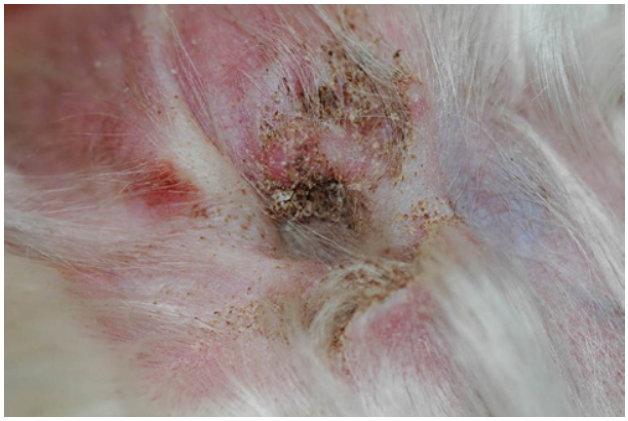

Figure 170.3 A 4-year-old male castrated Havanese with marked, fine white scaling associated with the medial and lateral aspects of the pinnae extending into the aural orifice and external ear canal.

in weight loss. Cutaneous signs are also more severe. Follicular casts and partial to generalized alopecia are present, but akitas also tend to develop diffuse erythema, greasy, generalized keratosebaceous scaling, and significant superficial and occasionally deep pyoderma.

In cats, few case reports exist describing the clinical manifestations of SA. Generalized adherent scaling and hypotrichosis has been described along with distinctive dark brown periocular scales/crusts.

Diagnosis

Initially, a tentative diagnosis of SA can be made based upon the signalment, history, and physical examination findings. Differential diagnoses include demodicosis, dermatophytosis, superficial bacterial folliculitis, keratinization disorders such as primary idiopathic seborrhea, ichthyosis, and vitamin A-responsive dermatosis, follicular dysplasia, zinc-responsive dermatosis, endocrinopathies, such as hypothyroidism, and hair cycle arrest (i.e., alopecia X). Autoimmune/immune-mediated differentials to consider include alopecia areata and pseudopelade. Surface cytology and deep skin scrapes should be performed in every case to evaluate for superficial bacterial folliculitis and *Malassezia* dermatitis, and to rule out demodicosis. A dermatophyte culture should be performed if clinically applicable. If an underlying endocrinopathy is suspected, appropriate screening tests, such as a complete blood count (CBC), serum chemistry profile, and urinalysis (UA), as well as thyroid function testing should be performed.

Biopsy and histopathology are needed in order to confirm the diagnosis of sebaceous adenitis. Multiple punch biopsies (3–5) should be procured from lesions of varying appearance and chronicity to improve confirmation of the diagnosis. It is important to include very early

lesions in order to identify the inflammatory reaction targeting the sebaceous glands. These lesions will likely be missed if only chronic, alopecic lesions are sampled. The histopathologic changes will vary depending upon the stage of the lesion sampled and include granulomatous to pyogranulomatous dermal inflammation targeting the sebaceous glands, to complete absence of sebaceous glands along with perifollicular fibrosis and varying degrees of follicular keratosis.

Therapy

As the pathomechanism of SA appears to be due to a combination of an immune-mediated inflammatory disease and a keratinization disorder, treatments have been aimed at controlling these two aspects and involve a combination of systemic and topical therapies to reduce further sebaceous gland inflammation and destruction, prevent secondary skin and otic infections, remove excessive scale, promote moisturization and protection of the skin, and improve the quality of the hair coat.

In mild cases of SA, topical therapy along with high doses of oral essential fatty acids (which can be used in all cases as an adjunctive therapy) can be effective. The suggested dose of omega-3 fatty acid supplementation is 180 mg eicosapentaenoic acid and 120 mg of docosahexanoic acid per 10 lb of body weight per day combined with omega-6 fatty acid supplementation. In general, topical therapy involves an initial bath using a keratolytic and keratoplastic shampoo, followed by an emollient rinse or oil treatment, and concluded with a final bath aimed at removing any residual oil and scale. In the interim, as often as daily to as infrequently as once-weekly treatments consisting of sprays and rinses, spot-on formulations, conditioners, and mousses with emollient, humectant, antimicrobial, and barrier repair functions are utilized.

Shampoos, such as those containing sulfur and salicylic acid, should be selected. These shampoos are commonly formulated with antimicrobials such as benzoyl peroxide (Oxiderm + PS®, Ceva Animal Health, Lenexa, KS, USA; DermaBenSs®, Dechra, Overland Park, KS, USA) or chlorhexidine (MPA Seba-Hex®, Vetoquinol, Forth Worth, TX, USA). Products containing benzoyl peroxide also act as excellent degreasers. The shampoo should be lathered well and allowed contact with the skin for 10 minutes while gently massaging followed by a fresh, lukewarm water rinse.

A variety of oil-based treatment regimens have been suggested to further assist in loosening and removing scales, follicular casts and crusts, and to replenish the skin barrier. These include a 50:50 mixture of water and baby oil or bath oil, such as Eucerin® skin calming dry skin body wash (Beiersdorf AG, Hamburg, Germany) or Alpha Keri® bath oil (Novartis Consumer Health, Parsippany, NJ, USA), or a mixture of 50–75% propylene glycol in water. The oil or propylene glycol mixture is allowed a contact time of 1–2 hours. Once soaking is complete, another bath is performed with the previous shampoo. Alternatively, a liquid dish-washing detergent can be used such as Dawn dish soap (Proctor and Gamble, Cincinnati, OH, USA), but may be too drying for some dogs. Frequency will depend on the severity of the disease, but it tends to be more frequent (1–3 per week) in the beginning and reduced as the patient improves (every 1–4 weeks). Between the bathing/oil treatment regimens, sprays such as DermAllay® oatmeal spray conditioner (Dechra) and Douxo® seborrhea micro-emulsion spray (Ceva) can be utilized for their moisturizing and humectant properties. Mousse formulations, such as Douxo seborrhea mousse (Ceva), provide another convenient means of restoring the skin barrier. When maintenance antimicrobial therapy is needed, Douxo chlorhexidine PS micro-emulsion spray or chlorhexidine climbazole mousse (Ceva) can be used once to twice daily to twice weekly for maintenance. For more refractory cases, daily application of 50–75% propylene glycol can be beneficial. Topical spot-on treatments, such as Dermoscent® Essential 6 spot-on (Bayer, Shawnee Mission, KS, USA) which contains omega-3/omega-6 fatty acids and essential oils, are easy to apply and can be efficacious. Initially, it is applied as directed once weekly for eight weeks and then decreased to once every two weeks. Another alternative is Douxo seborrhea spot-on (Ceva) which contains phytosphingosine, a natural component of the epidermis that plays a key role in barrier function. Oil soaks may eventually be replaced by these products if an acceptable response is noted. Finally, extra virgin olive oil and coconut oil have been anecdotally reported to be effective moisturizers. These products are inexpensive and also have mild antimicrobial properties.

In more severe cases of SA, systemic treatments should be utilized in conjunction with topical therapy and essential fatty acid supplementation. Among the systemic treatments, vitamin A, synthetic retinoids, a combination of a tetracycline antibiotic and niacinamide, and ciclosporin have been used for the management of SA with variable success. Retinoids have antiproliferative, antiinflammatory, and immunomodulatory effects and generally require 4–8 weeks before response is seen, although maximal response may not be appreciated until 3–4 months of therapy are achieved. Oral vitamin A (retinol) can be tried for milder cases of SA and appears to be a safe and efficacious form of adjunctive therapy for some dogs. Doses range from 400 to 1000 IU/kg PO daily. For more severe or refractory cases, synthetic retinoids such as isotretinoin or acitretin (1 mg/kg PO q12–24h) should be considered for a trial period of at least 4–8 weeks. If a positive response is

noted, the lowest effective dosage and frequency of administration should be used as maintenance therapy (i.e., 0.5–1.0 mg/kg PO q12–24h). These drugs are expensive and can be difficult to obtain as they are strictly regulated. Side-effects include keratoconjunctivitis sicca (KCS), polyuria and polydipsia due to xerostomia, vomiting, and diarrhea. Laboratory abnormalities can include elevation of liver enzymes, hypercholesterolemia, and hypertriglyceridemia.

All retinoids are potent teratogens. Monitoring should include pretreatment measurement of tear production via a Schirmer tear test (STT) and a serum biochemical profile at minimum. The authors typically repeat the STT and serum chemistry profile in 1–2 months and if no abnormalities are noted, then once to twice a year.

The use of tetracycline, doxycycline or minocycline and niacinamide may be beneficial for the treatment of SA, especially in short-coated breeds, given the antiinflammatory and immunomodulatory actions that can be gained when these drugs are utilized in combination. It generally requires 4–8 weeks before response to this therapy is seen, although maximal effect may not be appreciated until 3–4 months of therapy are achieved. Side-effects include vomiting, diarrhea, and decreased appetite. Hepatotoxicity is also possible, albeit rare. Tetracycline and niacinamide are dosed at 250 mg for dogs <10 kg and 500 mg for dogs >10 kg q8h. When doxycycline is utilized in place of tetracycline, a dosage of 5–10 mg/kg PO q12h is suggested and minocycline can be dosed at 5–12.5 mg/kg PO q12h. The dosage of niacinamide remains at 250 mg for dogs <10 kg and 500 mg for dogs >10 kg q8h. If a positive response is noted, the lowest effective dosage and frequency of administration should be used as maintenance therapy.

Ciclosporin is currently the preferred treatment for SA, especially in severe cases or those that have not responded acceptably to topical therapy and/or other systemic treatments. Ciclosporin is a calcineurin inhibitor with a number of immune-modulatory functions. Perhaps most important in the case of SA is its ability to impair T lymphocyte function. Ciclosporin has also been shown to increase the numbers of sebaceous glands. Ciclosporin (Atopica®, Elanco US, Greenfield, IN, USA) can be administered at an initial dosage of 5 mg/kg PO q24h. Ciclosporin has an extended lag time of 4–6 weeks before clinical response may be seen. If a positive response is noted, the lowest effective dosage and frequency of administration should be used as maintenance therapy. Side-effects include vomiting, diarrhea, anorexia, gingival hyperplasia, papillomatosis, secondary infections including opportunistic urinary tract infections, hirsutism, and involuntary shaking. More serious side-effects include nephropathy, hepatopathy, bone marrow suppression, and lymphoplasmacytoid dermatosis although these effects appear to be extremely rare with daily doses of approximately 5 mg/kg/day. The authors typically recommend a baseline CBC, serum chemistry profile, UA, and urine culture. These tests are repeated every six months to yearly to monitor for possible side-effects.

In general, response to corticosteroids is poor. They can be tried as a last resort if there has been no response to other therapeutic options or in cases where those options are cost prohibitive. A starting dosage of 1 mg/kg/day PO can be used and gradually reduced to the lowest dosage and frequency possible. There may be a more favorable response in cases where the histopathology findings reveal severe inflammation.

It is important to recognize and treat secondary infections, as they can greatly contribute to the patient's morbidity. The reader is referred to Chapters 158, 166 and 167 in this section regarding the diagnosis and treatment of pyodermas, *Malassezia* dermatitis, and otitis.

Prognosis

The prognosis of SA ultimately depends upon the severity and chronicity of the disease and the degree and recurrence of secondary infections. The response to therapy is quite variable from one patient to the next. The disease in the akita can be particularly refractory. There is no cure for SA and it has a chronic, often progressive nature which requires lifelong therapy. In and of itself, SA is not a lethal disease but a clinically and cosmetically acceptable response is not always obtained and/or may be too expensive or labor intensive for the owner. For these reasons, euthanasia may ultimately be chosen.

Eosinophilic Dermatitis

Etiology/Pathophysiology

Eosinophilic dermatitis, also known as eosinophilic dermatitis with edema and eosinophilic cellulitis, is an uncommon syndrome that has been described in dogs and has been compared to Wells syndrome in humans. The disease is presumably multifactorial with myriad possible triggers including allergic and parasitic diseases, arthropod bites, immune-mediated disease, stress, and drugs, which culminates in an allergic hypersensitivity and/or immune-mediated reaction. In one study, more than 50% of the dogs developed eosinophilic dermatitis following treatment for vomiting and diarrhea. In a more recent study that focused solely on the development of eosinophilic dermatitis in dogs with signs of gastrointestinal disease, particularly vomiting, diarrhea and

hematochezia, it was found that pancreatitis, inflammatory bowel disease, and adverse food reaction were the most common triggers, although the cause of the gastrointestinal signs could not be documented for all dogs. In some dogs, an adverse drug reaction was considered as a possible trigger.

Signalment

Labrador retrievers and their crosses appear to be overrepresented, but the disease can occur in any breed. Age and sex predilections have not been identified.

History and Clinical Signs

Eosinophilic dermatitis is a visually distinctive disease. Lesions develop acutely and are characterized by arciform and serpiginous erythematous macules and plaques with edema (Figure 170.4). The macules often have a targetoid appearance although diffuse erythroderma may be present. The ventral abdomen and thorax are commonly affected, as are the pinnae and face (Figure 170.5). Edema may be generalized, affecting the face and limbs. Often, patients are moderately to severely pruritic. Lymphadenopathy may be present.

Diagnosis

The diagnosis of eosinophilic dermatitis is based upon its distinct clinical presentation and disease course along with biopsy and histopathology. Differential diagnoses include erythema multiforme, vasculitis, and sterile neutrophilic dermatosis. Multiple biopsies should be procured early on from several different-appearing lesions. Edematous areas, if present, should also be sampled. Histopathologic findings are variable and include mild to severe perivascular to diffuse eosinophilic dermatitis with varying amounts of edema, which is often protein rich in severe cases. Flame figures (degranulating eosinophils associated with collagen fibers) may be noted along with variable degrees of vascular damage. CBC and serum chemistry abnormalities are not common. Occasionally, peripheral eosinophilia and basophilia may be documented. In cases associated with gastrointestinal disease, hypoalbuminemia is a common finding.

Figure 170.4 Abdomen of an adult male castrated Labrador retriever with serpiginous erythematous macules and edematous plaques.

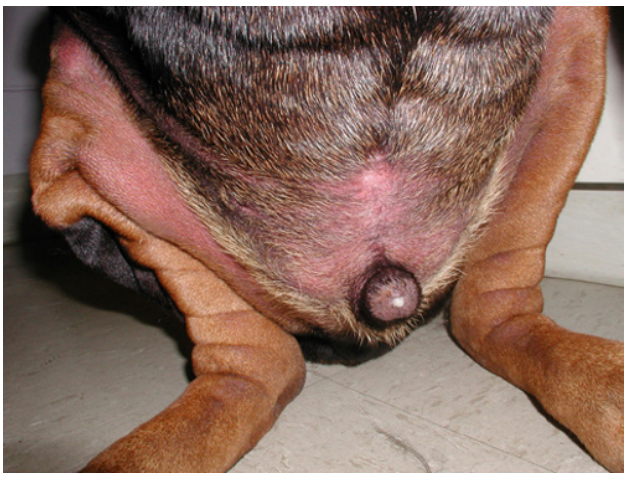

Figure 170.5 Diffuse erythroderma and edema present on the ventral abdomen and pelvic limbs of a 3-year-old female spayed dachshund.

Therapy

Appropriate drug withdrawal is paramount when a cutaneous adverse drug reaction is suspected. In addition, patients respond favorably to antihistamines and/or corticosteroids. Diphenhydramine or hydroxyzine may be administered at a dosage of 2 mg/kg PO q8–12h. In a recent study, cetirizine was the most commonly prescribed antihistamine with doses of 0.6–1.1 mg/kg PO q24h. Cetirizine has several antieosinophilic effects that may make it particularly effective for treating eosinophilic dermatitis. Reported starting dosages of prednisone include a range of 0.6–2.8 mg/kg/day. In milder forms of the disease, therapy may not be required with lesional self-resolution occurring within a few weeks. Topical glucocorticoid therapy with hydrocortisone, betamethasone, or triamcinolone may also be considered. However, the treatment duration should not extend beyond two weeks given the risk of localized cutaneous atrophy and other complications that may occur from prolonged topical steroid application.

Prognosis

Eosinophilic dermatitis usually carries a favorable prognosis. Disease resolution tends to be swift, especially when underlying triggers are identified and removed

(i.e., drugs). Typically, treatment duration varies from one to four weeks, and only rarely will there be recurrences or a waxing and waning course.

Sterile Neutrophilic Dermatosis

Etiology/Pathophysiology

Sterile neutrophilic dermatosis is a rare disease which closely resembles acute febrile neutrophilic dermatosis (Sweet syndrome) in humans. The few documented cases in the veterinary literature all involve dogs. In people, the disease is typified by pyrexia and a neutrophilic leukocytosis along with painful papular to nodular skin lesions that consist predominantly of a diffuse infiltration of mature neutrophils within the dermis on histopathology. Extracutaneous sites of neutrophilic inflammation and concurrent disease processes have also been identified in humans, including respiratory and gastrointestinal tract infections, inflammatory bowel disease, arthritis, and neoplasia, although many cases are idiopathic. Disease development has also been associated with various drugs.

In dogs, the clinicopathologic abnormalities mirror those observed in humans. Concurrent neutrophilic inflammation has been reported to affect the lungs, heart, esophagus, and various joints. Adverse drug reactions appear to be an important cause of the disease in dogs. Several case reports have been associated with the administration of carprofen. Firocoxib has also been implicated in an additional case report. The pathogenesis is not completely understood, but is thought to involve an immune-mediated process.

History and Clinical Signs

There are currently no known breed, gender, or age predilections given the paucity of reported cases. Similar to the disease in humans, extracutaneous signs are commonly associated with the cutaneous manifestations, but not obligatory. Pyrexia is a key feature, although it is not always documented. Other reported clinical abnormalities include anorexia, lethargy, weakness, lameness, and lymphadenomegaly. A mature neutrophilia may be present. Other laboratory abnormalities may be present and are reflective of the various underlying disease processes.

Cutaneous lesions include the acute development of erythematous macules and papules as well as pustules and plaques. Ulcerations of the oral cavity and the body have been reported. The ventral aspect of the abdomen, axillae, and groin are preferentially involved, although the lesions may occur anywhere. Edema may be present and can extend ventrally to involve the legs. Pruritus is usually absent.

Diagnosis

The diagnosis of sterile neutrophilic dermatosis is based upon recognition of the sudden onset of systemic signs that precede or occur simultaneously with the cutaneous lesions in conjunction with the presence of a neutrophilic leukocytosis and compatible histopathologic findings. Differential diagnoses include infectious dermatitides, superficial pyoderma, pemphigus foliaceus, sterile pustular erythroderma of miniature schnauzers, eosinophilic dermatitis and edema, erythema multiforme, and cutaneous adverse drug reactions. The diagnostic workup should include skin cytology, CBC, serum chemistry profile, and UA. Titers for tick-borne diseases should also be considered, depending upon geographic locale and potential for exposure. Thoracic radiographs and abdominal ultrasound are also indicated to evaluate for underlying diseases. Multiple skin biopsies should be procurred and tissue cultures submitted. Histopathologic findings that are supportive of sterile neutrophilic dermatosis include dermal edema with a moderate to severe perivascular to diffuse neutrophilic infiltrate.

Therapy

Treatment of this disease includes the discontinuation of potentially offending drugs, along with supportive care and immunosuppressive doses of corticosteroids. A positive response may be evident within 48 hours and remission has been documented to occur within a week in some cases. In other cases, therapy may be slowly tapered over the course of four weeks. In severe cases, intravenous or subcutaneous administration of dexamethasone followed by a tapering course of prednisone may be considered.

Prognosis

Sterile neutrophilic dermatosis has a fair to good prognosis depending upon the underlying etiology. It stands to reason that in cases where the underlying disease is severe and untreatable, the prognosis may be grave.

Ichthyosis

Etiology/Pathophysiology

Canine ichthyosis is a rare hereditary cornification disorder recognized in various breeds such as Norfolk terriers, Jack Russell terriers, golden retrievers, and American bulldogs. The disease in dogs has been typically classified as either epidermolytic or nonepidermolytic based on histopathologic findings. With the exception of Norfolk terriers and a Labrador cross, all

other breeds reported to date have had the nonepidermolytic form.

The disease is caused by the abnormal expression of protein or lipid molecules that form the stratum corneum structure. Genetic studies have identified different mutations of these molecules according to the breed investigated as follows:

- Norfolk terriers – a splice-site mutation in keratin 10 (*KRT10*)
- golden retrievers – a mutation in the *PNPLA1* gene that participates in lipid organization and metabolism in the outer epidermis
- American bulldogs– a mutation in the *NIPAL-4* gene resulting in decreased expression of the protein icthyin
- Jack Russell terriers – a loss-of-function mutation in transglutaminase 1 (*TGM1*) which mediates calcium-dependent cross-linking of proteins that form the cornified envelope.

A congenital ichthyosiform disease associated with keratoconjunctivitis sicca has been described in Cavalier King Charles spaniels but a candidate gene has not been identified to date.

More recently, a new variant of congenital ichthyosis was described in 14 Great Dane puppies based on clinical, histopathologic, and transmission electron microscopy findings. Pedigree analysis of 13 of the 14 puppies revealed that all dogs were related. The disease in these puppies most resembles the congenital, autosomal recessive, nonepidermolytic, lamellar ichthyosis described in the golden retriever. However, unique histologic differences were observed which have yet to be reported in ichthyotic dogs. Of note, enlarged sebaceous glands that were also composed of numerous degenerative sebocytes containing an alcianophilic, lipid-rich material within the cytoplasm were documented. This same material was also identified within dilated hair follicle lumina.

An autosomal recessive mode of inheritance has been reported for all breeds where a pedigree analysis could be performed thus far.

Signalment

As for most hereditary disorders, the clinical signs are typically recognized early in life. The disease presents at birth in Jack Russell terriers, Norfolk terriers, and Cavalier King Charles spaniels. It is reported to manifest before weaning in American bulldogs and has a variable age of onset in golden retrievers (3 weeks to 3 years).

History and Clinical Signs

The disease phenotype can vary according to the breed and this may be partially the result of different genetic mutations.

Golden Retriever

Affected dogs present with small to large, attached to loose, white to gray scales localized primarily on the neck, trunk, rump, and ventrum (Figure 170.6). A characteristic early sign is a dark, sandpaper-like appearance of the ventral glabrous skin (Figure 170.7). Pruritus is typically not present but, may occur if secondary infections develop. Clinical signs may wax and wane with periods of remission and exacerbation.

Norfolk Terrier

At birth, the disease is characterized by formation of superficial bullae and erosions after mild mechanical

Figure 170.6 One-year-old golden retriever with ichthyosis. Large, loose to adhered, white to gray scales localized to the lateral trunk.

Figure 170.7 Eight-month-old golden retriever with ichthyosis. The ventral abdomen is covered with adhered gray scales, giving a hyperpigmented appearance. The skin has a sandpaper-like texture when gently palpated.

trauma. In adulthood, the skin fragility persists but areas of dark gray hyperkeratosis and hyperpigmentation will develop and are worse in the intertriginous regions. Pruritus has not been described and footpads, claws, teeth. and hairs were reported to be normal.

Jack Russell Terrier

Affected dogs are born with thick, large, adherent, white to dark scales in areas with sparse hair coat and loosely adherent scales in other parts of the body. Footpads are reported to be moderately hyperkeratotic and the nails soft. Secondary bacterial and *Malassezia* infections may be a complicating problem.

American Bulldog

Shortly after birth, puppies present with a disheveled hair coat and erythema associated with tightly adherent tan scales localized to the hairless skin (axilla, abdomen, groin) which acquires a wrinkled appearance. In adulthood, the hairless areas develop a reddish-brown discoloration. Large, loosely adherent, white to tan scales are present throughout the body (Figure 170.8). Foodpad hyperkeratosis is a rare finding in adult dogs. Affected dogs are very prone to developing *Malassezia* overgrowth which can be severe and result in pruritus (Figure 170.9).

The clinical appearance of American bulldog ichthyosis is frequently misdiagnosed as atopic dermatitis which can indeed co-exist in some dogs.

Cavalier King Charles Spaniel

Puppies are born with a rough and curly hair coat and as they become older, the glabrous skin becomes hyperpigmented and hyperkeratotic, particularly around the nipples and inguinal region. Scales, footpad hyperkeratosis and abnormal nails, that may slough, develop at about 6 months of age or older (Figure 170.10). Keratoconjunctivitis sicca is noted as the puppies open their eyes and can be mild to severe.

Figure 170.8 Two-year-old American bulldog with ichthyosis. Loosely adhered scales localized throughout the trunk.

Great Dane

Clinically, Great Dane puppies present with generalized fine, dry, white to yellow scaling along with a greasy, leathery appearance to the axillary and inguinal regions. Marked skin wrinkling is present on the head, muzzle and distal limbs.

Other Breeds

Ichthyosis has been anecdotally reported in West Highland white terriers and English springer spaniels. An epidermolytic form was described in a Labrador cross based on histopathologic findings. More recently,

Figure 170.9 Same dog shown in Figure 170.8. *Malassezia* overgrowth present on the flank and ventral abdomen resulting in a brownish discoloration of the skin and hair coat.

Figure 170.10 One-year-old Cavalier King Charles spaniel with ichthyosiform disease showing severe footpad hyperkeratosis.

ichthyosis was documented in a goldendoodle dog based on histopathologic findings and genetic testing, which identified the *PNPLA1* mutation found in golden retrievers, indicating that the disease was likely inherited from its golden retriever predecessors.

Diagnosis

The diagnosis historically has been based on the characteristic history, clinical signs, and histopathologic findings. When performed, skin biopsies should be submitted to a pathologist with experience in dermatology. A commercially available genetic test is now offered through Optigen (www.optigen.com/) and is easily performed using a venous blood sample and has become the authors' primary means of confirming a diagnosis of ichthyosis in breeds where testing is an option. Electron microscopy and genetic studies are needed to characterize the molecular abnormality and mode of transmission.

Therapy

The treatment goals should be to prevent/treat secondary infections and reduce the excessive scaling, hyperkeratosis, and inflammation by restoring the stratum corneum barrier. This may be achieved by various topical therapies which should be tailored to the patient's needs. Shampoos with keratolytic and keratoplastic properties such as sulfur and salicylic acid, followed by a good moisturizer, can be used 2–3 times weekly. Products containing lipids such as phytosphingosine (Douxo seborrhea spot-on or spray), or fatty acids and essential oils (Dermoscent Essential 6 spot-on) can be used after bathing. Combinations of oral omega-3 and omega-6 fatty acids can be used as adjunctive therapy. Secondary infections should be treated appropriately with topical and/or systemic antifungals or antibiotics as required for each individual patient.

Prognosis

Clients have to understand that ichthyosis is a noncurable condition and the prognosis to achieve disease control is generally fair. Veterinarians should become familiar with the different clinical presentations and breed-related disease severity and educate clients on what to expect.

Eosinophilic Granuloma Complex

Etiology/Pathophysiology

Feline eosinophilic granuloma complex is a group of lesions that affect the skin, mucocutaneous junctions, and oral cavity. They can develop in cats with adverse food reaction, atopic dermatitis, flea bite allergy or mosquito bite hypersensitivity, suggesting an immunologic dysregulation. The role of bacteria in lesion development is still questionable but certain lesions have improved significantly or resolved with antibiotic therapy. Many cases remain idiopathic and some cats may be genetically predisposed to develop this condition. Cats can have a single lesion, multiples of the same type or a combination of different ones. Lesions may be refractory to treatment, resolve with or without treatment and not return, or be recurrent.

Signalment

There is no breed, sex or age predilection but linear granuloma lesions typically develop in cats less than 2 years of age.

History and Clinical Signs

Lesions associated with the complex include eosinophilic granuloma, eosinophilic plaque, and indolent ulcer.

Eosinophilic Granuloma

This is the only true granulomatous lesion of the complex and has various clinical presentations such as nodules, papules or linear plaques. They can be single or multiple and develop anywhere on the body, including the lips (pouting lip), chin (fat chin), oral cavity, footpads, pinnae, caudal aspect of thighs or other areas (Figure 170.11).

Figure 170.11 A cat with eosinophilic granuloma localized to the feet. The digits of the right hind foot are swollen and erythematous. The footpad of the third digit is also swollen and has a focal area of erosion to ulceration.

Lesions are often erythematous and those localized in the oral cavity and footpads are more likely to erode or ulcerate and have pale foci of necrosis. Pruritus is variable and circulating eosinophilia may be present.

Eosinophilic Plaque

Plaque lesions are typically multiple and coalescing, eroded to ulcerated and more often localized to the ventral abdomen and medial thighs (Figure 170.12). Pruritus is typically present and cats with eosinophilic plaques often have an underlying allergic disease. Peripheral lymphadenopathy and circulating eosinophilia may be present.

Indolent Ulcer

This is also known as eosinophilic ulcer or rodent ulcer. It is characterized by a well-demarcated ulcer which has an elevated border and a center that is pinkish to yellowish. The lesion is typically localized to the upper lip and can be very extensive and span the philtrum or be adjacent to the upper canine tooth (Figure 170.13). Pruritus is not present.

Diagnosis

Typically, diagnosis is based on the history and clinical appearance of the lesions. A biopsy will confirm the diagnosis and should be performed when lesions develop in older cats to exclude neoplasia, are refractory to treatment or have an unusual presentation. Cytology is important to determine the presence of bacterial infection. The presence of intracellular cocci indicates an infection but extracellular rods suggest oral contamination. Eosinophils may not be found on cytologic samples.

Figure 170.12 Five-year-old domestic longhair cat with eosinophilic plaques. Coalescing erythematous plaques with an eroded and moist surface are localized to the caudal-ventral abdomen and inner thigh.

Figure 170.13 One-year-old cat with an eosinophilic ulcer. This cat also has eosinophilic granuloma lesions localized to the oral cavity.

Therapy

Identifying and controlling the underlying disease is an important part of the treatment regimen as it may prevent recurrences. Most cases respond well to oral glucocorticoid therapy such as prednisolone (2.2–4.0 mg/kg), methylprednisolone (2.0–3.0 mg/kg), triamcinolone (0.2–0.3 mg/kg) or dexamethasone (0.3–0.6 mg/kg), all administered daily until remission and then every other (prednisolone and methylprednisolone) or every third day (triamcinolone and dexamethasone) as maintenance. Injection of methylprednisolone acetate should only be considered if the cat cannot receive oral therapy. The recommended dose is 4.0–5.0 mg/kg subcutaneously (SC) or intramuscularly (IM) given every 2–4 weeks until remission. Cats are more prone to develop diabetes mellitus with long-acting, injectable glucocorticoids. Ciclosporin at 5.0–7.5 mg/kg/day can be used in refractory cases or cases that cannot tolerate glucocorticoid therapy. The lowest possible maintenance dosage should be tried. Chlorambucil at 0.1–0.2 mg/kg/day until remission and then tapered to every other day can be used in recalcitrant cases. A small number of cats have responded to interferon-alpha at 300–1000 units/day PO or SC for 30 days.

Radiotherapy, cryosurgery, surgical excision, and laser therapy are options for single lesions refractory to medical therapy. Eosinophilic ulcers are most likely to benefit from these treatment modalities but recurrences are common.

Prognosis

Most lesions respond well to treatment but some are quite refractory. In addition, recurrences are common and a triggering cause for lesion development is often not determined.

Symmetric Lupoid Onychitis (Symmetric Lupoid Onychodystrophy)

Etiology/Pathophysiology

The cause of symmetric lupoid onychitis (SLO) is currently unknown but the predisposition of some breeds to develop the disease suggests that genetics plays a role. Moreover, the risk of developing SLO in the Gordon setter has been associated with the dog leukocyte antigen (DLA) class II alleles.

Signalment

Most dogs develop the disease between 2 and 6 years of age but it can occur at any age. Gordon setters, English setters, and German shepherd dogs appear to be predisposed but SLO has been recognized in various breeds. There is no sex predilection.

History and Clinical Signs

Onychomadesis (sloughing of claws), onycholysis (separation of claw structure distally and progressing proximally), and paronychia (inflammation of claw folds), causing the dog to lick the paws, along with lameness, are typically the initial clinical presentation (Figure 170.14).

It may start in one or more claws of a single paw but within weeks, it spreads to involve most, if not every, claw of all four paws. Regrown nails are short, misshapen, dry, and brittle (Figure 170.15). Secondary infection associated with purulent exudate is common. The disease only affects the paws.

Diagnosis

The diagnosis is generally based on the history and characteristic clinical presentation but a claw biopsy (onychectomy and submission of the entire third phalanx) may be needed to rule out other causes of nail disorders and confirm the histopathologic changes expected with SLO. Cytology of exudate is necessary to determine the presence of bacterial infection and culture and susceptibility should be considered based on the cytologic findings and the dog's history of antibiotic therapy.

Figure 170.14 Seven-year-old Labrador retriever with symmetric lupoid onychitis. The claw of the fifth digit is showing onycholysis (i.e., separation of the claw structure).

Figure 170.15 Four-year-old mixed-breed dog with symmetric lupoid onychitis. Claws are misshapen, short, and brittle.

Therapy

No single treatment is universally effective in SLO. High doses of omega-6/omega-3 essential fatty acids combined with a tetracycline antibiotic (e.g., doxycycline at 5.0–10.0 mg/kg q12h) and niacinamide (250 mg for dogs <10 kg and 500 mg for dogs >10 kg q8h) are commonly used as the initial therapy. Pentoxifylline at 15–20 mg/kg q12h to q8h can be added to the treatment regimen. More

severe cases may require other immunomodulatory drugs such as oral prednisolone (1.0–2.0 mg/kg/day), azathioprine (2.2 mg/kg/day) or ciclosporin (5 mg/kg/day). Remission should be expected in two weeks with the prednisolone and 4–6 weeks with the ciclosporin and azathioprine; therefore, taper the dose to avoid undesirable side-effects or discontinue treatment if no improvement. Amputation of the third phalanx should be considered in cases that are refractory to medical therapy.

