About the pagination of this eBook

This eBook contains a multi-volume set.

To navigate the front matter of this eBook by page number, you will need to use the volume number and the page number, separated by a hyphen.

For example, to go to page v of volume 1, type “1-v” in the Go box at the bottom of the screen and click "Go."

To go to page v of volume 2, type “2-v”… and so forth.

Dedication

To CB Chastain, Dick Nelson and Ed Feldman for trying their best to make me a better clinician. For someone interested in internal medicine and endocrinology I could not have had better mentors.

To all of my former students, interns and residents, thanks so much for always keeping me honest and forcing me to try to stay ahead of those I was supposed to be teaching.

To all the wonderful folks at Wiley (Erica Judisch, Gillian Whitley, Purvi Patel, Holly Regan-Jones, and Katrina Maceda) that made this book possible and tried their best to keep me on track. You turned the idea into reality and improved the book at every step in the process.

To my amazing children McKenna, Taylor, Ivy and Cole, thanks for letting me be a part of your lives. Being your Dad is the best job in the world.

To my amazing wife and best friend Maya. You make my life complete and I look forward to sharing every day with you.

Contents

Preface *xix*
List of Contributors *xxi*
About the Companion Website *xxix*

VOLUME I

Section 1 Evaluation and Management of the Patient *1*

1 **The Concept of One Medicine** *3*
Lonnie J. King

2 **Statistical Interpretation for Practitioners** *7*
Philip H. Kass

3 **Using Data for Clinical Decision Making** *17*
Philip H. Kass

Section 2 Endocrine Disease *27*

4 **Principles of Endocrinology** *29*
Robert Kemppainen

5 **Neuroendocrinology** *35*
Maya Lottati

6 **Feline Acromegaly** *43*
David S. Bruyette

7 **Pituitary-Dependent Hyperadrenocorticism in Dogs and Cats** *49*
David S. Bruyette

8 **Polyuria and Polydipsia** *65*
Jennifer L. Garcia

9 **Canine Hypothyroidism** *71*
David S. Bruyette

10 **Feline Hyperthyroidism** *75*
David S. Bruyette

11 Hypoadrenocorticism in Dogs and Cats 81
Patty Lathan

12 Diabetes Mellitus in Dogs and Cats 93
Jacquie S. Rand

13 Hypoglycemia in Patients without Diabetes Mellitus: Evaluation and Management 103
Rhett Nichols

14 Canine Autoimmune Polyglandular Syndromes 113
Deborah Greco

Section 3 Cardiovascular Disease 117

15 Approach to the Patient with Suspected Cardiovascular Disease 119
Ingrid Ljungvall and Jens Häggström

16 Imaging in Cardiovascular Disease 127
Valérie Chetboul

17 Electrocardiography 165
Anna R.M. Gelzer and Marc S. Kraus

18 Pathophysiology of Heart Failure 175
Barret J. Bulmer

19 Management of Heart Failure 185
Steven Rosenthal and Mark A. Oyama

20 Ventricular Arrhythmias 199
Amara H. Estrada and Romain Pariaut

21 Supraventricular Arrhythmias 205
Romain Pariaut and Amara H. Estrada

22 Systemic Hypertension 219
Rebecca L. Stepien

23 Pulmonary Hypertension 225
Heidi B. Kellihan

24 Congenital Heart Disease 231
Brian A. Scansen

25 Valvular Heart Disease 245
Michele Borgarelli

26 Canine Myocardial Disease 253
M. Lynne O'Sullivan

27 Feline Myocardial Disease 267
Virginia Luis Fuentes

28 Pericardial Disease 275
Ashley B. Saunders and Sonya G. Gordon

Section 4 Respiratory Disease 287

29 A Respiratory Pattern-Based Approach to Dyspnea 289
Christopher G. Byers

30 Feline Bronchial Asthma 297
Christine M. Serafin

31 Canine Chronic Bronchitis 305
Kevin Kumrow

32 Pulmonary Thromboembolism 313
Robert Goggs

33 Surgical Approaches to Thoracic Disease 325
Raegan Wells

34 Pleural Effusion 333
Ashley Allen and Gareth Buckley

Section 5 Critical Care Medicine 345

35 Approach to the Patient in the Critical Care Setting 347
Sarah Allen

36 Fluid Therapy 355
Teresa Rieser

37 Cardiopulmonary Resuscitation 365
Nathan Peterson

38 Respiratory Monitoring in Critical Care 373
Mathew Mellema

39 Acute Respiratory Failure 381
Matthew Mellema

40 Mechanical Ventilation 393
Kate Hopper and Mathew Mellema

41 Approach to the Patient with Shock 403
James W. Barr

42 Cardiogenic Shock 413
Nathan Peterson and James W. Barr

43 Septic Shock 421
James W. Barr

44 Disorders of Heat and Cold 431
Sarah Allen

45 Acute Poisoning 437
Ben O'Kelley

46 Medical Management of Trauma and Burns 445
Nathan Peterson

47 Venomous Snake Bites 459
Nathan Peterson

Section 6 Gastrointestinal Disease 467

48 Gastrointestinal Imaging 469
Susanne M. Stieger-Vanegas

49 Gastrointestinal Endoscopy 507
Craig Ruaux

50 Diseases of the Oral Cavity and Salivary Glands 533
Maria M. Soltero-Rivera and Alexander M. Reiter

51 Gastritis and Gastric Ulceration in Dogs and Cats 547
Katie Tolbert and Emily Gould

52 Disorders of the Esophagus 557
Silvia Funes and Craig Ruaux

53 Motility Disorders of the Alimentary Tract 563
Reto Neiger and Silke Salavati

54 Exocrine Pancreatic Insufficiency in Dogs and Cats 583
Panagiotis G. Xenoulis

55 Pancreatitis in the Dog 591
Caroline Mansfield

56 Pancreatitis in the Cat 601
Craig Ruaux

57 Rectoanal Diseases – Medical and Surgical Management 609
Craig Ruaux and Milan Milovancev

58 Dysbiosis and the Use of Pre-, Pro- and Synbiotics 621
Jan S. Suchodolski

59 Diagnosis and Management of Chronic Enteropathies 627
Karin Allenspach

Section 7 Diseases of the Liver, Gallbladder, and Bile Ducts 639

60 Approach to the Patient with Liver Disease 641
Emma O'Neill

61 Imaging in Hepatobiliary Disease 659
Esther Barrett

62 Metabolic, Toxic, and Neoplastic Diseases of the Liver 677
Jan Rothuizen

63 Feline Inflammatory Liver Disease 687
Nicki Reed

64 Canine Inflammatory Liver Disease 695
Nick Bexfield

65 Cirrhosis and its Consequences 705
Katherine Scott

66 Portosystemic Shunts and Microvascular Dysplasia 713
Geraldine Hunt

67 Diseases of the Gallbladder and Extrahepatic Biliary Ducts 721
Ben Harris

Section 8 Neurologic Disease 727

68 The Neurologic Examination 729
Alexander de Lahunta

69 Central Nervous System Trauma 741
Simon R. Platt

70 Seizures and Movement Disorders 759
Michael Podell

71 Disorders of the Forebrain 773
Sam N. Long

72 Vestibular Disease 789
Tammy Stevenson

73 Meningoencephalitis and Meningomyelitis 795
Christopher L. Mariani

74 Diseases of the Neuromuscular Junction 803
David Lipsitz

75 Myopathies 811
Marguerite F. Knipe

76 Myelopathy 815
Joan R. Coates

77 Neuroophthalmology 823
Bradford J. Holmberg

VOLUME II

Section 9 Infectious Disease 829

Part 1 Diagnostic Considerations 831

78 Epidemiology of Infectious Disease 833
Peggy L. Schmidt and Helen T. Engelke

79 Laboratory Diagnosis of Infectious Diseases 839
Laia Solano-Gallego and Gad Baneth

Part 2 Select Infectious Diseases and Disease Agents 849

80 Canine Distemper 851
David S. Bruyette

81 Canine Herpesvirus 855
Yvonne Drechsler

82 Canine Viral Enteritis 857
Margaret C. Barr

83 Viral Papillomatosis 861
Margaret C. Barr

84 Canine Influenza Virus 865
Ellen Collisson

85 Feline Parvovirus 869
Margaret C. Barr

86 Feline Coronavirus 873
Yvonne Drechsler

87 Feline Leukemia Virus 877
David S. Bruyette

88 Feline Immunodeficiency Virus 883
Tom Phillips

89 Feline Viral Upper Respiratory Tract Disease 887
Yvonne Drechsler

90 Rabies in Dogs and Cats 891
Emily Beeler and Karen Ehnert

91 West Nile Virus 899
Tracey McNamara

92 Ebola Virus 901
Linda Kidd

93 **Ehrlichiosis and Anaplasmosis** *903*
Pedro P. Vissotto de Paiva Diniz

94 **Salmon Poisoning Disease** *913*
Pedro P. Vissotto de Paiva Diniz

95 ***Wolbachia pipientis* Infection** *917*
Pedro P. Vissotto de Paiva Diniz

96 **Bartonellosis** *919*
Pedro P. Vissotto de Paiva Diniz

97 **Hemotropic *Mycoplasma*** *927*
Séverine Tasker

98 **Nonhemotropic *Mycoplasma*, *Ureaplasma*, and L-Form Bacteria** *931*
Joachim Spergser

99 **Spotted Fever and Typhus Group Rickettsia** *937*
Linda Kidd

100 **Lyme Borreliosis** *941*
Meryl P. Littman

101 **Leptospirosis** *945*
Katharine F. Lunn

102 **Yersiniosis** *951*
Maria Grazia Pennisi

103 **Tularemia** *955*
Linda Kidd

104 **Q Fever** *959*
Linda Kidd

105 **Brucellosis** *963*
Erin E. Runcan and Marco A. Coutinho da Silva

106 **Tetanus and Botulism** *967*
Andrea Fischer

107 **Anthrax** *971*
Wayne E. Wingfield and Jerry J. Upp

108 **Actinomycosis, Nocardiosis, and Mycobacterial Infections** *977*
Joanna Whitney and Vanessa R. Barrs

109 **Fungal Infections** *985*
Jane E. Sykes

110 **Protozoal and Protozoa-Like Infections** *1003*
Gad Baneth and Laia Solano-Gallego

111 Coccidia 1023
Chris Adolph

112 Surgical, Traumatic, and Bite Wound Infections 1029
Laura L. Nelson

113 Canine Infectious Respiratory Disease Complex 1035
Jonathan Dear

Part 3 Therapeutic Considerations 1039

114 Antimicrobial Therapy in Dogs and Cats 1041
Katrina R. Viviano

115 Antifungal Therapy 1049
Daniel S. Foy

Part 4 Special Topics 1055

116 Nosocomial and Multidrug-Resistant Infections 1057
Jason W. Stull and J. Scott Weese

117 Management of Infectious Disease in Kennels and Multicat Environments: Creating a Culture of Compliance 1063
Frank Bossong

Section 10 Renal and Genitourinary Disease 1067

118 Disorders of Sodium and Water Homeostasis 1069
Julien Guillaumin and Stephen DiBartola

119 Disorders of Phosphorus and Magnesium 1079
Rosanne Jepson

120 Acute Kidney Injury 1089
Adam E. Eatroff

121 Glomerular Disease 1101
Shelly L. Vaden

122 Obstructive Uropathy 1109
Edward Cooper and Brian A. Scansen

123 Urolithiasis in Small Animals 1123
Alice Defarges, Michelle Evason, Marilyn Dunn, and Allyson Berent

124 Prostatic Diseases 1157
Serge Chalhoub

125 Management of Chronic Kidney Disease 1165
Jessica Quimby

126 The Role of Dialysis 1175
Adam E. Eatroff

127 Micturition and Associated Disorders 1181
Julie K. Byron

128 Urinary Tract Infections 1189
Nicole Smee

Section 11 Oncologic Disease 1197

129 Approach to the Cancer Patient 1199
Lisa DiBernardi

130 Biology of Cancer and Cancer Genetics 1205
Mary-Keara Boss

131 Endocrine Manifestations of Cancer: Ectopic Hormone Production 1213
Cory Brown

132 Paraneoplastic Syndromes 1217
Cory Brown

133 Lymphoid Leukemias, Myeloid Neoplasia, and Myelodysplastic Syndrome 1223
Angela R. Kozicki

134 Lymphomas 1231
Kristine Elaine Burgess

135 Plasma Cell Disorders 1241
Orna Kristal

136 Central Nervous System Tumors in Dogs and Cats 1247
David Ruslander

137 Cancer of the Nose and Mouth 1253
Lauren Askin Quarterman

138 Tumors of the Eye and Ocular Adnexa 1261
Erin M. Scott and Paul E. Miller

139 Cancer of the Heart 1271
Nick A. Schroeder and Lisa DiBernardi

140 Cancer of the Airway and Lung 1277
Joanne L. Intile

141 Cancer of the Esophagus and Stomach 1283
Avenelle I. Turner

142 Cancer of the Small and Large Intestine 1287
Edwin Brodsky

143 Exocrine Pancreatic Cancer 1293
Avenelle I. Turner

144 Pancreatic Endocrine Tumors 1297
Karen Eiler

145 Liver and Biliary Tract Tumors 1303
Amanda K. Elpiner

146 Tumors of the Urinary Tract 1307
Pedro A. Boria

147 Tumors of the Male Reproductive System 1311
Trina Hazzah

148 Gynecologic Cancers 1317
Trina Hazzah

149 Mammary Cancer 1321
Julie Bulman-Fleming

150 Tumors of Bone and Joint 1327
Stephanie L. Shaver, William T.N. Culp, and Robert B. Rebhun

151 Soft Tissue Sarcomas 1333
Lauren Askin Quarterman

152 Hemangiosarcoma 1339
Christine B. Oakley and John D. Chretin

153 Melanoma 1347
Philip J. Bergman

154 Nonmelanoma Skin Cancers 1353
Barbara E. Kitchell

155 Mast Cell Neoplasia 1359
Zachary M. Wright

156 Apheresis in Companion Animals 1369
Steven Suter

Section 12 Skin and Ear Diseases 1373

157 Approach to the Patient with Dermatologic Disease 1375
Lisa V. Reiter

158 Principles of Therapy of Dermatologic Diseases 1397
Sandra N. Koch

159 Atopic Dermatitis 1403
Alison Diesel

160 Allergic Skin Diseases 1413
Patrick Hensel

161 Cutaneous Adverse Food Reactions 1419
Ralf S. Mueller

162 Autoimmune and Immune-Mediated Skin Diseases 1423
Nicole A. Heinrich

163 Approach to Alopecia 1433

Preface

Internal medicine is hard. Progress in science and technology makes it almost impossible to keep abreast of recent advances and on top of that, all of us want to balance our life both at work and home. Is there enough time in the day for everything?

There are a variety of ways in which we learn and the path is not the same for everyone. For those of us with an interest in internal medicine, and I'm assuming that includes the reader of this book, we rely on a number of resources. Our colleagues, continuing education seminars, the literature, professional educational networks, and reference textbooks. A concern of mine over the past few years has been the increasing reliance on technology to arrive at a clinical diagnosis rather than emphasizing the need to understand physiology and the value of a complete history and a thorough physical examination. We feel increasing pressure to arrive at a specific and definitive diagnosis and, more importantly, to arrive at that diagnosis almost immediately.