An expected response to therapy translates to cessation of onycholysis and onychomadesis and resolution of pain. In these cases, affected claws will regrow but will have an abnormal structure. It may take months before any significant improvement can be noted.

Prognosis

Prognosis is poor for cure and fair for disease control. Owners have to understand that claws will appear abnormal despite satisfactory improvement of the claw disorder.

Skeletal Development and Growth

Skeletal Development

The first evidence of the developing axial and appendicular skeleton is seen during the embryonic period (day 19–35 after fertilization) when mesenchymal cells condense in the areas of the future bones. The mesenchymal model transforms into a cartilage model (the anlage), which then enlarges and transforms into mature bone both pre- and postnatally. The enlargement of the cartilaginous bones occurs by formation of new cartilage in diaphyseal and epiphyseal growth centers and growth plates. The newly formed cartilaginous bones transform into mature bone via the processes of endochondral and intramembranous ossification (see later). Joints cavities between the developing bones are formed by the processes of segmentation and cavitation. The formation of the joint surfaces (see later) and intraarticular structures follows thereafter.

Most of the longitudinal growth of long bones is contributed by the growth plates (approximately 75–80%) and epiphyseal growth centers (approximately 20–25%), with a minor contribution by the diaphyseal growth center. In dogs, most bone length growth occurs when the animal is between 12 and 26 weeks of age. This period is characterized by the most rapid rate of bone length growth and endochondral ossification, both in epiphyseal growth centers and growth plates, that a dog will experience during its entire lifetime. In addition, growth and mineralization of many epiphyseal growth centers commence and cease at predetermined times. At the end of this period, cartilage only persists between the epiphysis and the metaphysis (growth plate) and at the articular surface covering the epiphyses. Growth plate-associated longitudinal growth continues thereafter at a much slower rate until the process stops completely and the cartilaginous growth plates are replaced by bone (growth plate fusion). Just as with the epiphyses, the growth cessation and "fusion" of growth plates occur at predetermined times (Table 171.1). The rate of skeletal development and the final bone size vary widely among canine and feline breeds.

Intramembranous and Endochondral Ossification

Bone is formed through two fundamentally distinct mechanisms: endochondral ossification (EO) and intramembranous ossification (IO). The key feature of EO is that it involves the sequential resorption of hyaline cartilage that is replaced with bone. Under physiologic conditions, EO takes place in diaphyseal and epiphyseal growth centers, growth plates and – at a very slow rate – at articular surfaces. Endochondral ossification also occurs under pathologic conditions and as a repair process. Examples are secondary fracture healing, osteophyte formation, synovial osteochondromatosis, and heterotopic bone formation.

Intramembranous ossification occurs through condensation and differentiation of mesenchymal tissues, without the requirement for an intermediate cartilage form. During the embryonic period, it plays a role in the development of flat bones (e.g., desmocranium). Later during development, IO takes place in basic multicellular units (BMU or osteon) in Haversian canals, and on endosteal, periosteal, and trabecular surfaces. It provides an important mechanism for appositional bone growth at the periosteal (outer) surface of bone, resulting in diaphyseal circumferential growth (i.e., widening) of bones over time. Intramembranous ossification occurs under pathologic conditions and/or as repair process seen, for example, in panosteitis, hypertrophic osteoarthopathy, and primary fracture healing.

Growth-Plate Associated Growth

Growth plates facilitate bone length growth by the formation of new cartilage. The volume increase of cartilage in a growth plate is a function of chondrocyte proliferation, chondrocyte enlargement, and matrix formation. Because growth in width of a growth plate is constrained, the newly formed cartilage pushes the epiphysis away from the metaphysis, thus elongating the bone. At about the same time – albeit with a different circadian rhythm – growth plate cartilage is converted into bone at the junction of the growth plate and the metaphysis via EO. Because the rate of bone length growth and the rate of advancement of the EO mineralization from the metaphysis are approximately the same, the thickness of a growth plate will not vary much from day to day.

The growth plate is located between the epiphysis and metaphysis, and may be divided into a resting zone, a proliferative zone, a hypertrophic zone, and a mineralization zone.

Changes in the morphology of the chondrocytes and the volume and composition of their surrounding matrix in the different zones of the growth plate represent the temporal alterations taking place through a chondrocyte's life-span. Chondrocytes in the resting zone are primarily stem cells, that divide at a slow rate, and daughter cells. The daughter cells initially assume a flat morphology and divide, slowly enlarge, and synthesize a type 2 collagen and proteoglycan rich matrix; they are organized in so-called clones, chondrons or columns. Cells in this stage of the lifecycle are located in the proliferative zone. Then, chondrocytes suddenly and rapidly increase their cell volume by active swelling, while continuing the synthesis of matrix. Chondrocytes in this stage of their life cycle are spheroidal and relatively large and are located in the hypertrophic zone. Shortly thereafter, chondrocytes achieve their final size and shape and convert their surrounding matrix into one that is permissive of mineralization. This cell type is located in the zone of mineralization on the metaphyseal side of the growth plate. Chondrocytes abutting the metaphyseal vasculature die abruptly, presumably via the process of apoptosis. The life-span of chondrocytes varies and is mostly dependent on the growth plate location, the animal's age, breed, and species.

The regulation of chondrocytic proliferation and hypertrophy, the main determinants of bone length growth, is complex and facilitated by various growth factors, transcription factors, extracellular matrix proteins, and cell–matrix interactions. The traditional understanding is that growth hormone while acting on stem cells promotes the formation of insulin-like growth factor-1 (IGF-1)-responsive daughter cells. Then, through autocrine and paracrine systems, IGF-1 stimulates clonal expansion of chondrocytes (dual effector theory). The change from a proliferative chondrocyte phenotype to a hypertrophic chondrocyte phenotype is mainly controlled by a local feedback loop involving parathyroid hormone-related peptide (PTHrP), Indian hedgehog (IHH), and transforming growth factor-beta (TGF-beta). However, other regulators also may be involved. More recently, transcription factors, extracellular matrix proteins, and cell–matrix interactions functioning as regulators of chondrocytic proliferation and differentiation have been identified. Research in this area is largely driven by these regulators' role in the etiology and pathogenesis of skeletal dysplasias. Discussion of these regulatory mechanisms and canine and feline skeletal dysplasias is beyond the scope of this chapter.

Essential to EO in the growth plate is the sequential resorption of growth plate cartilage and its replacement by metaphyseal bone. Chondrocytes with increased membrane activity of alkaline phosphatase, in the zone of mineralization, undergo their terminal differentiation. They synthesize type X collagen and the surrounding matrix now includes chondrocalcin, osteonectin, and osteopontin. Chondrocytes juxtaposed to the metaphyseal vasculature (terminal hypertrophic chondrocytes) die abruptly by apoptosis and their space is invaded and taken over by metaphyseal blood vessels, a process facilitated by metalloproteinases (MMPs) and vascular endothelial growth factor (VEGF) produced by hypertropic chondrocytes. Osteoprogenitor cells migrate via the newly formed metaphyseal vessels, differentiate into osteoblasts, and form woven bone on the calcified cartilage matrix of the longitudinal septa. The so-called primary spongiosa thus formed consists of a lattice of calcified cartilage and woven bone. The move from hyaline cartilage to bone is completed with the replacement of primary spongiosa by secondary spongiosa, a lamellar bone. The regulation of the conversion of cartilage to woven bone is complex, but it appears that genetic, nutritional, metabolic and mechanical factors all play a role. Defects of growth plate EO are often seen with skeletal dysplasias and metabolic bone diseases.

Epiphysis-Associated Growth

The epiphysis of developing bone consists of a mineralized center surrounded by hyaline cartilage. The cartilage on the end of immature bones, the articular-epiphyseal complex (AEC), consists of two functionally different layers: a relatively thin outer layer and a relatively thick inner part.

The outer layer is specialized immature articular cartilage, is avascular, and does not participate in epiphyseal EO. Following maturation, the articular cartilage will consist of a superficial zone, a transitional or middle zone, a radial or deep zone and a zone of calcifying cartilage. Completion of the maturation process of the articular surface is indicated by the presence of the tide mark, a microscopically visible line(s) separating the uncalcified radial zone from the zone of calcifying cartilage. The inner layer of the AEC is functionally similar to the growth plate and is responsible for epiphyseal enlargement by new cartilage formation and mineralization of the newly formed cartilage.

The cartilage on the metaphyseal side of the mineralized center of the epiphysis also consists of two layers. Adjacent to the mineralized epiphysis is true epiphyseal cartilage, while the cartilage on the metaphyseal side represents growth plate cartilage. Morphologically, there are two main differences between epiphyseal and growth

plate cartilage. First, the chondroepiphysis is visually disorganized and does not have the ordered zonal and columnar arrangement of the growth plate. Furthermore, in contrast to the proliferative, hypertrophic and mineralization zones in the growth plate, the chondroepiphysis has a rich blood supply. Chondroepiphyseal blood vessels originate from the perichondrium and are located in so-called cartilage canals. Under physiologic conditions, these cartilage canals play a role in the nourishment of epiphyseal chondrocytes, in the formation and maintenance of the epiphyseal ossification center and in providing mesenchymal stem cells. It has been suggested that damage to cartilage canal vessels may result in osteochondrosis. Cartilage canal vessels are distinct from vessels on the metaphyseal side of the growth plate.

Just as with growth plate-associated growth, enlargement of the epiphysis-associated growth is a function of chondrocytic proliferation, chondrocytic enlargement, matrix formation, and duration of chondrogenic activity in the chondroepiphysis. Chondrocyte proliferation mostly takes place on the epiphyseal periphery, whereas EO occurs towards the center, where chondrocytes are larger and surrounded by more matrix. Cartilage canals regress through the process of chondrification as the ossification front from the center of the epiphysis reaches newly formed epiphyseal cartilage. Towards the end of the growth period, blood vessels from the epiphyseal bone marrow anastomose with cartilage canal vessels. When epiphyseal growth and ossification are completed, a thin layer of avascular articular cartilage and an avascular growth plate remain. The regulation of epiphyseal enlargement and endochondral ossification is not well understood and certainly not as well studied as the regulation of the growth plate. However, most likely there will be strong similarities with the regulation of the growth plate.

Bone Morphology

Composition of Bone

Bone is a composite material consisting of a fiber-reinforced matrix (similar to reinforced concrete, or Kevlar body armor). The fibers and the matrix in which they are embedded are manufactured by bone-forming cells (osteoblasts) and are susceptible to breakdown by bone-resorbing cells (osteoclasts).

Bone Matrix

Bone is initially deposited as nonmineralized matrix (osteoid), the major components of which are a proteoglycan-rich ground substance with embedded fibers of type 1 collagen. A number of important noncollagenous proteins are also found in bone, including osteocalcin (also known as bone Gla protein), osteopontin, and osteonectin. The importance of type 1 collagen is most clearly evidenced by the profound clinical signs seen in patients with congential defects in collagen 1 synthesis (osteogenesis imperfecta, also known as "brittle bone disease"). Abnormalities in either the quality or quantity of type 1 collagen result in dramatic alterations in the material and mechanical properties of bone by compromising the fiber reinforcement of osteoid. As a result, the bone is embrittled and prone to fracture.

The next stage after formation of the osteoid is deposition of mineral, in the form of hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$). The process of matrix mineralization remains incompletely understood but is thought to involve selective mineral deposition within matrix vesicles released by osteoblasts. Once they reach a certain size, the needle-like hydroxyapatite (HA) crystals are released from the matrix vesicles into the extracellular space, where they serve as templates for ongoing deposition of mineral within the collagen fibrils. The tissue-nonspecific isoform of alkaline phosphatase is believed to play a role in controlling the release of HA crystals from the matrix vesicle, as well as in the progression of mineralization in the extracellular matrix.

Cells of Bone

Osteoblasts are the cells that synthesize new bone. They are derived from mesenchymal precursor cells (variously referred to as mesenchymal stem cells or marrow-derived stem cells) and exist either as flat resting cells or as more metabolically active cuboidal cells. In both cases, osteoblasts remain intimately attached the bone surface. Over time, as additional osteoid is deposited and then mineralized, osteoblasts become encased in bone, forming osteocytes. These cells are known to be critical determinants of cell–cell and matrix–cell signaling within bone, playing an active role in transducing mechanical stimuli (strain) into bone cell activity. Signaling is facilitated by the presence of long cellular extensions (filopodia) on osteocytes; the filopodia run through small channels (canaliculi) within the bone. The extended surface area of the filopodia allows the osteocytes to sense changes in the composition of the extracellular fluid within the canaliculi, while their connectivity allows for efficient signaling between cell bodies.

Osteoclasts are the cells that resorb bone. In contrast with the mesenchymal origins of osteoblasts, osteoclasts derive from hematopoietic cells via the recruitment, activation, and fusion of mononuclear cell precursors. Hallmarks of the osteoclast include a multinucleate cell with a highly invaginated basal membrane (the so-called "ruffled border") apposing the bone surface, expression of the enzymes tartrate-resistant acid phosphatase and

cathepsin K, and the formation of a "sealing zone" through which cells attach to bone.

The process of osteoclastic bone resorption involves local acidification by means of a vacuolar ATPase. Under acid conditions, calcium and phosphorus are liberated from the bone matrix. At the same time, cathepsin K degrades the type 1 collagen, as well as other noncollagenous proteins within the bone matrix.

In cancellous bone, bone resorption occurs at the bone surface; in cortical bone, osteoclasts may act either directly on an exposed bone surface (e.g., on the endosteum or periosteum) or within the interstitium of bone, by resorbing bone within the longitudinally oriented Haversian canals, in a process known as intracortical remodeling.

Structure of Bone

The canine skeleton consists of approximately 319 bones that can be classified as follows.

- Long bones (e.g., femur, humerus)
- Cuboidal bones (e.g., carpus, tarsus)
- Flat bones (e.g., skull, rib)
- Irregular bones (e.g., vertebrae, pelvis)
- Sesamoid bones (e.g., fabellae)

Macrostructure of Bone

The shape of an individual bone is genetically determined but can be altered by changes in mechanical loading, blood supply, trauma, etc. For long bones, three anatomically distinct regions are recognized.

- Diaphysis – the shaft of the long bone, composed of cortical bone surrounding the medullary cavity.
- Epiphysis – the end of a long bone that is initially separated from the rest of the bone by the presence of a growth plate (physis).
- Metaphysis – the region between the epiphysis and the diaphysis.

Bone is present in one of two forms, cortical or cancellous. Cortical bone is very dense (it is also known as compact bone) and is mainly found as an envelope for the flat bones and in the diaphyseal regions of long bones. Cancellous bone is less dense and exists as a three-dimensional network of interconnecting struts (trabeculae), primarily within the metaphyseal and epiphyseal regions of the long bones, as well as in the irregular bones. Cancellous bone has a significantly higher surface area (per unit volume) for cellular activity than cortical bone and, as a result, is more metabolically active. The regions of the skeleton in which there are increased amounts of cancellous bone tend to be the high turnover sites; in humans, these are the sites that are most sensitive to hormonal change and most likely to develop osteoporosis (proximal femur, spine, distal radius).

Microstructure of Bone

Bone is organized as either lamellar bone or woven bone. Woven bone is an immature form of bone and is only seen in the skeletally mature animal at sites of fracture healing, bone growth, and skeletal diseases such as neoplasia or panosteitis. When present in the adult skeleton, it is rapidly remodeled into lamellar bone. Woven bone is more cellular than lamellar bone and its collagen fibers are aligned at random; as a result, woven bone is isotropic (i.e., mechanical properties do not depend on specimen orientation).

Lamellar bone is found throughout the mature skeleton in both cortical and cancellous bone, irrespective of whether the bone was formed by intramembranous or endochondral ossification. The collagen fibers in lamellar bone are oriented in parallel with one another and, as a result, lamellar bone displays anisotropy when tested mechanically.

This means that the mechanical properties depend on the direction of loading – similar to plywood, which is easily cut in one plane ("with the grain") but hard to cut at right angles ("across the grain").

Under polarized light microscopy, lamellar bone appears to have a regular sheet-like structure rather than the irregular structure of woven bone. In cancellous bone, the sheets of lamellar bone are oriented parallel to the surface of individual trabeculae. In cortical bone, lamellar bone is usually arranged in osteons, consisting of a central vascular channel surrounded by multiple concentric layers of lamellar bone; the osteons that comprise the osteonal complex are bounded externally by circumferential lamellae and separated one from another by interstitial lamellae.

The arrangement of bone within osteons provides the cortical bone with strength and some limited flexibility in bending and torsion.

Vascular Supply to Bone

In the long bone, there are three separate but related circulatory systems.

- The *nutrient artery* enters the long bone through the nutrient foramen in the diaphysis. Once within the medullary canal, the nutrient artery divides into ascending and descending medullary arteries that are the primary blood supply to diaphyseal cortical bone. Blood flow is centrifugal.
- The *metaphyseal vessels* arise from geniculate arteries that form the blood supply to periarticular tissues.

These vessels penetrate the cortex at the level of the metaphysis. In addition, smaller proximal and distal metaphyseal arteries derive from the ascending and descending medullary arteries. The metaphyseal arteries are the primary blood supply to cancellous bone.

- The *periosteal capillaries* supply the outer one-third of the cortex. These capillaries are derived from adjacent soft tissues (muscles, fascia) that insert on the bone (e.g., at the linea aspera on the femur). This blood supply is centripetal in nature.

There is considerable overlap and interplay between the circulatory systems in bone, perhaps most evident when bone is injured. If the medullary system is compromised, for example as a consequence of fracture or intramedullary reaming, the periosteal blood supply will increase in an attempt to revascularize the diaphysis. External fixation devices and bone plates affect both the endosteal supply and the periosteal supply. The design of modern bone plates, with limited contact with the periosteal surface, represents an effort to try to reduce the negative impact of plating on periosteal blood supply. Preservation of an effective blood supply is a basic principle of surgery since it is a critical determinant of tissue healing and subsequent function. Disturbances in blood supply play a role in the pathophysiology of several important orthopedic conditions, including ischemic necrosis, osteomyelitis, delayed union, and nonunion of fractures.

Bone Physiology

Bone Modeling and Bone Remodeling

Bone remains a dynamic structure throughout life. This is critical for both the maintenance of skeletal strength and the continued role of bone as a mineral reservoir. Mineral sequestered within the bone matrix can be mobilized rapidly in response to calcitropic hormones such as parathyroid hormone, vitamin D3, and calcitonin that respond to, and modulate, circulating calcium concentration.

Bone modeling is the process through which changes in bone shape occur. In modeling, bone formation and bone resorption can occur at different surfaces, resulting in shape changes. For example, radial growth of a long bone is achieved through new bone deposition at the periosteal surface. If there was not concurrent removal of bone from the endosteal surface, the net result would be a bone with a very thick cortex and a very narrow medullary canal. Removal of bone from the endosteum leads to expansion of the medullary canal and preservation of a space for trabecular bone (important for both structural support and bone turnover) and bone marrow (important for hematopoiesis).

Bone remodeling, the process in which bone is first removed and then replaced, is executed by the coupled activities of bone-resorbing osteoclasts and bone-forming osteoblasts. Bone remodeling is temporally and spatially coupled, and proceeds through defined stages of activation ⇒ resorption ⇒ formation. Bone remodeling activity proceeds as a surface phenomenon on bone trabeculae within cancellous bone, or on the endosteal or periosteal surfaces of cortical bone. However, cortical bone remodeling also occurs through osteonal (Haversian) remodeling that is carried out by a complex and unique structure, the basic multicellular unit (BMU), that consists of a cutting cone of osteoclasts in front and a closing cone of osteoblasts at the rear. The BMU moves through bone over a period of several months, removing damaged or unnecessary bone and replacing it as dictated by local mechanical and/or biologic stimuli. The removal of damaged bone is critical to the replacement of bone that has been microfractured, for example as a result of chronic overload (as may be seen in elite human, canine or equine athletes in training).

In the healthy adult animal, bone formation and resorption (i.e., overall remodeling) are balanced. However, imbalances in remodeling occur with aging. The most important example of remodeling imbalance is seen in postmenopausal osteoporosis in women, in which loss of estrogen results in a relative increase in bone resorption, reduced bone mass, and an increased risk of "fragility" fracture.

What Controls Bone Remodeling?

The last 15 years have seen an explosion in what is known about osteoclast biology, driven in large part by the quest for greater understanding of disease states caused by dysregulated osteoclast activity. The major clinical and research emphasis has been on postmenopausal osteoporosis in women. Although the role of estrogen deficiency has long been recognized, we now know that local paracrine factors play a critical role in driving the excessive bone resorption that characterizes this disease. At a cellular and molecular level, the control of bone resorption depends on the availability of osteoclastic precursor cells, local levels of macrophage colony-stimulating factors (M-CSF) and the activities of the receptor activator of NF-kappa B (RANK), its ligand (RANK ligand, or RANKL) and its decoy receptor, osteoprotegerin (OPG). These interactions are illustrated in Figure 171.1. RANK is expressed as a surface receptor on mononuclear osteoclast precursors; binding of RANKL to the receptor results in cell–cell fusion to form the

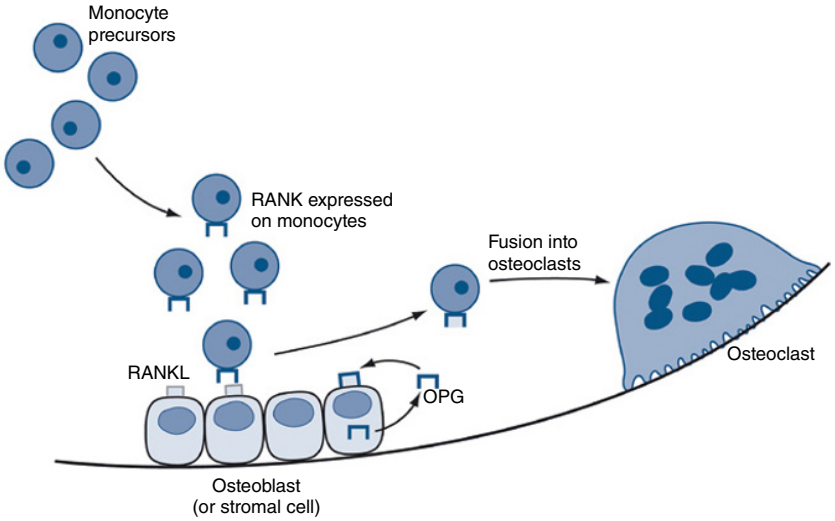

Figure 171.1 Molecular control of osteoclast differentiation. Monocytes stimulated by M-CSF and RANKL fuse to form multinucleate osteoclasts. Interruption of the RANK-RANKL axis offers a therapeutic approach to disease characterized by increased osteoclastic activity. *Source:* Reproduced with permission from Allen MJ. Cellular and molecular biology. In: Damron T, ed. *Oncology and Basic Science (Orthopaedic Surgery Essentials)*. Baltimore, MD: Lippincott, Williams and Wilkins, 2007.

multinucleate osteoclast. Increases in the ratio of RANKL to OPG favor net bone loss, while decreases favor net bone accrual.

A number of drug therapies have now been developed for modulating osteoclastic activity. The most widely used antiresorptive agents are bisphosphonates such as pamidronate, clodronate, alendronate, and zoledronate. These compounds, which bind to mineral within the bone matrix, are released when mineral is resorbed by osteoclastic activity. Direct exposure of the osteoclast to high levels of these drugs leads to osteoclast apoptosis and a decrease in bone resorptive activity. Although initially introduced for osteoporosis, bisphosphonates are now widely used in the management of patients with other forms of pathologic bone resorption, including hypercalcemia of malignancy (e.g., with anal sac adenocarcinoma), primary bone cancer (e.g., osteosarcoma, feline oral squamous cell carcinoma) or secondary bone metastases (e.g., from mammary or prostatic carcinoma).

An alternative approach to controlling osteoclastic activity involves targeting the RANK-RANKL pathway by administration of exogenous OPG or RANK-Fc antibodies that serve as competitive antagonists for the RANK receptor.

Decreases in normal bone resorptive activity are also not without consequence. The most extreme example of this can be seen in patients with osteopetrosis, a congenital disease in which there is failure of osteoclast formation or functionality. The classic clinical features of bone fragility, osteoarthritis, and marrow failure can all be explained by failures of osteoclastic resorption, including an inability to remodel and expand the medullary canal (and an absence of space for hematopoiesis), failure to remodel cortical and trabecular bone (leading to increased bone mineral density) and failure to resorb and replace damaged bone (leading to bone fragility secondary to bone fatigue failure).

Since net bone mass is sensitive to changes in both formation and resorption, attention has also been paid to the role of anabolic factors that modulate skeletal activity. In the context of long bone growth, it has been shown that growth hormone is capable of enhancing longitudinal bone growth in the immature skeleton. In the adult animal, preclinical studies have confirmed the anabolic potential of both exogenous parathyroid hormone (PTH) and bone morphogenetic proteins (BMPs). Intermittent (daily) treatment with recombinant or synthetic forms of human PTH is effective in enhancing overall bone mass and accelerating bone repair after fracture. Bone morphogenetic proteins, including BMP-2 and BMP-7, have been studied extensively in dogs and BMP-2 is now available commercially as a potential treatment to accelerate or enhance fracture healing.

Effects of Mechanical Loading on Bone

Julius Wolff (1836–1902) was a German surgeon who first identified the relationship between mechanical forces and bone structure. He likened the arrangement of trabecular bone in the neck of the femur to the arrangement of supports in a crane, with the trabeculae being oriented to best resist the forces to which the femoral neck was being exposed. Although originally published in German in 1892, Wolff's law can be summarized thus: "Bone changes its structure according to the mechanical loads to which it is exposed."

Once the adult skeleton has formed, it continues to adapt to the prevailing mechanical environment. Graphic evidence of the importance of mechanical loading in driving the change in bone shape and bone mass (bone modeling) comes from professional tennis players

(who develop significant increases in bone mass in their dominant forearm) or astronauts (who lose significant bone mass after even a few weeks in the microgravity of space). Practical examples of modeling in the context of veterinary orthopedics include the remodeling of fracture callus, functional adaptation of the metacarpal, metatarsal and central tarsal bones of racing greyhounds, bone loss following limb disuse, the development of stress fractures secondary to accelerated bone remodeling in racing thoroughbreds, and "stress shielding" around orthopedic implants.

Bone Pathophysiology

Bone Response to Injury

The basic biology of bone's response to trauma has been a subject of intense investigation over the years, particularly within the context of understanding what happens after bone fractures. The fundamental response of bone to trauma is similar to that seen in other tissues, and includes cellular recruitment, differentiation, and formation of an appropriate replacement tissue. In the context of normal bone healing after fracture, three overlapping stages are recognized: the inflammatory stage, the repair phase, and the remodeling phase.

Inflammatory Phase

Significant trauma, such as fracture, inevitably result in disruptions to the medullary blood supply, leading to extravasation of blood and the formation of a clot between and around the ends of the fractured bone. Damage to the periosteum also results in formation of clot around the external surface of the bone. Although mechanically incompetent, the clot acts as a rich source of growth factors for angiogenesis and subsequent fracture healing. This last point is of critical significance when contemplating surgery for a fracture – excessive manipulation of the soft tissue clot results in loss of many of the cells (and signaling molecules) that are ultimately required for successful healing. An "open but do not touch" approach allows the surgeon to assess the fracture and to apply fixation methods that do not interfere with (but instead harness) the body's innate healing response. This is the concept of biologic osteosynthesis.

Repair Phase

Macrophages that are brought in through the newly forming capillary bed serve to remove tissue debris and initiate the conversion of the clot into first granulation tissue and then callus. Callus formation starts with the deposition of collagen (initially types 1, 2, and 3) by fibroblasts. At the same time, mesenchymal cells that were brought into the area during the inflammatory response differentiate into chondrocytes and deposit a cartilage framework that is subsequently mineralized. It should be noted that the progressive transition from clot ⇒ granulation tissue ⇒ soft callus ⇒ hard callus recapitulates the process of endochondral bone formation that occurs during normal bone formation.

Remodeling Phase

The final stage of fracture healing involves the gradual incorporation of the relatively disorganized hard callus into the skeleton. This is the longest phase of fracture healing. Remodeling of the callus is governed by Wolff's law and, ultimately, the process of bone remodeling results in a structure that is best able to resist the mechanical forces to which it is subjected.

Thermal Injury to Bone

Bone is damaged by temperatures exceeding 47 °C for more than one minute. The most common scenarios for thermal injury to bone occur during orthopedic surgery and are related to the use of power tools to cut and shape bone, or the bone cement that is used to secure total joint replacement implants.

Power tools such as saws, drills, and reamers are used every day in orthopedic surgery. In the operating room, every effort is made to reduce the risk of thermal injury. This involves the use of sharp drills or saw blades (old, dull blades or drill bits will mill bone and generate heat); low-speed cutting and drilling whenever possible; short rather than sustained bursts of drilling or sawing; and copious saline lavage, which serves both to cool the tissue and to remove bone debris that can otherwise clog up blades and drill flutes.

The standard bone cement used in orthopedic surgery is acrylic cement based on polymethylmethacrylate (as used in Plexiglas). Bone cement is used to secure joint replacement implants into bone. Cement is typically injected in a liquid state but then hardens through a chemical process of polymerization that is exothermic. Since bone cement is usually placed immediately adjacent to cortical or trabecular bone, there is potential for heat injury to the constituent bone cells, as well as to the vascular supply to the endosteum. Data from preclinical animal models indicate that this thermal injury is typically reversible. However, care should be taken to use the minimum volume of cement necessary and to ensure protection of adjacent neurovascular structures.

Vascular Injury to Bone

Vascular trauma to bone may occur secondary to a fracture or as an unwanted consequence of surgical

interventions. Traumatic disruptions during fracture typically involve significant injury to the blood supply on both endosteal and periosteal surfaces. Vascular injury secondary to surgical procedures may affect the entire bone (if, for example, a nutrient vessel is cut by accident) or it may preferentially affect one region (for example, damage to the outer surface of the bone or to the adjacent soft tissues has a greater effect of periosteal blood supply, while introduction of an intramedullary pin or bone cement into the medullary cavity will selectively damage the endosteal blood supply). Application of a plate to the surface of the bone also may damage the periosteal supply.

In most cases, regional changes in blood flow will be able to restore effective vascularity to the bone. For example, loss of periosteal blood supply results in an increase in centrifugal blood flow through the cortex, while endosteal damage results in increased centripetal blood flow from the periosteal vascular network.

Periosteal Trauma

Periosteal trauma occurs either as a consequence of fracture, secondary to surgical manipulation of the bone, or as a consequence of bone pathologies such as infection or neoplasia. Data from preclinical animal models have shown that traumatic loss of periosteum has the potential to result in overall bone loss and an increased risk of fragility in the affected bone. At least two factors appear to be involved in this response. First, loss of periosteal bone-forming cells will lead to a decreased ability to make new bone at the periosteal surface. Second, loss of the vascular supply to the periosteum results in transient derangements in bone blood flow. In healthy animals, the extent of periosteal trauma would have to be significant to cause a whole-bone effect. However, if the bone is otherwise compromised by disease, periosteal damage may result in further bone loss and an increased risk of catastrophic bone failure.

Reactive New Bone Formation

Reactive new bone is a relatively common radiographic finding and a not uncommon confounding factor in bone biopsies taken from sites of bone pathology. While the underlying process of forming new bone represents a biologically conserved and logical response to bone trauma, the response is not specific to any one initiating cause, making it extremely hard for radiologists or bone pathologists to ascribe a specific underlying disease entity as the cause of the new bone formation. Some information may be gleaned from the location of the new bone, with both endosteal and periosteal surfaces being potential sources of reactive new bone formation.

At the periosteal surface, fracture, infection, and neoplasia are the most common causes of a reactive periosteal new bone formation ("periosteal response"). The role of periosteal callus in fracture healing will be discussed shortly. In the context of bone infection and neoplasia, situations in which the periosteum can be underrun by inflammatory or neoplastic infiltrates, the typical response is for new bone formation. The mechanisms responsible for this are not well understood but likely relate to the ability of periosteum to react to increased local mechanical deformation by depositing new bone. There are significant numbers of nociceptors at the periosteal surface, and periosteal involvement in neoplasia and infection tends to be extremely painful. Radiographically, the observation of focal to local periosteal new bone is highly suggestive of aggressive bone conditions such as neoplasia or osteomyelitis.

With neoplasia, disruption and lifting of the periosteum proceed too rapidly for the bone to mineralize in the normal layered fashion, and the net result is that only the edge of the lifted periosteum ossifies. Radiographically, the mineralized flap of periosteum is described as Codman's triangle.

At the endosteal surface, reactive new bone formation is seen predominantly in fracture healing and also as a component of canine panosteitis, which will be discussed later.

Pathologic Bone Resorption

Excessive and dysregulated activation of bone resorption is a hallmark of several important developmental, inflammatory, infectious and neoplastic disorders in animals, including periodontal disease, osteomyelitis, multiple myeloma, and aseptic or septic loosening of total joint replacement implants. A complete description of the pathobiology of these conditions is outside the scope of this short discussion, but it is important to note that the fundamental biologic mechanisms through which bone is removed are the same as are seen in normal (physiologic) bone remodeling. The major differences lie in the nature of the inciting cause; for implant-related bone resorption (osteolysis), it is the inflammatory response to metallic and polymeric debris liberated from the surfaces of the implant that stimulates the inflammatory cascade. In metastatic tumors that target bone, proinflammatory cytokines released from the tumor appear to modulate the osteoclastic response immediately adjacent to the tumor deposits.

Irrespective of the inciting cause, strategies for managing pathologic bone resorption focus on eliminating the underlying inciting cause with appropriate medical therapy (antibiotics, chemotherapy) or surgical intervention (to remove a loose or infected implant). The use of oral

or injectable bisphosphonates also represents a logical approach to suppressing ongoing bone loss in these patients.

Bone Healing after Fracture

The goal of fracture fixation is to restore structure and function to the skeleton. Fracture healing is influenced by a wide array of factors, including the animal's age, location and type of fracture, stability of the fragments, extent of soft tissue and vascular compromise, and presence or absence of necrotic and/or infected tissues. Mechanical stability is known to be of paramount importance in determining the nature, time course, and efficiency of the fracture healing response. Under stable conditions, the fracture will unite via direct (primary) bone healing, in which new bone forms a direct bridge across the fracture plane. Under unstable conditions, a soft tissue callus first forms and it is this callus that is then progressively mineralized in a process known as indirect (secondary) fracture healing.

Role of Mechanical Factors in Fracture Healing

Fractures that are anatomically reconstructed and maintained under stable conditions through the use of internal fixation heal without significant callus. However, even under conditions of ideal bone fragment alignment, it is common to find microscopic discontinuities between the ends of the fragments. The extent of the gap dictates the nature of the reparative response that will predominate. In very small gaps, woven bone forms and continuity is restored between the ends of the bone. If the gap is larger than ~1 mm, the gap will fill in with soft callus. As long as the fracture site remains stable, the callus will successfully mineralize and remodel. In fact, controlled amounts of micromotion have been shown to accelerate bone repair, a finding that has been used to great benefit in distraction osteogenesis, a procedure in which controlled axial distraction of a small bone fragment is used to stimulate and maintain new bone formation. Over time, the regenerated bone formed in this way is capable of filling in a significant defect in the original bone. Distraction osteogenesis can be useful in the management of both large bone defects (e.g., secondary to trauma or neoplasia) and the correction of angular limb deformities.

In the presence of mechanical instability, either with comminuted fractures or with fractures that are unstable despite attempts at fixation, fracture healing is characterized by the formation of abundant callus that unites the bone fragments. The biologic processes that underlie the formation of callus have been described previously. The mechanical properties of the callus similarly evolve as the callus matures from a fibrous connective tissue, through a cartilaginous intermediate and finally to bone. The total area (volume) of the callus depends on (i) the degree of displacement of the fragments and (ii) the extent of mechanical instability at the site of fracture. Once the mechanical properties of the callus are sufficient to minimize interfragmentary strain (2% is often cited as the threshold for new bone formation), primary bone repair can occur and the callus will be remodeled to restore the medullary cavity and cortical profile. It should be noted that the presence of external callus leads to a rapid increase in the mechanical integrity of the bone, so that bone that heals with abundant callus is able to withstand physiologic forces within a relatively short period of time after fracture.

Other Factors that Influence Bone Healing

Certainly, any factor that compromises the ability of callus to form or to differentiate would be expected to delay or prevent fracture healing. In addition to mechanical instability due to incomplete reduction or stabilization, other factors that can lead to delayed or nonunion after fracture include vascular compromise, premature or excessive weight bearing after surgery (hence the importance of controlling activity levels after surgery), infection, radiation therapy, systemic illness, or concurrent treatment with prolonged courses of drugs such as corticosteroids. In humans, smoking is a critically important determinant of wound healing in general and a major risk factor for complications following fracture repair. The potential negative effects of nonsteroidal antiinflammatory drugs (NSAIDs) on bone healing have been the subject of significant research efforts in humans but data in animals are less clear, and there does not appear to be any objective evidence that short-term treatment with NSAIDs has a significant effect on bone healing after trauma or surgery.

Complications with Fracture Healing – Delayed Union, Malunion, and Nonunion

Although the majority of straightforward fractures will go on to heal (unite) without complication, a subset of patients will experience problems with healing. The primary causes of suboptimal fracture healing have been described in the preceding sections, and include incomplete reduction of the fracture, uncontrolled or excessive weight bearing, vascular compromise, infection, and concurrent medical disease or therapy. Three general categories of abnormal fracture healing have been recognized: delayed union, malunion, and nonunion. The diagnosis of disturbed fracture healing is made on

the basis of careful physical examination and radiographic findings.

Delayed union is probably the most challenging to diagnose definitively since it represents healing that occurs at a slower rate than would be expected for a given fracture. As mentioned earlier, the rate and completeness of healing are sensitive to a range of variables, and as a result there can be significant variations in how fast a given fracture heals. Most delayed unions can be managed conservatively, without the need for additional surgical intervention.

Malunions are fractures that have gone on to clinical union but with abnormalities in the alignment of the fragments. In the middiaphysis, this may manifest as rotational abnormalities or angulation between the proximal and distal ends of the bone. At the articular surface, healing without complete restoration of the articular surface would be considered a malunion. The consequences of malunion depend on both severity and location; minor angular malalignment may be clinically asymptomatic, while discontinuities or irregularities in the articular surface can predispose to the development of posttraumatic osteoarthritis.

Nonunion represents the most extreme disturbance in normal fracture healing. The extent and nature of the healing response can be quite variable, but nonunions can broadly be classified into viable nonunions, in which the tissues are still capable of biologic activity, and nonviable nonunions that are devoid of biologic activity. The management of these fractures can be complex and lies outside the scope of this discussion, but often involves aggressive surgical intervention. In select cases, there may also be a role for local (e.g., BMP) or systemic (e.g., PTH) anabolic drug therapies to boost new bone formation.

Metabolic Bone Diseases

Keren E. Dittmer, PhD, BVSc, DACVP

School of Veterinary Science, Massey University, Palmerston North, New Zealand

Metabolic bone diseases include osteoporosis, rickets and osteomalacia, fibrous osteodystrophy (secondary hyperparathyroidism), and scurvy (vitamin C deficiency). Fibrous osteodystrophy is an important skeletal disease of young dogs and cats. On the other hand, rickets and osteomalacia are relatively rare. While osteoporosis is the most common metabolic bone disease of humans, it is seldom diagnosed in small animals, possibly due to the lack of sensitive techniques to reliably diagnose the disease. Dogs and cats have the hepatic microsomal enzyme L-gulonolactone oxidase and can synthesize vitamin C (ascorbic acid), therefore scurvy does not occur in these species. The metabolic bone diseases covered in this chapter include fibrous osteodystrophy, rickets and osteomalacia, with a brief discussion of osteoporosis.

Calcium and Phosphorus Physiology

In order to truly understand the pathophysiology of the metabolic bone diseases, good knowledge of normal calcium and phosphorus metabolism is required. Therefore a brief description of calcium and phosphorus homeostasis will be included here.

The hormones vitamin D, parathyroid hormone (PTH), calcitonin, and fibroblast growth factor 23 (FGF23) are essential for controlling plasma calcium and phosphorus concentrations. These hormones facilitate calcium and phosphorus transportation in three main organs: the kidney, intestine, and bone.

Calcium transport is predominantly under the control of PTH and 1,25-dihydroxyvitamin D ($1,25(OH)_2D_3$). Parathyroid hormone is a small peptide secreted by the parathyroid gland when the calcium-sensing receptors on chief cells detect low plasma calcium concentrations. PTH binds to the PTH receptor 1 in renal tubules, resulting in activation of adenylate cyclase and phospholipase C cell pathways, ultimately leading to opening of calcium channels (such as transient receptor vanilloid potential 5, TRPV5), and increased resorption of calcium from the renal filtrate. Increased plasma phosphorus concentrations may also lead to increased PTH secretion by an unknown mechanism. Increased PTH leads to increased breakdown of phosphate channels (Na^+-P_i ATPase pump, NPT2), resulting in decreased resorption of phosphorus from the renal filtrate.

The actions of PTH on bone are dual and antagonistic. Secretion of PTH in response to low plasma ionized calcium leads to increased expression of receptor activator of NF-kB ligand (RANKL) by osteoblasts. When RANKL binds to the RANK receptor on osteoclast precursors, it leads to differentiation and maturation of these cells into mature osteoclasts. At the same time, PTH leads to decreased expression of osteoprotegerin (OPG/OCIF), a decoy receptor that prevents binding of RANKL to RANK. Increased production of osteoclasts ultimately results in increased osteoclastic bone resorption and release of calcium and phosphorus from bone matrix into blood. The anabolic actions of PTH are used in the treatment of osteoporosis in humans. Intermittent low-dose treatment with PTH analogs results in increased differentiation and production of osteoblasts, and therefore increased bone formation.

Low plasma calcium concentration and PTH activate the 1-alpha-hydroxylase enzyme in the kidney, resulting in increased production of $1,25(OH)_2D_3$. Active vitamin D ($1,25(OH)_2D_3$) binds to the vitamin D receptor in the nucleus of intestinal epithelial cells and renal tubular epithelial cells, leading to increased production of vitamin D-responsive proteins, such as calcium channels (TRPV5, 6 and Na^+/Ca^{2+} exchanger), phosphate channels (NPT2a, 2b, 2c), and calcium-binding proteins (calbindin-D_{9k} and D_{28k}). Increased production of these proteins results in increased absorption of calcium and

Companion website: www.wiley.com/go/bruyette/clinical

phosphorus from the renal tubules and intestinal tract. Active vitamin D also has a negative feedback effect on its own production. In the parathyroid gland, $1,25(OH)_2D_3$ directly inhibits PTH production and increases the sensitivity of the calcium-sensing receptors to calcium, thereby acting to control PTH secretion.

Like PTH, vitamin D may also have dual and antagonistic effects in bone. When plasma blood calcium concentrations decline, $1,25(OH)_2D_3$ leads to increased bone resorption by upregulating RANKL production and inhibiting OPG production, likely in association with PTH. In addition, $1,25(OH)_2D_3$ upregulates inhibitors of bone mineralization. However, $1,25(OH)_2D_3$ can be produced locally in bone, by chondrocytes, osteoblasts, osteocytes and osteoclasts, where it leads to increased bone formation and mineralization.

Calcitonin is the antagonistic hormone to vitamin D and PTH and is released in response to increased plasma ionized calcium concentrations. It inhibits osteoclast motility and leads to retraction of osteoclasts from bone, resulting in decreased bone resorption and therefore decreased release of calcium and phosphorus into the blood.

Traditionally, it was thought that the control of plasma phosphorus concentrations was indirect, as a result of the tighter control of calcium. However, a suite of compounds, known as phosphatonins, are critically involved in phosphorus control, the most important of which is FGF23. Increased plasma phosphorus concentrations and increased $1,25(OH)_2D_3$ may both independently increase FGF23 production by osteocytes in bone. The main target organ for FGF23 action is the kidney. FGF23, together with its co-factor klotho, downregulates the NPT2a and 2c phosphorus channels in the kidney, leading to decreased resorption of phosphorus from the renal tubules. FGF23 also acts on the parathyroid gland to decrease secretion of PTH. FGF23 in combination with the decrease in PTH leads to inhibition of the renal 1-alpha-hydroxylase enzyme decreasing production of active vitamin D. At the same time, there is activation of the enzyme (24-hydroxylase) that breaks down active vitamin D, ultimately resulting in decreased $1,25(OH)_2D_3$.

Fibrous Osteodystrophy

Fibrous osteodystrophy (FOD) is a skeletal disease characterized by the replacement of bone with a combination of fibrous tissue and poorly mineralized woven bone. While the focus of this section is on nutritional hyperparathyroidism, primary and renal hyperparathyroidism may cause similar skeletal lesions.

Etiology/Pathophysiology

Fibrous osteodystrophy is the skeletal consequence of hyperparathyroidism or a chronic increase in PTH. There are four main causes of hyperparathyroidism.

- *Primary hyperparathyroidism* – due to a functional tumor of the parathyroid gland, resulting in autonomous secretion of PTH. The increased PTH leads to hypercalcemia and mineralization of soft tissues, and in long-standing cases clinical FOD. This will be discussed in the endocrine section. A probable hereditary primary hyperparathyroidism has been reported in a litter of German shepherd puppies.
- *Renal hyperparathyroidism* – due to chronic kidney disease. While renal hyperparathyroidism is common in animals with chronic kidney disease, clinical signs due to skeletal changes are usually minimal in adult animals. Nonetheless, recent studies have shown that dogs and cats with chronic kidney disease have decreased bone mineral density and increased bone porosity. Young rapidly growing animals with familial renal disease may develop severe skeletal lesions.
- *Nutritional hyperparathyroidism* – due to a decreased calcium to phosphorus ratio in the diet. This is a common condition of young rapidly growing cats and dogs fed poorly balanced diets post weaning.
- *Pseudohyperparathyroidism or hypercalcaemia of malignancy* – due to a tumor that produces calcitropic hormones. Parathyroid hormone-related peptide (PTHrp) is the best characterized of these calcitropic hormones and has the same effect as PTH. Tumors that most commonly produce PTHrp are lymphoma and apocrine gland adenocarcinoma of anal sac origin. Occasionally, other carcinomas, malignant melanoma, and other tumors may produce other factors that cause hypercalcaemia, such as $1,25(OH)_2D_3$, prostaglandins, and various cytokines (TGF-beta, IL-1-beta). Skeletal changes are mild and difficult to detect; clinical signs are the result of hypercalcemia.

Signalment

Nutritional hyperparathyroidism is typically a disease of rapidly growing young animals after weaning. A case of nutritional hyperparathyroidism in an adult dog has been reported; the Rottweiler was on a home-made diet due to the diagnosis a year previously of lymphocytic-plasmacytic enterocolitis and lymphangiectasia.

History and Clinical Signs

Nutritional FOD occurs when the diet contains excessive phosphorus or deficient calcium. In actual practice, most commonly it is due to a combination of decreased

calcium and increased phosphorus in the diet. The most frequent cause of nutritional FOD is an all-meat diet. The ideal Ca:P ratio of a diet is 1:1. Meat and liver have calcium to phosphorus ratios of 1:20 and 1:50 respectively, and a diet based solely on these components can lead to clinical signs of FOD within four weeks.

Animals with nutritional hyperparathyroidism most commonly present with an ill-defined lameness, disinclination to move, and a failure to thrive. Some animals may have angular limb deformities. In more severe cases, pathologic fractures may occur with only mild trauma. Resorption of alveolar bone in the mandible and maxilla may lead to loosening of teeth. A few animals may develop vertebral compression fractures, which in some cases may lead to neurologic signs. While another term for fibrous osteodystrophy is rubber jaw, this is usually only seen in severe prolonged cases, and is more common in young animals with familial renal disease and renal secondary hyperparathyroidism, rather than nutritional hyperparathyroidism.

Diagnosis

Biochemistry

Animals with nutritional fibrous osteodystrophy have low to low-normal plasma total and ionized calcium concentrations. The calcium deficiency in the diet stimulates PTH release, which subsequently leads to osteoclastic resorption of calcium from bone, thereby maintaining plasma calcium concentration to the detriment of bone mineral content. If the dietary deficiency of calcium is severe or the amount of calcium released from the bones is inadequate then the dog or cat will have hypocalcemia.

The increased PTH concentration leads to increased excretion of phosphorus from the kidney, and so results in an increase in the fractional excretion of phosphorus. Depending on the balance of dietary intake to renal excretion, plasma phosphorus concentrations may be low, normal or increased.

Serum alkaline phosphatase concentrations are increased due to increased bone remodeling but, along with the phosphorus concentration, need to be interpreted with caution as both may be increased in younger animals due to growth.

Plasma intact PTH concentration will be increased but there are a number of cautions to be considered when interpreting plasma PTH concentrations. The first is collection of the sample. PTH is highly susceptible to proteolysis, so serum or plasma should be separated from red cells immediately (samples should be at room temperature for less than two hours) and tested directly, refrigerated for no more than 24 hours or stored frozen at −20 °C. Samples should be shipped chilled/frozen. Serum separator tubes should not be used as they lead to decreased PTH concentrations. In addition, visible hemolysis of the sample interferes with the assay.

Second, there are several different assays available for measuring PTH, including radioimmunoassays (RIA/ERMA) and enzyme immunoassays (EIA/ELISA). In addition, assays are available for whole PTH (W-PTH), intact PTH, N-terminal fragment of PTH, and C-terminal fragment of PTH. PTH undergoes proteolysis in the liver, blood, and other organs, forming N-terminal and C-terminal fragments. The N-terminal PTH fragment cannot bind to the PTH receptor and so does not elicit the classic response to PTH; it is in fact thought to inhibit PTH action. N-terminal PTH fragments are increased in chronic renal failure.

The W-PTH assay is a third-generation PTH assay that is specific for whole 1-84 PTH, while the I-PTH is a second-generation assay that, in addition to measuring 1-84 PTH, also measures large N-terminal PTH fragments. Human two-site RIA/IRMAs for I-PTH have been validated in both cats and dogs, as has a combined W-PTH/I-PTH assay. Human EIAs may not cross-react with canine or feline PTH. Canine-specific I-PTH ELISA assays are also available. Reference ranges are assay specific and ideally should not be extrapolated from other types/brands of assay.

The third important point is that ionized calcium, total calcium, and phosphorus concentrations should be measured on the same sample as PTH. These analytes are essential for the interpretation of the plasma PTH concentration.

Radiography

The predominant change seen on radiography is generalized osteopenia of all bones. It may be most obvious in those bones with a greater proportion of cancellous bone which is more readily resorbed, such as the vertebrae. The mandible may show a marked reduction in bone density, particularly the alveolar bone around the teeth (Figure 172.1). There may be evidence of pathologic fractures (see Figure 172.1), such as compression fractures in the vertebrae and infractions in the long bones. In more severe cases, there may be complete fracture of the long bones. The growth plates are normal in animals with fibrous osteodystrophy, but there may be increased radiopacity in the primary spongiosa directly beneath the growth plate (see Figure 172.1). The cortices appear thinner and more porous. The limbs may show angular deformities, and lordosis of the spine can be present.

New technology such as dual-energy X-ray absorptiometry (DEXA/DXA) and computed tomography (CT) give a more accurate assessment of bone mineral density than plain radiographs. Bone mineral density must be decreased by more than 30% before it is detected on

Figure 172.1 Radiograph from 12-week-old greyhound puppy with fibrous osteodystrophy. (a) Tibia/fibula showing osteopenia, with normal growth plate width, sclerosis of the metaphysis beneath the physis, and a folding fracture. (b) Mandible showing loss of alveolar bone surrounding the teeth. *Source:* Courtesy of K.G. Thompson.

plain radiographs. DEXA and CT may be useful for monitoring the success of treatment. In one study, bone mineral density, as measured by both DEXA and CT, showed substantial improvement once the diet had been corrected.

Therapy

Animals with nutritional FOD should be fed a commercial balanced diet with the recommended 1:1 ratio of Ca:P. Affected animals may also benefit from receiving additional calcium, enough to raise the total Ca:P ratio of the diet to 2:1. The additional calcium may be in lactate, carbonate or gluconate forms and should be continued for two months, after which time the animal can be maintained on a commercial balanced diet. Animals with microfractures or infractions may require pain relief. An important component of treatment is confining affected animals for the first 3–4 weeks of treatment in order to decrease the risk of further pathologic fractures.

Prognosis

With correction of the diet, and provided catastrophic fracture does not occur, the prognosis for a return to normality is excellent. With time and the normal remodeling process, the poor-quality woven bone and fibrous tissue laid down will be replaced with well-mineralized trabeculae and the bones will return to normal strength.

Rickets and Osteomalacia

Rickets is a disease of young animals and is due to a failure of mineralization of osteoid and cartilage at the provisional zone of calcification in the growth plate. Osteomalacia is essentially the same condition but in adult animals. Since adult animals do not have growth plates, in osteomalacia only new osteoid laid down during the normal remodeling process is poorly mineralized. Both conditions are rare in dogs and cats.

Etiology/Pathophysiology

Rickets and osteomalacia are due to either dietary vitamin D deficiency or phosphorus deficiency. Phosphorus deficiency is very rare in dogs and cats, and as described in the FOD section, phosphorus excess is far more common.

Dogs and cats are unusual in mammalian species in that they do not appear to produce vitamin D in the skin under the influence of ultraviolet light. In most animals, ultraviolet B light results in the conversion of 7-dehydrocholesterol, in keratinocytes and the dermis, to previtamin D3 which then undergoes thermal isomerization to vitamin D3. However, cats and dogs have been shown to have only 10% of the 7-dehydrocholesterol in their skin that rats do, and cat skin contains a 7-dehydrocholesterol-delta^{7}-reductase which breaks down 7-dehydrocholesterol. Therefore, irradiation of cat and dog skin with ultraviolet light does not cause an increase in plasma vitamin D concentration. Cats and dogs are, for that reason, reliant on their diet for their vitamin D requirements. However, there are few reports of naturally occurring rickets in dogs and cats in the literature, likely due to the widespread feeding of commercial pet food. In addition, the most common inappropriate diet fed to puppies and kittens is meat and offal, which contain high levels of phosphorus and adequate vitamin D.

Vitamin D deficiency leads to decreased absorption of calcium and phosphorus from the intestine and decreased reabsorption of calcium and phosphorus from the kidney, leading to hypocalcemia and hypophosphatemia. Animals that have rickets due to vitamin D deficiency will often have concurrent FOD due to hypocalcemia. Decreased plasma ionized calcium concentration leads to increased PTH secretion and therefore increased osteoclastic resorption of bone and FOD.

In humans, rickets and osteomalacia are described in patients with gastrointestinal malabsorption disorders, due to failure to absorb fat-soluble vitamins such as vitamin D, and reduced absorption of calcium. Rickets has been described in a 17-week-old male border collie with extrahepatic biliary atresia.

Aluminium toxicity from chronic antacid administration or long-term total parenteral nutrition may also cause rickets and osteomalacia in humans.

Osteomalacia may occur in combination with FOD in dogs and cats with chronic kidney disase. Hyperphosphatemia results in increased plasma FGF23 concentrations, leading to inhibition of the renal 1-alpha-hydroxylase enzyme, causing decreased production of $1,25(OH)_2D_3$. This combination of osteomalacia and FOD is often termed renal osteodystrophy. As mentioned earlier, while bone changes do occur in adult animals with chronic kidney disease, the changes seldom result in clinical signs.

Vitamin D also has an important role in the immune system, and has been associated with many different diseases in both humans and animals. Low serum 25OHD concentrations in dogs have been associated with immune-mediated disorders, various types of cancer, acute pancreatitis, progression of leishmania, chronic enteropathy, chronic valvular heart disease, and poor outcome in congestive heart failure, while in cats, low serum 25OHD has been associated with inflammatory bowel disease, intestinal small cell lymphoma, and mycobacteriosis. However, care should be taken not to overinterpret the role of vitamin D in these diseases. Correlation is not causation, and randomized clinical trials are required to determine the significance of vitamin D in the pathogenesis of different diseases and whether changes in serum 25OHD are primary or occur secondary to the disease.

Signalment

Rickets occurs in young animals and cases of rickets in the literature have been reported in 10–14-week-old puppies and kittens. Nutritional rickets has been reported most commonly in greyhound litters, presumably because these animals are more likely to be fed unusual diets.

Rickets is extremely rare in cats, and naturally occurring nutritional rickets has not been reported in the literature. However, rickets has been induced experimentally in both cats and dogs fed vitamin D-deficient diets.

History and Clinical Signs

As with nutritional FOD, animals with rickets usually have a history of an unusual postweaning ration. In two of the reported cases of rickets in the literature, puppies were fed a diet of milk and meat. Such a diet would likely meet the calcium and phosphorus requirements for the animals, but not vitamin D, as the vitamin D concentration of milk is low.

A case of rickets has occurred in a 10-week-old Shetland sheepdog on a commercial renal failure diet. Such diets are designed to be low in phosphorus and protein in order to alleviate some of the clinical and biochemical changes associated with the disease. However, the level of phosphorus in the diet fed to this young dog was inadequate for a growing animal, leading to phosphorus deficiency and rickets. Similarly, osteomalacia has been reported in an adult dog with food allergies fed an unbalanced elimination ration.

Affected animals present with lameness, reluctance to walk, and a failure to grow and gain weight. Animals may have angular limb deformities, particularly affecting the forelimbs. Rickets most commonly affects rapidly growing physes, such as the distal radius, proximal tibia, distal femur, and proximal humerus. The metaphyses of long bones, particularly the distal radius, may be swollen. Animals may have swollen costochondral junctions, known as the rachitic rosary. Affected animals may have pathologic fractures, and delayed eruption of teeth and enamel hypoplasia may also be seen. In animals with severe hypocalcemia, seizures may be the presenting clinical sign.

Osteomalacia is reported rarely in dogs, and this may partly be due to the subtlety of the clinical signs. The most common clinical sign of osteomalacia in humans is bone pain, and in older dogs this may easily be mistaken as reluctance to move due to chronic degenerative joint disease and not investigated further.

Diagnosis

Biochemistry

Animals with rickets due to vitamin D deficiency will have decreased or low normal serum calcium concentration, hypophosphatemia, increased serum alkaline phosphatase activity, and increased plasma PTH concentration. Serum vitamin D concentrations depend on the inciting cause of the rickets. In vitamin D deficiency rickets, usually both serum 25OHD and $1,25(OH)_2D_3$ concentrations are decreased. However, confusingly in some cases, the increase in PTH as a result of hypocalcemia leads to increased activity of the renal 1-alpha-hydroxylase and normal to increased serum $1,25(OH)_2D_3$ concentrations. Despite this, low serum 25OHD indicates there is insufficient vitamin D being obtained from the diet.

In phosphorus deficiency rickets, animals have severe hypophosphatemia but serum calcium and 25OHD

concentrations are normal. Serum $1,25(OH)_2D_3$ concentrations may be normal to increased.

Radiography

The key radiographic change seen in animals with rickets is widening and increased lucency of the long bones physes (Figure 172.2). A 10-point radiographic scoring method for rickets based on the severity of radiographic changes in the wrists and knees, to produce a score indicating the severity of nutritional rickets, has been developed for human patients. The key features of this scoring system include widening of the growth plate, irregularity of the physeal–metaphyseal interface, and concavity or cupping of the metaphysis. Other radiographic changes may include swollen costochondral junctions, infractions and other pathologic fractures, delayed appearance of ossification centers, curving of long bones, metaphyseal sclerosis, and generalized osteopenia. Stress fractures and decreased bone density are seen radiographically in osteomalacia. In humans, the presence of Looser zones is considered consistent with osteomalacia; these are radiolucent areas surrounded by a zone of sclerosis in the cortex.

Figure 172.2 Radiographs of the carpus from a 5-month-old Pomeranian with hereditary vitamin D-resistant rickets. There is substantial widening of the radial and ulnar physes, irregularity of the physeal–metaphyseal interface and cupping of the metaphyses. The metaphyseal-epiphyseal bone of the radius and ulna is flared. *Source:* Reproduced with permission from LeVine DN, Zhou Y, Ghiloni R, *et al*. Hereditary 1,25 dihydroxyvitamin D-resistant rickets in a Pomeranian dog caused by a novel mutation in the vitamin D receptor gene. *J Vet Intern Med* 2009; **23**: 1278–83.

Radiography can only give a qualitative indication of bone mineral density (BMD). DEXA or quantitative CT is required for a quantitative measurement of BMD. These techniques are also more sensitive in detecting mild to moderate decreases in BMD, and would be useful for monitoring response to treatment.

Therapy

Animals with nutritional rickets should be placed on a commercial balanced diet with the recommended 1:1 Ca:P ratio and adequate levels of vitamin D. This may be supplemented with additional calcium, phosphorus, and vitamin D as required. Care must be taken with vitamin D administration, as vitamin D is toxic at high doses, leading to widespread soft tissue mineralization, so regular monitoring of serum calcium and phosphorus concentrations is recommended. A recent study found that treatment with 25OHD increased serum 25OHD faster than cholecalciferol (vitamin D) treatment, although sample numbers were small and a safe dosage was not determined. Other vitamin D metabolite options include dihydrotachysterol, calcitriol ($1,25(OH)_2D_3$), and alfacalcidol.

Vitamin D_2 or ergocalciferol may be used but large doses are required initially, and its long half-life means that if an animal becomes hypercalcemic it takes up to four weeks for the effects of ergocholecalciferol to wane. Therefore, it is not considered an ideal treatment for rickets in dogs and cats.

Dogs and cats with rickets will benefit from 3–4 weeks of confinement in order to prevent further stress and microfractures. Pain relief for those with microfractures may be helpful.

Prognosis

The prognosis for dogs and cats with nutritional rickets for return to normality is good, providing catastrophic fracture does not occur and the predisposing reason (such as malabsorption, total parenteral nutrition) is removed. Once the poorly mineralized bone laid down during the period of dietary deficiency is replaced during remodeling, the bones will return to normal strength.

Inherited Rickets

Inherited forms of rickets resulting from inborn errors in metabolism have been diagnosed in both cats and dogs. There is confusion in the literature with regard to articles on inherited rickets; a number of reported cases are more consistent with a diagnosis of nutritional FOD than inherited rickets. Care should be taken in making a

diagnosis of inherited rickets, and the diagnosis should be confirmed with genetic testing.

There are three main groups of inherited rickets.

Vitamin D-Dependent Rickets Type I

An autosomal recessive disorder caused by a mutation in the *CYP27B1* (1-alpha-hydroxylase) gene that catalyzes the conversion of 25OHD to $1,25(OH)_2D_3$. Affected animals have clinical signs of rickets, hypocalcemia, hypophosphatemia, very high serum 25OHD concentrations, and low serum $1,25(OH)_2D_3$ concentrations. One unconfirmed case has been reported in a St Bernard dog, and a number of cases reported in cats; however, only two have reported causative mutations in the *CYP27B1* gene. Long-term treatment with $1,25(OH)_2D_3$ (calcitriol) is successful.

Hereditary Vitamin D-Resistant Rickets (Vitamin D-Dependent Rickets Type II)

An autosomal recessive disorder caused by a mutation in the vitamin D receptor (*VDR*) gene. In order to produce its calcemic effects, $1,25(OH)_2D_3$ must bind to the VDR-retinoid X receptor which then binds to vitamin D response elements in the promoter region of the vitamin D-responsive gene. Animals with mutations in the VDR are severely hypocalcemic and hypophosphatemic and have serum $1,25(OH)_2D_3$ concentrations 5–20 times greater than normal. Approximately 70–80% of human cases also have partial to total alopecia that may be obvious at birth or develop over the first few months of life. Confirmed cases have been diagnosed in a Pomeranian dog (see Figure 172.2) and a cat. A small number of human patients have been successfully treated with large doses of $1,25(OH)_2D_3$, but for most patients vitamin D treatment is not successful. Long-term intravenous calcium infusion has been the most successful treatment option for patients that did not respond to high doses of $1,25(OH)_2D_3$.

Hypophosphatemic Rickets

This form may have X-linked, autosomal dominant or autosomal recessive inheritance. Mutations have been found in the *FGF23*, dentin matrix protein 1 (*DMP1*), and ectonucleotide pyrophosphatase/phosphodiesterase 1 (*ENPP1*) genes. Whichever gene is affected, the pathogenesis behind the disease involves increased plasma FGF23 concentration resulting in renal wasting of phosphate and severe hypophosphatemia, normal serum calcium concentration, and low to low-normal serum $1,25(OH)_2D_3$ concentration. This form of rickets has not been described as yet in dogs or cats, but the description of one case in a cat from the 1990s appears clinically similar to an inherited phosphate wasting disorder.

Tumor-induced osteomalacia (TIO) is a disease with a similar phenotype to inherited forms of hypophosphatemic rickets and occurs due to paraneoplastic production of FGF23 by a tumor. TIO occurs in humans with tumors known as phosphaturic mesenchymal tumor, mixed connective tissue variant (PMT-MCT), which have many similarities to soft tissue sarcomas of dogs. One study found that three of 49 soft tissue sarcomas from dogs had high relative expression of FGF23, although no animals had clinical signs consistent with osteomalacia.

Osteoporosis

Osteoporosis is the result of an imbalance between bone resorption and bone formation. In contrast to fibrous osteodystrophy and rickets, the quality of the bone that is formed is normal; there is just less of it. Although the studies done on ovariectomized dogs have generally been poorly controlled for diet, age and other variables, it seems that unless dietary calcium is restricted, neutered dogs do not develop the postmenopausal osteoporosis that occurs in women. Potential causes of osteoporosis in dogs and cats include the following.

- *Senile osteoporosis* – general decline in bone mineral content with age, as osteoclastic resorption slowly outstrips bone formation during normal bone remodeling. Generally, this decline is not clinically significant.
- *Disuse osteoporosis* – lack of weight bearing due to immobilization or paralysis results in rapid loss of BMD in the immobilized limb and increased BMD in the contralateral limb. This effect is reversible once weight bearing resumes, particularly in young animals.
- *Inflammatory bowel disease and malabsorption* – likely due to a combination of reduced absorption of vitamin D and calcium, with increased inflammatory cytokines such as IL-6 leading to increased osteoclastic bone resorption.
- *Corticosteroid-induced* – glucocorticoids decrease calcium absorption from the intestinal tract, increase calcium excretion from the kidney, decrease osteoblast activity and increase bone resorption, all of which may lead to osteoporosis. A study in beagles with hyperadrenocorticism found that bone trabecular volume was decreased by 25% due to decreased bone formation.
- *Hyperthyroidism* – increased thyroid hormone concentrations lead to increased osteoblastic bone formation and increased osteoclastic bone resorption; however, the rate of bone resorption is greater than bone formation, resulting in osteoporosis. Pharmacologic doses of thyroxine administered to

dogs led to increased bone remodeling. While markers of bone formation (alkaline phosphatase and osteocalcin) may be increased in cats with hyperthyroidism, definitive data on the effect of thyrotoxicosis on bone are lacking.

- *Drugs* – in humans, ciclosporin and phenobarbital have been associated with osteoporosis.

Osteoporosis is rarely diagnosed in cats and dogs, in part possibly due to not considering it as a differential diagnosis for lameness or bone pain, and the insensitivity of radiography for its diagnosis. The future use of improved diagnostic testing such as DEXA and CT may reveal that osteoporosis is more common in these species than is currently thought.