Your goal in internal medicine is not to arrive at a diagnosis. I would much prefer to see a pet respond to my treatment and recover without a definitive diagnosis than to arrive at a definitive diagnosis at necropsy. If you are successful in achieving a diagnosis, that can be very rewarding. However, your goal should be to accurately identify problems and address those problems in a logical, timely, and cost-effective manner, always weighing the risk/benefit of running myriad diagnostics versus improving the quality of life of your patient and the pet owner. While not every pet owner will be able to afford or desire to follow each and every one of our recommendations, it is our job to make sure that whatever decision the owner makes is based on being fully informed.

Illness is really physiology gone awry. If you have an understanding of what is normal, it makes your job of identifying the abnormal much easier. The body has a limited repertoire of responses to an insult so often many diseases will have very similar clinical presentations. While we all like to make lists of the 20 differential diagnoses for a given patient's abnormalities, it's important to recognize that in clinical practice, common things occur commonly and those differentials should be at the top of your rule-out list.

There are numerous excellent textbooks on the market and I use many of them on a daily/weekly basis. Some serve as definitive reference works for the topic under discussion. Some are brief, bullet point, clinically oriented texts that one can use to find something quickly. What I thought was currently lacking was a text that would be continually updated, provide enough background physiology to help the reader understand normal versus abnormal, and provide useful and, more importantly, clinically relevant material to help you with your patients.

The goal of this text was to first identify section editors who were recognized experts in their field both academically and clinically. The section editors then identified topics they felt were of greatest clinical importance and selected authors who could translate this information into a text that would be used every day. I hope we have achieved that goal. We will be updating the text online with new information and updated references on a quarterly basis, adding additional sections and chapters with future editions, and uploading podcasts consisting of interviews with the authors to highlight and emphasize the material in the text and any recent advances in the field.

We hope that you will find the text helpful and all credit for that success goes to the authors. Any omissions or errors lie with me so please let me know both the good and the bad so we can improve things going forward.

As my favorite philosopher once said "It's a magical world, Hobbes, ol' buddy, let's go exploring."

All the best and enjoy exploring the mysteries of medicine.

Dave

Evaluation and Management of the Patient

1

The Concept of One Medicine

Lonnie J. King, DVM, MS, MPA, DACVPM

Department of Veterinary Preventive Medicine, The Ohio State University, Columbus, OH, USA

Today's world is rapidly changing, complex, and progressively more interconnected. The convergence of people, animals, and our environment has created a new dynamic characterized by a profound and unprecedented interdependence in which the health of all three domains is now inextricably linked and elaborately connected. Over the last three decades, approximately 75% of new emerging human diseases have been zoonotic. The human–animal interface is expanding, accelerating, and becoming increasingly more consequential. At the same time, we have permanently altered a significant portion of our environment, ecosystems, and habitats and have created a new ecological milieu that is changing both the conditions of our human–animal interface and the conditions for microbial adaptation and the emergence and reemergence of infectious diseases worldwide.

Our new interdependence includes social, economic, political, and biological conditions that are creating new threats to the health of people, animals, and our environment. We can no longer focus on these threats separately from each other. Our contemporary challenge is to create and implement a new mindset and strategies to address our threats to health based on a holistic and integrated approach with a special emphasis on prevention and attacking problems closer to their origin that is often within the animal and environmental domains. This approach is the essence of the concept of One Health.

One Health can be defined as the collaborative effort of multiple disciplines – working locally, nationally, and globally to attain optimal health for people, animals, and our environment. The scope of One Health is impressive, broad, and growing. Much of the recent focus on One Health has been limited to emerging infectious diseases yet the concept clearly embraces environmental and ecosystem health, social sciences, biodiversity, ecology, noninfectious diseases and chronic diseases and much more.

While the concept of One Health is not new, it has enjoyed a new recognition based on today's complex challenges to our health. The veterinary profession is especially well equipped through our broad training in herd health, comparative medicine, epidemiology, problem solving, and disease ecology to play an important role in implementing new One Health strategies.

Factors Driving One Health

In a publication entitled *Microbial Threats to Health: Emergence, Detection, and Response*, authors from the Institute of Medicine suggested that a group of factors have simultaneously converged to create a "perfect microbial storm" [1]. The most important of these factors include:

- adaptation of microbes
- global travel and transportation
- host susceptibility
- intent to do harm
- climate change
- economic development and land use
- human demographics and behavior
- a breakdown of both public and animal health infrastructures.

The Human Domain

The world population has a growth rate of 1.2% per year and the next century will represent a period of exponential growth. We add approximately 10 000 people per hour to our global population every day. Approximately 90% of the world's population growth is occurring in the developing countries where we are most concerned about a lack of adequate public and animal health infrastructure. In addition, almost 1 billion people live in

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

periurban or slum settings in the developing world's largest cities and these sites are where the most rapid growth in our human populations will continue. Concurrently, there is unprecedented immigration, translocation, and movement of people worldwide. Unique diasporas have emerged and there are large numbers of immunocompromised individuals dispersed throughout the US and global populations who are especially susceptible to infections involving food- and water-borne illnesses.

The Animal Domain

While there is also legitimate concern about the approximately 800 million people who are undernourished, we are concurrently observing a relative increase in wealth in the developing world and as per capita incomes rise, people eat more calories and consume different products, including a demand for meat and protein from animal sources. Thus, a new agricultural phenomenon is emerging – the Livestock Revolution; we will need to increase protein from animal sources by 50% over the next several decades. We will also need to increase food-animal production with minimal impacts on the environment and our ecosystems. Veterinarians will be engaged with ecologists to help ensure the sustainability of our lands.

At the same time, companion animals and pets are also rapidly increasing globally and there are untold numbers of wildlife that are increasingly involved at the human–animal interface and responsible for carrying and transmitting more and more zoonotic diseases. West Nile virus, Lyme disease, Nipah, Hendra, and hantaviruses are some important examples.

With a new appreciation of the need for detecting and identifying human infectious disease threats at animal and ecosystem level, our scope of disease surveillance must also be expanded to include these domains. Currently, 80% of select agents are zoonotic which further emphasizes the need for integrating animal disease surveillance into human disease surveillance programs. In addition to the benefits of earlier detection and warning, surveillance within these domains will give us new insights and analyses on disease prediction and new possibilities to prevent future disease occurrences and exposures. Thus, animal disease surveillance has taken on a new importance and relevance.

Until we address the underlying factors that lead to disease emergence and reemergence, we will continue to address infectious disease problems one at a time and based on reactive responses. A new commitment is necessary to refocus our efforts to prevent and control diseases in ways that also address these underlying conditions and the animals, animal products, and their vectors.

For example, human exposure to *Borrelia burgdorferi*, the etiologic agent of Lyme disease, is maintained and spread based on the complex relationships among wildlife populations, tick life cycles, host preferences, habitat, ecosystem, and landscape design and other dynamics of this disease ecology. Effective prevention and control may need to focus on ecologic interventions rather than treating the human illness after exposure and infection. Thus, rather than a narrow focus on humans and their interactions with pathogens, we need to focus on the dynamic interplay among humans, animals, and animal products, and our changing environment – in other words, a One Health approach.

Role for Companion Animal Experts

The purpose of including this introduction on One Health for a text on internal medicine is to help create a new awareness of the concept across the veterinary profession and to suggest that companion animal practitioners also have new opportunities, as well as obligations, to support public health in the future.

Practitioners can be extremely helpful and contribute in the following ways:

- enhance surveillance for emerging and zoonotic diseases
- identify cases of zoonoses that will then prevent human illnesses
- educate clients regarding One Health and zoonotic diseases
- be involved in a potential surge capacity in case a significant epidemic or natural disaster calls for your support
- promote the human–animal bond but with knowledge of both the benefits and potential negative impacts of the human–animal interface, including wildlife.

Conclusion

Our global interdependence and growing convergence of animals, animal products, and people ensure that diseases will continue to be a significant threat to health. There is nothing on the horizon suggesting that the era of the perfect microbial storm will lessen or be abated. The factors creating this reality are well entrenched and emerging and reemerging zoonoses are growing and expanding in scope, scale, and impact. These diseases now have a much greater impact and influence beyond health. Global outbreaks of SARS and influenza have demonstrated how such diseases create immense economic losses in goods, services,

travel, and trade in addition to their profound health costs and consequences.

Contemporary societal issues such as global trade and commerce, movements and migrations of populations, changes and insults to our ecosystems, population growth in developing countries, the Livestock Revolution, and disruptions of the environment are helping to create a complex, nonlinear and disruptive world that is riskier and impacts health in the domains of people, animals, and our environment. The ability to improve and optimize health in the future will depend on working in these three domains concurrently, holistically, and synergistically. A One Health mindset and accompanying actions are now a necessity and no longer just a concept. In order to reconcile our significant contemporary challenges and threats with our habitual, narrow and traditional thinking in medicine, new levels of thinking across disciplines and professions will become the new normal. Veterinarians are becoming essential leaders in this movement and a new concept of community health, including veterinary medicine, is emerging.

Public health and animal health are no longer the domain of any single discipline, profession or boundary; rather, they require the work of epidemiologists, clinicians, ecologists, veterinarians, entomologists, engineers, and many more experts coming together to provide new insights and perspectives using new scientific and technological tools. Addressing, predicting, and preventing diseases certainly demand the richness of new scientific and medical teams.

For veterinary medicine, our horizon has never been richer nor our possibilities more promising. Our profession's challenge is to be relevant and meet the changing needs of society regarding public health, global food systems, ecosystem management, and biomedical research. One Health is the framework, mindset, and new collective purpose to help define our expanding responsibilities, including, and beyond, traditional clinical medicine.

Statistical Interpretation for Practitioners

Philip H. Kass, BS, DVM, MPVM, MS, PhD

Department of Population Health and Reproduction, School of Veterinary Medicine, University of California, Davis, CA, USA

The need for an understanding of how to conduct statistical analyses and, more importantly, how to interpret them derives from a natural tension between aspiration and reality: the desire to make encompassing statements concerning the characteristics and causal properties about populations of animals, juxtaposed with the inability to study more than a small sample of them. Statistical inference therefore provides the necessary linkage between using samples to make inferences about populations.

External Validity

It is often taken as a matter of faith that studies conducted in relatively circumscribed subpopulations (such as a cohort of patients seen at an individual hospital in a defined period of time) can have relatively generalizable findings. For example, a hospital-based study examining the relative clinical efficacy of two or more chemotherapeutic regimens to treat newly diagnosed canine lymphoma by inducing remission may motivate the authors to make recommendations for adoption well beyond the hospital's patient catchment area. When are such generalizations justified?

Sampling of populations is required to scientifically justify extrapolating results from sample-based studies to target populations. Thus, to make scientific inferences about a population, it is necessary to study a representative sample. In many cases, the sample size need not be particularly large, and can be obtained through random (or more complex) sampling schemes. The process of random sampling ensures representative selection, and that in turn provides the key link between a study sample and a target population.

Because few studies are actually conducted using true sampling of a target population, the ability to generalize study findings (that is, having "external validity") typically depends on prior medical belief and knowledge, as well as key assumptions. For example, the initial epidemiological research into the association between tobacco smoking and lung cancer was performed in the 1950s in a cohort of male British doctors [1]. Technically, the findings of this research strictly applied to the entire population of male British doctors who were contemporaries of the study subjects. The choice to generalize these findings – namely, that the incidence of lung cancer was many-fold higher among smokers than nonsmokers – to other populations rested on key assumptions motivated by scientific reasons independent of the actual research. These assumptions included that the effect of tobacco smoking on lung cancer incidence should not meaningfully vary by gender, occupation, country of origin, ethnic identity, and birth cohort. Nothing in the original research could have provided evidence to support these assumptions; nevertheless, they helped create the basis for the landmark 1964 report in the US officially affirming a causal link between tobacco smoking and lung cancer [2].

A more recent example of the dangers of extrapolating study results to nonstudy populations can be found in an article on the association between mitotic index (MI) and survival in dogs diagnosed with mast cell tumors [3]. The authors found a substantially lower survival in dogs seen at a California veterinary medical teaching hospital whose MI was 5 or fewer versus those whose MI was 6 or greater. In contrast, Elston *et al.* performed similar analyses on dogs from Brazil and recommended somewhat different MI cut-off values [4]. The original authors responded by underscoring the difficulty of externally validating studies:

> This underscores the fallibility of classification schemes in clinical veterinary medicine: they may work well in a study population and its corresponding reference population but may not perform nearly as well in a target population of inherently different animals or where measurement standards may not necessarily be completely

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

> concordant. The latter can be influenced by how different pathologists measure, count, and ultimately determine MI, and whether such determinations are so precise as to be perfectly replicable by others. Such studies are then relegated to determining average effects across potentially heterogeneous patient populations even within a community, much less between countries. Thus, patient characteristics such as age, breed, sex, and owner propensity for diagnosis (including biopsy) would be expected to vary, perhaps substantially, between institutions such as ours and Elston et al.'s. [5]

These illustrations should presumably compel veterinarians to be circumspect about relying too heavily on any single study, particularly one conducted in a geographically restricted region, and for authors to exercise restraint in advocating wider than justified implications for a single study. Although the heterogeneity existing across populations may have a negligible impact on the universality of study findings, a cautious approach to generalizability is often warranted.

Internal Validity

Unlike external validity, which relies on information not usually obtained in a study to make inferences beyond the bounds of a study population, internal validity depends on the relative presence or absence of two sources of error pervasive to all clinical studies: imprecision (random error) and invalidity (systematic error).

Imprecision has multiple formal statistical definitions and interpretations, but can best be understood as how variable the results are expected to be from multiple studies measuring the same quantity. As an example, if a veterinarian were to repeatedly weigh a patient using a scale, precision would imply obtaining similar weights each time; conversely, imprecision implies considerable disagreement in weights with each attempt. Standard deviations, standard errors, variances, and ranges are all statistical measures for quantifying imprecision. We can make two broad qualitative statements about variability without resorting to mathematical formulas: (1) the further apart observations are from each other, the more imprecise any summary statistic based on them will be; and (2) the larger a study is, the more precise any statistic derived from it will be. This has an intuitive appeal: the findings from a large study are more likely to be accepted as more precise than those from a small study. Provided there are no biases, the source of statistical variability in a study is typically ascribed to random error.

It would be a grievous error, however, to accept a study's outcomes solely on the basis of high precision. Invalidity, another source of error in studies and equivalently called *bias*, is a distinctly different statistical measure, and represents the disparity between what one empirically measures in a study and what one strives to measure (namely, factual truth). Returning to the previous example, if a hospital scale is miscalibrated, then regardless of how precise or imprecise the replicate measurements are, the average weight will invariably be incorrect (biased), with the degree of the bias proportional to the degree of miscalibration.

All medical research is potentially susceptible to imprecision and bias, and it is only through circumspect study design that these errors can be prevented or controlled. Such errors exist on a quantitative continuum (parenthetically often reduced to crude descriptors, such as "very" imprecise or "small" bias), so it becomes important to recognize that all studies must be judged by both error criteria and not just one (or neither). Such lack of circumspection is pervasive, even in academic settings, and helps explain the often contradictory results one so often reads about in the popular media [6]. It also underscores the often unappreciated theme that even very large-sample studies are susceptible to bias, and despite their exceedingly high precision can conceivably be as misleading as a much smaller study.