Osteoarthritis in Small Animals

Steven A. Martinez, DVM, MS, DACVS, DACVSMR

Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, WA, USA

Osteoarthritis (OA, syn. osteoarthrosis, degenerative joint disease, DJD) is a syndrome that affects synovial or diarthrodial joints and may manifest its presence by causing pain in association with degeneration of articular cartilage (loss of extracellular cell matrix and chondrocytes, inflammatory response of synovium, and critical changes in proteoglycan ratios within matrix and synovial fluid) and changes in periarticular soft tissues. Since typically a low-grade inflammatory process is associated with the development and maintenance of the degenerative process of articular cartilage, the underlying subchondral bone response (e.g., sclerosis), intra- and periarticular response (e.g., synovial hypertrophy, periarticular fibrosis), the term *osteoarthritis* describes the disease process of the diarthrodial joint better than the older term *degenerative joint disease*. Typically, OA is an insidiously progressive, degenerative condition that targets high-motion synovial joints. Osteoarthritis can occur in two forms: primary and secondary, with secondary OA being the more common form presenting clinically in veterinary medicine.

Etiology/Pathophysiology

Primary OA is considered a "wear and tear" phenomenon of joint degeneration occurring in older patients. Although primary OA may be more common in cats than previously appreciated, it appears to be rare in dogs compared to clinical presentations for secondary OA issues. Causes of this form of OA in humans have been linked to obesity, the hormone leptin, and the development of OA. The target or targeted effected tissues that initiate the development of primary OA are unknown but could involve the initial degeneration of the subchondral bone resulting in secondary degeneration of articular cartilage, primary degeneration of articular cartilage, the synovium, or another tissue or combination of degeneration of tissues yet to be determined.

Secondary OA is due to an underlying or secondary cause for the development of the disease. Joint instability, direct joint trauma, infection, toxins, immune-mediated disease, and developmental/congenital disease are some of the known etiologies for the development of secondary OA and others may include infectious (e.g., septic arthritis) or noninfectious (e.g., immune mediated, trauma, developmental/congenital) environment development within the joint. The hyaline cartilage matrix (type 2 collagen, proteoglycan molecules and chondrocytes) is directly damaged which results in chondrocyte death. Synoviocytes are then stimulated to produce myriad cytokins and inflammatory mediators (e.g., interleukins, inducible encosinoids, nitrous oxide, tumor necrosis factor-alpha, etc.). These synoviocyte-based products then in turn stimulate surviving chondrocytes to produce many of the same cytokines and inflammatory mediators which result in the production of chondrocyte-based matrix metalloproteinases which catalytically digest more cartilage matrix (increased aggrecans content of matrix and synovial fluid drawing more water into matrix and synovium) and reduces the matrix's ability to biomechanically manage normal load and shear forces at the cartilage surface (resulting in more matrix loss and debris as well as fracturing of the supporting subchondral bone deep to the cartilage matrix). In addition, the chondrocyte-based cytokines and inflammatory mediators directly result in chondrocyte apoptosis. The cartilage matrix is now in a continuous metabolic state of catabolism which will drive the progression of osteoarthritis in the affected joint (Figure 173.1).

Micro- and macroscopic changes within the synovial joint may result in the clinical signs of lameness due to joint pain (synovitis, microfractures of subchondral bone, osteophytes, and joint effusion/distension) (Figure 173.2).

Epidemiology

The radiographic incidence of OA in referral hospital-based cats is estimated at 26–82% depending on age (older cats, greater incidence). In dogs, OA has been estimated to clinically affect 20% of the dog population in the United States.

Signalment

Primary OA typically occurs in older males or female cats with a higher incidence with older age. As previously

stated, primary OA appears to be relatively uncommon in dogs but would also be hypothesized to occur in older dogs.

Secondary OA can occur in any breed or sex of dog at any age. Certain juvenile skeletal developmental diseases (e.g., elbow dysplasia, hip dysplasia, osteochondritis dissecans. etc.) that result in secondary OA have the propensity to clinical affect dogs between the ages of 5 and 11 months. Skeletally mature dogs of either sex (>1 year of age) may on occasion present with clinical signs of OA due to juvenile skeletal developmental diseases. Many of the juvenile skeletal developmental diseases that affect joints are breed specific or may be breed nonspecific.

Osteoarthritis secondary to etiologies other than juvenile skeletal developmental diseases can occur with any sex and any age of dogs. Cranial cruciate ligament rupture continues to be a common cause of OA in mature dogs. With the exception of hip dysplasia, secondary OA is usually recognized in cats of any sex, breed, or age following joint trauma such as articular fractures.

History and Clinical Signs

The clinical history of most canine OA patients will commonly be a noted lameness of the affected limb following activity. Typically, the lameness will worsen with progressive activity. Hip dysplasia patients have a different gait history from other causes of OA which centers on the appearance of stiffness to rise and then sudden halting of activity (e.g., "sitting down") rather than increasing lameness. Owners may also note a classic "bunny hopping" gait in a hip dysplasia patient when running. With any form of OA, owners may also note pain on flexion, extension, and/or with other manipulation of the affected joint.

The clinical history of most feline OA patients will center on behavior/activity changes; more fractious or more subdued with owner or other animal interactions and less active than noted previously (sitting/crouching for long periods of time).

The clinical signs associated with OA vary from patient to patient and may range from subclinical to a severe functional disability. The following clinical findings are typical of patients with OA.

Gait Assessment

- Reduced weight bearing of affected limb
- Shorten stride length of contralateral normal limb
- Audible clicking or "clunking" during gait
- Pelvic swings enhanced to the contralateral side of the affected pelvic limb
- Head dorsiflexed on affected thoracic limb side
- Narrowed pelvic limb stance

Physical Exam Findings

- Asymmetric or symmetric muscle atrophy
- Asymmetric or symmetric joint thickening/joint effusion/heat
- External rotation of pelvic limb or thoracic limb
- Decreased joint range of motion (flexion and/or extension)
- Crepitus during joint motion
- Pain/discomfort on one or more aspects of joint manipulation (flexion, extension, abduction, adduction, internal or external rotation)

Diagnosis

Diagnostics are initially directed towards orthogonal view radiographs of the affected joint and should include the contralateral joint for comparative assessment. Radiographic features indicative of OA include osteophytes, effusion, subchondral bone sclerosis with or without lucencies or erosive patterns (Figure 173.3).

Other nonimaging modalities can be used for more detailed joint evaluation, including computed tomography (CT) and magnetic resonance (MR) imaging . These modalities may be beneficial if radiographic findings are minimal or equivocal for radiographic features to support a diagnosis of OA.

Arthrocentesis with synovial fluid cytology and fluid analysis may be beneficial to confirm the diagnosis of OA or to rule out other forms of joint disease, including immune-mediated arthropathies, septic arthritis, or neoplasia. Typical secondary OA cytologic findings in dogs are 1000–5000 nucleated cells/mm^3, 88–100% mononuclear cells, and 0–12% neutrophils. Viscosity may be normal to low.

If indicated (and rarely required beyond radiographic diagnostics), minimally invasive diagnostics in dogs can also be performed with arthroscopy. Direct macroscopic visualization of the articular cartilage for evidence of fibrillation, erosions, the presence of osteophytes, and examination of the synovium for hypertrophy and inflammation can provide a definitive diagnosis of OA in a patient (Figure 173.4). Usually, arthroscopy can provide the etiology for the secondary OA as well (e.g. ostochondritis dissecans (OCD), fragmented medial coronoid disease, medical compartment disease of the elbow, cranial cruciate ligament disease, etc.).

Therapy

Management strategies for clinical OA patients are focused on the fact that OA progression cannot be halted or reversed. Fundamentally, no one treatment will be all-encompassing for all patients with OA. An individualized

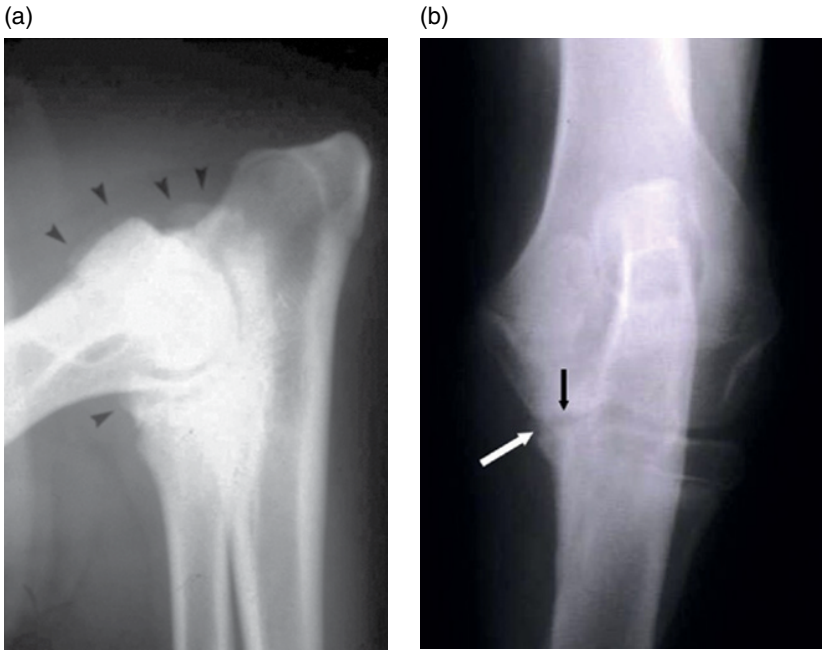

Figure 173.3 (a) Radiographic appearance of osteoarthritis. Two-year-old female-spayed Labrador retriever with chronic elbow dysplasia (mediolateral projection of the left elbow). Note osteophyte development (*black arrowheads*) and marked subchondral bone sclerosis of the ulna. (b) Eleven-month-old male-castrated Labrador retriever with elbow dysplasia due to an OCD lesion of the medial side of the humeral condyle. Note osteophyte development on the medial side of the coronoid process of the ulna (*white arrow*) and the subchondral bone lucency on the medial side of the humeral condyle (*black arrow*).

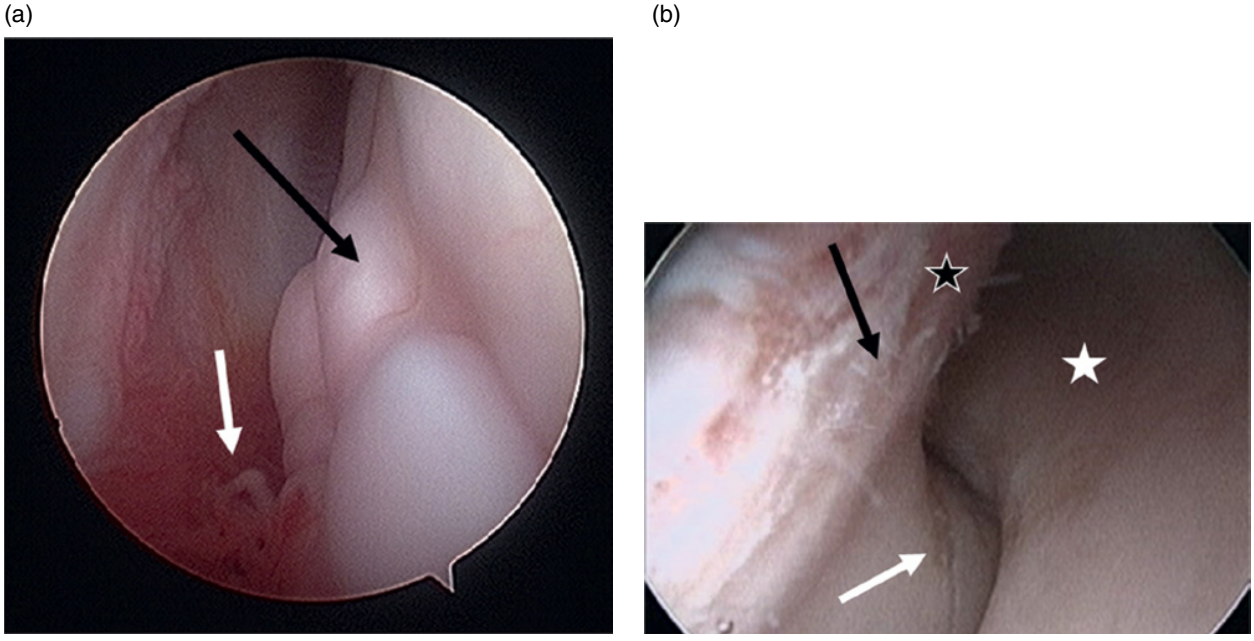

Figure 173.4 (a) Arthroscopic appearance of osteoarthritis. Four-year-old female-spayed Rottweiler with cranial cruciate ligament rupture of the right stifle. Note osteophyte development on the lateral aspect of the trochlear ridge of the right femur (*black arrows*) and synovitis (*white arrow*). (b) Twelve-month-old female-spayed Labrador retriever with elbow dysplasia. Note articular cartilage fibrillation (*black arrow*), erosions (*white arrow*), and ebernation (*black star*) on the humeral condyle and ebernation on the anconeal process of the ulna (*white star*).

approach must be taken to successfully treat OA patients. Current treatment strategies used to treat OA patients are multimodal medical management, surgery or, more commonly, the integration of both treatment modalities.

A multimodal management "pyramid" with three major components – weight control, exercise modification, and pharmaceuticals/nonpharmaceuticals – must be considered when nonsurgically managing a patient with OA (Figure 173.5). Exclusion of one or more of these components from a treatment protocol will result in an overall poorer clinical response from the patient.

Weight Control

Obesity is a major risk factor for the development of OA in people and weight loss can reduce the symptomatic

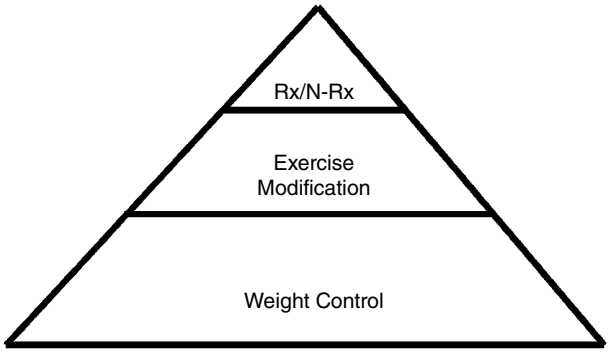

Figure 173.5 Multimodal approach to treating osteoarthritis. Three basic components of the multimodal strategy for the management of the clinical signs of osteoarthritis. The size of the area of each component within the pyramid reflects the importance of that component for successful management of the patient.

effects of OA. Recently, research shows the same is true for other animals. A clinical study investigating the effects of obesity in dogs with hip dysplasia concluded that overweight dogs that achieved an 11–18% body weight reduction were significantly less lame compared to their preweight reduction lameness scores.

Weight control can be one of the most challenging aspects of the medical management of OA in dogs for several reasons.

- A patient that is clinically inhibited by moving an OA joint(s) will not be able to utilize consumed or stored body energy efficiently and will instead increase body stores of energy (fat) when given a constant caloric intake.
- Dogs with underlying endocrine disease (e.g., hyperadrenocorticism, hypothyroidism) will have the metabolic propensity to maintain body fat stores even in the face of a reducing diet.
- Dogs in a multipet household (e.g., other dogs and cats) are more prone to consume greater volumes of food than dogs in single-pet households.
- An inaccurate estimation of the animal's ideal body weight.
- An inaccurate estimation of the animal's energy requirements.
- The owner's lack of willingness to be proactive in trying to reduce their pet's body weight.

Any one or a combination of the above factors will maintain the obese patient indefinitely.

Prior to starting a weight-reducing program, a complete physical exam should be performed. The clinical history (attempted weight reduction in the past with poor results, lethargy, "heat seeking," polyuria/polydipsia, etc.) and physical exam findings (pendulous abdomen, symmetric alopecia, recurrent dermatopathy, etc.) may warrant a complete minimum database (complete blood count [CBC], serum chemistry profile, urinalysis [UA]) to rule out metabolic disease or endocrinopathies.

Weight reduction can be obtained in healthy patients by four methods.

- Reducing current caloric intakes, using reductions by 33–50% of the "normal" volume of the regular diet.
- Calculating caloric content of regular diet and caloric needs based on basal metabolic rates.
- Using specially formulated commercial diets with recommended intake volumes per the manufacturer.
- Pharmacologic management (e.g., dilotapide).

Appropriate caloric restriction should result in the loss of 1–2% of body weight per week.

All weight reduction/control programs must include an exercise element to ensure constant weight loss and eventual body weight maintenance. To encourage activity in the debilitated OA patient, regular pharmacologic treatment may be required for a short period until the patient becomes more ambulatory and physiologically acclimated to the new level of physical activity.

Exercise and Activity Modification

Exercise is very important in people for maintaining strength, stamina, and joint range of motion; there is also less dependency on medication when OA patients are allowed to exercise. It is assumed that the same is true in other animals as well and this is supported by a study in hamsters. Therefore, an important aspect in the management of OA in animals should be controlled exercise. Depending on the animal's activity history, it may be necessary to modify a patient's regular level and type of activity.

It may seem intuitive that an OA animal should not be allowed to have hard-impact, prolonged exercise activity, but controlled clinical studies have not been performed to evaluate this recommendation. However, from clinical experience, practitioners are used to hearing the usual owner's report of greater clinical signs in OA patients after hard, prolonged activity. It is known from kinetic and kinematic gait analysis that dogs with OA will modify their gait to reduce the load of weight bearing and motion of the affected joint. It is therefore safe to assume that prolonged "overactivity" should result in greater modification of gait due to exacerbation of the discomfort associated with an OA joint. Some recommendations for the duration of certain activities in dogs have been made but recommendations for activity duration can also be based on common sense and owner observations of their pet's apparent gait response/comfort level to an activity period.

Just as important as duration of activity is the type of activity undertaken in the animal's daily lifestyle.

Low-impact activities (e.g., walking, cycling) have positive effects on human OA patients. In veterinary medicine, low-impact activities (walking, swimming) have been traditionally favored over hard-impact aerobic activities (jumping, hard starting/running, vigorous climbing/running on irregular terrain) which can overstress degenerative joints. High-impact activities may overstress OA joints and increase the inflammatory condition of OA. Low-impact activities are thought to reduce loads on an OA joint and result in less discomfort for the patient in maintaining good muscle strength/mass and joint function. Walking under controlled conditions (leash restraint) and/or swimming can be recommended to the owner with further instructions to eventually attempt to have the patient increase the duration of these activities gradually so long as the animal appears to remain comfortable in doing so. To strengthen the active stabilizers (muscles and tendons) and to improve the range of motion of joints in OA patients, several physical rehabilitation modalities such as passive and active range of motion exercises, message, deep ultrasound heat applications, and laser therapy can be administered by certified small animal physical rehabilitation technicians and specialists. In many OA cases, the adjunct use of physical rehabilitation can help improve patient comfort and function with very good to excellent clinical results.

Pharmacologic/Nonpharmacologic OA Agents

The primary goal in the pharmacologic management of OA is to relieve the patient of discomfort associated with joint movement. Ideally, this would involve oral or injectable agents with analgesic, antiinflammatory, and potential chondromodulating properties (disease-modifying OA agents, DMOA). Such agents would ideally biochemically block the inducible cyclooxegenase-2 (COX-2) and lipoxygenase pathways. Several FDA-approved "COX-selective" nonsteroidal antiinflammatory drugs (NSAIDs) have been developed for this purpose (e.g., carprofen, meloxicam, firocoxib, etc.). Robenaxocib is currently the only approved NSAID for cats in the United States. Grapiprant, a newer class of prostaglandin receptor antagonist; a non-COX pathway inhibitor for the treatment of the clinical signs of OA, has been developed with the intent to reduce the potential of adverse events of GI. renal, and liver disease seen in the small percentages of patients administered select and non-select COX-2 inhibitors. Grapiprant is specific to the blockage of Prostaglandin E2 receptor 4 (EP4); a primary mediator of OA-based pain and inflammation. Although touted as a "non-NSAID" anti-inflammatory and analgesic drug, OA patients administered grapiprant can have the risk to develop adverse events that include GI disease (emesis, diarrhea, and anorexia), and subclinical hyperalkaline phosphatemia and hypoproteinemia.

All COX-selective (and nonselective) NSAIDs have toxicity potential. Hepatic toxicosis due to NSAID administration has been reported; however, all NSAIDs have a toxicity potential especially if a patient has underlying hepatic or renal disease, or thrombocytopathy. Several *in vivo* studies using chondrocyte cell cultures or cartilage explants have reported a decrease in proteoglycan synthesis in those tissues incubated with selected NSAIDs. It would appear to be a wiser clinical practice to administer NSAIDs on a PRN basis, especially for the patient that has only intermittent discomfort due to osteoarthritis.

Disease-modifying osteoarthritis agents have recently been developed for the treatment of human and veterinary OA patients. These agents have become commonplace in the treatment of OA despite the lack of definitive scientific studies confirming their efficacy. Most of these products contain mixtures of glucosamine and chondroitin sulfate, which supposedly enhance cartilage health by providing the necessary precursors to maintain and repair cartilage. Glucosamine and chondroitin sulfate reportedly have a positive effect on cartilage matrix by enhancing proteoglycan production and inhibiting catabolic enzyme production or activity in OA joints. These properties have contributed to the labeling of these agents as "chondroprotective." With the exception of one product which is a true pharmaceutical by definition (Adequan®, Luitpold Pharmaceuticals, FDA approved in horses and dogs), these agents are marketed as oral nutritional supplements ("nutricueticals") and not "drugs" and as such, the FDA does not require the manufacturer to provide efficacy data for their product. Bioavailability of orally ingested forms of glucosamine and chondroitin sulfate is 87% and 70% in humans and experimental animals, respectively. Limited investigations have been performed on the *in vitro* and *in vivo* activity of glucosamine and chondroitin sulfate separately, but products containing both agents have become popular for treating OA symptoms in humans and other animals. Synergism with glucosamine and chondroitin sulfate has recently been demonstrated histologically and with *in vivo* biochemical analysis in a rabbit OA model.

Glucosamine and chondroitin sulfate are two regular nutricuetical combinations used in many dietary supplenets for dogs and cats. Examples of these formulations are Cosequin® and Dasuquin® (similar to Cosequin® but with the additions of with avocado/soybean unsaponifiables and methylsulfonylmethane (MSM) (Nutramax) and Glycoflex® (Vetri-Science Laboratories). Although clinically noted not to have predictable

efficacy in all dogs, this combination of a precursor glycosaminoglycan and a glycosaminoglycan appears to have a prophylactic effect on the development of OA in dogs. Dogs undergoing a Pond-Nuki model for the development of OA with or without stifle stabilization that were administered Cosequin for five months following surgery subjectively had less OA and less periarticular fibrosis than dogs not receiving Cosequin. Chymopapain- induced acute carpal synovitis was significantly attenuated based on nuclear scintigraphy and lameness evaluation when dogs were pretreated with glucosamine and chondroitin sulfate (Cosequin). Current research suggests that glucosamine and chondroitin sulfate products may be prophylactically beneficial in patients that are prone to develop OA (e.g., canine hip dysplasia [CHD], elbow dysplasia, OCD, cranial cruciate ligament injury, etc.) or patients that may aggravate preexisting OA with activity. Further controlled clinical studies are still warranted to support these statements.

Injectable forms of DMOA available include Adequan, which is a polysulfated glycosaminoglycan (PSGAG) product, and hyaluronic acid (HA), a nonsulfated GAG. The US (Adequan) and European products (Arteparon®) have been used in horses and dogs. Although conflicting evidence exists that PSGAGs have a positive anabolic effect on hyaline cartilage, studies have shown that PSGAG may decrease hyaline cartilage catabolism. In one study, immature dogs prone to hip dysplasia administered Adequan developed better hip conformation than dogs that were not treated with Adequan. A clinical study investigating the use of PSGAG on hip dysplasia patients found no significant difference in orthopedic scores (lameness, range of motion, pain on manipulation of hip joints) compared to PSGAG nontreated dogs. In a meniscectomy model in dogs, PSGAG provided partial protection to articular cartilage damage associated with the meniscectomy. PSGAG has been reported to have chondroprotective properties in joints with a chemically induced articular cartilage damage model versus no effect on a physical articular cartilage damage model in horses. Anecdotal reports have appeared indicating that there may be a positive synergism between injectable PSGAG and oral glucosamine and chondroitin sulfate when administered concurrently to a patient.

Hyaluronic acid (sodium hyaluronate, HA) is a major component of synovial fluid. HA acid is postulated to enhance joint health by increasing the viscosity of the joint fluid and reducing inflammation and scavenging free radicals. A study using a Pond-Nuki model for OA in dogs followed by intraarticular injections of HA did not modify OA and reduced overall proteoglycan concentrations in treated stifles.

Other products reported that have disease-modifying, anti-OA potential include pentosan polysulfate, tetracyclines (doxycycline, minocycline, and modifications of these molecules), methylsulfonylmethane (MSM), capsaicin, and fatty acid ratio manipulation (omega-6:omega-3). S-adenosyl-L-methionine (SAMe) has objectively not been shown to have efficacy in dogs to resolve the clinical signs of OA. Dietary management using omega-3 fatty acids has been reported to improve clinical scores and ground reaction forces in approximately 25–82% of patients. Metaanalysis evaluating the efficacy of various nutritional-based DMOAs concluded that only fatty acid diet modifications appear to have the strongest evidence-based results to ameliorate the clinical signs of OA in dogs. There are several commercially available OA diets that incoroprate the use of omega-3 fatty acid in the dietary formulations with other formulations adding antioxidants such as Vitamin E, C, as well as glucosamine and chondrotin sulfate.

Adjuncts to pharmacologic, exercise/activity, and weight control treatments that can also be considered are the application of heat, cold, massage, hydrotherapy, ultrasound/diathermy, and electrotherapy. Although based on anecdotal observations only, these adjuncts appear to help some patients. Laser, chiropractic, extracorporeal shockwave therapy (EST), and acupuncture are professed to improve canine patients with the clinical signs of OA. EST results reported can be variable with regard to the joint evaluated and to date, acupuncture has not been evaluated to be efficacious in dogs with OA of the hip or elbow. Laser and chiropractic procedures are anecdotally proclaimed to have efficacy in OA patients or at best, may have only limited *in vivo* support for efficacy. Unfortunately, placebo or negative controlled clinical studies are needed to test the supposition that these and other developing modalities (e.g., radiation) have efficacy in veterinary OA patients.

Recently, the use of autogenic tissues such as adipose-derived mesenchymal stem cells and platelet-rich plasma or platelet-enhanced plasma intraarticular injections has been investigated as therapies to attenuate the clinical signs of OA in dogs. Although early results appear promising for these therapies, additional controlled clinical trials are needed to provide better evidence-based proof that they justify their high costs to the owner of an OA patient.

Surgical management for the clinical signs of OA are limited to arthroplasty (via arthroscopy or arthrotomy), arthrodesis, total joint replacement for selected joints, or limb amputation. Nonexcisional arthroplasties will typically require the integration of a multimodal medical approach to provide better long-term function for the patient.

Prognosis

Dogs and cats can be significantly affected by OA; however, new concepts with a balanced multimodal management approach to treat the clinical signs of OA can result in an acceptable quality of life for the majority of OA patients, providing fair to excellent prognoses for lame-free function. Included in the formula for prognosis will be the consideration of a specific joint affected by OA (biomechanics, e.g., shoulder vs tarsus) and the degree of disease present in that joint (e.g., cartilage erosions vs minimal cartilage disease). Nonsurgical management must be considered beyond conventional and nonconventional pharmacologic treatment to include a balance created between exercise/activity and weight control management. Failure to consider this multimodal approach to OA treatment, especially in an individualized medicine approach (i.e., not all dogs or cats will respond the same with the same treatments), will usually result in a poorer clinical response to therapy (surgical and nonsurgical) and quality of life as perceived by the owner of the OA patient.

Excellent progress continues in the development of new pharmaceuticals and other agents to combat or even reverse the degenerative processes of OA. In contrast, research and development into exercise/activity management for the OA companion animal lag significantly behind those of human medicine, but since the mid-1990s, it has become a major treatment focus in veterinary medicine. Nonetheless, large controlled clinical trials are still needed for "evidence-based" treatment protocols (controlled clinical trials) that will allow us to treat our OA patients beyond the individual clinician's clinical experience.

Developmental orthopedic diseases (DODs), a subset of canine pediatric orthopedic diseases, are a group of bone and joint diseases that initiate and develop during postnatal skeletal growth, mostly during the first 26 weeks of life. During this period, joints attain their adult morphology and bones assume their mature length and shape. Pediatric orthopedic diseases are aberrations of this ordered process (including endochondral ossification), described in more detail in Chapter 172. Most DODs are caused by multifactorial traits, with presumed or demonstrated genetic, nutritional, and environmental risk factors. Developmental orthopedic diseases may affect bones or joints. In this section, we will discuss hip dysplasia, osteochondrosis, patella luxation, Legg–Calvé–Perthes disease, craniomandibular osteopathy, panosteitis, hypertrophic osteodystrophy, and slipped capital femoral epiphysis (SCFE). Although all these diseases develop and usually manifest during the period from birth to skeletal maturity, their long-term clinical effects may be persistent and profound.

Developmental Orthopedic Diseases Affecting Joints

Canine Hip Dysplasia

Etiology and Pathophysiology

Hip dysplasia literally means abnormal development of the hip joint. The abnormal development appears to start with laxity of the hip joint, with subsequent subluxation and abnormal wear and tear of the joint. The joint capsule becomes inflamed, the cartilaginous joint surface is mechanically disrupted, and progressive osteoarthritis (OA) ensues. The condition is usually bilateral.

At birth, the hip joints of puppies that will develop canine hip dysplasia (CHD) are indistinguishable from joints that will develop normally. After birth, laxity has been associated with increased synovial fluid volume, as well as swelling, damage, and excessive lengthening of the ligament of the head of the femur. Dysplastic puppies have a delayed onset and abnormal progression of mineralization of the head of the femur compared to nondysplastic puppies. Muscular development is also abnormal, with predisposed breeds often having reduced pelvic muscle mass, and atypical pectineal muscle fiber composition having been demonstrated in affected dogs.

In dysplastic animals with subluxated joints, greater muscle forces are required to generate equivalent hip motion compared to healthy animals. This, combined with the smaller contact area of the incongruent opposing joint surfaces caused by the subluxation, results in abnormal wear and tear of the articular surfaces with subsequent synovitis and OA.

The etiology of laxity is not fully understood but includes genetic, endocrine, and nutritional factors. Canine hip dysplasia is mostly diagnosed in medium- and large-breed dogs and strong breed predispositions have been identified (Table 174.1). The condition is considered a polygenic trait with a heritability varying from 0.2–0.3 (based mostly on arthritic changes on the ventrodorsal extended hip joint radiographs) to 0.5–0.6 (mostly based on distraction index or dorsolateral subluxation index). Thus, somewhere between 20% and 60% of the phenotype of a patient affected with CHD may be attributed by its genetic make-up. Several quantitative trait loci (QTLs; chromosomal regions

Table 174.1 Breed predispositions for selected developmental orthopedic diseases (DODs).

Trait	Breeds at increased risk	Comments
DODs affecting bones		
Craniomandibular osteopathy	Cairn terrier, Scottish terrier, West Highland white terrier	Autosomal recessive in West Highland white terriers
Hypertrophic osteodystrophy	Boxer, Chesapeake Bay retriever, German shepherd dog, golden retriever, Great Dane, Irish setter, Labrador retriever, Weimaraner	–
Panosteitis	Afghan hound, akita, American cocker spaniel, American Staffordshire terrier, basset hound, bearded collie, Bernese mountain dog, boxer, bull terrier, bulldog, Chesapeake Bay retriever, chow chow, Dalmation, Doberman pinscher, English Setter, English springer spaniel, giant schnauzer, German shepherd dog, German shorthaired pointer, golden retriever, Great Dane, Great Pyrenees, Irish wolfhound, Labrador retriever, mastiff, Neapolitan mastiff, Newfoundland, Rhodesian ridgeback, Rottweiler, St Bernard, shar-pei, shih tzu, Weimaraner, West Highland white terrier	–
DODs affecting joints		
Osteochondritis dissecans (OCD) shoulder	Bernese mountain dog, border collie, bouvier, boxer, bullmastiff, Chesapeake Bay retriever, Dalmation, English setter, German shorthaired pointer, German shepherd dog, German wirehaired pointer, golden retriever, Great Dane, Great Pyrenees, Irish wolfhound, kuvasz, Labrador retriever, mastiff, Munsterland, Newfoundland, Old English sheepdog, Rottweiler, St Bernard, standard poodle	Polygenic mode of inheritance
OCD elbow	Chow chow, German shepherd dog, golden retriever, Great Dane, Labrador retriever, Newfoundland, Rottweiler	Polygenic mode of inheritance
Fragmented coronoid process	Basset hound, Bernese mountain dog, bouvier, bullmastiff, chow chow, German shepherd dog, golden retriever, Gordon setter, Irish wolfhound, Labrador retriever, mastiff, Newfoundland, Rottweiler, St Bernard	Polygenic mode of inheritance
Ununited anconeal process	Basset hound, Bernese mountain dog, chow chow, English setter, German shepherd dog, golden retriever, Labrador retriever, mastiff, Newfoundland, Pomeranian, Rottweiler, St Bernard, shar-pei	Polygenic mode of inheritance
Hip dysplasia	Airedale, Alaskan malamute, bearded collie, Bernese mountain dog, bloodhound, border collie, bouvier, Briard, Brittany spaniel, bulldog, bullmastiff, Chesapeake Bay retriever, chow chow, English springer spaniel, German shepherd dog, German wirehaired pointer, giant schnauzer, golden retriever, Gordon setter, Great Dane, Great Pyrenees, keeshond, kuvasz, Labrador retriever, mastiff, Neapolitan mastiff, Newfoundland, Norwegian elkhound, Old English sheepdog, pointer, Portuguese water dog, Rottweiler, St Bernard, Samoyed, tree walking coonhound	Polygenic. Heritability of 0.2–0.6
Legg–Calvé–Perthes disease	Australian shepherd, cairn terrier, Chihuahua, dachshund, Lhasa apso, Manchester terrier, miniature pinscher, pug, toy poodle, West Highland white terrier, Yorkshire terrier	Autosomal recessive or multifactorial with high heritability
OCD stifle joint	Boxer, bulldog, German shepherd dog, golden retriever, Great Dane, Irish wolfhound, Labrador retriever, mastiff, Rottweiler	-
Patella luxation (medial and lateral)	Akita, American cocker spaniel, Australian terrier, basset hound, bichon frise, Boston terrier, bulldog, cairn terrier, Cavalier King Charles spaniel, Chihuahua, chow chow, flat-coated retriever, Great Pyrenees, Japanese chin, keeshond, Lhasa apso, Maltese, miniature pinscher, miniature poodle, papillon, Pekingese, Pomeranian, pug, sha-rpei, shih tzu, silky terrier, standard poodle, toy fox terrier, toy poodle, West Highland white terrier, wirehaired fox terrier, Yorkshire terrier	Multifactorial, polygenic. Low heritability
OCD talocrural joint	Labrador retriever, Rottweiler, bullmastiff	-

containing a gene or group of genes influencing the phenotypic expression of a trait) for CHD and hip OA have been identified on multiple canine chromosomes. Several upgraded genes like *COX-2*, *MIG-6/Gene 33*, *DNCLl*, *LAMS*, and *ATF3* have been identified. Only genetically predisposed animals exposed to certain specific environmental factors may develop clinical hip dysplasia, and dogs not predisposed but exposed to the same environmental factors will not.

The hormones estrogen and relaxin have also been implicated as etiologic factors of CHD. Both are present in colostrum and may be absorbed from the puppy's gastrointestinal tract. Estrogen is probably not a strong etiologic factor, as estrogen fluctuations during the estrus cycle do not result in joint laxity changes. One of relaxin's functions prepartum is to relax the ligaments of the maternal pubic symphysis, and in dogs and humans it is associated with joint laxity. However, the significance of relaxin in the etiology of CHD is unclear.

Rapid growth and body weight have been associated with the development of CHD. In recent studies, heavier puppies developed hip OA requiring treatment at a much younger age than lighter littermates. Similarly, *ad libitum* feeding of Labrador retrievers accelerated the onset of hip OA when compared to a control group fed a restricted diet. High dietary concentrations of calcium and/or vitamin D3 have also been implicated, but not conclusively proven, as etiologic factors. A high dietary anion gap and vitamin C deficiency have also been proposed as causes of CHD, but their clinical significance has not been demonstrated.

Epidemiology

Hip dysplasia is the most commonly diagnosed canine orthopedic condition and in one North American epidemiologic study of canine appendicular musculoskeletal disorders, it comprised 9.6–12.8% of all patients. In this population, the incidence of CHD ranged from 21.1 to 28.1 per 1000 patients, but incidences as high as 50–70% in some large breeds have been reported. Hip dysplasia in cats is thought to be uncommon.

Signalment

Canine hip dysplasia is most commonly diagnosed in medium- and large-breed dogs (see Table 174.1). Male and female dogs are equally affected. Patients younger than 1 year of age are usually presented because of pain and lameness caused by synovitis following hip laxity. As a result of progressive joint capsule fibrosis, older, mature patients usually have minimal laxity but suffer from subsequent hip OA.

History and Clinical Signs

Young patients with hip dysplasia (hip laxity) usually present with uni- or bilateral lameness, bunny hopping, difficulty rising, reluctance to walk, trot, jump, or climb stairs, and exercise intolerance. Hips are often very painful in these animals. Older dogs mostly present with similar signs but with a more chronic presentation due to the slow progression of arthritic changes. Differentials for these signs include panosteitis, iliopsoas myopathy, bilateral cruciate disease, and lumbosacral disease.

Diagnosis

Affected hip joints have a decreased range of motion and pain on extension and abduction, and may exhibit crepitus on manipulation. There is often atrophy of the large muscles round the thigh and hip joint. Hip laxity may be clinically assessed using the Ortolani test. With this test, the presumed lax hip joint is first manually subluxated and then reduced. If the joint is lax, the subluxated hip will reduce with a palpable or audible clunk or click. This evidence of reduction is regarded as a positive Ortolani sign and is suggestive of hip laxity. In the awake, unsedated patient, the Ortolani test can be most easily performed with the dog in lateral recumbency, affected side up. The test may induce pain and should be performed humanely. In the sedated patient, the Ortolani maneuver also can be performed with the patient in dorsal recumbency.

The diagnosis of CHD is confirmed using well-positioned, ventrodorsal extended hip and lateral pelvic radiographs. The lateral pelvic view is mostly evaluated for evidence of lumbosacral disease. The ventrodorsal hip-extended (VD) view is assessed for hip joint laxity, osteophytes, hip remodeling, and enthesophytes of the lesser trochanter suggestive of iliopsoas muscle injury. This view is also helpful in identifying transitional vertebrae, for example sacralization of the last lumbar vertebra. Hip laxity is suspected if on the VD view less than 50% of the femoral head is within the acetabulum or if the cranial half of the joint space is not uniformly wide and diverges medially. Unfortunately, with this technique actual hip laxity may be present in the absence of radiographic signs. Thus this technique has limited sensitivity for the detection of hip laxity as false-negative results may be obtained. Early nonspecific osteoarthritic signs can be found around the femoral head (circumferential femoral head osteophyte) and the femoral neck (caudolateral curvilinear osteophyte = Morgan's line). Osteophytes may also be seen on the cranial and caudal acetabular margins, and sclerosis of the craniodorsal acetabulum may be noted. Later stages of the disease are characterized by varying degrees of remodeling of the femoral head (flattening) and acetabulum (shallowing) and thickening of the femoral neck.

Radiography is also used as a screening tool to identify dogs suffering from CHD and at risk for OA, to predict progression of the disease, and to assist in identifying suitable breeding animals. Several techniques are in use. In the USA, the Orthopedic Foundation for Animals

requires ventrodorsal hip-extended views of the pelvis for their examination. Their evaluation is mostly based on evaluation of arthritic changes, and prediction of future disease and suitability for breeding is based on radiographs of dogs 2 years of age and older. Another US registry for CHD, PennHIP, requires three views: a ventrodorsal hip-extended view, a ventrodorsal hip view with the limb in a neutral, weight-bearing position with the femoral heads pressed into the acetabula (compression view), and a ventrodorsal hip view with the limb in a neutral, weight-bearing position with the femoral heads pulled out of the acetabulum (distraction view). The latter two views are used to determine joint laxity and the "fit" of the femoral heads into the acetabula, respectively. Crucial in the evaluation is the so-called distraction index (DI): a DI >0.3 is suggestive of laxity and an indicator of future disease. The DI can be used as a predictor of CHD in dogs 16 weeks and older.

Prevention

The incidence of CHD may be reduced by selective breeding based on the results of radiographic screening. Restricted dietary intake and perhaps a diet with a low calcium density may reduce the severity and/or slow down the development of hip dysplasia and OA.

Treatment

Treatment may consist of conservative (nonsurgical) or surgical management. The choice of treatment will depend on the severity of clinical signs, the stage of the disease, the patient's age and the owner's commitment and expectations. The goal of nonsurgical management in dogs younger than 1 year of age (predominantly hip laxity) is to control the synovial pain and adjacent muscle spasm and increase muscle mass to stabilize the hip joint. The treatment consists of NSAIDs, skeletal muscle relaxer, weight management, nutritional supplements (omega-3 fatty acids, glucosamine/chondroitin sulfate), exercise control (avoidance of intense/high-impact exercise, roughhousing and stairs; long walks and swimming are beneficial), and physical therapy (electrotherapy, joint manipulation and others). Most young dogs respond well to conservative management and the pain is well controlled although normal hip function is not restored.

If a patient is refractory to conservative management, has evidence of substantial hip dysplasia at young age or is at risk to develop clinical hip dysplasia, surgical intervention may be required. Employed surgical interventions include juvenile pubic symphysiodesis (JPS), triple pelvic osteotomy, intertrochanteric osteotomy, total hip replacement, femoral head and neck ostectomy (FHNO), and pectineal myectomy. Juvenile pubic symphysiodesis, surgically induced premature closure of the pubic symphysis, is recommended for 10–20-week-old dogs with palpable hip laxity and a distraction index of 0.3–0.5. The goal of this procedure is to improve the dorsal acetabular coverage of the femoral head by limiting mediolateral length growth of the cranial pubic rami. In patients between 6 and 11 months of age with no to minimal osteoarthritic changes, a triple pelvic osteotomy (TPO) may be recommended. With this procedure, the acetabular segment of a hemipelvis is rotated to increase the acetabular coverage of the femoral head. Just as with the JPS, this may retard the development of OA.

For patients over 1 year of age with moderate to severe hip dysplasia, a total hip replacement (THR) may be considered. In the past decade, THR has to a large extent replaced TPO. Pectineal myectomy is a procedure that may provide pain relief for patients with hip dysplasia by releasing the tension of the spasmodic muscles across the inflamed synovium, although it will not alter the hip joint congruity and the development of OA. Femoral head and neck ostectomy is a salvage procedure that may be employed if concerted medical management is unsuccessful and THR is not possible. Its outcome is most predictable in patients weighing less than 23 kg.

Dogs over 1 year of age (suffering from predominantly secondary OA) may be treated as any other OA patient with nonsurgical methods as above. If animals become refractory to nonsurgical management, surgical treatment is indicated. The main surgical options are THR and FHNO. Even though FHNO can benefit patient of all body weights, it is most beneficial in patients under 23 kg. In patients over 23 kg, THR is preferred. Denervation of the synovium of the hip joint is a more recently described surgical procedure for the treatment of hip dysplasia. The goal of this procedure is palliative and the procedure is not meant to change the course of the disease. However, the pain relief is variable, and may not be accompanied by improved limb function.

Prognosis

No treatment has been developed that can arrest or revert the pathologic changes associated with hip dysplasia. However, conservative and surgical treatments provide adequate pain relief and acceptable but not normal clinical function.

Osteochondrosis

Osteochondrosis (OC) is a disease of endochondral ossification (EOS), the normal process whereby epiphyseal and growth plate cartilages expand (lengthen the bone) and gradually transform into bone. It is a focal or multifocal disorder with an often bilaterally symmetric distribution, seen in young growing animals and humans. The term most commonly refers to a disturbance of

Table 174.2 Manifestations of osteochondrosis

Widely reported and accepted	Presumptive/proposed
Osteochondrosis in the dog • Caudomedial aspect of the proximal humeral head • Medial aspect of the distal humeral condyle • Lateral or medial femoral condyles • Medial or lateral trochlear ridge of the talus	*Osteochondrosis in the dog* • Caudal glenoid osteochondritis diseccans (OCD) • Ununited caudal glenoid ossification center • Fragmented coronoid process • Ununited anconeal process • "Erosion" of the medial aspect of the humeral condyle • Ununited medial humeral epicondyle • Retained endochondral cores of the distal ulna • Asynchronous growth between radius and ulna • Slipped femoral capital epiphysis • Femoral condylar deformity • Genu valgum • Tibial tuberosity avulsion • Medial tibial trochlea • Lumbosacral OCD • Cervical vertebral malformation-malarticulation *Osteochondrosis in the cat* • Caudomedial aspect of the proximal humeral head • Lateral femoral condyle

Source: Breur GJ, Lambrechts NE. Osteochondrosis. In: Johnston SA, Tobias KM, eds. *Veterinary Surgery: Small Animal*, 2nd edn. St Louis, MO: Elsevier Saunders, 2017, pp. 1299–315. Reproduced with permission of Elsevier.

endochondral ossification of epiphyseal growth centers, resulting in articular cartilage disorders of the shoulder, elbow, stifle or hock joints. Sometimes, disturbances of endochondral ossification of growth plates of long and cuboidal bones are also classified as OC. Generally accepted and proposed manifestations of OC are listed in Table 174.2.

In this section, we will first discuss the common etiology/pathophysiology and epidemiology of all OCs, followed by a description of signalment, history and clinical signs, diagnosis, treatment and prognosis of OC of the shoulder, elbow, stifle and hock joint, and the presumed manifestation of growth plate OC, retained cartilaginous core of the distal ulna.

Etiology and Pathophysiology

Osteochondrosis has a multifactorial etiology with several suggested risk factors playing a role: heredity, rapid growth, dietary factors, and trauma.

Strong breed and bloodline predispositions for the different forms of OC strongly suggest a heritable etiologic component. Reported heritability for these conditions ranges from 10% to 45% and it is thought that most forms of canine OC are inherited as a polygenic trait. In humans and pigs, severity of OC lesions may be associated with certain joint shapes and joint morphology also may be an etiologic factor for canine OC.

Several nutritional factors have been implied in the etiology of OC. The relatively increased growth rate resulting from overnutrition (*ad libitum* feeding) presumably predisposes the development of OC lesions by increasing muscle mass and body weight, resulting in biomechanical overload of structurally weak joint surfaces. However, in a recent review, a direct role of rapid growth from overnutrition in the etiology of osteochondrosis was questioned. Another suggested nutritional predisposition is a diet high in calcium and/or vitamin D3. It is evident that such diets cause a disturbance in endochondral ossification but there is no clear evidence that high dietary calcium concentrations will cause or increase the risk for OC in breeds other than Great Danes.

Both macro- and microtrauma have been implicated in OC etiology. Microtrauma may presumably damage cartilage canal blood vessels at the chondroosseous junction of the epiphysis, thus initiating OC. In dogs, exercise has been suggested as a risk factor for osteochondrosis. There are no studies demonstrating that in dogs macrotrauma will cause or initiate OC. However, studies in pigs and humans suggest that macrotrauma may hasten the conversion from an *osteochondrosis manifesta* to an *osteochondrosis dissecans* lesion (see later).

A series of elegant, primarily histologic studies in horses and pigs have suggested that the primary lesion of OC is a focal necrosis of epiphyseal cartilage canals at

the chondroosseous junction of the epiphysis, resulting in areas of epiphyseal cartilage ischemia and chondronecrosis. Necrotic cartilage cannot undergo EOS. This early lesion is called *osteochondrosis latens*. With progression of the epiphyseal mineralization, the area of ischemic chondronecrosis may become located at the cartilage–bone interface. This stage is called *osteochondrosis manifesta* and the resulting shape change of the subchondral epiphyseal bone may be seen on radiographs. Several sequelae have been proposed. The chondronecrotic focus may heal, may develop into a bone cyst, or may deform, resulting in an altered joint contour and congruency. Commonly, fissures, clefts or cracks may start at the necrotic cartilage lesion and propagate along the osteochondral junction or tide mark. Fissures may further propagate to the joint surface and form a cartilage flap off the underlying subchondral bone, resulting in synovitis, joint effusion, arthralgia, lameness, and OA. At this stage, OC is commonly known as *osteochondritis dissecans* (OCD) or (more physiologically) *osteochondrosis dissecans*. This is the most well-known and described manifestation of OC. Cartilage flaps may reattach, resorb, undergo dystrophic calcification or detach and form a so-called joint mouse.

Epidemiology

In a large epidemiologic study of more than 400 000 canine patients, articular OC was diagnosed in approximately 3.7% of all dogs presented with an orthopedic problem, translating into an incidence of 8.1 cases per 1000 patients. In dogs younger than 1 year of age, OC was diagnosed in approximately 9% of the dogs presented with an orthopedic problem. Male dogs are more commonly affected than female dogs and strong breed predispositions for all forms of OC have been identified (see Table 174.1). Feline OC is very uncommon.

Osteochondritis Dissecans of the Shoulder Joint

Osteochondritis dissecans of the shoulder joint is a common form of epiphyseal OC. The lesion is located on the caudomedial humeral head.

Signalment

The disease is most commonly seen in large- and giant-breed dogs (see Table 174.1), and males are more commonly affected than females. Most dogs are presented between 4 and 10 months of age.

History and Clinical Signs

Most dogs suffering from shoulder OCD develop clinical signs between 4 and 8 months of age, but some dogs only experience discomfort later in life. Most patients present with an insidious unilateral lameness that worsens with exercise and improves with rest. The condition is bilateral in 27–68% of cases but signs will predominate on one side and can shift sides. Differentials include elbow dysplasia, panosteitis, hypertrophic osteodystrophy (HOD), injuries of the shoulder muscles, and cervical nerve root pain. These conditions can occur concurrently with shoulder OCD.

Diagnosis

The presumptive clinical diagnosis is based on signalment, history, and pain on shoulder hyperflexion and/or hyperextension. Crepitus and swelling of the shoulder joint are usually not detected. The final diagnosis is based on characteristic radiographic changes on the mediolateral and craniocaudal view of the shoulder joint. Most radiographic changes are seen on the mediolateral projection and include flattening to saucer-shaped and radiolucent defects of the subchondral bone of caudal humeral head. Occasionally, mineralizations representing dystrophic calcification of the cartilage flaps are evident either over the subchondral lesion if the flaps are still attached, or removed from the lesion if they have detached and become joint mice. These may appear anywhere in the joint, but most commonly are seen in the caudoventral joint pouch or occasionally in the bicipital tendon sheath. Because the disease is often bilateral, both shoulders should be radiographed.

Treatment

Patients diagnosed with shoulder OC may be initially treated with restricted activity, weight control, and NSAIDs. If the patient is refractory to conservative management, the lameness has persisted for more than six weeks, or the patient is older than 6 months of age, surgical treatment in the form of arthrotomy or arthroscopy is indicated. The goal of the procedure is to remove the flap and/or joint mouse, debride necrotic cartilage within the defect, stimulate the formation of fibrocartilage, and remove synovial fluid cytokines and wear debris through joint lavage.

Prognosis

More than 90% of surgically treated patients return to normal limb function. Long term, arthritic changes may develop but these changes usually do not result in serious discomfort and lameness. Because shoulder OC is a heritable trait, the owner should be advised that the patient should not be used for breeding.

Elbow Dysplasia

Elbow dysplasia is an abnormal development of the elbow joint due to fragmented medial coronoid process (FMCP), OCD of the medial humeral condyle, elbow

incongruity, and/or ununited anconeal process (UAP). These diseases have in common that they will cause varying degrees of OA. It is thought that FMCP, OCD of the medial humeral condyle and UAP may be associated with humeroradial and/or humeroulnar joint incongruity secondary to asynchronous growth of the radius and ulna. It has been speculated that activity or exercise-induced microtrauma to a vulnerable medial coronoid process or the growth plate of the anconeal process, due to asynchronous growth of the radius and ulna, could facilitate the initial chondronecrosis associated with FCMP, OCD of the medial humeral condyle, and UAP respectively. It also has been demonstrated that chondronecrosis is associated with a delay of endochondral ossification of the medial coronoid process in animals afflicted with FMCP. All three traits are thought to be multifactorial. The reported heritability of FCMP ranges from 0.18 to 0.31.

Signalment

Large- and giant-breed dogs are most commonly affected and unique breed predispositions for FMCP, OCD and UAP have been identified (see Table 174.1). For all three diseases, males are more often affected than females.

History and Clinical Signs

Dogs affected with elbow dysplasia are usually presented for unilateral forelimb lameness. The lameness usually starts insidiously, worsens with exercise, and improves with rest. Clinical signs often develop between 4 and 8 months of age, but may be missed if the condition is bilateral and the gait is symmetrically affected. Patients also may present at later age, but then clinical signs are usually due to secondary OA. Differentials are similar to those of shoulder OC.

Diagnosis

The presumptive diagnosis of elbow dysplasia is based on the patient's signalment, history, clinical signs, and orthopedic exam findings. Muscles of the affected limb may be atrophied and affected joints may be swollen, initially due to joint effusion but later secondarily to capsular fibrosis. Hyperextension and/or hyperflexion of the joint are painful and a decreased range of flexion and/or extension may be present. Internal rotation of the antebrachium with the elbow joint in 90° of flexion may elicit pain as the medial compartment is compressed (so-called Campbell maneuver). Crepitus may be noted during joint manipulation. The final diagnosis is based on characteristic radiographic or computed tomography (CT) findings. Recommended radiographic views include a neutral and a flexed mediolateral view and a craniocaudal view. Because the condition is often bilateral, both elbows should be radiographed.

Fragmented medial coronoid process and OCD of the medial humeral condyle both are characterized by secondary OA of the medial joint compartment as seen on the craniocaudal view (osteophyte formation on the medial coronoid process and the medial humeral condyle), but osteophytes also can be present on the anconeal process, caudodistal humerus, and the cranial portion of the radial head (mediolateral view). Primary changes of FMCP include fragmentation, blunting or deformity of the medial coronoid process and sclerosis of the subchondral bone of the trochlear notch (mediolateral view). Direct evidence of OCD includes flattening or a radiolucent concavity of the medial humeral condyle (craniocaudal view). Radiography often results in false-negative interpretations for FMCP, OCD and elbow incongruity and therefore oblique elbow views have been suggested. However, CT is a much better technique for visualization of FMCP and OCD defects and elbow incongruity than orthogonal radiographic views. The diagnosis of UAP is made after 22 weeks (the normal time of growth plate fusion), on the basis of a persistent lucent line or zone in the area of the growth plate. This lesion is best seen on the flexed mediolateral radiograph. Comparison radiographs of the opposite elbow may aid with establishing the diagnosis.

Treatment

After an initial diagnosis of FMCP or OCD, the patient may be treated conservatively with rest, weight control, and NSAIDs. However, conservative management will not arrest or retard progression of OA. Surgical intervention may be needed if conservative management does not improve the clinical signs. The goal of the intervention is to remove loose fragments, debride the affected coronoid process down to healthy subchondral bone, stimulate the formation of fibrocartilage in areas with eburnated cartilage, and remove synovial fluid cytokines and wear particles. Recently, repair of OC defects of the medial humeral condyle with osteochondral autografts was reported. Patients with more advanced OA and refractory to medical management may temporarily benefit from surgical intervention to remove loose fragments, wear particles, and cytokines in the synovial fluid. The elbow joint can be approached by open arthrotomy or arthroscopy. Ulnar or humeral corrective osteotomies may be indicated if significant elbow incongruity exists. A total elbow replacement may be considered if a patient with advanced OA has become unresponsive to conservative management.

Dogs with suspected UAP should be treated conservatively with rest, weight reduction, and NSAIDs until the diagnosis can be confirmed when the patient is older than 22 weeks of age. Once the diagnosis is

made, surgical intervention should be considered. Proposed procedures include excision of the ununited anconeal process, ulnar osteotomy, or a combination of ulnar osteotomy and lag screw fixation. Excision controls a major trigger for secondary OA but does not stop its progression. Ulnar osteotomy is an effective treatment of lameness, and in dogs younger than 7–8 months of age may lead to reattachment of the process. These procedures are not recommended for use in older dogs with UAP and advanced OA; these patients should be treated for their OA. If the patient becomes refractory to conservative management, a total elbow arthroplasty may be considered.

Prognosis

The prognosis for FMCP and OCD depends on the extent of articular cartilage damage, the state of joint congruity and severity of the arthritic changes. In cases with minimal cartilage damage and OA, the prognosis may be good. If the articular cartilage damage is more substantial, the prognosis is not as favorable and OA will progress. In these cases, the condition can be particularly debilitating and hard to manage. The prognosis for UAP following surgical treatment in young dogs is usually good if treated before secondary changes develop. However, severe OA may develop, particularly if in combination with FMCP.

Osteochondritis Dissecans of the Stifle Joint (Medial or Lateral Femoral Condyle)

Osteochondritis dissecans of the stifle joint is an uncommon form of epiphyseal OC. The lesion is located on the weight-bearing surface of the medial or lateral femoral condyle.

Signalment

The disease is most commonly diagnosed in large- and giant-breed dogs (see Table 174.1). Males are more commonly affected than females.

History and Clinical Signs

Dogs affected with stifle OCD become lame between 4 and 8 months of age, similar to other forms of joint OC. Some dogs may develop lameness later in life. The lameness may range from mild to severe, and tends to worsen with exercise.

Diagnosis

The presumptive clinical diagnosis is based on signalment, history, and pain on stifle hyperflexion and/or hyperextension. Joint effusion and crepitus are usually present. Mild cranial drawer also may be detected, but an abrupt stop of the cranial drawer motion will suggest that the cranial cruciate ligament is intact. The final diagnosis is based on characteristic radiographic changes on the mediolateral and especially the craniocaudal view of the stifle joint. Lesions are located on the medial or lateral femoral condyle. Oblique views of the stifle may improve visualization of the defect. Radiographic changes range from subchondral bone flattening and subchondral sclerosis to more severe radiolucent concave defects. Effusion is always seen and secondary arthritic changes are usually present.

Treatment

Patients may be treated initially with restricted activity, weight control, and NSAIDs. If the patient does not respond to conservative management, surgical treatment in the form of arthrotomy or arthroscopy is indicated. The purpose of the surgical intervention is to remove the cartilage flap and debride the defect, stimulate the formation of fibrocartilage, and remove synovial fluid cytokines and wear particles. The OC defect also may be repaired with osteochondral autografts, or resurfaced with a single-layer or bilayered implant. Dogs that have developed severe secondary OA unresponsive to conservative management may be treated with a total knee replacement.

Prognosis

Treatment, including surgical treatment, does not change the progression of secondary OA. Conservatively managed dogs usually end up with an intermittent lameness. Surgical treatment usually improves the limb function but lameness may persist, especially after exercise. There is no long-term evidence yet that the currently used osteochondral transplant techniques improve the treatment outcome. The owner should be advised that stifle OC most likely is a hereditary trait and that the patient should not be used for breeding.

Osteochondritis Dissecans of the Hock Joint (Medial or Lateral Trochlear Ridge of the Talus)

Osteochondrosis of the hock joint is an uncommon epiphyseal OC. Lesions are localized on either the medial (most common) or lateral trochlear ridge of the talus. Most patients present between 4 and 10 months of age.

Signalment

Just as with the other articular OCs, this condition is mostly seen in large- and giant-breed dogs, and Rottweilers, retrievers, and Great Danes are most predisposed (see Table 174.1). Male dogs are more commonly affected than female dogs.

History and Clinical Signs

Affected dogs usually present between 4 and 8 months of age, but some dogs develop clinical signs later in life. Affected dogs usually present with an insidious unilateral lameness that worsens with exercise and the patient may be mildly exercise intolerant.

Diagnosis

The presumptive clinical diagnosis is based on signalment, age of presentation, history, and pain on hock hyperflexion and/or hyperextension. A decreased range of motion of the hock joint, as well as joint crepitus and joint swelling/effusion, are often present. The final diagnosis is based on characteristic radiographic changes on a neutral mediolateral and extended craniocaudal view of the hock joint. Flexed mediolateral and craniocaudal views facilitate visualization of the defect if not obvious on the aforementioned views. With OC of the medial ridge of the talus, flattening of the medial trochlear ridge can be seen on both orthogonal views; widening of the medial joint compartment (craniocaudal view) and periarticular mineralizations are also often present. OC of the lateral trochlear ridge is characterized by subchondral fissures at the base of the lateral trochlear ridge. CT may help to establish the diagnosis, particularly with lateral trochlear ridge OC.

Treatment

Patients suffering from hock OC may be initially treated with restricted activity, weight control, and NSAIDs. If the patient does not respond to conservative management, arthrotomy or arthroscopy is indicated. The goal of the procedure is to remove the flap and/or joint mouse, debride the defect and stimulate the formation of fibrocartilage, and remove synovial fluid cytokines and wear particles.

Prognosis

Most dogs will have a fair to good quality of life despite continued lameness. Conservative management usually results in a continuous or intermittent lameness and progressive OA. Surgical management may improve limb function, but progressive OA still may cause exercise-induced lameness. Affected dogs should not be used for breeding as hock OC appears to be a heritable trait.

Retained Cartilaginous Core

Generically, retained cartilaginous core is caused by a failure of endochondral ossification and can occur in any metaphyseal growth plate. It is characterized by the projection of cones of unmineralized growth plate cartilage, predominantly hypertrophic chondrocytes, into the adjacent metaphyseal bone. The local thickening of the growth plate may be caused by vascular events on the epiphyseal or metaphyseal side of the growth plate. Most cartilaginous cores will heal spontaneously and in most growth plates will not have clinical consequences. However, a retained cartilaginous core may have clinical significance in the distal ulnar growth plate, a growth plate with a rapid rate of length growth and with an adjacent paired radius. Here, they may be associated with a reduced length growth of the ulna, leading to angular limb deformities (radial bowing and valgus deformity) and/or elbow incongruity, similar to cases with traumatic closure of the distal ulna growth plate.

Signalment

The condition is most commonly seen in rapidly growing, large- and giant-breed dogs. Most patients are presented between 4 and 10 months of age.

History and Clinical Signs

Patients are presented with angular limb deformity, radial bowing, and/or valgus deformity that developed during adolescence.

Diagnosis

The presumptive diagnosis is based on the patient's signalment, history, clinical signs, and orthopedic exam findings. Angular limb deformity, including radial bowing and/or valgus deformity, is often a prominent feature and elbow incongruity (pain on hyperextension/hyperflexion) also may be present. The final diagnosis is based on radiographic evidence of the presence of a cartilaginous core in the distal ulna (a long-tapering radiolucent triangle based on the physis) in combination with the classic signs of angular deformity. Orthogonal radiographic views of the elbow joint, radius/ulna, and manus are recommended to identify and assess the extent of the deformities. If limb shortening is suspected, radiographs of the humerus and comparative radiographs of the opposite limb are useful.

Treatment

The choice of treatment is dependent on the age of the dog, the remaining growth potential, and the severity of the angular deformity. Treatment may consist of conservative management for patients with mild deformity and limited remaining growth potential, or surgical intervention in patients with more substantial deformity and/or bone shortening and more remaining growth potential. Surgical techniques include ulnar ostectomy (for elbow incongruity and mild deformity), static surgical deformity correction (radial and ulnar osteotomy, followed by deformity correction stabilized with an external fixator or bone plate), and dynamic deformity correction (radial and ulnar osteotomy, followed by deformity correction

and bone lengthening with an adjustable external fixator). Surgical planning can be facilitated by 3D printed (plastic) models of the deformity, based on a CT study of the affected limb.

Prognosis

The prognosis for a normal limb function is good, particularly for patients with mild to moderate deformity. In patients with significant limb shortening and elbow joint incongruity, the prognosis may not be as favorable.

Patella Luxation

Etiology and Pathophysiology

Patella luxation (PL) may occur nontraumatically as a consequence of quadriceps mechanism (quadriceps muscles, patella, and patellar tendon) malalignment with the underlying bone and/or femoral trochlea articular surface secondary to the development of femoral and tibial deformities during skeletal growth. Patella luxation also may be acquired traumatically. The etiology of nontraumatic medial or lateral PL is not well understood. It has been hypothesized that medial PL is initiated by a decreased angle of inclination and a diminished angle of anteversion of the proximal femur early in the postnatal period. The resulting medial malalignment of the quadriceps mechanism produces eccentric forces across growth plates and may cause bone deformities, such as coxa vara, genu varum, distal femoral varus or external torsion, proximal tibial varus or valgus, internal tibial torsion, and medial rotation of the tibial tubercle. The malalignment also may lead to rupture or weakening of periarticular structures, thus facilitating PL. Malarticulation of the patellofemoral joint may result in poor development and shallowness of the trochlear groove, diminishing the normal retention of the patella.

It has been suggested that PL is a multifactorial polygenic disease. Strong breed predispositions have been recognized (see Table 174.1). For instance, according to the Orthopedic Foundation for Animals, 43% of examined Pomeranians had PL. A PL heritability of 0.17 was reported and quantitative trait loci were identified on chromosome 7 and 31 in a Dutch flat-coated retriever population. This moderate heritability suggests that environmental factors play an important role in the development of the disease.

Epidemiology

In general, small-breed dogs are more likely to be affected than large-breed dogs. Medial PL is more common than lateral PL in dogs of all sizes and lateral PL is more often seen in large-breed than in small-breed dogs. Many breeds have strong predispositions (see Table 174.1). In small-breed dogs, females appear to be more commonly affected than males, while the opposite has been reported for large-breed dogs. Bilateral disease is common.

History and Clinical Signs

This condition is often asymptomatic, particularly in small-breed dogs, and may go unrecognized until incidentally discovered. Large-breed dogs are rarely asymptomatic. Dogs suffering from PL may present with lameness, intermittent skipping, a history of short acute pain episodes, and/or exercise intolerance. Differential diagnoses, particularly in small breeds, include cranial cruciate disease, which often occurs concurrently, and intervertebral disc disease.

Diagnosis

The diagnosis of medial or lateral PL is based on the examiner's ability to manually luxate the patella in medial and/or lateral directions. Starting with the leg in full extension, the patella is located and pushed in the medial or lateral direction, while simultaneously slowly flexing the hock and stifle joint and internally or externally rotating the limb respectively. Simultaneously abducting or adducting the limb may further encourage the patella to luxate medially or laterally. This test is considered positive (patella luxation) if during flexion of the stifle joint the patella can be moved medial or lateral to the medial or lateral femoral trochlear ridge. It should be noted that with the stifle in full extension, the patella easily can be moved in medial and lateral direction; this patellar mobility is normal and not indicative of patella luxation.