Hypothesis Testing

Perhaps the most obvious manifestation of the use of statistical analysis in clinical research is through much misunderstood hypothesis testing. Although investigators and clinicians typically want to know if the differences between study groups are real, or if the association between risk factors and health outcomes is real, hypothesis tests are unable to answer these questions. Moreover, the *P*-values so ubiquitously reported in clinical articles fail to inform readers about the probabilities that measured differences or associations are real. In reality, their interpretation is surprisingly counterintuitive.

Consider the example of comparing the average (mean) alanine aminotransferase (ALT) levels between young dogs and geriatric dogs. The average in young dogs is 40 μ/L, and in geriatric dogs is 80 μ/L. The null hypothesis is that the averages in the two groups are equal; the two-sided (meaning that either group could have a higher/lower average than the other) alternative hypothesis is that they are unequal. A two-group Student's t-test is performed, and a *P*-value of 0.10 is calculated. If the level of significance (α) is 0.05, then the difference is not statistically significant. What can one conclude from this?

First, it would be an error to state that there was "no difference" between the groups. Clearly, there was a difference (of 40 μ/L). It would, however, be correct to state that because the null hypothesis of no group difference was not rejected, there was no significant difference between the groups, assuming the assumptions of the statistical model are correct (because (P = 0.10) > (α = 0.05)).

Second, the P-value does not provide a quantitative assay of the probabilities that the null or alternative hypotheses are correct. Conventional (superiority) hypothesis testing is predicated on the veracity of the null hypothesis, and so does not provide any assessment of its truth. Instead, the P-value addresses an entirely different question: how likely (probabilistically speaking) is it that one would observe differences at least as large as the one found in the study (40 μ/L) when the null hypothesis is true? In other words, instead of the P-value equaling the probability that the null hypothesis is true given the data observed in the study, it provides the probability of observing the difference in the data observed (or more extreme) given the null hypothesis is true. It follows that "large" P-values indicate substantial concordance with the null hypothesis, while "small" P-values indicate poor concordance with the null hypothesis (presumably motivating its rejection in favor of its alternative).

Third, a P-value is only numerically correct under a particular statistical model. With the Student's t-test example, the underlying model assumes that the ALT values in each group are approximately normally distributed. If the assumption of normality is violated, however, the P-value will no longer be correct; the greater the departure of the data distribution from normality, the more incorrect the P-value will be.

Fourth, another assumption is that the study data are independent, meaning that knowing one individual's ALT value does not allow the ability to predict another individual's ALT value. In this example, such an assumption is reasonable when each individual contributes only one ALT value. However, when replicates from a single individual are included, it is plausible to assume that knowing an individual's value at one time can better predict the same individual's value at another time than the value from a different individual. Such a violation of the data independence assumption leads to the estimation of an incorrect P-value; typically, the use of correlated (nonindependent or dependent) data underestimates P-values, and hence more type I statistical errors (improperly rejecting the null hypothesis) arise.

Fifth, it is important to recognize that statistical analysis is more than the analysis of single numbers (i.e., point estimates, as in averages) in groups; instead, it is more correctly described as the analysis of variability. For this reason, the presence or absence of statistical significance is more than just reflective of the magnitude of differences or associations and the chosen level of significance; it is also a function of the variance of the point estimates. Because such variances are inversely proportional to sample sizes, two studies with identical differences or associations can have completely different P-values: the smaller study's differences could be nonsignificant, while the larger study's differences may be significant.

Sixth, it directly follows that any group differences or associations can eventually be made statistically significant if the study size becomes sufficiently large. To illustrate this, two random samples of 25 individuals each were created, one assuming blood hemoglobin was normally distributed with a mean of 15 g/dL and standard deviation of 2 g/dL, and the other with a mean and standard deviation of 15.1 and 2 g/dL, respectively. No one would seriously argue that a hemoglobin difference of 0.1 g/dL is clinically important, and indeed it is not significant at α = 0.05 (P = 0.79). However, if the two groups were constructed to have 2500 individuals each, with the same means and standard deviations, this same clinically unimportant difference (0.1 g/dL) becomes statistically significant (P = 0.023). This underscores an important distinguishing principle of statistical analysis: statistical significance is distinctly different from and does not imply medical importance. In a large enough study, even trivial and unimportant differences can become statistically significant; in a small study, differences that appear to be worthy of medical pursuit may be statistically insignificant. In recognition of this principle, alternative methods of hypothesis testing have been developed that instead of examining superiority of one group over another, evaluate whether groups are noninferior or equivalent based on a determination of what constitutes an acceptably important difference or association [7].

Finally, each decision to reject or not reject a null hypothesis following hypothesis testing is prone to error. What is often unappreciated is that the more tests that are performed, the greater the probability that at least one decision will be incorrect. In a clinical setting, this is perhaps most manifest when performing clinical laboratory testing panels to screen for hematologic or chemical abnormalities in blood. Reference ranges for blood parameters are typically constructed to encompass approximately 95% of normal animals, implying that 5% of normal animals will have values falling outside the ranges.

When a reference range is appropriate for a patient's age, sex, and any other factors that can influence a particular blood parameter, it is reassuring that a normal animal's value will fall within the reference range 95% of the time. However, a universally accepted practice is to run laboratory panels simultaneously evaluating many parameters. Suppose, for example, that a blood chemistry

panel contains 30 different parameters to evaluate. Although each separate parameter has a 5% probability of being incorrect in a normal animal, when considering all parameters the probability of at least one error rises to 78.5%. In other words, a veterinarian should be surprised if at least one parameter does not fall outside the reference range even in a healthy patient.

Another related problem arises when using screening tests with imperfect properties (false-positive and -negative results) in populations with low prevalences of illnesses. Even when the test properties are excellent, with error rates less than 5%, if a disease is rare enough in a population of patients being screened, there can paradoxically be more false-positive results than true-positive results. This should be discomforting to veterinarians whose clinical decisionmaking depends on the veracity of diagnostic testing.

One approach to resolving this issue (apart from running the test again to see if the result was aberrant) is to use screening tests judiciously, reserving them for patients with a heightened suspicion of actual illness. In other words, clinical judgment and experience are as integral to the use and interpretation of diagnostic tests as contrasting the actual test results to reference ranges. Such circumspection serves to elevate the likelihood of illness in the patient being tested, or analogously the prevalence of the illness in the population being screened. This will contribute to making fewer unjustified conclusions about abnormal results in otherwise healthy patients.

Parametric versus Nonparametric Tests

All statistical tests have assumptions underlying their use. Those that assume that data follow a particular probability distribution function (also known as the sampling model) are called parametric tests (by virtue of the fact that the functions have one or more parameters in them). Probably the most common distribution function used in parametric statistical analyses is the normal distribution (with two parameters: the mean and standard deviation). As noted earlier, Student's two-group t-test assumes that the data in each group are approximately normally distributed. Other well-known parametric tests also rely on normality: the paired t-test assumes the differences are approximately normally distributed; analysis of variance and least-squares linear regression assume the model residuals (the difference between observed and predicted values) are approximately normally distributed.

How can a clinician know if data are normally distributed? Various approaches exist, including distributional tests (for example, Shapiro–Wilk, Shapiro–Francia, Kolmogorov–Smirnov tests) and plots (for example, normal probability plots). Such tests assume data are normally distributed; rejection of the null hypothesis indicates incompatibility with the null hypothesis of normality.

The problem with such tests is that they are notoriously inadequate to detect departures from normality when sample sizes are small. For example, consider the following six data points: 100, 100, 80, 70, 50, 50. This is a U-shaped distribution and so is clearly not normally distributed. Nevertheless, a Shapiro–Wilk test fails to reject the null hypothesis that the data are normally distributed when $\alpha = 0.05$ ($P = 0.22$), so if we relied on this test result we would erroneously conclude that the sample data derived from a population with a normal distribution. Interestingly, if this dataset is doubled in size (n = 12), then the Shapiro–Wilk test would become significant ($P = 0.019$) and the null hypothesis of normality would be rejected.

When sample sizes are small or when normality is an untenable assumption, then alternative statistical tests are sometimes available. These tests are called nonparametric tests, because they do not assume that data follow a particular distribution, and hence are also known as distribution-free tests. Table 2.1 contains a list of the most commonly used nonparametric tests, as well as their equivalent parametric test (if one exists).

These tests have more statistical power (for example, the ability to reject the null hypothesis when it is false) than parametric tests when data do not conform to a parametric distribution (such as normality), and are almost as powerful as parametric tests when the data do conform to a parametric distribution. When the assumption of normality is questionable based on statistical tests or the sample size is too small for reliable testing, nonparametric tests are preferable whenever possible.

Describing Data Distributions

For data that are approximately normally distributed, it is customary to describe the center of the distribution with the sample average (i.e., mean), and to describe the dispersion around the mean with either the standard deviation or the standard error of the mean (i.e., the standard deviation divided by the square root of the sample size). When data are not normally distributed, however, it is generally advisable to describe the data with statistics that do not assume a symmetric distribution around the mean. Preferable measures to use include medians, ranges, and percentiles of the data (for example, the 2.5th and 97.5th percentiles provide a 95% percentile-based interval).

Table 2.1 Commonly used parametric and equivalent nonparametric statistical tests in biomedical research.

Types of data	Type of statistical problem	Parametric test	Nonparametric test
Continuous	Two independent samples	Student's t	Wilcoxon-Mann-Whitney
	Two dependent samples	Paired t	Wilcoxon signed rank
	Three or more independent samples	Analysis of variance (one-way)	Kruskal-Wallis
	Three or more ordered independent samples		Jonckheere-Terpstra
Categorical	Unordered 2 × 2 table		Fisher's exact
	Unordered R × C table[a]		Pearson's Chi-square
	Single ordered R × C table[a]		Kruskal-Wallis
	Doubly ordered R × C table[a]		Jonckheere-Terpstra
	Two dependent samples		McNemar's (two levels) Marginal homogeneity (three or more levels)
	K independent ordered proportions[b]		Cochran-Armitage trend
	K dependent samples	Repeated measures analysis of variance (one-way)	Friedman
Ordinal	Association of two samples	Pearson correlation	Spearman correlation

[a] R = number of rows, C = number of columns.
[b] K = number of proportions or samples, K > 2.

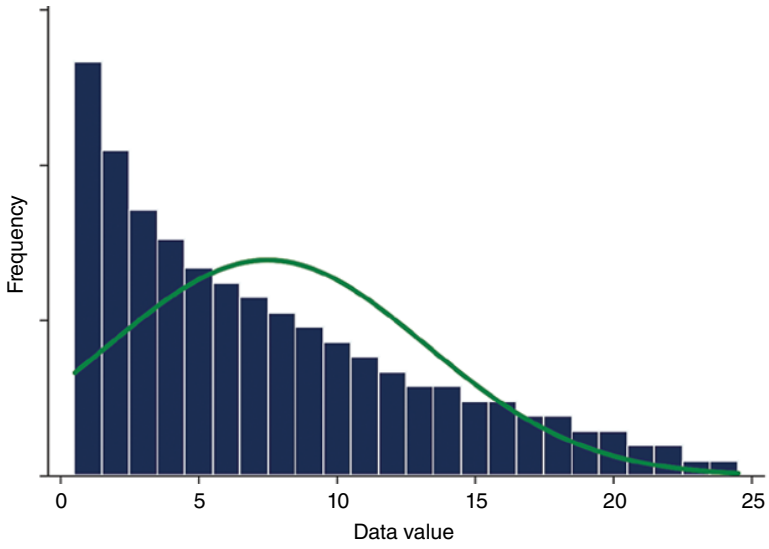

Figure 2.1 Histogram showing a hypothetical asymmetric data distribution. The green line illustrates the poor fit of a normal (Gaussian) distribution to the data.

To illustrate this point, Figure 2.1 shows a histogram of a data distribution that is clearly not normally distributed. Superimposed over the histogram is a curve of a normal distribution whose shape is completely determined by the mean and standard deviation of the actual data. Because the curve fails to closely approximate the histogram, the mean and standard deviation used to create the curve similarly fail to describe the center and dispersion of the data. For example, the mean = 7.5 while the median (i.e., the 50th percentile) is only 6.0. Similarly, the range of the data extends from 1 to 24, but a 95% confidence interval of the data distribution based on the mean and standard deviation would have a lower bound less than 0, which is less than the smallest possible

observed value. This underscores the point that when data do not conform to a particular parametric distribution, it is preferable to use a method of describing the data that does not depend on specifying a particular distribution.

Graphically representing such data is likewise inappropriate when using bar charts based on means and error bars using standard deviations or standard errors. One indispensable way of graphically portraying such data is through the use of a box and whiskers plot, as shown for the data above in Figure 2.2.

The advantage of such graphs is that they are constructed based only the data, and not on any distributional assumptions (such as normality). The lower and upper ends of the box correspond to the 25th and 75th percentiles respectively; the horizontal line within the box corresponds to the 50th percentile (i.e., the median), the bars (i.e., the "whiskers") above and below the box contain all data above and below 1.5 times the vertical width of the box (i.e., the interquartile range), and the individual points beyond the whiskers represent extreme (outlying) values. Figure 2.2 reinforces the observation from the histogram that the data are skewed towards higher values, which causes the mean to be larger than the median. This type of plot is also valuable in assessing symmetry of a data distribution (asymmetric distributions should not be described with means and standard deviations) and for identifying outliers that may represent data errors.

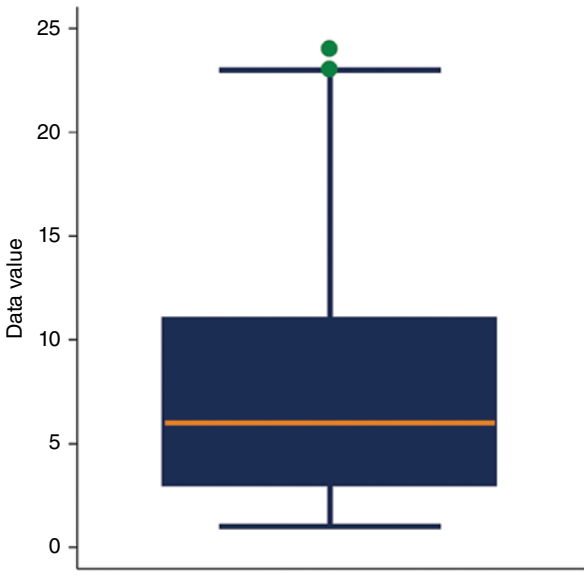

Figure 2.2 Box and whiskers plot for data shown in Figure 2.1. Lower and upper ends of the box represent the 25th and 75th percentiles, respectively; the orange line within the box equals the 50th percentile (median), the bars ("whiskers") above and below the box contain all data above and below 1.5 times the interquartile range, and individual points beyond the whiskers represent outliers.

Another common error arises when replicate measurements are taken from the same patient over time. This arises, for example, when two or more treatments are successively tested in patients with before/after comparisons, or when monitoring blood values over time. As mentioned earlier, *n* replicate measurements taken from a single individual cannot be treated as equivalent to single measurements coming from *n* different individuals.

Figure 2.3 illustrates this principle by examining before/after measurements taken on five patients at different times. Both panel 1 (left) and panel 2 (right) contain the identical 10 points but panel 1 ignores the pairing within individuals, and a regression line fitted to the 10 points suggests a negative correlation between the measurements over time. Panel 2, in contrast, links the before/after pairs within individuals and an entirely different picture emerges: every individual's values actually increased over time. Ignoring such pairing not only obscures actual effects but also in cases such as this suggests a paradoxical reversal of effects. Therefore, in studies where two or more measurements are taken from the same patients over time, it is important to not combine the patients' values at individual time points through the use of histograms, boxplots, or other graphical representations. Panel B is often called a "spaghetti plot" because it can, with larger numbers of individuals, take on an appearance of many intertwined lines across two or more times.

Measures of Association and Effect

As noted earlier, the construct and interpretation of the *P*-value is unsatisfying, if not bewildering to consumers of statistical analyses who are not well versed in their subtleties. The preoccupation with statistical testing in the medical literature should presumably be subordinate to and supplanted by a more favorable inclination towards estimation: the mathematical calculation of statistics that measure the magnitude of differences and associations in data. The imperative for this is no more evident than in the often seen but erroneous exposition that "no differences were found from a set of analyses because none were statistically significant."

Among the most common intuitively appealing measures of association are those conjoined from descriptive measures of prevalence and incidence.

Prevalence

Prevalence represents the proportion of individuals in a population who, at a single point or restricted period of time, possess a health characteristic of interest, as in

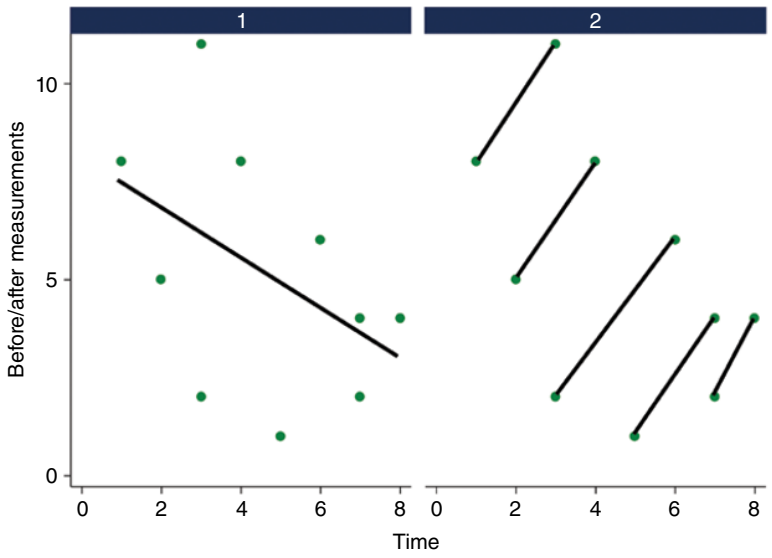

Figure 2.3 Scatterplots showing before and after measurements taken on five individuals. Panel 1 (*left*) contains a regression line with a negative slope estimated ignoring the pairing within individuals. Panel 2 (*right*) shows the paired observations, demonstrating that all measurements within individuals increased over time, in contrast to the incorrect impression conveyed in panel 1.

having a disease (or conversely being disease free). The factors that constitute why an individual possesses such a health outcome are intertwined, reflecting contributions from the risk of developing the outcome, the probabilities of recovering, succumbing, or remaining with it over a short or long time (i.e., its duration), and the probability of remaining in the population. Because the contribution of the risk of developing the outcome, also known as incidence, cannot be isolated from the effects of the other respective factors influencing prevalence, prevalence measures cannot serve as surrogates for measures of risk, incidence, or effects.

To illustrate this, suppose 100 dogs are born in January 2015 and all become chronically infected with a virus in their first three months of life so that their three-month risk of infection is 100%. Also suppose that infection only begins to be cleared after 18 months of age and is eliminated at 24 months of age. Then consider another 100 dogs born in January 2016, which all become infected in their first three months as well. Therefore, the three-month risk of infection in both groups is 100%. Unlike the other dogs, these dogs begin to clear their infection almost immediately (perhaps due to vaccination or postinfection treatment), and by six months are disease free.

However, suppose this incidence information was unknown, and a cross-sectional study of both sets of dogs (n = 200) is performed on June 30, 2016 (i.e., there is no attrition from the combined population). On this date, the prevalence in all 200 dogs will precisely be 50% because the prevalence will be 0% in the 6-month-old dogs (n = 100) and 100% in the 18-month-old dogs (n = 100). It would be an error, however, to use these prevalence figures to claim that older age is a risk factor for infection because, unknown to the study investigator, 100% of the dogs under three months of age developed the infection; if we assume recovery from infection confers immunity, it is impossible to even address the issue of age above 3 months as a risk factor. This underscores the fallacy of using prevalence to infer risk when factors that affect risk also affect recovery or mortality or leaving a population.

Prevalence nevertheless has value in quantifying the relative burden or presence of a health outcome in a population at a particular point in time. Clinicians may, for example, use disease prevalence to guide their pharmaceutical inventories or preventive medicine programs. Measures of relative prevalence can also be informative in hypothesis generation. To understand this, suppose the prevalence of antibodies to a particular organism is found more frequently in dogs with immune-mediated polyarthritis than in dogs without arthritis. This is no guarantee that the antibody response associated with infection of the organism causally leads to cross-reactivity with synovial membranes or joint surfaces, because there is no way by measuring only prevalence to distinguish infection occurring prior to onset of polyarthritis from infection occurring afterwards. Such a finding could, however, lead to experimental confirmation (or refutation) of the hypothesis that infection leads to polyarthritis. Serologic surveys are frequently used for this hypothesis-generating purpose.

Cumulative Incidence

In contrast, incidence is more appropriate for inferring risk (which can be defined as the average probability of developing a health outcome of interest in a specified time interval). Incidence, by definition, is predicated on the initial absence of the outcome among the members

of a population at risk of experiencing the outcome. The population is then followed forward in time, and within a specific time period cumulative incidence is defined as the proportion of the individuals initially at risk that newly develop the outcome (assuming no individuals have been lost to follow-up), and can only strictly fall between 0 and 1. If 300 Yorkshire terriers were followed from birth for five years without any dental interventions, and at the end of this time the presence of tooth resorption was found in 100 dogs, then the five-year cumulative incidence of tooth resorption would be 0.33 (assuming that there were no dogs that spontaneously recovered from it).

Cumulative incidence alone is not a measure of association. However, comparing two or more cumulative incidences under different conditions allows such associations to be quantified. Suppose that in addition to the finding in Yorkshire terriers above, the five-year cumulative incidence of tooth resorption in border collies was also measured as 0.10. Two important statements can now be made about these two figures. First, that over the five-year follow-up period the difference in cumulative incidences between Yorkshire terriers and border collies is 0.20 (0.30 – 0.10). Second, that over the five-year follow-up period there is a three-fold increase (0.30/0.10) in the cumulative incidence in Yorkshire terriers compared to border collies. These two measures of association are known as the *cumulative incidence difference* and the *cumulative incidence ratio*, respectively. Other terms that remain in use include risk difference and attributable risk for the former, and risk ratio and relative risk for the latter (these terms should be used with caution, however, because risk implies causation, and statistical measures are distinct from causal measures without corresponding strong causal assumptions that must be invoked).

Nevertheless, the cumulative incidence ratio is particularly well suited to effectively communicating relative impacts of factors on health in clinical practice because of its intuitive understandability. Statistical novices can appreciate, for example, a statement such as: "The incidence of parvovirus in unvaccinated puppies under 6 months of age is 10-fold greater than in vaccinated puppies."

Our understanding of how vaccines, the immune system, and viral infections work could also reasonably allow us to modify this statement by substituting the word "risk" for "incidence." Such strong biologic knowledge is not always apparent, however, which should motivate caution when using words with causal interpretations like "risk" or "likelihood." Physicians would have no hesitancy in making the correspondence between the association of tobacco smoke with lung cancer and heart disease with the statement that the risk of lung cancer and heart disease is greater among smokers than nonsmokers. However, no one would seriously entertain making such a correspondence between the association of carrying matches with lung cancer and heart disease and any causal effect. Therefore, statements about "risk" differences and ratios are best reserved for situations where the justification for alleging a causal relation is supported by knowledge other than purely statistical.

Incidence Rates

When patients are not all followed for the same amount of time, the cumulative incidence should not be utilized because the reasons for loss to follow-up (known as *right censoring*) could be related to the risk of the outcome developing. Instead, another, less intuitive measure of incidence that allows for different follow-up in each individual is the *incidence rate* (also sometimes called the hazard rate). In contrast to cumulative incidence, a proportion that has an interpretation always linked to a defined period of time, the incidence rate in a population is a joint function of the number of new (incident) outcome occurrences divided by the sum of the individual times at risk of an outcome among the members of the population, and is expressed as the number of outcomes per unit of time (for example, days, months, years, etc.). Incidence rates are analogous to speeds; across populations, they estimate the average number of outcomes expected to occur per quantity of time.

Incidence rates have particular utility in studies measuring the time from onset of follow-up to when an event occurs. Such events can be recovery, death, remission, or other outcomes. One of the most common applications for incidence rates is in survival studies of comparative treatment efficacy, where particular interest is in the rate of death (or, conversely, survival).

Suppose that in Yorkshire terriers the incidence rate of tooth resorption = 0.3 case/dog-year (or, equivalently, 30 cases/100 dog-years). This can be interpreted to mean that if 100 dogs were each followed for one year, that 30 cases would be expected; it can also be interpreted to mean that if 50 dogs were each followed for two years, 30 cases would be expected, and so on. The independence of the incidence rate from the number of individuals is perhaps best understood through the analogy of measuring the average speed of automobiles: whether 60 cars each travel one mile in one minute or one car travels 60 miles in 60 minutes, under both scenarios the total distance traveled is 60 miles, the total amount of time traveled is 60 minutes, and the speed is 60 miles per hour.

As with cumulative incidence, it is frequent to see incidence rates compared on a ratio scale to measure relative associations; these are called *incidence rate ratios* or *hazard ratios*. An incidence rate ratio greater than 1 implies

that the rate of the outcome occurring under the numerator condition (such as treatment A) is faster than the rate under the denominator condition (such as treatment B); conversely, an incidence rate ratio between 0 and 1 indicates that the rate of the outcome occurring under the numerator condition is slower than the rate under the denominator condition.

Returning to the above example, if the rate of resorption in Yorkshire terriers is 30 cases/100 dog-years, and the rate of resorption in border collies is 10 cases/100 dog-years, then the incidence rate ratio is 3.0. Not only does this indicate that the rate of developing tooth resorption is three times faster in Yorkshire terriers compared to border collies, but it also means that the time to developing tooth resorption is less in Yorkshire terriers, and that the proportion of dogs remaining free of tooth resorption (i.e., "surviving") is greater in border collies at all times.

Incidence Odds and Incidence Odds Ratios

Perhaps the least understood yet ubiquitously found measure of association in the veterinary medical literature is the *odds ratio*. Although odds ratios arise under different study designs (both experimental and nonexperimental), and their interpretations can vary, these differences are less critical than the properties they share as measures of association and potential impact of factors on the incidence of health outcomes. In order to understand odds ratios, it is necessary to first understand the statistical meaning of an *odds*.

Probabilities are measures of the likelihood of an event occurring, and are only strictly between (and including) 0 and 1; a probability of 0 implies impossibility and a probability of 1 implies inevitability. The odds is another measure of likelihood, and is calculated as the probability of an event occurring divided by the probability of an event not occurring (note that the sum of these two probabilities must equal 1). When the probability of an event occurring equals 0, the odds equals 0. However, when the probability of an event occurring equals 1, then the probability of an event not occurring equals 0, and the odds (which would equal 1 divided by 0) is undefined but infinitely large.

The restricted range for probabilities versus the infinitely large range for odds necessarily makes the former more understandable and desirable when communicating biostatistical findings. For example, if the probability of a 14-year-old cat developing hyperthyroidism in the ensuing years of its life is 0.60 (which can equivalently be expressed as 60%), then the odds of developing hyperthyroidism is 1.5 (but there is no percentage equivalent). This leads to two related but important findings. First, as the probability approaches 1, the odds becomes unintelligibly large (for example, a probability of 0.95 corresponds to an odds of 19, while a probability of 0.999 corresponds to an odds of 999). Second, when the probability is small (between 0 and 0.05), such as with the incidence of a rare disease, the odds is similarly small (between 0 and 0.053, respectively). This implies that *for rare events*, probabilities and odds are nearly equal, and for interpretive purposes are essentially interchangeable.

While odds, just like probabilities, can be expressed as unconditional (not depending on the values of other factors) estimates, it is more common to see them expressed as conditional odds; for example, the odds of developing tooth resorption among Yorkshire terriers is a conditional statement because it only applies to Yorkshire terriers and not other dog breeds. Just as ratios of two different cumulative incidences and two different incidence rates can be calculated to measure proportionate changes in incidence between two levels of a variable, so can ratios of odds. Returning to the earlier example of the cumulative incidence of tooth resorption, if the five-year cumulative incidence in Yorkshire terriers is 0.3 and the five-year cumulative incidence in border collies is 0.1, then the five-year incidence odds in the two breeds are 0.43 and 0.11, respectively. Therefore, the odds ratio relating five-year incidence of tooth resorption in Yorkshire terriers compared to border collies is 0.43/0.11 = 3.86. This can be contrasted with the cumulative incidence ratio of 3.00, and the disparity between the two measures primarily arises because the odds in (0.43) does not closely approximate the cumulative incidence (0.3) in Yorkshire terriers because the latter is not rare.

Just as cumulative incidence, as a probability, is much more comprehensible than an incidence odds, so the cumulative incidence ratio is more comprehensible than an *incidence odds ratio*. Knowing in the above example that the cumulative incidence ratio = 3.0 makes the interpretation straightforward: the five-year cumulative incidence in Yorkshire Terriers is three times the incidence in border collies. In the absence of any biases, we could attach a causal interpretation to this and claim that the average five-year risk of dental resorption in Yorkshire terriers is three times the corresponding risk in border collies.

In contrast, no such interpretation can be attributed to the odds ratio of 3.86 above, because it is not in general interpretable either as a relative measure of either risks or incidence rates. While it is legitimate to interpret it literally as a relative odds, other interpretations that include "risk," "likelihood," "probability," and "cumulative incidence" are incorrect and should not be used. This begs

the question: of what value is the incidence odds ratio if it is interpretatively inferior to other ratio measures?

The answer is that in case–control studies, where study groups are selected based on whether or not they possess (cases) or do not yet possess (controls) the outcome of interest, it is not possible to directly calculate measures of incidence because the ratio of cases to controls is determined by the study investigator. Without the ability to calculate individual conditional incidence measures in subgroups, investigators are therefore similarly unable to calculate cumulative incidence or incidence rate ratio measures of association that depend on knowing individual ones. Fortunately, case–control studies are often reserved for studying rare diseases, even conditional on the levels of other variables such as potential risk factors, so using the aforementioned rarity condition that interpretatively equilibrates the cumulative incidence and the incidence odds, the incidence odds ratio can essentially be understood as the cumulative incidence ratio. Subtle modifications in case–control study designs can also sometimes provide more interpretative latitude in extending such equivalence to incidence rate ratios [8].

Conclusion

This chapter addresses many, but certainly not all, of the most common statistical interpretive issues that face readers of the veterinary medical literature. Appreciating these issues is an important avenue to understanding the basis for evaluating clinical research articles. But statistical analyses only represent one component of medical research; not addressed here are the myriad issues that arise in the course of designing and implementing experimental and nonexperimental studies. Because study design is also inextricably linked to precision and validity issues, statistical inference complements and cannot be divorced from causal inference in evidence-based veterinary medicine. Topics involving the design of studies to generate data for clinical decision making are the subject of the following chapter.