The disease is classified according to the anatomic relationship of the patella and trochlear groove during the gait cycle. Patients with a grade I PL are usually asymptomatic. Their patella is normally positioned in the trochlear groove but the patella can be manually luxated. Grade II is characterized by a normally positioned patella that may spontaneously luxate and relocate, which may cause acute pain and/or "skipping." The luxated patella may reduce spontaneously or can be manually reduced. With a grade III PL, the patella is found in a luxated position; the patella can be easily reduced manually. In patients with a grade IV PL, the patella is permanently luxated and cannot be reduced. Bone angular deformities and trochlea maldevelopment become more severe with increasing grade of PL.

The main purpose of radiography is to assess the severity of secondary osteoarthritic changes, determine the location of the patella in the trochlear groove (lateral or medially displaced or abnormally proximal or distal to the normal central position, termed patella alta or patella baja, respectively) and elucidate the degree of femoral and tibial deformity. In cases of low-grade PL and mild

skeletal abnormalities, mediolateral and caudocranial views of the stifle will suffice. If more deformity is detected during the orthopedic exam, additional orthogonal ("alignment") views of femur and tibia to characterize the angular deformities are recommended. CT allows better evaluation of the deformities and may be beneficial in patients with severe deformities.

Treatment

Patients with grade I PL are asymptomatic and usually do not require treatment. Grade II PL patients may require treatment if the pain or skipping episodes increase in duration or frequency. If clinical signs are mild, fewer than 2–3 episodes per month, or if the owner is unable to pursue surgical treatment, nonsurgical treatment is a reasonable option. However, just as with grade I luxation, the patient should be reevaluated if the lameness becomes more severe or frequent.

Surgical intervention is indicated for patients with persistent lameness due to grade II, III or IV PL. The purpose of the intervention is to realign the patella and quadriceps complex over the trochlear groove and the long axis of the femur, and to stabilize the patella in the trochlear groove. In most patients with grade II or III PL and mild femoral and tibial deformity, the alignment is obtained with a transposition of the tibial tuberosity in the medial, lateral and/or distal direction. The patella is stabilized in the trochlear groove with a combination of trochleoplasty (deepening of the trochlear groove) and parapatellar soft tissue release and imbrication techniques. Transposition is performed after the apophyseal physis of the tibia has closed. In patients with grade III or IV and more severe deformity, particularly large-breed dogs, corrective distal femoral osteotomies may be needed to obtain adequate alignment, in addition to the aforementioned techniques. In patients with grade III or IV PL and severe osteoarthritic changes refractory to conservative management, a partial or total stifle replacement may be indicated. The long-term utility of partial stifle replacement (trochlea arthroplasty) in clinical patients has yet to be described.

Prognosis

The prognosis for lateral and medial PL is similar and mostly depends on the severity of the deformity. For Grade II and III luxations, the prognosis for return of function is good, while for most grade IV luxations the prognosis is fair to good. However, for some patients with chronic grade IV luxation with severe femoral and tibial deformity, severe OA and/or severe muscle atrophy and contracture, the prognosis is much more guarded.

Legg–Calvé–Perthes Disease

Etiology and Pathophysiology

Legg–Calvé–Perthes disease (LCP) is an uncommon cause of pelvic limb lameness in small-breed dogs. The lameness is associated with lysis, fragmentation, collapse, and deformity of the femoral head, including the joint surface. These changes are the result of avascular necrosis and structural weakening of the bone of femoral head. Synonyms for LCP include osteochondritis coxae juvenilis, osteochondrosis, coxa plana, aseptic necrosis of the femoral head, and avascular necrosis of the femoral head.

The etiology of LCP is unknown but increased intracapsular pressure, abnormal anatomic conformation, infarction of the femoral head, hormonal influences, and heredity have been implicated as etiologic factors. Strong breed predispositions exist (see Table 174.1) and it has been suggested that LCP is a simple autosomal recessive trait in West Highland white terriers and miniature poodles. In Manchester terriers, the trait is a simple autosomal recessive or multifactorial with high heritability.

Epidemiology

In one study, 277 of 33 633(0.82%) patients diagnosed with an appendicular bone diseases were suffering from LCP.

Signalment

Predisposed breeds include terriers and toy-breed dogs, with affected dogs most commonly being presented between 4 and 11 months of age. Males and females are equally represented.

History and Clinical Signs

Patients present with unilateral or bilateral pelvic limb discomfort, lameness, and muscle atrophy. Lameness can be mild to nonweight bearing, although in minimally affected cases the disease may be subclinical. Bilateral involvement occurs in 12–16.5% of cases.

Diagnosis

Orthopedic exam findings may include muscle atrophy, pain on hyperextension and manipulation of the hip joint, and crepitus. An extended ventrodorsal and a mediolateral view of the hip joint that include the proximal femurs are recommended. If positioning for this view is causing discomfort, a flexed ventrodorsal (frog-leg) view of the coxofemoral joint may be used. An additional advantage of this view is that it may help elucidate the defect on radiographs. Early radiographic signs sometimes include increased epiphyseal opacity but more commonly, patients are presented with focal lytic lesions of the femoral head. In later stages of the disease, collapse and flattening of the femoral head and

remodeling of the acetabula, femoral neck lysis, and possible associated compression fractures may be seen. Computed tomography may be beneficial for the detection of small lesions in patients with early-stage disease where LCP is suspected but no radiographic evidence of the disease is seen. Orthopedic examination will rule out common differential diagnoses such as patellar luxation and cranial cruciate ligament rupture. Less common differential diagnoses include septic arthritis, neoplasia, and osteomyelitis.

Treatment

Analgesics and rest result in lameness resolution in less than 25% of cases. Surgical treatment with femoral head and neck excision or total hip replacement is recommended if patients do not respond to conservative management. At the time of surgery, excised tissue should be submitted for histopathology and bacterial culture to rule out neoplasia and osteomyelitis.

Prognosis

Surgery resolves lameness and discomfort in 84–100% of LCP cases. Persistent lameness may be due to the resultant change in biomechanics and reduced range of motion associated with femoral head and neck excision.

Developmental Orthopedic Diseases Affecting Bone

Craniomandibular Osteopathy

Etiology and Pathophysiology

Craniomandibular osteopathy is characterized by unilateral or bilateral irregular symmetric osseous proliferation on mandibles and/or tympanic bullae, causing difficulties opening the mouth. Temporal, frontal, maxillary, and long bones can also be affected. The disease can be self-limiting. Synonyms for craniomandibular osteopathy (CMO) include lion jaw, Scotty jaw, Westie jaw, craniomandibular osteodystrophy, mandibular periostitis, and craniomandibular osteoarthropathy.

In affected mandibulae, lamellar bone is resorbed and new bone originating from the periosteum invades the adjacent connective tissue and muscle fibers. Bone marrow is replaced by a highly vascular fibrous-type stroma and inflammatory cells (lymphocytes, neutrophils, and plasma cells) that surround the lesions. The etiology of the disease is unknown but strong breed predispositions suggest a hereditary etiology. The condition is autosomal recessive in West Highland white terriers. A test to determine genetic predisposition for the test is available.

Epidemiology

The disease has a reported incidence of 1.4 per 100 000 cases. The incidence of the disease is highest in the southern and western regions of the United States.

Signalment

Dogs from many breeds, including large- and small-breed dogs, can be affected (see Table 174.1). Females and males are equally represented. Patients younger than 6 months are at the highest risk for being affected by CMO, while the probability for diagnosis decreases in patients over 12 months of age.

History and Clinical Signs

Patients affected by CMO are most commonly presented with complaints of not eating, difficulty eating or drinking or complete inability to open the mouth. Additional clinical signs that have been reported include discomfort, swelling of the mandibles, intermittent hyperthermia, increased salivation, exophthalmia, and strabismus.

Diagnosis

Clinical signs include inability to partially or completely open the patient's mouth and swelling of the mandibles and/or temporomandibular joint region. The final diagnosis is based on demonstration of osseous proliferation on mandibles and/or tympanic bullae using ventrodorsal, lateral, and oblique radiographs of skull and mandibles. Computed tomography may be useful in identifying small lesions in early stages of the disease and may also allow the extent of the lesions to be more accurately characterized. A complete blood count, serum chemistry, and urinalysis are recommended when systemic signs are present. Fine needle aspirate/biopsy for histopathology and culture are recommended to rule out other diseases, including osteomyelitis, neoplasia, and metabolic bone diseases.

Treatment

There is no known medical or surgical cure for this condition. Treatment is primarily aimed at supportive care. Feeding soft food, gruel food, or syringe-fed food, and/or placement of a feeding tube may be needed for as long as the patient is unable to take in an adequate amount of water and food. The level of treatment is based on the severity of the condition and the patient's ability to drink and eat, so hydration and nutrition must be carefully and frequently evaluated. Analgesics should be prescribed if indicated. During febrile periods, patients may be treated with antibiotics and steroids or NSAIDs. These treatments are empirical and the benefits of these medications are variable. Excision of osseous proliferations and/or rostral hemimandibulectomy may be considered as salvage procedures for severe cases to permit improved alimentation.

Prognosis

The condition is often self-limiting by 11–13 months of age and until this time, supportive care is paramount. There are no predictive factors to determine if the bony proliferations will regress partially or completely. For owners who are unable to provide adequate care, for the rare severe case, and for cases with intractable discomfort, euthanasia is an option.

Panosteitis

Etiology and Pathophysiology

Panosteitis is a self-limiting disease of the bone marrow of fore- and hindlimb long bones. Synonyms for panosteitis include shifting leg lameness, enostosis, and eosinophilic panosteitis.

The earliest changes in affected long bones are seen around the nutrient foramen. Vascular proliferation and bone formation result in vascular congestion and increased intraosseous pressure. In response to the increased intraosseous pressure, dogs develop lameness of the affected limb and form bone in periosteum and medullary cavity. Eventually, the affected bone marrow is replaced by normal, healthy adipose bone marrow. The etiology of panosteitis is unknown but strong breed predispositions (see Table 174.1) suggest a genetic component.

Epidemiology

The reported incidence of panosteitis is 2.6 per 1000 patients. The disease incidence is higher in north central and northeastern regions of the United States, especially in the summer and fall.

Signalment

Panosteitis is primarily a disease of medium- and large-breed pure-bred dogs. However, smaller dogs (either mixed breed or pure bred) such as the American cocker spaniel and the West Highland white terrier can also be affected. Males are more frequently affected than females (4:1), with patients most commonly affected between 5 and 12 months of age. However, patients have been diagnosed as young as 2 months and as old as 5 years. In a study of 100 dogs, the median age of affected dogs was 12.4 months.

History and Clinical Signs

Panosteitis patients are often presented with a history of lameness, often shifting between limbs (shifting lameness). Lameness ranges from mild to nonambulatory. The occurrence can be acute in onset and may run a waxing–waning course. There is a 4:1 ratio of lesions in the forelimbs to hindlimbs, with 42%, 25%, 14%, 11%, and 8% occurrence in the ulna, radius, humerus, femur, and tibia, respectively. The affected bones may be painful on palpation. Systemic signs including fever, anorexia, lethargy, and weight loss may accompany the lameness. The signs may regress and reoccur, but rarely continue past 2 years of age.

Diagnosis

Depending on the disease phase, radiographic findings from orthogonal views of the affected bone(s) may vary from completely normal to the classic blurring and inhomogeneity of the medullary cavity trabecular pattern. The first stage, rarely seen, is characterized by a decrease of the radiodensity of the medullary cavity near the nutrient foramen. In the next stage, an increased medullary opacity with a granular pattern or loss of trabeculation, as well as periosteal bone formation, is seen. In a later stage, changes in the medullary cavity become more diffuse and homogeneous. After 4–6 weeks the lesions regress and a coarse trabecular network develops. It should be noted that radiographic signs are not correlated with patient discomfort or lameness.

Differential diagnoses include elbow dysplasia, OCD, hip dysplasia, and HOD.

Treatment

There are no known medical or surgical cures for this condition. Treatment consists primarily of analgesics (NSAIDs) and rest.

Prognosis

The disease is self-limiting, although recurrences are possible, reportedly even until the patient is 5 years of age.

Hypertrophic Osteodystrophy

Etiology and Pathophysiology

Hypertrophic osteodystrophy (HOD) is a disease of predominantly young, growing large-breed dogs, characterized by metaphyseal swelling of affected bones and lameness. Synonyms for HOD include infantile scurvy, Moller Barlow disease, juvenile scurvy, osteodystrophy II, skeletal scurvy, and metaphyseal osteopathy.

The etiology of HOD is unknown. Proposed theories include overnutrition, vitamin C deficiency, infection, vaccinations, and heritability. In more recent reports, the etiologic roles of overnutrition and vitamin C deficiency have been questioned.

Many large dog breeds are predisposed to HOD (see Table 174.1) and therefore a genetic etiology has been suggested. In a litter of affected Weimaraners, the heritability was estimated to be 0.68.

Several lines of evidence suggest an infectious etiology. Specifically, many affected dogs have a history of, or actually are suffering from, a systemic illness (for instance, a respiratory infection). Active bacteremia (*E. coli*) in an

affected dog has also been reported. Canine distemper virus transcripts have been detected in the metaphysis of dogs with HOD, but a direct relationship with canine distemper has not been demonstrated. More recently, it was reported that clinical signs of HOD developed in six Weimaraner puppies (five of the six were related), 10 days after administration of a modified live vaccine of canine distemper virus and canine adenovirus type 2. It was suggested that the HOD may have been facilitated by an inherited immunodeficiency with low concentrations of circulating immunoglobulins.

Epidemiology

Hypertrophic osteodystrophy is reported to occur in 2.8 per 100 000 cases. In one study, the incidence was highest in the northeastern regions of the United States, and was highest in the fall and lowest in the winter.

Signalment

Several breeds are predisposed to HOD (see Table 174.1). Males are more often affected than females (2.3:1) with patients most commonly being presented between 2 and 6 months of age.

History and Clinical Signs

Hypertrophic osteodystrophy is a disease of young, rapidly growing dogs. The distal radius, ulna, and tibia are the most commonly affected bones but the condition has also been diagnosed in the humerus, mandible, ribs, maxilla, femur, skull, vertebra, and scapula. Affected patients have unilateral or bilateral swelling at the metaphyseal region(s) of affected bone(s). If the distal radius and ulna are affected, an angular limb deformity may be seen if a synostosis develops between radius and ulna. Warmth and varying degrees of discomfort can be appreciated when palpating the swellings, with subsequent lameness ensuing. The lameness may range from mild to a complete inability to stand or walk. Additional systemic clinical signs may include anorexia, depression, hyperthermia, and diarrhea.

Diagnosis

The hallmark radiographic finding is a metaphyseal radiolucent zone with adjacent sclerosis parallel and adjacent to the growth plate. In a later stage, periosteal and endosteal bone proliferation may be noted. Metaphyseal enlargement and irregular widening of the growth plate may be present in advanced disease stages. As the condition resolves, resolution of the radiolucent line and remodeling of the periosteal reaction will occur. In severely affected dogs with a secondary synostosis, an angular limb deformity may develop. If a patient has systemic clinical signs, a complete blood count, serum chemistry and urinalysis, as well as blood or synovial fluid culture, may be indicated. Differential diagnoses include septic polyarthritis, panosteitis, polyarthropathies, polyneuritis, polymyocytis, secondary nutritional hyperparathyroidism, neosporosis, and toxoplasmosis. In Newfoundlands, metaphyseal dysplasia also may be considered.

Treatment

There are no known medical or surgical cures for this condition. Treatment varies depending upon the severity of the disease. In mildly affected dogs, a balanced diet (a nutritional association has been reported) and NSAIDs will be sufficient. In more severely affected dogs, more supportive care may be needed, particularly if the patient is reluctant to eat, hyperthermic, and/or unable to get up. Antibiotics are indicated for patients with bacteremia. Severely affected Weimaraner puppies without bacteremia may respond better to steroids than to NSAIDs.

Prognosis

The prognosis is generally good to excellent for mild to moderate cases. The disease is usually self-limiting, typically within days to weeks, but can persist for months with multiple recurrences possible. In severe cases, death may occur. In cases with intractable disease and/or refractory to treatment, euthanasia should be considered. All owners should be counseled on the potential for secondary angular limb deformities.

Slipped Capital Femoral Epiphysis

Etiology and Pathophysiology

Slipped capital femoral epiphysis (SCFE) is a nontraumatic, slowly progressive lateral slippage of the proximal femoral metaphysis through the growth plate, resulting in separation of the proximal femoral metaphysis from the capital femoral epiphysis, causing pelvic limb lameness. The disease is most commonly seen in mature cats but also has been reported in dogs. Synonyms include spontaneous femoral capital physeal fracture, femoral neck metaphyseal osteopathy, and femoral capital physeal dysplasia.

The etiology of the metaphyseal slippage is unknown. Some have suggested that in cats, the slippage is the result of weakening of the capital physis due to a multicentric dysplasia. Others proposed that SCFE in cats is the result of early (juvenile) castration. The ensuing delayed growth plate closure due to hypotestosteronism, together with obesity, exposes the physis to increased/excessive/supraphysiologic cyclic shear forces during the gait cycle, resulting in spontaneous slippage and separation. The latter hypothesis is consistent with the pathophysiology of SCFE in children and other animal species.

Epidemiology
The disease is uncommon, but an incidence has not been reported.

Signalment
Cats are more commonly affected than dogs. Reported feline cases are almost all neutered overweight males presented when they were 4.5–42 months of age. In one study of 13 cats, 23% were Siamese.

History and Clinical Signs
Clinical signs include uni- or bilateral lameness, decreased ability to jump, weakness, and crepitus and pain during palpation. Lameness can be acute in onset but is mostly insidious and possibly intermittent. It was reported that at initial presentation, 24–38% of cases were affected bilaterally but not necessarily symmetrically.

Diagnosis
Radiographic lesions vary with the stage of the disease. Early on in the disease, the capital growth plate is slightly widened compared to the normal contralateral one and slippage may be demonstrated on extended ventrodorsal pelvic radiographs. In later stages, the proximal femoral metaphysis may be craniodorsally displaced relative to the epiphysis, with resorption and sclerosis of the femoral neck. Ultrasound (slippage and periphyseal fluid accumulation) and/or computed tomography may be helpful in early stages without obvious radiographic signs.

Treatment
The most common method of treatment is femoral head and neck ostectomy because of progressive femoral neck resorption. Successful primary stabilization with Kirschner wire and total hip replacement have been reported.

Prognosis
The prognosis for patients treated with femoral head and neck ostectomy is excellent, although limb function is not normal. Unilateral cases can present with contralateral disease later in life.

Social and Ethical Issues in Veterinary Medicine

175

Canine and Feline End of Life Care

Robin Downing, DVM, MS, DAAPM, DACVSMR

The Downing Center for Animal Pain Management, LLC, Windsor, CO, USA

The Buddhists say "Pain is inevitable; suffering is optional." Our obligation in veterinary medicine is to recognize, relieve, and prevent pain and suffering in the animals entrusted to our care. At no time is this obligation to advocate on behalf of beings who cannot advocate for themselves more imperative than when an animal approaches the end of its life.

Veterinary medicine and human medicine are intimately intertwined. Many of the life-saving procedures now used for human patients had their roots in animal models. Likewise, most pharmaceuticals undergo animal testing before they are brought to trials in human subjects. The flow of medical knowledge, information, technology, and techniques between human and veterinary medicine is bidirectional. Advanced surgical techniques (e.g., arthroscopy), advanced diagnostic technologies (e.g., magnetic resonance imaging [MRI]), and critical care interventions (e.g., mechanical ventilation) have been embraced by veterinary medicine and have proved to be game-changers, allowing countless animals who would otherwise have succumbed to their conditions or been euthanized to be restored to life and health. It is a logical extension of the search for better and broader ways to practice veterinary medicine for veterinarians to recognize the utility of evaluating human palliative medicine and hospice care for application to animal patients.

Companion animals have made a migration of Biblical proportions from the backyard to the bedroom and from the kennel to the couch. The evolving role of pets as members of the family, coupled with advances in preventive and interventive medicine, has resulted in dramatically longer life expectancies among dogs and cats. One consequence of longer lifespans in pets is the emergence of age-related diseases and physiologic breakdowns that were once considered unusual. Examples include multiple joint osteoarthritis, pulmonary hypertension, systemic hypertension, advanced renal disease, and cancers of all types. When pets did not generally live as long as they do now – when their cause of death was an infectious disease or a violent event like being hit by a car – neither veterinarians nor pet owners were faced with the slow, incremental declines so often witnessed now. Squiring companion animals into advanced old age has opened the door to a new discipline of veterinary palliative medicine and hospice care. Human palliative and hospice medicine can provide veterinarians with a template to follow when adapting and adopting these principles and practices for veterinary application.

But a simple translation is not enough. In human end of life care, the patient must, with rare exceptions, die on his or her own. Exceptions at the time of this writing are found in the states of Oregon, Washington, Montana, California, New Jersey, and Vermont where physician-assisted death with dignity has been affirmed as legally available. Of note, however, is that physician-assisted death with dignity remains ultimately the act of the *patient*, generally by refusing food and water or by ingesting a lethal dose of a barbiturate drug previously prescribed by a physician. Only in a few jurisdictions worldwide, most notably the Netherlands, can the physician take an active role in the patient's death by performing voluntary active euthanasia. What that means for the majority of dying humans is that they *must* die on their own.

The gift of euthanasia, translated from the Greek as "good death," remains, at least in the Americas, exclusively in the hands of veterinarians. The single most important caution to the veterinary profession in embracing wholesale the palliative medicine and hospice care model provided by human medicine is to resist the temptation to force animals to suffer to death rather than providing compassionate, humane euthanasia. It is equally important to resist the temptation to force heroic

interventions with little hope for success on animals who are approaching their end of life. Finally, it is also a veterinarian's obligation to the pet, the pet owner, and the precious human–animal bond not to force or rush euthanasia on a patient whose care has shifted from that of curative to palliative. Ours is a delicate balance to negotiate.

In addition to drawing palliative care strategies from the disciplines of pain management, physical rehabilitation, behavior medicine, and oncology, it is to the discipline of clinical bioethics that the veterinary profession should turn for guidance when evaluating the application of interventive, palliative, or hospice techniques in end of life care. The foundational principles of biomedical ethics – respect for autonomy, nonmaleficence, beneficence, and justice – all have a role to play during the decision making that occurs as an animal approaches the end of its life. Before exploring the application of the principles of biomedical ethics in end of life clinical veterinary medicine, it is appropriate to consider the development and evolution of veterinary palliative medicine and hospice care, as well as the many techniques that can be used to sustain a life-limited pet's comfort and quality of life until the time when humane euthanasia becomes the most reasonable choice.

Veterinary Palliative Medicine and Hospice Care

Veterinary palliative medicine and hospice care derive their basic principles from human palliative and hospice care, both directly and by analogy. Historically, hospices were first places of refuge for travelers, often those on a religious pilgrimage. In the 11th century, the focus shifted to care of the incurably ill who either had no family or could not afford other care. Hospice providers were typically members of various religious orders. In the 19th century, the formal concept of caring for the dying emerged, first in France in 1842. In the late 1800s and early 1900s, several facilities that are still in existence opened in England and Australia to attend to the dying. Religious orders continued to provide care, as this preceded the phenomenon of "medicalizing" the dying process. Hospice in the US began in earnest in the 19th century, mirroring activities in the US and Australia. A leap forward in the development of palliative care and hospice occurred following the 1969 publication of Dr Elisabeth Kübler-Ross' seminal work, *On Death and Dying*. She and others created awareness about the lack of adequate care for the dying, and sharpened the focus on the important role palliative care and hospice can fill.

While the original hospices were *places* for the dying, it is important to understand that hospice is a *philosophy* of caring that "affirms the concept of palliative care as an intensive program that enhances comfort and promotes … quality of life … When cure is no longer possible, hospice recognizes that a peaceful and comfortable death is an essential goal of health care…" This commitment to quality of life and comfort care brought to the patient lends itself well to the veterinary profession. Animal patients can be seen and cared for in many settings, including the clinic and the home. The emergence of ambulatory companion animal veterinary practices clearly demonstrates the response of the veterinary profession to the demand for veterinary care provided in the comfort of the animal's home. This paradigm of sophisticated in-home care further reinforces the opportunity to provide palliative and hospice care to pets who are approaching the end of their lives.

The first formal discussion of hospice for animals was presented at the Delta Society's 10th Annual Conference in Portland, Oregon by Drs Guy Hancock and James Harris, and Ms Bonnie Mader. The presentation, "The hospice concept for animals," was delivered at multiple regional, national, and international conferences by Dr Hancock between 1995 and 2005. Dr Eric Clough, a veterinarian in New Hampshire, alongside his wife, June, a registered nurse with expertise in human hospice, were also pioneers in applying the concepts of animal hospice and palliative care. In 2001, the American Veterinary Medical Association approved the first "Veterinary Hospice Care Guidelines," an open-access document available at www.avma.org. In 2003, the Pet Hospice Volunteer Student Outreach Program was launched by the Argus Institute at the Colorado State University College of Veterinary Medicine and Biomedical Sciences.

During the ensuing years, a clear focus on quality of life during the end of life of companion animals has emerged, leading to the establishment of the International Association for Animal Hospice and Palliative Care (www.iaahpc.org) as well as the provision of postgraduate continuing education on the subject for both veterinarians and veterinary technicians/nurses. Clearly, there is a need for the veterinary profession to understand its critical role in a pet's end of life care. There truly is a "space" between ceasing to pursue a cure and the time when humane euthanasia is in the best interest of the patient. It is also worth noting that while only recently has the term "palliative care" entered the mainstream veterinary vocabulary, veterinarians routinely provide what qualifies as palliative care. Palliative medicine is care that is not focused on a cure but rather on improving and maintaining good quality of life. Pets with many

different conditions enjoy the benefits of this approach long before they are at the end of life, including those with diabetes mellitus, systemic hypertension, and chronic kidney disease.

At the end of life, with the many sophisticated interventional options available, it is appropriate for veterinarians to exercise a more formal approach to the necessary decision making that occurs. Veterinarians must combine the following elements in order to help the pet owner make ongoing care decisions that are in the best interest of the pet approaching its death.

- Regular evaluations of the animal's quality of life in dialogue with the pet owner.
- Regular assessment of the human family's quality of life as they care for the pet.
- Regular reevaluation of the therapeutic goals of care.
- Application of the foundational principles of clinical bioethics (respect for autonomy, nonmaleficence, beneficence, and justice) to both the patient and the human family during decision making to maximize outcomes and to act in the best interest of all parties.

When considering any intervention as a pet approaches the end of its life, it is important to ask the question, "Just because we can, does that mean we should?"

Evaluating and Maintaining Quality of Life in End of Life Care

As soon as a life-limiting disease is diagnosed, it is appropriate to open a dialogue with the pet owner about the anticipated arc of the disease process on the way to the end of the pet's life. Likewise, it is important to lay the foundation for periodic ongoing evaluations of the pet's quality of life. Finally, it is important to consider the effects of pet end of life care on the family's quality of life. Caring for a beloved animal family member at the end of life can become overwhelming and fraught with emotional overload. The veterinarian's obligation is to advocate on behalf of a being who cannot advocate for itself, and that obligation becomes even more critical when choreographing care at the end of life (Figure 175.1).

Quality of life is an exquisitely subjective concept. Quantifying a particular pet's quality of life is equally subjective. Each pet's quality of life must be assessed on a case-by-case basis as every animal is unique. Likewise, every family situation must stand on its own merits in order to assess both the financial and emotional resources that are available for care of the pet approaching its death.

Figure 175.1 A comfort room lends itself well to end of life consultations with pet owners. *Source:* Courtesy of Robin Downing, DVM.

Dr Alice Villalobos has created a Quality of Life Scale to use in dialogue with pet owners to offer a somewhat objective assessment of what is a very subjective experience (Table 175.1). The scale considers seven parameters, each scored 1–10 (10 is best). A score at or above 5 in each category with an overall score of 35 or greater generally suggests an acceptable quality of life. While a particular score is important, the trend of scores over time is a more accurate representation of how the pet is doing. A single low score may illuminate a weakness in the palliative care plan, calling for a fine-tuning of care. On the other hand, a low score in even a single category may signal the time when humane euthanasia is in the pet's best interest. The seven parameters follow the mnemonic HHHHHMM.

- Hurt
- Hunger
- Hydration
- Hygiene
- Happiness
- Mobility
- More good days than bad

Table 175.1 Villalobos Quality of Life (HHHHHMM) Scale

Pet caregivers can use this Quality of Life Scale to determine the success of Pawspice care. Score patients using a scale of 0 to 10 (10 being ideal).

Score	Criterion
0–10	**HURT** – Adequate pain control and breathing ability is of top concern. Trouble breathing outweighs all concerns. Is the pet's pain well managed? Can the pet breathe properly? Is oxygen supplementation necessary?
0–10	**HUNGER** – Is the pet eating enough? Does hand feeding help? Does the pet need a feeding tube?
0–10	**HYDRATION** – Is the pet dehydrated? For patients not drinking enough water, use subcutaneous fluids daily or twice daily to supplement fluid intake
0–10	**HYGIENE** – The pet should be brushed and cleaned, particularly after eliminations. Avoid pressure sores with soft bedding and keep all wounds clean
0–10	**HAPPINESS** – Does the pet express joy and interest? Is the pet responsive to family, toys, etc.? Is the pet depressed, lonely, anxious, bored or afraid? Can the pet's bed be moved to be close to family activities?
0–10	**MOBILITY** – Can the pet get up without assistance? Does the pet need human or mechanical help (e.g., a cart)? Does the pet feel like going for a walk? Is the pet having seizures or stumbling? (Some caregivers feel euthanasia is preferable to amputation, but an animal with limited mobility yet still alert, happy and responsive can have a good quality of life as long as caregivers are committed to helping their pet)
0–10	**MORE GOOD DAYS THAN BAD** – When bad days outnumber good days, quality of life might be too compromised. When a healthy human–animal bond is no longer possible, the caregiver must be made aware that the end is near. The decision for euthanasia needs to be made if the pet is suffering. If death comes peacefully and painlessly at home, that is OK
TOTAL	A total over 35 points represents acceptable life quality to continue with pet hospice (Pawspice)

Dr Alice Villalobos (09/2004), scale format created for author's book (2007), revised for IVAPM (2011) Palliative Care and Hospice Guidelines. Reproduced with permission of Dr Alice Villalobos and Wiley-Blackwell.

Hurt

Adequate pain management is the cornerstone of end of life care, and a key to sustaining an acceptable quality of life. Dr Lloyd E Davis wrote in 1983:

> [o]ne of the psychological curiosities of therapeutic decision making is the withholding of analgesic drugs because the clinician is not absolutely certain that the animal is experiencing pain. Yet the same individual will administer antibiotics without documenting the presence of an infection. Pain and suffering constitute the only situation in which I believe that, if in doubt, one should go ahead and treat.

Because pain is such a major factor in diminished quality of life, excellent, aggressive, and comprehensive (e.g., multimodal) pain management plays a critical role in applying palliative care and hospice principles to pets. While humans have eschewed overt cruelty to animals from Biblical times, it is only within the past several decades that human understanding of nonhuman pain and suffering has expanded to include a more proactive approach to recognizing and relieving that pain. Richard D. Ryder, in his groundbreaking work *Painism: A Modern Morality*, coined the term "panience" to describe the principle that a moral code should be based on the capacity to feel pain. He went on to state that the terms "pain" and "suffering" are interchangeable and "what matters morally is the degree of pain and not who or what experiences it." In Ryder's worldview, pain is the common enemy of all beings. Ryder's work, alongside that of scientists like Marc Bekoff and Frank McMillan, lays the foundation for applying clinical bioethical principles to pet end of life and quality of life considerations. There are several excellent resources for practitioners to access in creating appropriate pain management plans for patients approaching the end of life.

Appropriate pain management at the end of life is a function of striking a balance between risks and benefits. Regardless of the root of the palliative care patient's pain, the practitioner must always start with a careful pain palpation assessment to determine all the uncomfortable areas on the body in order to create as comprehensive a pain management strategy as possible. The ability to breathe falls into this category, and trouble breathing trumps all other concerns about quality of life. Because animals cannot self-report, measurement of oxygen saturation may be an important part of patient assessment if breathing is compromised in any way.

Figure 175.2 Foam steps up to bed. *Source:* Courtesy of Robin Downing, DVM

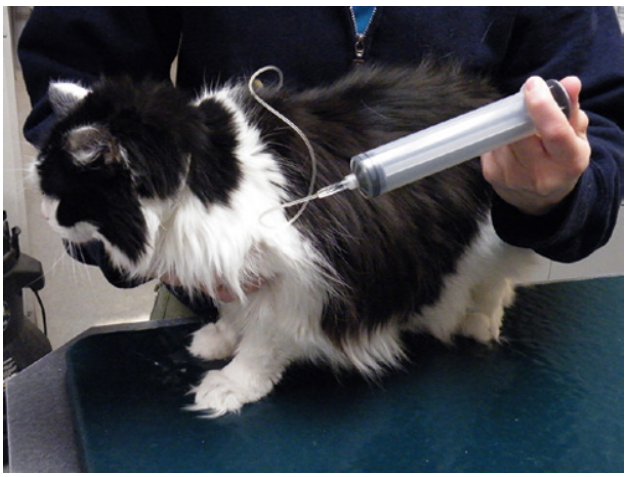

Figure 175.3 Delivering subcutaneous fluids. *Source:* Courtesy of Robin Downing, DVM.

One final consideration for managing pain at the end of life is to use nonpharmacologic strategies. These include modifying the pet's environment and everyday handling in order to maximize comfort (Figure 175.2). Environmental modifications may include:

- raising food and water dishes to shoulder height
- using a form-fitted lift harness for gait assistance
- using a fabric sling under the abdomen for support
- limiting access to stairs
- covering slippery floor surfaces
- using a ramp for vehicle entry and exit.

Many techniques commonly employed in physical medicine lend themselves very well to relieving pain and supporting comfort in veterinary palliative and hospice care patients. Application of heat and cold, stretching, joint mobilizations, massage, neuromodulatory acupuncture, photobiomodulation via therapeutic laser, transcutaneous electrical nerve stimulation (TENS), neuromuscular electrical stimulation (NMES), as well as some proprioceptive retraining and therapeutic exercise, can all contribute to pain relief in this population of patients.