Using Data for Clinical Decision Making

Philip H. Kass, DVM, MPVM, MS, PhD

Department of Population Health and Reproduction, School of Veterinary Medicine, University of California, Davis, CA, USA

The advent of the electronic medical record was accompanied by a new-found feasibility for veterinary medical practitioners, either at individual hospitals or through multiinstitutional collaborations, to gather, analyze, interpret, and publish their clinical data. While it is still common to read individual case or case series reports in medical journals, electronic data and searchable databases extend the ability of veterinarians to design more sophisticated studies that go beyond the bounds of being purely descriptive. Such design enhancements allow the measurement of differences and associations between two or more factors of interest, and in some cases lead to estimation of measures of effect that under assumptions of unbiasedness can lead to causal inferences.

Using clinically derived data to make informed medical decisions is a central tenet underlying the practice of evidence-based medicine, an evolving form of scientific scholarship that seeks to bring objectivity and elucidation to the implementation of medical investigation, and that exists at the confluence of medicine, basic sciences, applied mathematics/biostatistics, epidemiology, and causal inference. Using data analytically is only one component of evidence-based medicine, and cannot be dissociated from equally important others. While collaboration is all but essential in ensuring that these respective component specialties are well represented, of most proximate importance to veterinarians seeking to advance beyond the hypothesis phase of their clinical research is a fundamental understanding of hospital-based epidemiologic study design, for this is the study type that determines the data collected, and in turn how it should be analyzed and interpreted [1].

The most common study designs employed in clinical veterinary research will be considered in subsequent sections of this chapter. These will be broadly partitioned into two temporal types. The first involves data measurements taken on an assemblage of patients all present at a point in time, or on a succession of patients enrolled over a typically brief period of time to obtain an adequate total sample size, which are called "cross-sectional studies." The second involves those with data on groups of patients with some defining inclusion criteria collected over a specified period of time, allowing measurement of a temporal change in patient characteristics and health status, which are called "longitudinal" studies. The latter can be further subdivided into those that are interventional (the clinical analog of experimental), where the investigators have control over the treatment(s) of primary interest the patients receive, and observational (nonexperimental), where the investigators can passively or actively record, but not manipulate, the treatment(s) of primary interest. The focus here on treatments arises from the nature of clinical research: any treatment in a clinical setting should be pursuant to the best interests of the patient and owner, and should not be any lesser quality of treatment than the accepted standard of care in veterinary medical practice.

As noted, analyses of treatments are not restricted to interventional longitudinal studies, although it will be shown that observational longitudinal studies of treatment effects are prone to potentially severe biases. Longitudinal studies also need not be restricted to studying treatment effects: intrinsic characteristics of patients, and how those may be associated with clinical sequelae, may instead be a primary objective of a researcher.

Hospital-Based Cross-sectional Studies

Cross-sectional studies are conducted when a clinician wants to establish an inventory of disease burden, patient characteristics, and exposure to factors in a population. A shelter veterinarian, for example, may be interested in knowing the crude proportion of a shelter population at any defined time point that has clinical signs of upper respiratory disease. This proportion is

called the "prevalence" (see Chapter 2 for examples), and is contextually tied to a specific point in time. Knowing such information may be valuable in planning preventive initiatives and having an appropriate inventory of pharmaceuticals available. Hospitals, however, may not have an adequate number of patients at a single time to estimate prevalence, so instead patients fitting inclusion criteria may be captured over a period of time, and the frequency of the factor of interest is then obtained as patients are enrolled. This special type of prevalence is called "period prevalence" and is contextually defined by the beginning and end dates of patient accrual (e.g., the proportion of patients entering a hospital over one month present with clinical signs of upper respiratory disease). It is important to note that no assumptions need be made about when individuals with the outcome actually developed it; it is sufficient to note that at the time of measurement, they either had it or did not (the latter from either never having developed it or from recovering from it).

Prevalences measured from cross-sectional studies are not restricted to being crude (unconditional) measures. Factor-specific (conditional) prevalences are also estimable, as in sex-specific or age-specific prevalences. Moreover, such specific measures can be jointly used for comparative purposes, as in relative prevalences (prevalence ratios). For example, it may be of interest to estimate the proportionate change in the prevalence of feline leukemia virus (FeLV) infections in intact outdoor males compared to sterilized outdoor males.

Sampling in cross-sectional studies can be accomplished in several ways. The most straightforward is to either study an entire population of individuals or take a random sample from one. With either approach, individuals can be cross-classified by their health outcome status as well as other factors to assess joint associations. Using the previous example, the prevalence of FeLV can be measured in intact and sterilized outdoor male cats, or conversely the prevalence of male sexual status can be measured in cats with and without FeLV. Prevalence ratios provide an objective measure of how relatively common or rare an outcome of interest is between groups, but should not be used for causal inference (such as making statements about likelihood, risk, or probability of a health outcome) because when measured simultaneously, it is often not possible to know if prevalence factors, as putative risk factors, occurred prior to or after the health outcome occurrence. In addition, such factors may not potentially alter only disease incidence but also disease duration and recovery, all of which affect prevalence. Prevalence ratios, as measures of association, therefore have utility for hypothesis generation but lack a foundation for making inferences about causal associations.

An alternative approach to obtaining prevalence ratios when there is a health outcome is to sample subsets of a population defined by certain characteristics. For example, an investigator may choose to deliberately sample a fixed number of sexually intact and sexually altered male outdoor cats, and subsequently ascertain the prevalence of FeLV in these two groups. A prevalence ratio relating the prevalence of FeLV in one sexual status group versus the other is estimable, but not the converse due to the sampling being based on sexual status.

Another sampling variant of cross-sectional studies is the two-stage prevalence case–control study. This approach is indicated when a relatively rare disease in a clinical population is studied, and the goal is to estimate not the prevalence of the disease but instead factors that may be associated with it but cannot be readily measured without additional data gathering and consideration of cost/time expenditures. Initially, a cross-sectional study is undertaken in a clinical population to ascertain disease status. When the cost and effort of obtaining prevalence factor information prohibit procurement of it for every individual in the population, those with the rare disease (prevalent cases) can have it measured, along with only a sample of the remaining nondiseased individuals (nonprevalent controls). Thus, prevalence factor information is efficiently obtained only on a subset of the entire population – either all or some of the diseased individuals and a sample of the nondiseased individuals. The ratio of individuals in the two groups is at the discretion of the investigator, although a 1:1 ratio is statistically the most efficient for a fixed study size. The prevalence case–control study is the cross-sectional counterpart of the (longitudinal) incidence case–control study discussed later.

Longitudinal Observational Studies

The distinguishing feature of longitudinal medical studies, compared to cross-sectional studies, is that individuals are monitored over time, typically being followed from a state absent a particular health outcome to a later state that may or may not have experienced a change in outcome status. The two principal types of such studies are cohort studies and case–control studies, which differ in how individuals in them are sampled for study inclusion. Longitudinal studies may also be characterized by their temporality; relative to the study onset, they can be retrospective, with historical data being used during the follow-up period, or prospective, with future data being collected following study onset. Less commonly, studies can be ambispective, with both retrospective and prospective components.

Cohort Studies

Assemblages of patients that share one or more defining conditions, typically diseases or syndromes, are often referred to as a "case series" but can be more expansively thought of as a patient cohort. In a hospital setting, such patients present over a period of time; if the condition is common then the period of time for sufficient patient accrual may be brief, but if the condition is rare, it may take many years for an adequate number of patients to be enrolled unless a decision is made to extend patient enrollment to multiple hospitals. While population-based (epidemiologic) cohort studies typically study risk factors for disease incidence, the goal of hospital-based cohort studies is different: to study the outcomes of patients already diagnosed with diseases. Such outcomes are contextual to the specific diseases, but often include the occurrence of or time to remission, relapse, development of another disease condition, recovery, or death. By subdividing cohort members into groups defined by factors thought to influence the respective outcomes, it becomes possible to quantify and compare their effects.

There are two main types of outcomes of interest in the study of factors affecting cohorts of patients that share a disease in common. In this example, death will be the illustrative outcome, and sex will be the hypothesized determinant of death. The duality of outcomes is:

- whether or not death from the disease occurs following its occurrence in patients
- how long it takes death from the disease to occur (if it does) following its occurrence in patients.

The first outcome is not as straightforward to evaluate as might initially appear, because it depends on two related factors: how long a patient is diseased, and how long a patient is followed up.

To illustrate these points, consider a patient diagnosed with immune-mediated hemolytic anemia (IMHA) on January 1, 2013, and that succumbed to the disease on January 1, 2019. From the perspective of the investigator, did death occur? The answer is no if the follow-up time is less than six years (although death occurred after six years, the investigator would not have been aware of it); the answer is yes if the time period evaluated is longer than six years. Therefore, the qualified answer to the question depends on specifying the time of follow-up after the diagnosis is made. Clearly, the longer a patient is followed up, the greater the probability they will die (although not necessarily from IMHA). By convention, patients who do not experience the health outcome at the point that they are no longer observed at risk of it, because they were lost to follow-up, withdrew from the study, recovered, or died from a competing cause, are called "censored."

Suppose that the patient was lost to follow-up after four years, but was known to be alive up to that time. Did death from IMHA occur? The answer at the four-year time point is no, because the patient was not observed long enough for death to occur and be recorded. However, such an individual who did not die from IMHA after four years should not statistically be treated as equivalent to a patient still alive after an even longer period of observation. Because most patients are followed for different periods of time after disease diagnosis, an investigator would provide a distorted impression of the natural course of the disease by responding to the simplistic question, "What proportion of patients died?" A legitimate analysis would instead have to be limited to specifying an identical follow-up period for each patient, such as "What proportion of patients succumbed to IMHA within one year of diagnosis?" Of course, patients followed for less than one year would necessarily be excluded even from this analysis.

Because follow-up times vary so much in patients recruited over long periods of time, a preferable analytic approach takes into account not only if a patient eventually died from the disease, but also how long they were alive prior to death. The apposite question instead becomes: "What is the probability of patients dying from IMHA after accounting for different periods of time under observation following diagnosis?" The answer, a probability that depends on the time interval after diagnosis and characteristics of patients that influence survival, will fall between 0 and 1. This kind of analysis is generically known as a "survival analysis." One approach commonly used to estimate these probabilities is called the "product-limit method of survival/failure function estimation" or, equivalently and eponymously, a "Kaplan–Meier analysis."

To illustrate the distinction between counting the proportion of patients who die and the probability of a patient dying as a function of time, consider a hypothetical cohort of 12 patients. Four patients each have either five, six, or seven years of follow-up, and within each group of four patients, two die and two either do not die or are lost to follow-up at the end of their follow-up period.

The crude proportion of these 12 patients dying is 50%, but that figure is entirely misleading because of unequal follow-up times. In contrast, a statistical analysis projects that the probability of dying after five years is 17%, after six years is 38%, and after seven years is 69%. The latter analysis is valid because it accounts for not only whether or not death occurred, but also how long a patient was at risk of dying (by including censored patients).

It is also possible to estimate the time it takes to reach a certain probability of death. For example, the time it

takes for an estimated 50% probability of patients to die is called the median survival time. In the above example, the median time to death is seven years. With larger datasets, it would also be achievable to estimate the time it would take for a 10%, 25%, 75%, 95%, etc. probability of death.

In the less common case that patients are followed for identical periods of time, or inferences are restricted to briefer periods that most or all patients were followed through, it becomes possible to estimate the risk of outcomes for such time periods, either unconditionally or conditional on possible determinants of the outcomes. For example, the one-year risk of death from patients diagnosed with IMHA conditional on sex can be calculated, and expressed (typically) as a risk ratio (sometimes referred to as a relative risk). It is conventional to report ratio statistics accompanied by: (1) their respective 95% confidence intervals to demonstrate the degree of precision associated with the statistic, and (2) *P*-values corresponding to a test of the null hypothesis that the risk ratio = 1 (i.e., there is no difference in the risks of the outcome between the groups compared in an analysis), which are interpretable as the probabilities of finding risk ratios >1 at least as large (or risk ratios <1 at least as small) as those observed in the study when the null hypothesis (of no difference in risks) is correct.

In the preceding paragraph, the phrase "rate of death" was deliberately not used because a rate is neither a proportion nor a probability. Instead, a rate can be thought of as a "velocity" – how much of an event occurs as a function of time (e.g., miles traveled per hour). In this setting, it is possible to estimate such a rate: the number of expected deaths for each year(s) of being a patient. Using the example above, the average (constant) rate of death equals 0.0833 death/patient-year as a patient (obtained by dividing the number of deaths [6] by the total amount of time all patients spent alive and at risk of dying [72 years]). Although this number is admittedly difficult to understand because it is not possible to have a fractional death, it is better understood when inventorying multiple years as a patient: 8.3 deaths for every 100 patient-years alive, six deaths for every 72 patient-years alive, etc.

Using rate information is invaluable in assessing the course of a health outcome because it is possible for the probability of the outcome to be the same across groups for the same amount of follow-up, even while the rates of the outcome occurring are different. To illustrate this, consider two drugs (drug A and drug B) used to cure a particular disease, both of which are 100% effective. However, drug A cures the disease much faster than drug B, making drug A more desirable than drug B (ignoring other relevant issues such as cost, side-effects, etc.). This is equivalent to saying that the rate of cure under drug A is higher than the rate of cure under drug B.

We can assign hypothetical numbers to further the discussion. Suppose the six patients receiving drug A were cured at 1, 2, 3, 4, 5, and 6 weeks following administration; those receiving drug B were cured at 7, 8, 9, 10, 11, and 12 weeks following administration. In both groups the probability of cure by 12 weeks was 100%. However, the rate of cure in the drug A group is 0.29 case/week, while the rate of cure in the drug B group is 0.11 case/week (calculations not shown). This is illustrated in the Kaplan–Meier plot in Figure 3.1.

Having now calculated the rates of cure (by drug group), it becomes possible to finally ask the question: how does the rate of cure from drug A compare (relatively speaking) to the rate of cure from drug B? The answer to this is to simply take the rate from drug A and

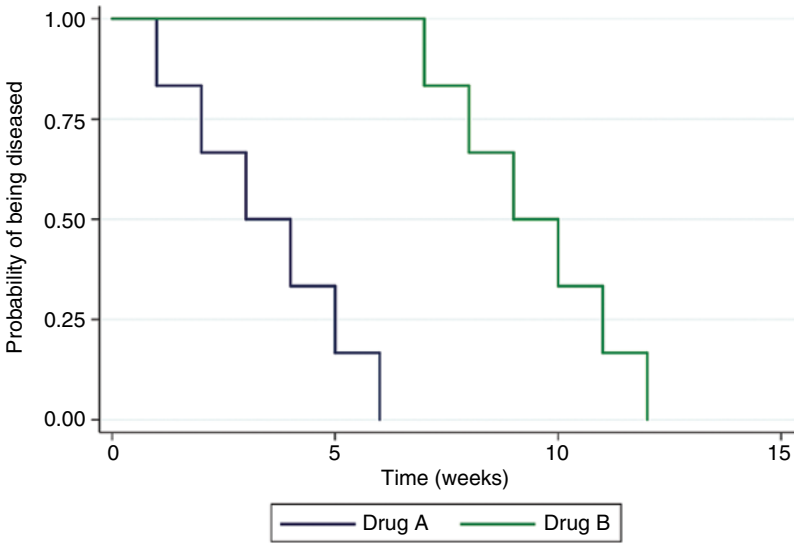

Figure 3.1 Rate of cure illustrated in a Kaplan–Meier plot.

divide it by the rate from drug B; this is called the incidence rate ratio, which is often equivalently reported as the hazard rate ratio or incidence density ratio. In this example, the rate ratio = 0.29 / 0.11 = 2.7; this can be interpreted to mean that the rate of cure from drug A is 2.7 times greater than the rate of cure from drug B, even though the eventual probability of being cured is 100% in both drug groups.

When the rates in the two groups being compared are identical, then no matter what those rates are, the rate ratio will always equal 1.0. Typical significance tests that are performed on such cohort data assume that the rate ratio equals 1.0 – this is the "null hypothesis." Rejection of the null hypothesis (using a type I error proportion of 5%) implies that the rate ratios at least as large (or small) as those observed are unlikely (with a probability of less than 5%) to have arisen when the null hypothesis and model assumptions are correct – and thus the data are relatively incompatible with the null hypothesis. It is conventional to report rate ratio statistics accompanied by: (1) their respective 95% confidence intervals to demonstrate the degree of precision associated with the statistic, and (2) *P*-values corresponding to a test of the null hypothesis that the rate ratio = 1 (i.e., there is no difference in the rates of the outcome between the groups), which are interpretable as the probabilities of finding rate ratios >1 at least as large (or rate ratios <1 at least as small) as those observed in the study when the null hypothesis (of no difference in rates) is correct.

There are, however, compelling reasons not to use hospital-based cohort studies to study treatment efficacy between groups of patients. In contrast to intervention studies, where treatment is randomly assigned, cohort study patients are intentionally (and, pointedly, non-randomly) administered a particular treatment by choice. For example, one treatment may have been available during earlier years of patient enrollment, but was later superseded by an alternative preferred treatment. A cohort study comparing these treatments would be unable to discriminate between any possible effects they had and any effects related to time (such as from amended standards of care, veterinarian experience and adeptness at treating cases over time, different clinicians of potentially different abilities treating patients across times, trends in disease severity seen over time at the hospital, etc.). In addition, clinicians administer treatments in part by using their acuity to judge patient severity; one treatment may be indicated for milder cases, while an alternative treatment, that may be more costly and risky but potentially superior, may be earmarked for cases with the poorest prognoses. Again, it would be problematic for the investigator to distinguish whatever treatment effects may exist that are distinct from the effects of disease severity (or any other influences) that inspired a particular treatment regimen by a veterinarian. This type of bias is called "confounding by indication," and all nonrandomized studies of treatment efficacy are potentially susceptible to it. The inability to statistically control for this bias, particularly in retrospective studies where the reason for selecting a treatment may not be in the medical record, should presumably dissuade investigators from conducting nonrandomized studies of treatment efficacy.

Case–Control Studies

In one sense, a case–control study is a size- and cost-efficient variant of a cohort study. Both are longitudinal (retrospective or prospective), can be performed on the same population, and are designed to investigate how one or more potential measured risk factors may affect the occurrence of measured specified health outcomes (such as becoming diseased). An important way in which they differ is in how populations are sampled for study inclusion. In cohort studies, investigators take a census of a population, unconditionally sample it, or sample it conditional on risk factor status. In contrast, in case–control studies, investigators always sample conditional on outcome (typically disease) status, selecting cases and controls. The studies also differ with respect to the statistical interpretation of their respective effect measures. Cohort studies, by virtue of their ability to estimate rates and risks, allow the use of these statistics to construct comparative measures of putative effect, such as risk ratios and incidence rate ratios. Case–control studies, because of their unique sampling design, estimate odds ratios (see Chapter 2 for a detailed explanation of this statistic).

For illustration, consider a study designed to test the hypothesis that vaccination leads to a transient (two months) increase in the risk of IMHA in dogs. A hospital-based cohort study could be undertaken by either: (1) enrolling some or all patients at risk of IMHA to the hospital, assessing their vaccination histories, and observing the subsequent incidence of IMHA conditional on vaccination histories, or (2) conditionally enrolling dogs known to have been vaccinated and comparing them to enrolled dogs confirmed to have not received vaccines, and then measuring subsequent IMHA incidence. Both approaches could be done retrospectively, provided vaccination histories were in the medical record and there was sufficient patient follow-up to determine if IMHA occurred, or could be done prospectively by placing the enrolled dogs with recorded vaccine histories under surveillance for disease onset.

The problem with this approach is that IMHA is a relatively rare disease, and regardless of whether the cohort study was done retrospectively or prospectively, it would

be unlikely to have many cases of IMHA enrolled unless the population was very large, adversely affecting statistical precision and jeopardizing the ability to make conclusions. Moreover, it would require comparing vaccination histories on a disproportionately large number of dogs that never developed IMHA for comparison to a disproportionately small number of dogs that did, adversely affecting study efficiency.

If an adequate number of cases exist in a hospital registry (or those of multiple hospitals or diagnostic laboratories, etc.), a far more efficient approach to studying factors affecting the incidence of a rare disease is to take a census or sample of the cases from the registry, and for comparative purposes take a sample of dogs (controls) never diagnosed with IMHA (but theoretically at risk of getting it later in life) from the same registry. The ratio of controls to cases is at the discretion of the investigator; if resources dictate that only a fixed number of cases and controls can be included in the study, a 1:1 ratio is most efficient. If the cost of obtaining risk factor information on the patients is not an important consideration, then a ratio of up to 4–5 controls per case is usually sufficient for statistical precision.

Although controls can be taken at any time during the period of case accrual, there are distinct statistical and interpretive advantages to selecting them at the same time that cases are diagnosed. Such matching on time can be extended to additional confounders, such as hospital (in a multicenter study) and age, but most other confounders can be controlled for by an appropriate matched analysis.

The advantages to matching controls to cases on time are several-fold. First, if time itself was a confounder of the risk factor–disease relationship (i.e., if disease incidence and the distribution of the risk factor in the population change over time), then effective analytic control of it would almost certainly be impossible without matching if the period of case accrual was long. Second, the odds ratio calculated from the case–control study can be interpreted as a risk ratio when the incidence of disease is believed to be rare in all categories of the risk factors (and confounders). Third, if the disease incidence is not rare, the odds ratio can still be interpreted as an incidence rate ratio, described earlier for cohort studies. However, analyses of matched case–control data are complex when more than one control is matched to a case, and require a computer with software capable of performing conditional logistic regression.

The most difficult design issue in case–control studies is that of proper control selection. Cases can be thought of as originating from an underlying source population of individuals at risk of developing the disease, and controls are, simplistically, a sample of that source population. Just as the distribution of risk factors is measured in the cases, the distribution of the same risk factors is also measured in controls. Setting aside the issue of matching, conceptually the distribution of risk factors in a control group not subject to selection bias effectively mirrors that same distribution in the source population. Matching is a technical violation of this principle, because matching on a confounder alters the distribution of the risk factors in the controls to be more aligned with that of the cases, but this intentional design feature that leads to an unintentional selection bias can be remediated through a proper matched statistical analysis.

The problem with this conception of a control group as a representative sample of a source population of cases is one of practicality: for a hospital that is not in a geographically restricted region, it is not at all clear what the source population is. There are many reasons, known and unknown, why owners elect to have their pets treated or not treated, and why they choose one hospital over another. The reasons why owners make such choices could be influenced in some way by the very risk factors being studied, so without appreciating the subtleties of selecting controls, it is possible to introduce selection bias into a case–control study.

To illustrate this point, suppose that an investigator at a community hospital wishes to determine if vaccinations lead to IMHA development, and observes that 50% of new cases had a history of vaccination in the prior two months. The odds of exposure to the risk factor is therefore 0.50 / 0.50 = 1.0. To obtain controls, a random survey by the investigator of pet owners in the community around the hospital reveals that 8.3% of their pets were vaccinated in the prior two months; the odds of exposure in the community-based controls is 0.083 / 0.917 = 0.091. The odds ratio relating two-month prior vaccination to IMHA incidence is 1.0 / 0.091 = 11.0.

The assumption behind using a random sample of dogs in the community as controls is that they represent the source population of cases of IMHA seen at the hospital; namely, had those dogs in the community developed IMHA, they would have been brought to the hospital and undergone the same diagnostic work-up as other cases of IMHA. In cases when only a single hospital serves a well-circumscribed region, this may be a tenable assumption. However, if there are multiple hospitals that serve communities, the reasons why some owners select one hospital over another may be related to factors associated with the study exposure. Moreover, the proportion of owners who are willing to bear the costs of seeking medical diagnosis and care for their pets for serious illnesses is likely to be lower than the proportion of people who would seek medical care for their own serious illnesses.

Now suppose that the investigator's hospital is known for higher medical costs relative to other hospitals that

serve the same community. For economic reasons, some pet owners utilize less expensive hospitals, and these owners are less likely (say, 50%, so assuming no month is any more or less likely for vaccination the two-month vaccination percentage is (2 months/12 months) × 50% = 8.3%) to provide consistent vaccination coverage for their pets. In contrast, the pet owners who utilize the investigator's hospital are more likely (90%) to provide such vaccination coverage; their pets' two-month vaccination percentage is substantially higher: (2 months/12 months) × 90% = 15%, with an exposure odds of 0.15 / 0.85 = 0.176 in the hospital-based controls. The odds ratio relating two-month prior vaccination to IMHA incidence is therefore 1.0 / 0.176 = 5.7, almost half that when using the random community controls.

This illustrates an important point of selecting controls for hospital-based case–control studies: the source population of cases to be sampled as controls should be restricted to those patients who, had they developed the disease under study, would have gone to the same hospital as the cases, and would have proceeded through the same mechanism of diagnosis and case ascertainment that occurred for the actual cases. There is no way to know whether such a hypothetical scenario would actually hold when randomly sampling members of a population; even asking the question of owners is conjectural at best.

To accommodate this concern about selection bias, an alternative approach involves selecting controls with particular diagnoses from the patient registry at the same hospital(s) or laboratory(s) that provide the cases. The singular advantage of this tactic is that whether or not an owner would utilize a particular hospital is no longer an issue; what remains unknown, of course, is what the owner would have done if their dog developed the actual disease of interest. While this too is conjectural, the choice of control diagnoses provides some guidance, if not assurance. That is, if alternative diagnoses could be identified for the case illness that are similar with respect to severity of clinical signs to warranting the owner to seek medical assistance, cost of diagnosis, and owner propensity to seek diagnostic confirmation, then those patients may be acceptable as controls. Using the IMHA example, diseases would be sought as control inclusion criteria that required presentation at the same hospital, with similar laboratory work and diagnostic procedures performed as that of the cases. Many alternative diagnoses could potentially qualify.

An additional critical requirement to impose on controls is that their medical condition should be unassociated with the exposure(s) of interest in the study (note: in this context unassociated means no more or less likely to be exposed than individuals in the source population; it does not mean unexposed). If this exposure were to cause both the case and control conditions, then the frequency distribution of exposure in the controls would become more like that of the cases than of the source population of cases, leading again to a selection bias, and specifically to an underestimation of the odds ratio. In the IMHA example, one diagnosis would be particularly ill advised: patients diagnosed with immune-mediated thrombocytopenia (IMTP). While vaccination may or may not be associated with its etiology, the hypothesis that it could lead to IMHA leaves room for the possibility that it could lead to other immune-mediated diseases affecting the bone marrow.

The choice of controls therefore necessarily depends on a decidedly thorough and insightful understanding of the relative benefits of particular control diagnoses for particular exposures and case conditions; acceptable controls for one hypothesis or study may be unacceptable for another. Control selection is perhaps the most contentious and challenging component of case–control study design, and should be carefully considered in advance of study commencement.

Clinical Trials

The defining characteristic of these studies is their interventional nature; unlike cohort studies, where treatments are not under investigator control, in clinical trials investigators have the ability to randomly assign treatments to their patients in a way that allows valid estimation of their effects. Although many experimental designs exist and have been adapted for clinical settings, this section will focus on the two most common: the randomized masked clinical trial, and the cross-over trial.

Randomized Masked Clinical Trials

The drawback of using hospital-based cohort studies to evaluate treatment efficacy, as noted earlier, is that of confounding by indication; it is difficult, if even at all possible, to distinguish actual treatment effects from those of the underlying indications (which may or may not be consciously evident) for treatment choice. Random assignment of treatment, known as "randomization," is the most powerful tool an investigator has to avoid this source of bias. The goal of randomization is beguilingly simple: to establish distinct but comparable groups of individuals whose incidence of the outcome of interest would be essentially identical if none received the treatment of interest. With such established groups, it could then be possible to isolate the treatment's effect if administered to one of them [2].

Randomization itself is not a guarantee of group comparability, however. Consider two patients enrolled in a study to compare a novel treatment to a placebo in treating a disease. Unknown to the investigator, one patient

was doomed to die from the illness regardless of treatment, and the other would have inevitably recovered even if treatment had been withheld; thus the correct (but unknown) interpretation would be that treatment could not have any effect on survival. Clearly, the two groups, composed of one individual each, are not comparable in the sense that their outcomes (death versus survival) would differ even if both received the placebo. But if treatment had been randomized, the study would remain invariably confounded, leading to incorrect conclusions. If the doomed individual received the treatment, then without knowing the individual was doomed the inference would erroneously be that treatment resulted in the patient's death. Conversely, if the recovered individual received the placebo, the incorrect conclusion would be that treatment prompted a recovery.

This example underscores an important characteristic and drawback of randomization: its effectiveness in establishing group comparability is proportional to the study size. In small studies, the possibility of group imbalances of characteristics or risk factors that could influence health outcomes cannot be discounted, but fortunately declines as study size increases. Sample size calculations therefore take on importance when undertaking a randomized study, and would be expected in any study proposal seeking approval from an institutional review board.

Sample size estimation for randomized studies is not trivial, however, and it is a fallacy to believe that there is a universal sample size that is adequate for all clinical trials. For example, information required to perform a sample size calculation to determine if two group means significantly differ requires an investigator to know *a priori* the type I (α) and type II (β) error percentages (the latter is one minus the "study power"), whether the test will be one- or two-tailed, the standard deviations of the outcome measurements in both groups, and the minimum difference in means the investigator believes is medically important enough to warrant a finding of statistical significance (the null hypothesis is that the means are equal, or equivalently the difference in means is zero). If instead the goal is to determine if the proportions of individuals in two groups that experience an outcome significantly differ, then the two expected proportions that are medically important enough to find significantly different must alternatively be specified (in addition to α and β). Issues related to sampling, sample size, and power can become complex [3], and separate calculations for these would ideally be undertaken for every independent hypothesis test in a study, with the necessary sample size being the largest of all the ones calculated. Once a study is completed, however, there is little value or justification in performing *post hoc* sample size or power calculations because the sample size has already been determined, and for any statistical test performed there was either sufficient power (i.e., $p \leq \alpha$) or not (i.e., $p > \alpha$) for a particular significance test.

The above examples present clinical trial outcomes as means and proportions. However, it is not uncommon in clinical trials to instead use interval-scaled ordinal variables, such as pain or severity indices, when quantitative measurements are unavailable. These variables generally require nonparametric statistical analyses for group comparisons, as well as for sample size and power calculations, rather than ones that assume that the group outcomes follow a normal (Gaussian) distribution. Nonparametric methods are invaluable for clinical research, particularly when sample sizes are small and underlying distributional assumptions are tenuous (as with interval-scaled data), and are discussed in more detail in Chapter 2.