Hunger

Hunger can serve as an important barometer of a pet's quality of life. If the pet remains hungry and willing to eat, it is reasonable to presume that it is still interested in living. On the other hand, a decline in appetite is one part of the natural process as the end of life approaches.

Nutritional support is important if hospice care is to continue, and malnutrition and weight loss occur quickly in an anorectic pet. Hand feeding or feeding a different texture (canned versus dry kibble) may enhance appetite. Appetite stimulants as well as antinausea medications may be indicated, at least in the short term. For an animal experiencing difficulty prehending, chewing, or swallowing food, placing an esophagostomy tube may be appropriate if other quality of life parameters remain high. This is a minimally invasive technique requiring a very short period of general anesthesia, and the contribution to overall quality of life can be significant.

Hydration

Many animals approaching the end of life do not drink enough to sustain metabolic functions. Dehydration not only undermines quality of life, it hastens the decline of all metabolic functions, particularly waste elimination by the kidneys. Many animals readily accept the delivery of subcutaneous (SC) fluids, and this is an easy technique to teach pet owners (Figure 175.3). It is important to link the delivery of SC fluids with something that the pet enjoys, like tasty treats or gentle combing or brushing, in order to minimize any objection the pet may have to receiving fluids. If a pet receiving end of life care vigorously objects to receiving SC fluids in spite of all attempts to make the procedure as comfortable as possible, it is important to respect the animal's expressed preference. To force fluids on an uncooperative hospice patient compromises quality of life.

Hygiene

Good hygiene is an important component of good quality of life. As animals approach the end of their lives, they may develop fecal and/or urinary incontinence, which is the most likely hygiene issue these pet owners will face. Preventing urine and fecal scalding is a priority

in these patients. Keep hair trimmed short around the genitals and anus to facilitate cleaning. It may be worth considering a whole-body trim to make day-to-day grooming easier for both the pet and pet owner. Reusable/washable diapers as well as diapers with replaceable absorbent pads are available for animals whose incontinence is intermittent or unpredictable. Waterproof bedding covers facilitate clean-up. Cats may need to have one side of their litter pan cut away to make entry easy. If the pet has any areas of devitalized tissue that secrete serum and form crusts (e.g., a tumor that cannot be removed), lemon juice in a 1:1 dilution with water can be used to cleanse the area, and absorbent fabrics like cotton T-shirts may be used to help manage exudates. Waterless shampoos also work well to keep immobilized pets clean.

Happiness

Happiness may be the most subjective of the quality of life parameters to be measured during the pet's end of life time, but it is an important one. It is in this area in particular that the veterinarian must listen very carefully to the client's report of how the pet is doing overall. The pet's mental state and psychosocial well-being are critical components of quality of life. Dogs and cats communicate with their eyes, their facial expressions, and their actions. These are social creatures, and their happiness depends upon interaction with "their" humans. Animals engage in many mutual care behaviors that can be mimicked by the human caregiver to contribute to happiness, including stroking and sounds of contentment (e.g., purring while interacting with a cat patient).

Owners of animals receiving end of life care must be instructed to think through the activities the pet has enjoyed over its lifetime, and then to consider how those activities and interactions may be modified to provide joy to the pet. For instance, the author worked with a toy poodle who had been felled by a stroke. She became paralyzed in the rear legs and profoundly paretic in the front legs. Her greatest joy before her stroke was playing tug-of-war with a cloth toy. She would bring the toy to one or another family member and ask them to play. The family simply modified this game by initiating play sessions themselves. This dog obviously derived great joy from these play sessions.

Many end of life pets will cheer up and greatly anticipate their interactions with their human family members. Feeding, grooming, play, simple stroking, and strategic placement so that the pet may watch what the family is doing are all simple strategies for enhancing happiness. McMillan makes a strong case that animals not only do experience happiness, but that their happiness contributes immeasurably to their quality of life. In general, we can equate happiness with the will to live.

Figure 175.4 A cart can restore and maintain mobility. *Source:* Courtesy of Robin Downing, DVM.

Mobility

As the inevitable decline toward approaching death proceeds, animals may lose their ability to move independently. How much of an impact this makes on the pet's quality of life and the family's ability to continue end of life care may depend on the size/weight of the patient as well as the willingness of the pet to accept assistance. There are many mobility assistance options available for pets of all sizes, and simple environmental modification may make a profound impact, allowing a pet to sustain its own ability to get up and down and move around (Figure 175.4). Providing nonskid floor surfaces, preventing unsupervised access to stairs, utilizing ramps for entry and exit from vehicles, as well as slings, supportive vests, and pet wheelchairs are all simple strategies for sustaining mobility. The owners of immobilized end of life pets must be instructed in the details of preventing decubital ulcers. The size of the immobilized pet relative to the size and strength of the pet owner must be considered when deciding whether to proceed with palliative and hospice care versus opting for humane euthanasia.

More Good Days Than Bad

A single "bad day" in the end of life time of a pet is something to be expected, but more than a few bad days in a row suggests that quality of life may be too compromised to continue palliative and hospice care. If the pet is "turned off" to life, is no longer responding to activities in its immediate environment, or is withdrawing from interactions with family members, then quality of life is compromised. The overarching goal in a pet's end of life care is to maintain a healthy, two-way, interactive human–animal bond (Figure 175.5). When the HHHHHMM score drops below 35, it is likely that the end is near. It is the obligation of the veterinarian

Figure 175.5 An end of life care patient quietly resting near family activities. *Source:* Courtesy of Robin Downing DVM

coordinating end of life care to speak on behalf of the dying pet when compassionate, humane euthanasia is in the pet's best interest. It is critical, when there are more bad days than good, not to allow the beloved pet to suffer to death.

Pets Should Not Suffer to Death

Occasionally, the veterinary healthcare team will encounter a client whose personal or religious beliefs prohibit the active ending of a life – any life. If this is the case, then a deep discussion about the need to prevent an agonizing death must be a part of the dialogue between the veterinarian and the owner. In a case like this, it is extremely important to make available powerful pain medication that can provide heavy sedation and relieve any suffering that emerges as death approaches. The flipside of this is the client who wishes to pursue treatments, interventions, and procedures that are futile in the face of the pet's life-limiting disease. In both cases, it is essential to have a back-up plan in place to provide the gift of humane euthanasia at any time of the day or night should the need arise and should the family decide to pursue that option.

Applying the foundational principles of clinical biomedical ethics provides a useful framework and strategy for assisting families to negotiate the emotional minefield that end of life care represents. This formal approach to the decision making involved in end of life care serves all parties – the pet owner, the veterinary health care team, and, most importantly, the pet with a life-limiting condition who is receiving end of life care.

The Four Foundational Principles of Clinical Bioethics

In *Principles of Biomedical Ethics*, Tom L. Beauchamp and James F. Childress describe four foundational principles that may serve as an analytical framework for the formulation of rules guiding medical decision making.

- Respect for autonomy (respecting and supporting autonomous decisions).
- Nonmaleficence (avoiding the causing of harm).
- Beneficence (relieving, lessening, or preventing harm and providing benefits, and balancing benefits against risks and costs).
- Justice (fairly distributing benefits, risks, and costs – distribution of scarce resources).

These four principles, by the authors' assertion, do not constitute a general ethical theory, but rather provide a place to start in order to specify application to a particular patient or case. Application of these four principles of clinical bioethics requires balancing among them to decide what, ultimately, is in the best interest of the patient. These principles have a role to play in clinical veterinary medicine in general, but they should definitely play a role leading up to and during a pet's end of life care in order to maximize outcomes and quality of life for the pets and the families who love them.

A conventional application of the four pillars of clinical bioethics in the context of veterinary end of life care is to the interactions with the pet owner as the surrogate decision maker. It is, after all, the pet owner who ultimately makes all the caregiving decisions and who must carry out all the caregiving activities for the pet approaching the end of its life. Considering each of the four principles as described by Beauchamp and Childress, we begin with respect for autonomy.

Acting autonomously, according to Beauchamp and Childress, involves three steps.

1) Intentionality (to make and follow a plan).
2) Understanding the consequences of decisions that will be made.
3) Freedom from control or undue influence in the decision making process.

Respect for the autonomy of the pet owner during a pet's end of life care is fairly straightforward and hinges on the veterinarian providing the owner with enough information in an understandable form that he or she may act as autonomously as possible at each step of the decision-making algorithm as the pet's dying progresses. While, legally, the pet is property and can be subjected to nearly any decision the pet owner might make, aside from gross negligence or abuse, it is acknowledged that the human–animal bond helps to define us as humans. James Serpell

states that it is "hard to escape the conclusion that the child-like qualities of many animals can evoke in people a strong desire to nurture and provide parental care and protection." The pet owner must make end of life decisions analogous to those made by parents on behalf of children. The information that must be provided to the owner of a dying pet in order for him or her to make autonomous decisions on behalf of that animal includes the expected arc of progression of the co-morbidities the pet possesses as well as the expected cause of death, costs associated with various techniques and/or procedures that may be recommended, statistics for expected outcomes of any interventions, a balanced presentation of the pros and cons of any treatment or interventional options, as well as guidance when humane euthanasia is the better choice for the pet.

The principles of nonmaleficence and beneficence as applied to the owner of the pet approaching death are closely allied and related. According to Beauchamp and Childress, nonmaleficence "obligates us to abstain from causing harm to others" and beneficence "potentially demand(s) more than the principle of nonmaleficence" because it obligates us to "take positive steps to help others, not merely refrain from harmful acts." Nonmaleficence and beneficence in this situation demand full revelation of the facts, costs, and potential consequences of pursuing any particular treatment or care option during the pet's end of life care. The positive obligations of beneficence in veterinary palliative care and hospice include active and ongoing patient and client support by the veterinary healthcare team, a clear outline of the pet-specific care required, and contingency planning for unexpected or unplanned events.

Finally, applying the principle of justice to the owner whose pet has entered end of life care involves full disclosure of the costs and details about the anticipated care to each pet owner equally. Each pet owner and family is unique and must be able to conduct a fair appraisal of the investment (monetary and emotional) that they must make. It is not appropriate for the veterinarian to cherry-pick the information that is provided to the client based on his or her impression of what the client can and cannot afford or accomplish. Justice suggests that it is the veterinarian's obligation to the client to guide the decision making based on what is medically in the dying pet's best interest.

Bioethical Principles and The Life-Limited Pet

Turning our attention to the pet entering end of life care, it is not only appropriate but necessary to consider how at least three of the four foundational principles – respect for autonomy, nonmaleficence, and beneficence – apply, despite the fact that animals cannot participate in the caregiving decisions made on their behalf. This reflects a novel application of clinical bioethical principles in clinical veterinary medicine, and acknowledges that animals can and do express preferences, which can guide caregiving decisions.

In order to apply the principles of clinical bioethics to animals, we must first consider them as moral agents and thus appropriate targets of such an application. This involves issues of consciousness and a need to respect the preferences they express. Darwin himself recognized that animals possess the fundamentals of consciousness. His reasoning was that "if animals show emotion through behavioral expression, then the behavioral expression of emotion in man must share a similar neurobiological evolution with other animals capable of expressing similar emotions." As cited earlier, Richard D. Ryder laid the foundation for considering animals as moral agents in his work *Painism: A Modern Morality*. An updated narrative on the need for humans to recognize the moral agency and emotional richness of animals is presented in the provocative volume *Wild Justice: The Moral Lives of Animals* by Marc Bekoff and Jessica Pierce. They argue compellingly, based on robust behavioral science, that "differences between species are differences of degrees rather than differences in kind." They go on to state that in "including some animals within the sphere of morality, we force a reconsideration of what have been assigned to be the essential ingredients of morality – reflective judgment, agency, and conscience." This and other contemporary work opens the door to applying the principles of clinical bioethics in a serious way to the pets themselves who are entering end of life care.

Animals do express preferences, if only the human is willing to listen. When applying the principles of clinical bioethics to animals receiving end of life care, we accept the limitations presented by beings who do not possess decisional capacity as we strive to achieve optimal outcomes for them, ultimately leading to a peaceful and pain-free death. The animal receiving end of life care must be considered carefully. The pet's personality, willingness to be handled, willingness to take medication – basically, the pet's willingness to participate in its own care – must weigh in the balance. In applying respect for this pet's autonomy, we must evaluate these preferences, as expressed by the pet, before embarking on a complex path of end of life medical management. To force medication or painful wound care on an animal whose response is either anxiety or aggression clearly violates the autonomy the pet can express, independent of its inability to actively choose specific end of life care. McMillan would argue that forced medication or other forced procedures, performed without the animal's cooperation, present

a sufficiently aversive stimulus to activate a powerful sympathoadrenal response that can precipitate negative gastrointestinal and cardiovascular changes.

Nonmaleficence and beneficence are intertwined when applied to the pet receiving end of life care. Nonmaleficence is the requirement to avoid harm, and this principle is in play when considering a procedure or other interventive technique for an end of life patient. On balance, the benefit must clearly outweigh any potential harm to the patient. Beneficence means acting in the patient's best interest. At each decision-making step, it must be considered that the patient may be best served by the compassionate application of humane euthanasia. Nonmaleficence and beneficence are tightly aligned with the pet's willingness to participate in its own care. Without that willingness, the animal itself is expressing its preferences and we have an obligation to heed the message if we are unable to change the circumstances of care to improve quality of life. While animals cannot anticipate or fear their own death, they certainly can and do anticipate and fear pain, and unrelenting pain is a deal-breaker for the continued imposition of care on a dying pet.

McMillan might argue that one barometer of our ability to monitor and measure our success in applying the principles of respect for autonomy, nonmaleficence, and beneficence is the animal's ability to experience and express happiness. As elusive a concept as happiness is, ongoing active engagement with the environment and human family members, the ability to exert some level of control over activities, and modification of activities that had previously brought enjoyment (e.g., tug-of-war games) appear to contribute to an animal's happiness (Figure 175.6). This provides a slightly richer context for consideration of quality of life issues.

Figure 175.6 A healthy human–animal bond is a two-way relationship. *Source:* Courtesy of Robin Downing, DVM.

End of Life Care and The Human–Animal Bond

End of life discussions are among the most difficult for both the pet owner and the veterinary healthcare team, yet they are among the most important. Taking a systematic approach to the practicalities of end of life care allows the veterinarian to exhibit and express compassion while at the same time providing the client and family with a longer view of the arc of care that will be required as the pet's condition deteriorates.

The veterinarian should start with an initial consultation to assess the client's goals, beliefs, concerns, and financial resources/constraints. It is important to discuss all of the pet's co-morbidities to ensure that all relevant issues are addressed to maximize comfort and function. Schedule regular quality of life evaluations and pain reassessments. The trend over time of the quality of life scores is generally more important than individual scores. Provide regular ongoing guidance to the client about comfortable bedding for the pet, safe surroundings, medications, feeding, wound management when necessary, assistive devices, physical medicine techniques to enhance comfort and function, and environmental enrichment. Construct a preparedness plan for the inevitable decline in the pet's health status, including an advanced directive (e.g., "Do not attempt resuscitation" – DNAR) and options for euthanasia at any time of the day or night. Plan for unexpected escalations of pain or discomfort, providing the client with specific steps to take. Plan for in-home euthanasia if that is preferable to the client and available in the community. Plan ahead for preferred body handling when the animal dies. Be ready to refer the client and family for grief support services if that becomes necessary.

Planning ahead for the anticipated and inevitable events that occur at the end of life supports the human–animal bond and helps to prevent the client from being overwhelmed with decisions once the animal's death day arrives.

Conclusion

Veterinary medicine has long prided itself on its commitment to scrutinize advances in human medicine and to evaluate the possible application of those advances to

animal patients. In fact, many of the medical and surgical techniques now utilized in human medicine were first developed in animal models. There exists now a paradigm in human and veterinary medicine that recognizes the importance of interdisciplinary collaboration in order to foster synergistic attention to enhance the care of animals, humans, and the environment. This is the One Health Initiative –www.onehealthinitiative.com/). The mission statement of the One Health Initiative recognizes "that human health (including mental health via the human-animal bond phenomenon), animal health, and ecosystem health are inextricably linked" seeking to "promote, improve, and defend the health and well-being of all species by enhancing cooperation and collaboration between physicians, veterinarians, [and]other scientific and environmental professionals." With such a commitment to cross-pollination between medical disciplines, it is logical to consider ways in which palliative and end of life care options for animals may be expanded.

In pursuing such expansion, however, it is critical also to expand the ethical framework within which palliative and end of life care decisions are made on behalf of pets who are either experiencing life-limiting disease or actively dying. In addition to applying human *medical* principles and practices in end of life care for pets, including aggressive pain management and other palliative care techniques, it is appropriate for veterinary healthcare teams to understand and apply the foundational *clinical bioethical* principles and practices as well. The pet owner is in an analogous situation to the parent of a dying child when making decisions on behalf of the pet. The pet clearly does not possess decisional capacity – that is, the animal cannot weigh the evidence and decide for itself, among the care options, which one is in its best interest. It is up to the pet owner – the "pet parent" – to listen to the explanation provided by the veterinarian and veterinary healthcare team, to weigh the options to try to determine the risk to benefit ratio, and then to decide on behalf of the pet what treatment or procedure will be performed or withheld.

This huge responsibility to act in the best interest of the pet *must* be borne by *both* the owner and the veterinarian coordinating care. In no other context of veterinary care is this shared obligation greater than at the end of life. The veterinarian possesses knowledge about the procedures and probabilities for various outcomes that the owner simply cannot know in the same way. The late physician Edmund Pellegrino, MD, acknowledged to be the father of modern medical ethics, would affirm by analogy that every time a veterinarian sees a patient and client and asks, "What is wrong?" she is committing herself to having the competence to help that animal patient as well as the judgment "to use that competence in the best interests of the patient."

In the end of life time for animal patients, it is especially important for veterinarians to find guidance in the bioethical principles of respect for autonomy, nonmaleficence, and beneficence as applied to their patients in determining what actions – or withholding of actions – are in the best interest of *that* animal at *that* time, in dialogue with the pet's human family. It is important not to reach for euthanasia too early, but equally important not to withhold it when that action reflects the best interest of the animal. Reaching a decision about what will best serve the animal patient at the end of life may, in fact, demand answering the question mentioned earlier in this chapter: "Just because we *can*, does that mean we *should*?"

Preventive Care

176

Role of Immunization

Melissa Kennedy, DVM, PhD, DACVM

Department of Biomedical and Diagnostic Sciences, College of Veterinary Medicine, University of Tennessee, Knoxville, TN, USA

The immune system is a complex network of interacting cells and molecules. Manipulation of the immune response is an attractive prospect, and has been achieved in part through immunization. Immunization is the process of exposing an animal to whole or parts of microbes in order to stimulate an acquired response. Immunization takes many forms, and continues to advance as a field of research. This chapter focuses on several aspects of immunization in veterinary medicine.

Before one can understand immunization, one must understand the nature of the acquired or adaptive immune response. Acquired immunity is that which is developed after an animal is born and is restricted primarily to the T and B lymphocytes. This is to distinguish it from innate immunity with which an animal is born. This latter form of immunity is nonspecific in nature and involves many cell types and molecules such as cytokines and complement. Acquired immunity is distinct in that it has a high degree of specificity and diversity of antigen recognition, as well as memory. It is this latter trait that is exploited by immunization – the ability to establish an immunologic memory of an encountered foreign antigen.

The major cells involved in the specific immune response, and the only ones that manifest these properties of adaptive immunity, are the lymphocytes. Different lymphocyte lineages are distinguished by cell surface markers and perform different functions in the immune response. The B lymphocytes, the producers of antibodies, or the humoral response, are critical for defense against extracellular pathogens. The cytotoxic T lymphocytes, which force altered and invaded cells to undergo apoptosis, are critical for defense against intracellular pathogens. The overseers of the entire response, T helper lymphocytes, direct and modulate the response using cell surface molecule expression and cytokine production and secretion. It is important to understand how various lymphocyte lineages recognize antigens in order to design or select the most appropriate antigen delivery method.

B lymphocytes are able to detect free and soluble antigens, while T lymphocytes are only able to recognize antigens presented to them "on the pedestal" of the major histocompatibility complex (MHC) structures. For the latter to occur, the foreign antigen must be processed within a cell and displayed on the MHC for T lymphocyte recognition. MHC structures are classified as class I or class II. The former are expressed on all nucleated cells and express only antigens that are produced within that cell. The cytotoxic T lymphocytes recognize antigens presented in MHC I. MHC class II are expressed on antigen-presenting cells (APCs), such as macrophages, dendritic cells, and B lymphocytes. The antigen displayed by these structures is produced outside of and taken up by the APCs via endocytosis or phagocytosis. The antigen is then processed and inserted in MHC II for presentation to T helper lymphocytes. Understanding how lymphocytes differ in this antigen recognition process is critical to designing and selecting efficacious vaccines.

B lymphocytes bear immunoglobulins on their surface for antigen recognition. As mentioned above, these antigens are extracellular, such as free-living bacteria and parasites and the extracellular form of viruses and other intracellular parasites. In response to antigen recognition and assistance from T helper lymphocytes, naive B lymphocytes will proliferate and differentiate into plasma cells, which secrete antibody and are relatively short-lived, or memory cells, which are long-lived cells that are more easily activated and respond more quickly and with higher magnitude and antibody affinity than naive B lymphocytes. Producing a significant population of the latter is the goal of most vaccines. Antibodies, the effector mechanism of B lymphocytes, will opsonize, neutralize, clump for easy removal of, or activate complement to destroy the infecting agent.

T helper lymphocytes use the T cell receptor to recognize antigens displayed in MHC II by APCs. These antigens originate outside of and are "ingested" and processed by the APCs. Thus, as with B lymphocytes, the antigen is extracellular. In response to antigen recognition, the T helper lymphocytes begin to proliferate and differentiate into cytokine-producing cells. These cytokines, such as interleukin 2, enhance or modulate the immune response. In addition, depending on signals received by the T helper from the APC, the former will direct the immune response in the most appropriate direction – the humoral response for extracellular pathogens or cell-mediated immunity for intracellular pathogens. Thus, the T helper lymphocyte is critical to an effective immune response, whether humoral or cell mediated. T helper memory cells develop, as with B lymphocytes, into long-lived, easily activated cells, and their production is a critical goal of vaccination.

Cytotoxic T lymphocytes detect antigens presented to them in MHC I using T cell receptors on their surface. The antigen displayed in MHC I, as described above, is produced within a cell and displayed on the surface. The presence of foreign peptide from an intracellular invader in MHC I results in induction of apoptosis in the infected cell by the cytotoxic T lymphocyte. This type of response is critical for elimination of an intracellular pathogen, as it is inaccessible to most other defense mechanisms. Thus, for protective immunity against most intracellular pathogens, activation of cytotoxic T lymphocytes must occur; to do this, the vaccinal agent must be replicating in order to produce a peptide for display in MHC I. As with T helper and B lymphocytes, this process leads to proliferation and differentiation of the cytotoxic T lymphocyte into effector and memory cells.

It goes without saying that there are many other components to an effective immune response, including granulocytes, natural killer cells, cytokines such as interferon, and inflammatory mediators. But the goal of vaccination remains lymphocyte stimulation and memory cell production. How this is accomplished depends not only on the antigen presented but how it is delivered. Induction of adequate protection depends on appropriate vaccine selection and immunization protocols. As stated by Shams (2005), "an ideal vaccine should be inexpensive, stable, adaptable to mass administration, and confer a strong and long-lasting immunity with no or minimal adverse side effects in the vaccinated animal."

Antigen Delivery Systems

Vaccines can be divided into two basic groups depending upon whether or not there is transcription/replication of the agent after inoculation, referred to as infectious or noninfectious, respectively. There are an increasing variety of strategies to produce vaccines in both categories, and each has its advantages and disadvantages.

Noninfectious Vaccines

These vaccines may contain inactivated whole organisms or pieces (subunits) of the organism. *Killed* vaccines contain whole organisms that have been altered or inactivated to destroy their ability to replicate. These vaccines are generally inexpensive to produce. *Subunit vaccines* contain purified immunogenic and protective antigens, often microbial proteins. These proteins may be purified from the whole organism or may be generated using molecular technology (recombinantly produced). Conjugation to carrier proteins may be required for the antigen to stimulate an effective response; this is expensive and currently laborious. Peptide vaccines contain immunogenic epitopes that have been generated synthetically. Conjugation to carriers is required for effective immunogenicity of peptide vaccines.

In all cases, the vaccine is nonreplicating; thus, no amplification of the antigenic mass occurs after inoculation. In addition, because no transcription/translation/replication is occurring, MHC I presentation of microbial antigens, in general, does not occur. Thus, these vaccines stimulate primarily humoral immunity. They may require multiple inoculations to be effective, but this is not always the case. Most noninfectious vaccines also require an adjuvant to enhance the immune response. These substances nonspecifically increase the immune response, often by unknown mechanisms. Concern exists, particularly for feline vaccines, about the potential for adverse effects due to adjuvants.

Still, noninfectious vaccines have several advantages. Because they contain killed/inactivated organism or only a portion of the infecting agent, there is no chance for reversion to virulence. In general, they are safe for pregnant animals as well as for animals that may be immunocompromised or have an underlying disease. In addition, noninfectious vaccines are stable in field conditions and are usually inexpensive to produce.

Infectious Vaccines

Infectious vaccines contain metabolically active agents that undergo transcription and translation at a minimum and often the entire replication cycle of the inoculated organism. For infectious whole organisms, the agent is attenuated in some way such that it is no longer virulent while retaining its antigenicity. Examples of infectious vaccines include whole organism live vaccines, recombinant vectors, and DNA vaccines. Because infectious vaccines undergo transcription and translation after

inoculation, presentation of an antigen in MHC I will occur, thus enabling stimulation of cytotoxic T lymphocytes. Meanwhile, the extracellular form of the agent will be detected by B lymphocytes as well as APCs, which will process it for presentation and activation of T helper lymphocytes. Thus, both cell-mediated and humoral arms of the immune response are activated.

Modified Live Vaccines

Modified live vaccines contain organisms altered to remove their disease-causing ability. Attenuation may be accomplished by acquisition of multiple genetic mutations. Alternatively, virulence genes may be removed using recombinant technology. The attenuation process must remove the virulence without altering the immunogenicity of the organism. In addition, the attenuated organism must be genetically stable.

Recombinant Vector Vaccines

These are a variation on the theme of modified live vaccines in which one or more genes encoding immunogenic microbial proteins are engineered into a harmless bacterial or viral carrier. Examples of this technology are the canarypox virus vectored vaccines containing genes of rabies virus or feline leukemia virus. The recombinant vector expresses the cloned gene as well as its own genes during transcription and translation. This technology is useful for pathogens that would otherwise be too unsafe to administer as a live vaccine. DNA vaccines use purified DNA containing microbial genes of immunologic importance. They are taken up by cells after inoculation, and the cloned genes are expressed within the cell and presented in MHC.

Generally, for infectious vaccines, a lower antigen mass is required, and no adjuvant is needed to achieve a protective response. There are drawbacks to infectious vaccines. Attenuated organisms can potentially revert to a virulent state, though this is very uncommon. For recombinant vectors and DNA vaccines, reversion to virulence is not possible. Infectious vaccines may be less stable in field conditions than noninfectious vaccines. Finally, infectious vaccines are not generally recommended for pregnant or immunocompromised animals.

Vaccine programs may vary with each patient and client. Core vaccines, those recommended to be given routinely to all dogs and cats, are outlined in the guidelines published by various organizations, including the AAFP, AAHA, AVMA, and WSAVA (see list at end of chapter). Additional vaccines are available for a number of pathogens, including feline immunodeficiency virus and *Chlamydia* for cats, and *Leptospira*, Lyme, and canine influenza for dogs. Administration of these vaccines varies with epidemiology of the organism and risk of exposure to the animal. Also severity of disease, cost and efficacy of the vaccine, and potential for adverse reactions should be considered.

Vaccine administration for the majority of vaccines is parenteral, with subcutaneous being the route of choice for most vaccines. When multiple vaccines are given at the same visit, it is recommended that administration be done at different sites so that local adverse reactions can be documented for the specific vaccine that induced them.

Vaccine Failures

Vaccine failures do arise and have several potential causes. The most common reason in puppy- and kittenhood is interference from maternal antibodies. For the majority of puppies and kittens, the amount of maternal immunity present at any point in time is unknown. Thus, vaccination generally begins at the earliest point when most will begin losing protection from maternal antibodies and continues through the latest point at which the majority of animals do not have significant levels of interfering antibodies. The booster vaccine given during this period is actually a misnomer, as multiple vaccines are given not to boost preexisting immunity but to insure that the animal responds to at least one vaccine in the series. Because we do not know at what time point this occurs for each animal vaccinated, and it is not feasible to measure antibodies multiple times throughout this period, we give multiple vaccines with the intention that one of the series will work. For example, some puppies may have immunity that has waned by 6–7 weeks of age; these pups will respond to the vaccine given at 8–9 weeks of age. In reality, this would be the only vaccine necessary (for live vaccines) if we knew for certain that maternal immunity had waned and the pup had responded to the vaccine. The vaccines that follow at 12 and 16 weeks will in fact be neutralized by the antibodies induced from vaccination. If maternal immunity does not wane until 13–14 weeks of age, only the 16-week vaccine will induce full protection. Because we do not know the individual status at multiple time points for each animal and against multiple pathogens, we start at the early end of the susceptibility window and continue through the late end of this window.

Other causes of vaccine failure that are host related include immunosuppressive disorders and occurrence of a genetic nonresponder. The former should likely not be vaccinated with live vaccines until the disorder is corrected. For the latter, vaccinating with a different strain of the agent may be able to overcome the nonresponsiveness.

Vaccine factors also play a role in vaccine failures. Vaccine design, strain variation, and route of administration

may all factor in to the level of protection induced. Human error is also a concern, including improper storage, preparation, and administration.

Duration of immunity is likely much longer than current revaccination recommendations. Studies have shown duration of immunity of years, and in many cases it is likely lifelong, especially following infectious vaccines. Detectable antibody levels to administered vaccines have been found as long as 14 years after vaccination for canine distemper virus and canine parvovirus in dogs. Challenge studies in dogs vaccinated for canine distemper and canine parvovirus have shown protection as long as nine years post vaccination. Similar results have been reported in cats. Current guidelines recommend revaccinating every three years, but some are electing not to boost senior animals that have a strong vaccination history.

How young is too young? Generally, most live vaccines cannot safely be administered to neonatal animals, as they may cause disease in the neonate. Noninfectious vaccines can be used as can intranasal live vaccines. However, in the very young, the response may be less than adequate due to immaturity of the immune system and interference from maternal antibodies. The exception to this interference is the intranasal vaccines which can be used in high-risk settings where the history of the neonate may not be known.

How old is too old? This is a difficult question to answer, and varies with each animal. Health status of the animal, previous vaccination history, and exposure of the animal to infection all must be considered when vaccinating senior animals. Rabies requires adherence to local vaccination policies.

Conclusion

Vaccination remains an important tool in preventive veterinary medicine. Against the common pathogens affecting dogs and cats, their use has led to decline in disease prevalence. Canine rabies, for example, has been eradicated from the USA, though rabies from wildlife still occurs in dogs and cats. There are many choices among current vaccines, and selection of vaccines is an important action for any practitioner. The practitioner must remain vigilant as new strains of pathogens emerge and new vaccines appear on the market.

Behavior Triage for Internists and the General Practitioner

Karen Lynn C. Sueda, DVM, DACVB

VCA West Los Angeles Animal Hospital, Los Angeles, CA, USA

All veterinarians are behaviorists to some degree, whether they care for the mind or the body. Because we treat nonverbal species, our patients cannot tell us what hurts or how they feel. We rely upon behavioral observations – either our clients' or ours – to determine if a pet is ill and to evaluate its response to treatment.

Just as physical illness may produce behavioral changes, mental illness may also generate somatic signs. For example, anxiety may trigger compulsive behaviors such as psychogenic polydipsia or a proinflammatory response as in feline urologic syndrome. It is important that veterinarians recognize this mind–body interaction and be able to address the behavioral component when necessary.

The objectives of this chapter are to help veterinarians recognize the interplay between internal and behavioral medicine and to provide an algorithm and recommendations for triaging behavior cases. Diagnosis and treatment of specific behavioral problems are beyond the scope of this chapter. Recommended clinical small animal behavioral medicine texts which discuss the diagnosis, treatment, and prevention of canine and feline behavior problems are listed at the end of the chapter.

Behavioral Presentations

The relationship between internal and behavioral medicine is more complex than one may assume at first glance. In addition to physical illnesses triggering behavioral problems and vice versa, medical treatments may also affect a pet's behavior. Likewise, a pet's misbehavior may hinder the veterinarian's ability or the client's willingness to run diagnostic tests or implement treatment plans. Examples of ways in which the diagnosis and treatment of physical ailments may be influenced by the pet's behavior are listed below.

Physical Illness Causing a Behavioral Problem

While treating a pet for a physical problem, veterinarians may learn from the client that the pet has started to misbehave. For example, a polyuric cat may have urinated outside the litter box or a dog with pancreatitis may have begun growling when his owner picks him up. Although the behavior problem should resolve once the underlying physical cause has been addressed, the client may become frustrated with their pet's behavior during the treatment process. As such, veterinarians should query clients regarding behavioral changes at each appointment and be able to provide short-term treatment recommendations to alleviate them.