Cross-over Trials

In studies of medical interventions with transient effects, there can be a distinct advantage of using each patient as her or his own control. Earlier, when groups composed of randomized individuals were compared, there was always an assumption that they were similar with respect to the distribution of unknown or unmeasurable variables (confounders) that could influence the outcome. This assumption becomes tenuous when group-specific sample sizes are small or there is so much variability in these factors that the groups would still not be comparable. In this case, sequentially administering different treatments to the same individual allows them to "cross over" between exposure states, permitting within-individual comparisons and controlling for confounding by intrinsic patient characteristics.

This approach requires two important assumptions. One is "temporal stability": that time itself is not a determinant of the study outcome. It implies that over the study period, the incidence of the outcome remains constant in the absence of any treatments. The second is "causal transience": that order of treatment administered (e.g., an experimental drug versus placebo) is irrelevant because there are no carry-over effects of either treatment (i.e., the effects of both are transient), which implies an eventual return to an original state. To make this assumption more tenable, a "wash-out" period is typically included between treatment options, being sufficiently long to ensure that any effects have become dissipated.

Measurements are characteristically taken at multiple times under the different treatments, allowing the assessment of time effects, treatment effects, and the interaction between these two main effects. It is also possible to extend such studies to include evaluating the effects of subgroups of different individuals, such as those defined by age and sex categories.

Studies where individuals serve as their own controls lead to collection of dependent data, in which measurements from the same individual are correlated. This arises, for example, when readings are taken from both eyes, when blood parameters are sequentially monitored, or when drug concentrations are evaluated for half-lives. Conventional statistical procedures assume that data are independent, but when data are paired or repeatedly collected from the same individual, the independence assumption is violated, which leads to invalid hypothesis test results, typically erroneously low *P*-values and higher than planned type I error proportions. Analysis of dependent data typically requires specialized statistical methods, from Student's t-tests or the nonparametric Wilcoxon signed-rank tests for paired data, to one-way repeated measures analysis of variance or the nonparametric Friedman test for sequential observations, to multivariate models, such as mixed effects analysis of variance or linear regression models for more complex designs.

Conclusion

Using data to make causal inferences is a hallmark of evidence-based medicine, but no inferences will be correct if the evidence used to establish them is flawed. Research can generate new knowledge, but it can also embed flawed conclusions in the literature if sedulous attention is not afforded to proper study design and conduct. Even the most sophisticated statistical methods cannot supplant biases that insidiously enter studies through flaws in study design. Despite the zeal that investigators have for finding statistically significant study results, reported point and variance estimates, confidence intervals, and *P*-values will be incorrect unless great care is exercised in designing and establishing the central features of a clinical study: thoughtful selection of comparison groups, unbiased and masked collection of information, diligent follow-up of patients, proper specification of statistical models, and verification of the model assumptions.

Endocrine Disease

4

Principles of Endocrinology

Robert Kemppainen, DVM, PhD

Department of Anatomy, Physiology and Pharmacology, Endocrine Diagnostic Service, Auburn University, Auburn, AL, USA

Overview of Endocrinology

The classic definition of an endocrine tissue is a ductless gland specialized to release a hormone into the bloodstream to act on a distant target. Glands such as the pituitary, thyroid, islet cells in the pancreas, and adrenal fit this characterization. It is increasingly clear, however, that many (if not all) tissues in the body release substances into the blood (or at least locally) in a regulated fashion and these substances influence the activity of other cells. Examples include leptin and adiponectin from adipose tissue, natriuretic factors from the heart, and erythropoietin from the kidney.

Hormones regulate a vast array of biologic processes, including, but not limited to, fuel mobilization, storage, and distribution; maintenance of electrolyte concentrations in extracellular fluid; and control of metabolic rate. Each system employs checks and balances; most utilize some form of negative feedback control to maintain homeostasis. While some systems have as their principal goal maintenance of a steady level of a metabolite or electrolyte, others employ moving set points or thresholds that adapt to changing conditions. As an example of the latter, stress causes activation of the pituitary-adrenal system and increased adrenocorticotropic hormone (ACTH) release stimulates release of cortisol from the adrenal cortex. Normally, elevated cortisol concentrations suppress ACTH secretion via negative feedback, but in some long-term stressful situations, this negative feedback is overridden so that high ACTH concentrations in circulation are maintained in the presence of the steroid negative feedback signal.

Chemical Classes of Hormones

Classic hormones comprise three main chemical types. Each class has a different means of synthesis, storage, and mechanism of action on targets.

Protein/Polypeptide Hormones

Hormones in this class are composed at minimum of three amino acids. Some consist of subunits (e.g., the pituitary hormones luteinizing hormone [LH], follicle-stimulating hormone [FSH], and thyroid-stimulating hormone [TSH]) and may have additional modifications including additions of sugar residues (glycosylation), phosphates, and disulfide bonds.

Protein/polypeptides hormones are manufactured by classic transcription/translation of genes that are expressed in high amounts in the endocrine tissue of origin. Encoded in the genes are sequences that direct these molecules to the regulated secretory pathway, resulting in the storage of the hormone in vesicles, ready for release by exocytosis in response to the appropriate signal. The nature of this signal differs depending on the system involved. Most endocrine cells that produce and release hormones of this class store significant amounts of the hormone and have the ability to release a large amount of product if needed. Continual stimulation of release often causes induction of the gene necessary for its synthesis.

Protein/polypeptide hormones are released into circulation through the specialized capillaries in their tissue of origin and most circulate free or unbound in blood. Exceptions exist; for example, insulin-like growth factor-1 (IGF-1) and growth hormone are bound to varying extent to plasma proteins. In the case of IGF-1, the binding is significant, accounting for the prolonged half-life of this hormone. By contrast, most other protein/polypeptide hormones have relatively short half-lives, usually in the range of several minutes (e.g., the half-life of ACTH is less than 15 minutes). Protein/polypeptide hormones act on target cells by binding receptors located on the cell surface (see later), rapidly activating specific signal transduction systems in target cells.

Steroids

Steroid hormones include the adrenocortical hormones (e.g., cortisol, aldosterone), reproductive steroids (e.g., estrogen, testosterone), and vitamin D. They are manufactured in their tissues of origin from cholesterol. In turn, most of the cholesterol used for synthesis is transported in blood, taken up, and stored in the endocrine tissue. Each endocrine cell expresses a unique set of enzymes used in the conversion of cholesterol to final product. These cells typically possess large amounts of smooth endoplasmic reticulum and enzymatic conversions occur in this location as well as other intracellular sites (e.g., mitochondria). The final products accumulate and simply diffuse out of the cell because of their hydrophobic nature.

Steroids are relatively insoluble in water and are found in circulation bound to carrier proteins, including globulins and albumin. Because of this protein binding, steroids generally have longer half-lives in blood than proteins/polypeptides. While the free or unbound portion is available to enter and act in target cells, the loosely bound albumin fraction is available to deliver steroid to targets as well. The globulin-bound portion serves as a reservoir, buffering steroids in circulation and also assisting in delivery to tissues by releasing bound steroid as the complex permeates through tissues. Steroids act on target cells primarily by binding to intracellular receptors; the receptor hormone complex then binds to specific DNA sequences and affects rates of gene transcription. Steroids are removed by the liver and kidney. Active hormones are inactivated by processes including removal of double bonds, conjugation to glucuronic acid and sulfate, and excretion in urine and feces.

Hormones Made from Amino Acids

The principal hormones in this chemical class are the catecholamines and thyroid hormones, which are derived from the amino acid tyrosine by different means. Catecholamines (epinephrine and norepinephrine) are made by a series of enzymatic events involving hydroxylation, decarboxylation, and methylation in adrenal medullary cells. Catecholamines have short half-lives in blood and bind to receptors on the cell surface. By contrast, thyroid hormones (T4 and T3) are made in thyroid follicles (colloid) by iodination and coupling of iodinated tyrosines and are stored in thyroglobulin until colloid is taken up into the thyroid follicular cells, broken down, and T4 and T3 are secreted. Thyroid hormones behave much like steroids; they are carried in blood primarily in protein-bound form and act on target cells by binding to intracellular receptors.

Hormones in Circulation

Concentrations of hormones in circulation may vary significantly depending on a variety of circumstances. Specific hormones show characteristic secretory patterns in blood. For example, ACTH and cortisol show periodic and, to some degree, irregular spikes and troughs throughout the day (Figure 4.1). Stressful conditions elevate levels of both of these hormones. In addition, ACTH and cortisol levels may also vary with time of day. In humans, ACTH and cortisol levels in circulation are higher in the early morning hours. This circadian variation is significantly less (or absent) in dogs and cats. By contrast, T4 levels in blood do not change as dramatically and instead are relatively steady, varying by approximately 15–20% during the day (see Figure 4.1). Growth hormone is secreted in bursts or pulses and in humans, greatest levels are observed shortly after going to sleep.

These patterns of secretion and resultant normal fluctuations have practical consequences. For example, resting cortisol measurement is of little value in the diagnosis of hyperadrenocorticism. Overall, cortisol levels are greater in dogs with hyperadrenocorticism but because of the normal fluctuating nature of its secretion, values overlap when comparing single baseline levels between dogs with normal adrenals and dogs with hyperadrenocorticism. An additional confounding factor in evaluating baseline cortisol concentrations is that stress associated with blood sample collection may result in an elevated cortisol level. The fact that T4 concentrations are more stable throughout the day permits the use of resting or baseline T4 determination as a screening test for hypothyroidism in dogs and hyperthyroidism in cats.

Hormone Receptors

Receptors for the majority of protein/polypeptide hormones (and catecholamines) reside on the target cell

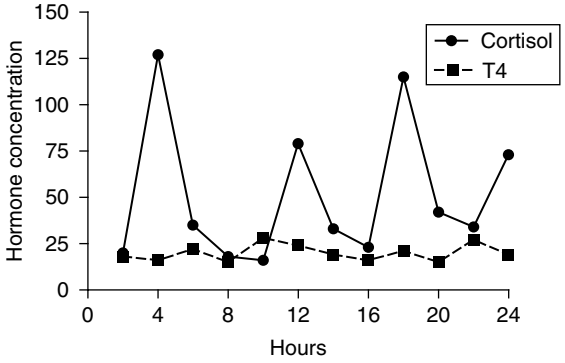

Figure 4.1 Fluctuations in levels of cortisol and T4 in a healthy dog during the day. Levels of cortisol show significant random variation, while levels of T4 are relatively stable.

surface. Hormone binding results in a subtle change in the three-dimensional structure of the receptor and this signal is carried into the cell where it is transduced into a message(s) that affects cellular biochemistry.

Cell surface receptors can be classified by their structure and the nature of the signaling pathway that they activate. Many protein/polypeptide hormones bind to G-protein (guanosine-protein) coupled receptors. This large family of receptors possess 7-transmembrane spanning domains and transfer signals to another membrane protein complex (the G-protein) consisting of three subunits (alpha, beta, and gamma). The alpha subunit at rest is bound to a GDP, hormone-receptor binding causes the G-alpha to replace the guanosine 5'-diphosphate (GDP) with guanosine 5'-triphosphate (GTP), resulting in activation of the G-protein and dissociation of its subunits. The free subunits then carry the signal to other downstream proteins, including enzymes (e.g., adenylyl cyclase) or ion channels. Hormone activation of a G-protein does not always result in activation of a cellular process, but may instead result in inhibition. For example, some G-alpha subunits (Gi), when activated, suppress the activity of adenylyl cyclase, reducing cyclic AMP production in cells.

Other types of cell surface receptors are enzymes themselves. For example, the insulin receptor has tyrosine kinase activity, meaning that after insulin binds, the intracellular portion of the receptor acts to place phosphates on tyrosine residues on the receptor itself and on substrate molecules that contact the activated receptor.

Cell surface receptor activation can activate many pathways in target cells, employing signal amplification and cross-talk. Signaling may also reach the nucleus, therefore affecting gene transcription.

Cell surface receptor number can change with conditions. Exposure to high levels of the activating hormone can result in receptor downregulation and reduce the target tissue response. In other situations, target cells express more receptors which can result in upregulation of the response. In many cases, "spare receptors" are present on targets, meaning that only a small percentage of receptors need to be occupied in order to obtain a maximal response in the cell.

Steroid and thyroid hormones principally affect their targets by binding to intracellular receptors followed by movement and binding of the hormone receptor complex to specific regions on DNA. This binding then affects (positively or negatively) the rate of gene transcription and ultimately the production of certain cell-specific proteins. The receptor molecules act in pairs. Thyroid hormone entry into target cells has been shown to be mediated by specific cell membrane transporters such as monocarboxylate transporter 8 and organic anion transporting polypeptide 1C1. Similar transporters have not been identified for steroid hormones. Evidence exists for steroid and thyroid hormone effects that do not involve the classic genomic signaling pathway, and in fact, membrane receptors for both steroids and thyroid hormones have been identified. In addition, these hormones may act inside cells by binding their receptors and then the hormone–receptor complex interacts with intracellular proteins, such as transcription factors, without the need to bind DNA. It is believed that much of the antiinflammatory activity of glucocorticoids comes about through this process, where the glucocorticoid receptor complex binds to nuclear factor kappa B (NFkappaB), preventing this molecule from stimulating the production of proinflammatory genes.

In general, activation of cell surface receptors results in rapid responses in target cells while the effects of steroid and thyroid hormones take longer to become apparent. This difference can be illustrated by comparing the response to ACTH (protein hormone) to that of thyroid hormone. When performing an ACTH response test, a post-ACTH blood sample is usually collected at one hour for cortisol measurement, the time it takes for the ACTH-induced cortisol secretion to reach maximum levels in circulation. On the other hand, noticeable clinical responses in a dog with hypothyroidism treated with T4 replacement therapy require several days (increase in activity) to weeks (stimulation of hair regrowth) to become apparent.

Regulation of Hormone Secretion

Although control of each endocrine system is unique, negative feedback is a dominant feature in most, if not all, systems. The nature of the feedback signal depends on the system; in some cases, it is an ion (calcium in the case of the parathyroid) or fuel molecule (glucose in the case of insulin) while in others it is a hormone itself (cortisol in the case of the ACTH-adrenal axis). Regulatory control in some systems is multifaceted and more complex; for example, regulation of aldosterone involves the renin-angiotensin system with sensing mechanisms tied to extracellular fluid volume and sodium levels. In others, such as calcium and parathyroid hormone, the relationship is straightforward with the parathyroid gland responding rapidly to a decline in calcium levels in the blood with an increase in secretion of parathyroid hormone that, in turn, works to restore calcium levels to a set point.