Ruling Out Physical Causes for a Behavior Problem

Clients may bring their pet to you to determine whether there is a physical explanation for their pet's behavior. When a behavioral change is the first or only clinical sign that the client observes, it is often unclear whether or not a physical ailment is to blame. Physical causes for behavioral problems should always be ruled out before assuming the issue is purely psychological in nature. At minimum, a complete physical exam, baseline bloodwork (i.e., complete blood count [CBC], chemistry panel, total thyroid level), urinalysis and any other indicated diagnostics tests (e.g., fecal exam for a pet defecating in the house; radiographs or other imaging if pain is elicited on physical exam) should be performed.

The likelihood of finding a physical cause for a behavior problem varies widely and depends in part on the clinical signs and history. For example, the odds of diagnosing a physical cause for a cat's sudden onset of house soiling are much higher than finding a medical reason for a dog's eight-year history of aggressive behavior toward strangers.

Of course, physical illness, if diagnosed, must be addressed. However, if no such cause is determined or if

Clinical Small Animal Internal Medicine Volume II, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

the behavior persists despite medical treatment, veterinarians should be prepared to offer behavioral treatment recommendations.

Behavioral Problem Causing a Physical Illness

A pet may present with a physical illness that was caused, either directly or indirectly, by a behavioral problem. The link between the pet's mental and physical ailments may be straightforward. Examples include toxicity or vomiting due to pica, polyuria secondary to psychogenic polydipsia, and hair loss caused by psychogenic alopecia. Because a psychological diagnosis for a behavior problem depends on excluding potential physical causes, it is extremely important to discuss the necessity of diagnostic testing with clients.

In other cases, the connection between the physical clinical signs and behavioral problem is less obvious. For example, a cat presenting for rodenticide toxicity may be hunting outdoors because he housesoils and is no longer allowed inside. A dog with unexplained weight loss may be suffering from separation anxiety, his weight loss occurring because he does not eat and constantly paces when home alone for 10 hours. In such cases, the client may be unaware that their pet's behavior plays a role in their physical ailment. The veterinarian should look beyond the presenting complaint to explore potential psychological or behavioral issues that may be contributing to the disease. If the underlying behavioral cause is not determined and addressed, it is very likely that the pet will present for the same issue on subsequent occasions.

Medical Treatment Causing a Behavioral Problem

Unfortunately, medical treatment may cause undesirable behavior in some cases. Patients may have idiosyncratic reactions to certain medications. For example, acepromazine may trigger aggressive behavior in some patients, while opioids and metoclopramide may elicit various behavioral changes, including agitation, in others. Steroid-induced polyphagia may result in counter-surfing, trash-raiding or resource-guarding behavior. Similarly, frequent veterinary visits, physical handling, restraint and manipulation, and constant medication administration may trigger anxiety, depression or aggressive behavior in pets that do not understand that the veterinary staff and their owners are trying to help them. In these situations – especially if the treatment cannot be discontinued or altered – veterinarians must provide behavioral recommendations to alleviate these behaviors or risk poor compliance with their treatment plan.

Preexisting Behavior Problem Hindering Medical Diagnostics and/or Treatment

Clients and veterinary staff may simply be unable to perform diagnostic tests or treatments because of the pet's behavior and temperament. The most common scenario is the client who is unable to give oral medication to his or her cat because the cat becomes aggressive when restrained and is too finicky to consume medication hidden in food. Clients may find it impossible to administer insulin injections to their diabetic dog that bites. A client living in a busy household may not be able to conduct a food trial if her dog knocks down her two-year-old son to steal cookies out of his hand. Similarly, veterinarians and staff may not be able to provide the best care to a patient that is fractious or difficult to work with. Clients may also hesitate to bring their pet to the hospital if the pet does not travel well (e.g., hides from the carrier; is agitated or anxious during car rides) or is fearful or aggressive at the clinic. If the veterinarian or client is unable to implement the ideal diagnostic or treatment plan because of behavioral reasons, discuss other treatment options or behavioral management solutions that may entail environmental changes, behavior modification and training and/or referral to a behavior practitioner.

Client Declines Diagnostics or Treatment Because of a Preexisting Behavioral Problem

The most insidious way in which behavior affects the veterinary practice occurs when the human–animal bond has been broken due to a pet's problematic behavior. Clients may elect to not pursue diagnostic or treatment options because their pet's poor behavior factors into their decision. In the client's mind, it may be difficult to justify spending money to treat a pet that bites, destroys their house, runs away or is a nuisance. Because clients rarely admit to this aspect of their decision-making process, it is especially important that veterinarians screen for behavioral problems at each visit, as part of a general "systems check." Behavioral problems can be caught early and dealt with before the human–animal bond has been affected.

Behavioral Triage

Once a behavior problem has been identified, obtaining complete medical and behavioral histories and conducting a physical exam and ancillary diagnostic tests will allow the veterinarian to determine whether the behavior is normal or aberrant/abnormal and whether it is physical or psychological in origin. The veterinarian may then recommend an appropriate course of treatment, which may include referral to an appropriate behavioral

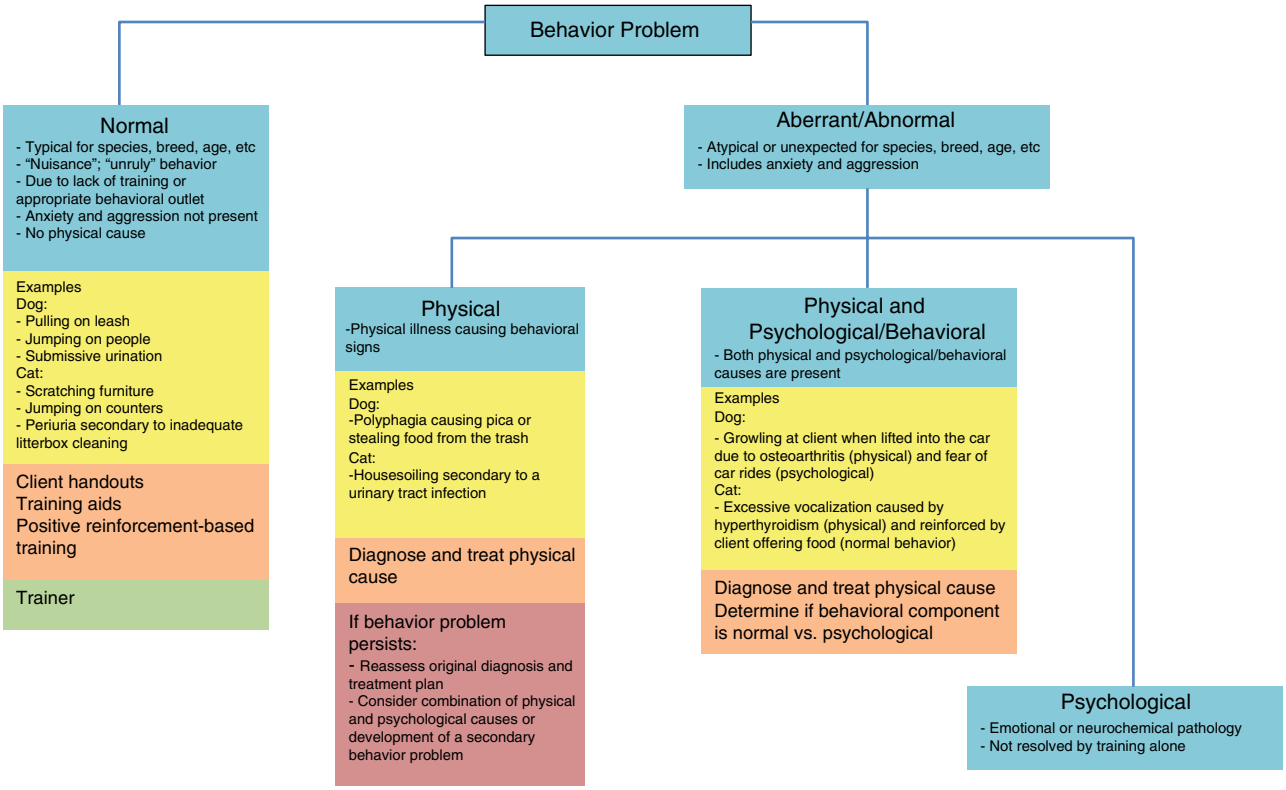

Figure 177.1 Behavioral triage algorithm.

professional depending on the type and severity of the issue. The algorithm in Figure 177.1 may help veterinarians triage behavioral issues they encounter.

1) Determine if the behavior is normal or abnormal.
   – *Normal*. These are behaviors you would expect from another animal of similar species, breed, age, lifestyle, experience, etc. These behavior problems arise because normal expression of canine or feline behavior is often incompatible with human rules. Labeled "nuisance" or "unruly" behaviors, these problems are often due to inadequate or inappropriate training or a lack of appropriate outlets for the expression of species-typical behavior. Anxiety and aggression are not present. An underlying medical cause is not present.

     Problems stemming from normal behaviors are extremely common and remain a frequent cause of relinquishment and euthanasia. It is important to identify these issues early and provide owners with treatment resources. Client handouts outlining treatment protocols are available in veterinary behavior textbooks and from veterinary, shelter, and training websites. Depending on the particular behavior, appropriate use of training aids such as head halters, body harnesses, puzzle toys, etc. may also provide clients with a "quick fix." Because the problem does not have an underlying physical or psychological cause, referral to a qualified trainer or other behavior professional is an appropriate measure.
   – *Aberrant/Abnormal*. An animal of similar species, breed, age, lifestyle, experience, etc. would not be expected to exhibit these behaviors. This category includes but is not limited to anxiety and aggression. Anxiety and aggression are normal behaviors when expressed in rational contexts and with appropriate intensity (e.g. cat hisses when a painful limb is manipulated). They are included in this category because anxiety and aggression may be clinical signs of an underlying physical and/or psychological disorder.
2) If the behavior is aberrant/abnormal, determine if the primary cause is physical, psychological or a combination of both.
   – *Physical*. If the primary cause of the behavior problem is determined to be physical, diagnose and treat the underlying physical cause of the behavior and continue medical management until both the physical and behavioral clinical signs have resolved.

     If the behavioral signs do not resolve or new behavior problems arise, reassess your original diagnosis and medical management and follow Step 1 accordingly. Consider the possibility that the original behavior problem had both physical and

psychological causes and that medical treatment only addressed the former. For example, a cat that continues to urinate outside the litter box despite elimination of its cystic calculi may have concurrent feline urologic syndrome (physical cause), litter box aversion due to inadequate cleaning by the client (normal behavior) or a learned litter box aversion because urination in the box had been associated with pain (psychological cause).

- *Both physical and psychological*. Diagnose and treat the physical component. Assess whether the behavioral clinical signs are normal or abnormal and follow Step 1 accordingly. For example, a dog that is aggressive when he is lifted into the car may be painful due to osteoarthritis (physical cause) but also fearful of car travel (psychological cause). Similarly, an elderly cat that vocalizes at night might have hyperthyroidism (physical cause) but has also been reinforced by his owners because they fed him when he cried (normal, learned behavior).
- *Psychological*. A primarily psychological etiology is diagnosed once physical causes have been ruled out or addressed. Unlike problems due to normal behaviors, "abnormal" behavioral problems typically stem from an underlying emotional (e.g., fear or anxiety) or neurochemical pathology rather than a lack of training or opportunities to express species-typical behavior. Simply reinforcing commands in these situations is unlikely to alter the animal's underlying emotional response to a situation they find threatening. These cases should be referred to a behavior professional both adept at interpreting canine or feline body language and behavior and who understands the clinical applications of learning theory.

3) If you prefer not to manage the behavioral aspects of the case yourself, determine the type of behavior professional to refer to based on the presence or absence of aggressive behavior, the severity of the behavior problem, and whether the behavior itself is common or atypical.
   - *Human-directed aggression*. Ideally, cases involving human-directed aggression should be referred to a veterinary behaviorist or a veterinarian experienced in treating aggression cases. Aggression cases often require extensive and protracted care, including an honest discussion with the owners regarding risk assessment, development of a treatment plan tailored to the owner and pet and ongoing communication – potentially for months to years – to assess and monitor the response to treatment. Because clients frequently inquire about the role medication might play in treating their pets' aggression, referral to a veterinarian with expertise in using and ability to prescribe behavior-modifying medications is best. Additionally, cases involving human-directed aggression may be at risk of future legal involvement. Documented referral to a veterinary specialist or another veterinarian who establishes their own veterinarian–client–patient relationship may be preferable to referring to a nonveterinarian in these cases. If a veterinary behaviorist or veterinarian with behavior experience is not locally available, consider a veterinarian-to-veterinary specialist consultation via phone to discuss treatment and/or referral to another behaviorist.
   - *Common problems (mild)*. A common behavior problem is one that, while abnormal, occurs frequently in that species. When they are mild in severity, common behavior problems typically do not require behavior-modifying medication and may be addressed through consistent behavior modification and environmental changes. Although it is always appropriate to refer to a veterinary behaviorist, these cases suitable for referral to a well-qualified trainer or nonveterinary behaviorist.
   - *Common problems (moderate to severe) or atypical problems*. This category includes any behavior that is moderate to severe in intensity, frequency or duration, atypical for that species or signalment, or for which a typical trigger or pattern cannot be discerned (e.g., behaviors that are idiopathic or occur "out of the blue"). These are cases in which medication and extensive, long-term behavior modification may be necessary. These cases should be referred to a veterinary behaviorist or veterinarian experienced with behavior cases.

Referrals

Clients have become increasingly educated regarding animal behavior and are seeking the advice of veterinarians when their pets misbehave rather than resorting to relinquishment or euthanasia. Whether or not to refer depends entirely on the individual veterinarian's comfort level and experience (Figure 177.2). "Normal" behavior problems or mild forms of common behavior problems may easily be addressed by the veterinarian "in house." Guidance on how to diagnose and treat canine and feline behavior problems is available in various texts (see the Further Reading list at the end of the chapter). If the veterinarian does not feel comfortable treating behavior problems or lacks the time or interest to do so, many referral options exist.

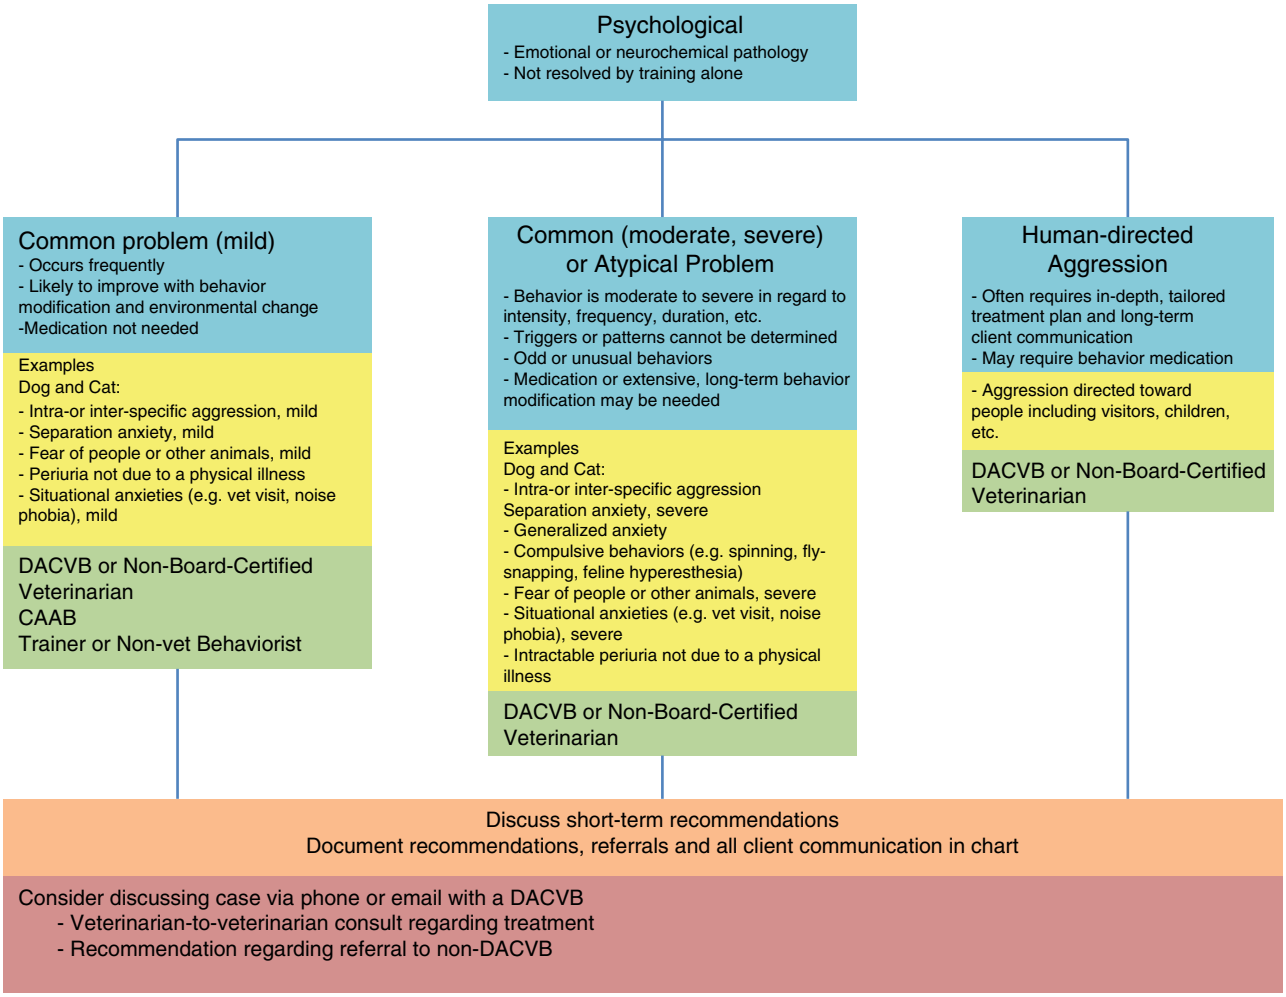

Figure 177.2 When to seek consultation with a veterinary behaviorist.

Veterinary Referrals

Veterinary Behaviorists

Board-certified veterinary behaviorists (Diplomates of the American College of Veterinary Behaviorists [ACVB]) are veterinarians who have completed a residency training program, published behavioral research and passed a qualifying exam covering medicine, ethology, pharmacology, and clinical behavior of domestic and nondomestic species. As specialists, they have a breadth of clinical experience and advanced knowledge of behavioral treatment options. Referral to a veterinary behaviorist is always appropriate and may be preferable in certain situations (Box 177.1).

If a board-certified veterinary behaviorist does not practice within a reasonable distance of your clinic, consider a veterinarian-to-veterinary specialist consult via phone or email to discuss the case or refer to a nonboarded veterinarian with behavioral experience in your local area.

Nonboarded Veterinarian with Behavioral Experience

These are veterinarians who are not board certified but are experienced with behavior cases. This category includes, but is not limited to:

- current veterinary behavior residents or residency-trained veterinarians. These are veterinarians currently in their university or private practice residency programs or who have completed their residency but have not yet passed their board-administered examination
- nonresidency-trained veterinarians with extensive behavior education and experience. There are many excellent veterinarians who have devoted their careers to the study and practice of veterinary behavior but have not completed a formal residency. They may have behavior-only private practices or see behavior cases as part of their general practice.

The American Veterinary Society of Animal Behavior (AVSAB) is an organization consisting of veterinarians and research professionals whose mission is to promote

Box 177.1 Situations in which referral to a board-certified veterinary behaviorist is warranted

Involvement of a board-certified veterinary behaviorist may be preferable over that of a nonveterinarian when one or more of the following factors are present.

- Human-directed aggression, particularly if aggression is severe or involves children
- Moderate to severe interdog or intercat aggression, especially if fights have resulted in injuries to pets or people
- Physical illness affecting the pet's behavior or treatment
  - Interplay between physical and behavioral issues warrant close monitoring
  - Medical issues may affect behavioral treatment or vice versa
- Possible use of behavior-modifying medication
  - Behavior is severe enough to warrant consideration
  - Owner inquires about medication
- Legal issues: ongoing or possible legal action
- Concerning client–patient dynamic
  - Human-animal bond is affected and/or euthanasia is a consideration
  - Client appears to be in denial regarding the severity of behavioral problem or risk involved

applied animal behavior and animal welfare. Many nonboarded veterinarians with behavior experience belong to the AVSAB.

Individual veterinarians' background training, experience level, and continuing education vary widely. Before referring to a nonboarded veterinarian, ask for a copy of their curriculum vitae and speak to them directly to discuss the case.

Nonveterinary Referrals

Certified Applied Animal Behaviorists (CAAB)

Most CAABs are not veterinarians but have a Master's or PhD degree in behavioral science, multiple scientific publications, hands-on experience with animals and have met coursework and experience requirements for certification as set forth by the Animal Behavior Society. Their scientific background makes CAABs knowledgeable about learning theory, ethology, and animal behavior. However, the amount of clinical or practical experience working with animals may vary by individual. Inquire as to their level of hands-on experience with clinical cases prior to referral.

Because most CAABs are not veterinarians, their insight into the interaction between physical and behavioral illness may be limited. It is therefore important that the referring veterinarian and CAAB work in partnership so physical issues are not overlooked. CAABs cannot prescribe medication and must refer cases back to a veterinarian for a prescription. It is the prescribing veterinarian's duty to ensure that the medication prescribed is appropriate for the patient and behavior being addressed. If the prescribing veterinarian is not familiar with psychopharmaceutical medications, it is appropriate to ask the CAAB for supporting documentation (in the form of journal articles, book references, etc.). The prescribing veterinarian must also obtain informed consent from the client, including discussing potential physical and behavioral adverse effects and conducting appropriate tests to ensure the health of the patient prior to starting medication.

Trainers and Animal Behaviorists

Many skilled, professional trainers and nonveterinary/non-CAAB animal behaviorists are available to help veterinarians, clients, and patients. These individuals may provide a range of services that veterinary and CAAB behaviorists do not, including private, in-home training, group classes, board and train, etc. Additionally, trainers are often able to work with clients and their pets on a more frequent and regular basis than a veterinary or CAAB behaviorist could. This is extremely helpful especially for clients who require extensive, hands-on training or encouragement to consistently comply with a treatment plan.

As a group, trainers and nonveterinary/non-CAAB behaviorists are a valuable resource. However, it is important to remember that individuals vary widely in regard to their knowledge, experience, training techniques, and ethics. This spectrum exists because there is no agency or governing body that oversees or regulates the qualifications of these professions. Anyone may label themselves a trainer or animal behaviorist regardless of their background. Animal behavior and training certifications can be obtained through various programs, some of which are more rigorous and require more education and experience than others. Training philosophies, such as the use of positive reinforcement versus punishment-based training techniques, also differ from school to school.

Always research the individual before recommending any trainer or animal behaviorist, veterinary or nonveterinary. Both the ACVB and AVSAB have published guidelines for selecting and working with trainers on their websites. These recommendations should be applied to any behaviorist, veterinary or nonveterinary, you may refer a client to. Because experience, training methods, and skillsets of trainers and behaviorists vary

widely, it is advisable to create different referral lists depending on the needs of the clients and patients. For example, some individuals may be highly accomplished trainers (able to teach basic obedience, agility, nosework, etc.) but do not have the background or education to treat behavior problems. Other behaviorists may feel comfortable treating "normal," training-related behavior problems but not "aberrant/abnormal" cases such as aggression or anxiety disorders. Some behaviorists specialize only in a particular species.

Summary

A team effort is required to successfully treat behavior problems. Every member of the team – referring veterinarian, behaviorist, and client – should feel comfortable working with each other for the pet's benefit. Ask your clients for feedback regarding their experience with the behaviorist or trainer they worked with so you know whom to refer to in the future. No matter to whom you refer, referrals reflect on you and your practice.

Safety and Avoidance: Short-Term Recommendations

Unless they have an interest in behavioral medicine, the veterinarian should not feel obligated to provide a comprehensive behavioral treatment plan to the client. However, the veterinarian should provide short-term, interim recommendations geared toward keeping the pet and people safe and to prevent the pet's behavior from worsening until referral to a qualified individual occurs.

- Treat physical conditions that affect the pet's behavior. Encourage clients to treat any medical problem that may contribute to the behavioral disorder.
- Avoid situations that cause the undesirable behavior to occur. Avoiding situations that cause anxiety or aggression may be necessary to prevent the pet from becoming self-injurious or harming other animals or people. Avoidance also prevents the pet from developing a progressively stronger averse response to the situation due to repeated exposure (sensitization). Rather than simply instructing clients not to let their dog or cat become anxious or aggressive, provide specific avoidance recommendations tailored to the pet and behavior problem. Relevant guidelines may be found in behavior textbooks.
- Recognize early signs of fear, anxiety, and aggression. Pets often exhibit subtle signs of discomfort before their anxiety or aggression intensifies. Teach clients to recognize physical cues such as pinned ears, crouched body posture and tucked or lashing tails as well as behavioral signs including refusing treats, not following commands and displacement behaviors like yawning, lip licking, and grooming. Handouts on canine and feline body language (available in behavior textbooks) may be sent home with clients to aid identification. To reduce the frequency and severity of subsequent undesirable behaviors, clients should remove their pet from the situation as soon as they recognize the initial signs of impending aggression or anxiety.
- Do not use punishment or confrontational training techniques as these may exacerbate fear, anxiety, and aggression. Warn clients that physical corrections – such as hitting, swatting, kicking, forcibly holding the pet down ("alpha rolling"), choke or prong collar use, scruffing, etc. – foster negative associations with the client and create anxiety and mistrust. If incorrectly used, punishment-based techniques may physically harm the pet and worsen their behavior. For additional information on the hazards of punishment-based training, see the AVSAB Position Statement on the use of punishment for behavior modification in animals available on the AVSAB website.
- Reward the pet for desirable behaviors. Encourage clients to reward their pet when it behaves appropriately (positive reinforcement). Recommend that clients think proactively rather than reactively by identifying desirable behaviors, creating situations that allow their pet to behave in an appropriate manner and rewarding it when it does so. For example, rather than punishing a dog for jumping on them, the client may preemptively instruct the dog to sit before he jumps up, and then reward him with attention while he is seated.

Encourage clients to formally train their pets. Training provides clients and their pets with a common language in which to communicate. Dogs and cats can be taught simple commands such as "sit," "down," "stay," and "come" which are used to facilitate behavior modification techniques such as desensitization and counterconditioning to specific triggers. When positive reinforcement training techniques are used, the pet enjoys interacting with the client and its anxiety decreases because interactions are consistent, predictable, and rewarding.

Managing Client Expectations

Many clients have unrealistic goals such as wanting their pet "to be friendly with every person and animal" or "to never to be anxious or aggressive again." Alternatively, clients may not realize that their dog or

cat's behavior puts the pet, people or other animals at serious risk of injury. A frank discussion regarding risk assessment and realistic prognosis may be necessary before the client invests time, money, and emotional effort in treating their pet's behavior.

An in-depth discussion of risk assessment is beyond the scope of this chapter but is addressed in several behavioral texts (see Further Reading).

Prognosis depends on the individual case but is usually guarded since most behavior problems cannot be "cured." Abnormal behavior problems not due to physical illness are caused by emotional and/or neurochemical disease states that cannot be fully eliminated. The goal of treatment is remission – management of the behavior and reduction in symptom severity and frequency such that the pet and client have an improved quality of life.

In most situations, consulting with a behavior professional and compliance with a behavior modification plan will improve the pet's behavior. The veterinarian or behavior professional should establish reasonable short-term and long-term goals for the pet. Ongoing communication between the behavior professional and client along with periodic recheck appointments are essential to ensure that the treatment plan is successful or, if not, to adjust the recommendations accordingly.

Conclusion

The goals of both behavioral and internal medicine are the same: establish a diagnosis and alleviate clinical signs of the disease. When behavioral issues complicate physical illness or vice versa, diagnosis and treatment will not be successful without identifying and addressing both. Once a behavioral cause has been established, veterinarians must be prepared to triage these cases and provide the clients with short-term recommendations and referral to the appropriate behavior professional. This multidisciplinary approach addresses both the physical and behavioral components of the disease process and provides the best prognosis for successful resolution of clinical signs, thus improving the quality of life for the pet and client.

  ventricular premature depolarizations/contractions 199–200, *202*
ventricular fibrillation 200, 202–204, *202*
ventricular premature depolarizations/contractions (VPC) 199–200, *202*
ventricular septal defect (VSD) 231, 232, 237, 241–243
ventricular synchrony 177
ventricular tachycardia (VT) 200, *202*, 204, 413–414, 419
vertebral heart score (VHS) 128–130, *130*, **131**
vesicles *1384*
vesicular cutaneous lupus erythematosus (VCLE) 1426–1427, *1426*
vestibular ataxia 732
vestibular disease 789–794
  anatomy/physiology 789
  anomalous/congenital causes 790, 792
  central vestibular disease 789–790, 792–794
  differentiating peripheral from central disease 789–790
  etiology 790–794
  idiopathic causes 791
  infectious causes 791
  inflammatory causes 791–794
  peripheral vestibular disease 790–792
  vascular causes 792–793
Veterinary Acute Kidney Injury (VAKI) staging scheme **1091**
veterinary bedside lung ultrasound examination (VetBLUE) 292–293, **293**
VHS *see* vertebral heart score
VIC *see* valvular interstitial cells
videotoscopy 1473, *1473*, 1478, *1478*
VILI *see* ventilator-induced lung injury
viral infections
  cutaneous manifestations of systemic disease 1484–1485, *1484*
  laboratory diagnosis 843–844

see also individual agents/diseases
viral papillomas 1261
viremia 878–880
virtual endoscopy 500, *500*
virulent babesiosis 108
visceral hemangiosarcoma 1340, 1344
visceral myopathy 570
viscoelastic coagulation testing 315, 316–317, *317*
vision 736–738
vitamin D deficiency 1524–1527
vitamin D-dependent rickets type I/II 1527
vitamin K1 antagonists 438–439
vitamin K agonists 322
vitamin supplementation 693, 702, 1487
vocalization 893
Vogt–Koyanagi–Harada-like syndrome 1430–1431
voiding urohydropropulsion (VUH) 1144–1145, *1146*
volvulus/torsion 496–497, 504, *505*
see also gastric dilation-volvulus
vomiting
acute kidney injury 1097–1098
acute poisoning 441–442
chronic kidney disease 1167–1168
endocrine manifestations of cancer 1215–1216
feline inflammatory liver disease 688, 693
feline parvovirus 870
gallbladder and extrahepatic biliary ducts 723
metabolic diseases 679–680
motility disorders 565–567, 570–572, 580
von Willebrand factor (vWF) 460
VPC *see* ventricular premature depolarizations/contractions
V–Q *see* ventilation–perfusion
VRA *see* vascular ring anomalies
VRE *see* vancomycin-resistant enterococci
VSD *see* ventricular septal defect
VT *see* ventricular tachycardia
VUH *see* voiding urohydropropulsion
vWF *see* von Willebrand factor

W

Walchia americana 1459–1460
Waldenström macroglobulinemia (WM) 1241–1246
wash-out 24
water balance *see* sodium and water homeostasis
water deprivation test (WDT) 67–68
weight change/management
cardiovascular disease 120–121
diabetes mellitus 94
osteoarthritis 1532–1533
Westermark sign 316, *316*
western immunoblotting 910
West Nile virus (WNV) 899–900
diagnosis 900
epidemiology 899
etiology/pathophysiology 899
prognosis 900
public health implications 900
signalment 899
treatment 900
wheals *1384*, *1407*
wheezes 125
WHO *see* World Health Organization
wild mammals
leptospirosis 945–946
rabies 891–895
yersiniosis 951–952
wipes 1398, 1469
withdrawal-flexor reflex 734–735
WM *see* Waldenström macroglobulinemia
WNV *see* West Nile virus
Wolbachia pipientis infection 917–918
diagnosis 918
epidemiology 918
etiology/pathophysiology 917
history and clinical signs 918
prognosis 918
public health implications 918
signalment 918
treatment 918
Wolff–Parkinson–White syndrome 414
Wood's lamp examination 439–440, 987
World Health Organization (WHO)
approach to the cancer patient 1200
hemangiosarcoma 1341–1342, **1342**
kennels and multicat environments 1064
lymphomas 1231–1232, **1232**
mammary cancer 1322, **1322**, 1324, **1324**
mast cell tumors **1361**
melanoma 1352, **1352**
oral tumors **1254**
World Small Animal Veterinary Association (WSAVA)
canine inflammatory liver disease 695
chronic enteropathies 635
endoscopy 508
feline inflammatory liver disease 687
hepatobiliary disease 659, 667
kennels and multicat environments 1064
wounds and wound management
bandaging 1032
critical care setting 352
exploration and initial debridement 1031
lavage 1032
nocosomial and multidrug-resistant infections 1058
surgical and traumatic wound infections 1029–1032, **1030–1031**
surgical, traumatic, and bite wound infections 1032
trauma and burns 450, 455
venomous snake bites 462, 463
wound closure 1032
wound preparation 1031
see also bite wounds
WSAVA *see* World Small Animal Veterinary Association

X

xanthine urolithiasis 1128–1129, *1128*
xanthomas 1483
xenogeneic DNA vaccination 1349–1350, *1350*
xylitol toxicity 109–110

Y

yersiniosis 951–954
diagnosis 953
epidemiology 952
etiology/pathophysiology 951
history and clinical signs 952–953
prevention 953–954
prognosis 953
public health implications 954
signalment 952
treatment 953

Z

zinc-responsive dermatosis 1486–1487, *1486*
Zollinger–Ellison syndrome 1215–1216
zoonotic infections
  approach to the dermatologic patient 1381
  canine brucellosis 965
  canine infectious respiratory disease complex 1037–1038
  kennels and multicat environments 1065–1066
  leptospirosis 945–949
  mycobacteriosis 980–984
  nocosomial and multidrug-resistant infections 1061–1062
  nonhemotropic *Mycoplasma*, *Ureaplasma*, and L-form bacteria 934
  One Health 3–5
  rabies 891–897
  tularemia 955–957
  West Nile virus 899–900