Feedback relationships are central to diagnostic testing and to localizing disease. Dexamethasone suppression testing relies on feedback, as this potent glucocorticoid activates negative feedback in the hypothalamus and pituitary, suppressing ACTH secretion and thus secretion (and therefore blood levels) of cortisol. ACTH-secreting

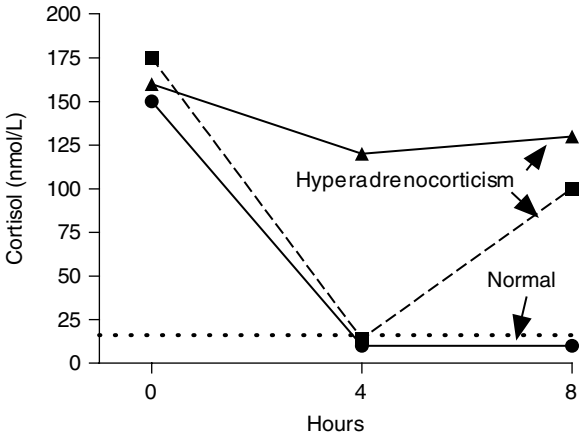

Figure 4.2 Low-dose dexamethasone (Dex) suppression patterns in dogs. Administration of Dex activates negative feedback in the hypothalamus and pituitary, resulting in a decline in ACTH secretion. In turn, the drop in ACTH rapidly results in a decline in levels of cortisol from the adrenal. In dogs with normal pituitary-adrenal function, cortisol levels are suppressed (stay below the dotted line) at four and eight hours after Dex. The pituitary tumor present in dogs with pituitary-dependent hyperadrenocorticism possesses resistance to feedback, so cortisol levels are not suppressed below the normal cut-off value at both time points.

pituitary tumors in canine hyperadrenocorticism (corticotroph tumors) have an inherent degree of resistance to feedback and therefore affected dogs do not demonstrate the same feedback responsiveness to a low dose of dexamethasone as do unaffected dogs (Figure 4.2).

Insulinomas also have abnormalities in negative feedback. Whereas the normal beta cell responds to a drop in circulating glucose levels by shutting off insulin secretion, in patients with insulinomas, the tumor cells do not respond appropriately to this decline in glucose and insulin secretion is maintained in the face of hypoglycemia. Documentation of an elevated insulin level in blood collected from a fasted animal experiencing hypoglycemia is diagnostic for this tumor. Levels of parathyroid hormone (PTH) should be evaluated in conjunction with calcium (total or free) levels. If normal parathyroid gland function is present, the presence of hypercalcemia will be accompanied by low levels of PTH. However, hypercalcemia occurring in conjunction with an elevated PTH concentration is consistent with a defect in parathyroid gland feedback, most likely related to a parathyroid adenoma (primary hyperparathyroidism).

Endocrine Disease

Endocrine diseases usually manifest as hypo- or hyperfunction of an endocrine tissue. In many cases, the cause of hypofunction involves the immune system (autoimmune attack) resulting in a gradual destruction of the endocrine tissue. Examples include primary hypothyroidism in dogs and hypoadrenocorticism (Addison disease) in dogs and cats. The immune-mediated destruction and gradual loss of hormone secretion activate negative feedback mechanisms so that a period of compensation typically occurs. For example, levels of TSH would be expected to rise in dogs with primary hypothyroidism, possibly even before clinical signs are noted. Eventually, the immune-mediated destruction results in loss of sufficient endocrine tissue so that the hormone secretion declines to the point that clinical signs of deficiency are seen.

Often, endocrine hyperfunction conditions result from overactivity of endocrine cells associated with either hyperplasia or neoplasia. Often, these affected cells not only possess increased cell division rates but also lose (or show lessened) negative feedback control. Examples include the most common form of hyperadrenocorticism in dogs (pituitary-dependent hyperadrenocorticism), primary hyperparathyroidism, and insulinoma. Feline hyperthyroidism is associated with a similar process occurring in follicles; these cells show increased activity (resulting in excessive secretion of T4) in the absence of trophic drive from TSH.

Endocrine diseases can result from many other potential mechanisms. Mutations in receptors can render them incapable of responding to the hormone ligand or can result in continual activation in the absence of hormone. In other situations, diseases occur as a consequence of receptor insensitivity to the hormone in the absence of mutations. For example, in type 2 or noninsulin-dependent diabetes, the insulin receptor has reduced responsiveness to insulin, often related to obesity.

Hormone Measurement

For many years, radioimmunoassay (RIA) was the standard method used to measure hormone concentration in blood. RIA employed a radioactive-tagged version of the hormone and an antibody made against it. Nontagged hormone, either in the form of standard, purified hormone or present in patient sample, was mixed with the tagged hormone and competed for a limited number of antibody-binding sites. In this way, displacement curves were generated, so that tubes containing increasing amounts of nontagged hormone displaced tagged hormone from antibody. Standard curves were generated by adding known amounts of nontagged hormone to tubes, and radioactivity in tubes with patient sample was then compared to that from the standards. Use of radioactivity as the mode of detection allowed for a high level of sensitivity in RIA, a must when attempting to measure substances circulating in pico- (10^{-12}) or nano- (10^{-9}) gram amounts.

While some diagnostic laboratories still use RIA, most hormone determinations today are made using reporters other than radioactivity. The basic methodology is similar to RIA (competitive binding to antibodies) but the tag employed is nonradioactive, using methods such as chemiluminescense or an enzyme label (as in enzyme-linked immunosorbent assay [ELISA]). Another method that is particularly well suited to the measurement of protein hormones employs two antibodies, directed against different regions of the molecule. The presence of the hormone allows for formation of a "sandwich" complex, which is reported by a tag present on one of the antibodies.

Measurement of hormones in companion and domestic animals presents some special challenges. Many assays are commercially available to measure hormones in samples from humans. Some, but not all, of these can be used to measure the hormone in samples from other animal species. Considerations involved in determining the usefulness of such assay methods include the fact that circulating levels of a particular hormone can vary significantly across species (e.g., T4 levels are approximately four times higher in humans compared with dogs and cats), protein binding differs across species and other materials in serum or plasma (e.g., lipid content) can impact results obtained in a particular assay. Protein hormones can vary structurally across species and this may have a profound effect on the usefulness of an assay to validate across species. For example, TSH levels cannot be determined in samples from dogs or cats using human TSH assay methods. Especially in the case of protein hormones, users should contact the reference laboratory to determine if the assay has been validated for use in that species.

Neuroendocrinology

Maya Lottati, DVM, PhD, DACVIM (SAIM)

TrueCare for Pets, Studio City, CA, USA

Neuroendocrinology refers to the orchestration between the nervous system and the endocrine system to maintain homeostasis by regulating various bodily functions such as stress responsiveness, growth and development, and metabolism. To achieve homeostasis, the body appropriately senses and responds to alterations in the external and internal environment through the modulation of chemical messengers, or hormones. The key players of the neuroendocrine system are the hypothalamus and pituitary gland which are intricately linked via secretory peptides and neuronal connections, as well as target end-organs (adrenal, thyroid, gonads, liver, and breast tissue) whose role is to exert a physiologic response. These players are integrated with one another through a series of feedback loops that allow controlled secretions of endocrine hormones throughout the body. In this way, the hypothalamus, pituitary gland, and target tissues regulate physiologic function. Alterations to these pathways and regulatory mechanisms may result in hormone disturbances that lead to disease processes.

Anatomic Considerations of the Hypothalamus and Pituitary System

The Hypothalamus

The hypothalamus is a highly specialized region of the posterior forebrain that is critical to regulation of vital bodily functions, including temperature regulation, immune function, growth, stress responsiveness, water balance, sexual behavior and reproduction, and metabolism. It is situated below the thalamus just above the midbrain, and arises from the diencephalon during embryologic development.

The hypothalamus is composed of neurosecretory neurons that produce various peptide hormones and biogenic amines (dopamine), which enter the circulatory system and act as endocrine hormones on distant target tissues. The unique capability of the hypothalamus to convert neural signals into hormonal output is called neuroendocrine transduction.

Hypothalamic hormones enter the general circulation in one of two ways (Figure 5.1). Some hypothalamic hormones are transported along axons to the median eminence where they enter the portal circulation to reach the anterior pituitary. Here, they stimulate or inhibit anterior pituitary hormone release into the general circulation. Other hypothalamic nuclei have axons that terminate at the posterior pituitary. These particular hypothalamic hormones (e.g., vasopressin and oxytocin) are transported to the posterior pituitary where they can be released into the general circulation. The intermediate lobe of the pituitary gland is under direct neural control by the hypothalamus.

Hypophysiotropic hormones can be releasing or inhibitory in nature. The hypothalamic and pituitary hormones and their primary effects are listed in Table 5.1.

The Pituitary Gland

The pituitary gland is referred to as the *hypophysis*, and it is situated beneath the hypothalamus at the base of the brain. It is securely nestled within a depression of the sphenoid bone called the *sella turcica* whose shape is described as "saddle-like." The pituitary is composed of an anterior lobe (AL; *adenohypophysis*) and a posterior lobe (PL; *neurohypophysis*). Their diverse function is a reflection of their distinct embryologic origin.

Adenohypophysis and Intermediate Lobe

The adenohypophysis is the glandular portion of the pituitary gland. During embryologic development, it arises from an ectodermal pouch (Rathke's pouch) growing upwards from the oral cavity. In many mammalian species, there is a distinct intermediate lobe (IL) that

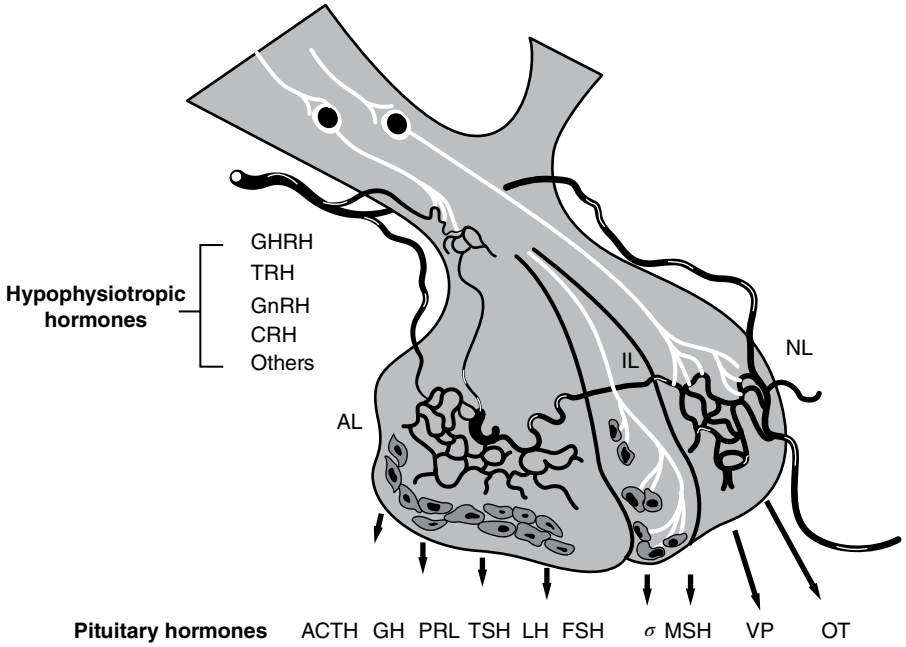

Figure 5.1 Schematic representation of the hypothalamus and pituitary gland. Hypothalamic hormones are released into the hypophyseal portal circulation for delivery to the anterior pituitary (AL) where they stimulate or inhibit release of the anterior pituitary hormones. The posterior pituitary (NL) is the direct neural extension of the hypothalamus. Vasopressin (VP) and oxytocin (OT) are produced by hypothalamic nuclei, and traverse the hypothalamic-pituitary stalk to reach the NL where they are stored for release. The intermediate lobe (IL) is under direct neuronal control by the hypothalamus. *Source*: Mol and Meij 2008. Reproduced with permission of Elsevier.

develops along with the adenohypophysis but is kept separate by a thin membranous remnant of Rathke's pouch. Therefore, it is often described as part of the adenohypophysis. The IL is absent or underdeveloped in humans.

The adenohypophysis contains specialized secretory cells that are classified according to the product(s) they secrete; thyrotrophs (thyroid-stimulating hormone [TSH]), gonadotrophs (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), somatotrophs (growth hormone [GH]), lactotrophs (prolactin [PRL]), and corticotrophs (adrenocorticotropic hormone [ACTH]). The IL is primarily composed of melanotrophs (alpha-melanocyte-stimulating hormone [alpha-MSH]), which cause pigmentation of hair and skin. The composition of AL secretory cells varies between mammalian species, but is approximately as follows in humans; somatotrophs 50%; lactotrophs 15%; corticotrophs 20%; gonadotrophs 10%; and thyrotrophs 5%.

These secretory products are further classified into three families according to their structure and function: glycoprotein hormones, somatomammotropic hormones, and derivatives of proopiomelanocortin (POMC).

Glycoprotein Hormones

The glycoprotein hormones include TSH produced by thyrotropin cells, and LH and FSH produced by gonadotropin cells. Each hormone is a peptide made up of single alpha and beta subunit. The amino acid sequence of the alpha subunit is homologous between the glycoprotein hormones, while the beta subunit is unique.

Thyroid-Stimulating Hormone Thyroid-stimulating hormone is involved in the regulation of energy homeostasis and metabolism. TSH is secreted in response to thyrotropin-releasing hormone (TRH), which is produced in the paraventricular nucleus of the hypothalamus. Upon release, TSH circulates to the thyroid gland where it stimulates follicular cells to synthesize and release the thyroid hormones triiodothyronine (T3) and thyroxine (T4) into the circulation. As thyroid hormone levels rise, they exert negative feedback on the hypothalamus and pituitary gland to suppress TRH and TSH production, respectively, thereby decreasing thyroid hormone production. Somatostatin (SS), a hypophysiotropic hormone that is also produced by pancreatic islet D cells and gut mucosa, is also a known inhibitor of TSH release.

Luteinizing Hormone and Follicle-Stimulating Hormone Luteinizing hormone and FSH, known collectively as the gonadotropins, regulate sex steroid synthesis and reproduction. In females, FSH regulates ovarian follicular development, and LH stimulates ovulation and

Table 5.1 Hypothalamic-pituitary hormones and their primary functions

Endocrine gland	Hormone	Primary function	Target
Hypothalamus	Thyrotropin-releasing hormone (TRH)	Stimulates the release of thyroid-stimulating hormone (TSH) and prolactin (PRL)	Anterior pituitary
	Gonadotropin-releasing hormone (GnRH)	Stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH)	
	Corticotropin-releasing hormone (CRH)	Stimulates the release adrenocorticotropic hormone (ACTH) and proopiomelanocortin (POMC)-derived peptides	
	Growth hormone-releasing hormone (GHRH)	Stimulates the release of growth hormone (GH)	
	Prolactin-releasing hormone (PRLH)	Stimulates the release of prolactin (PRL)	
	Somatostatin (SS)	Inhibits the release of GH and thyroid-stimulating hormone (TSH)	
	Dopamine (AKA prolactin-inhibiting hormone)	Inhibits the release of PRL	
Posterior pituitary[a]	Vasopressin	Regulates blood volume	Distal convoluted tubules and collecting ducts of kidney
		Stimulates smooth muscle contraction	Blood vessels
	Oxytocin	Stimulates uterine contraction during parturition	Uterine smooth muscle
		Stimulates milk ejection during lactation	Myoepithelial cells of mammary gland ducts
Anterior pituitary	ACTH	Stimulates the release of glucocorticoids and sex steroids	Adrenal cortex
	GH	Promotes growth and development	Various tissues[b]
	Prolactin	Stimulates milk production	Mammary tissue
	TSH	Stimulates the release of thyroid hormone	Thyroid gland
	FSH	Stimulates estrogen production and promotes ovarian follicle development in the female. Stimulates spermatogenesis in the male	Gonads
	LH	Stimulates progesterone production and promotes ovarian follicle maturation in the female. Stimulates testosterone production in the male.	

[a] These hormones are synthesized in the hypothalamus and released from the posterior pituitary gland.
[b] See GH section.

maintenance of the corpus luteum. Together, the gonadotropins stimulate production of the sex hormones estradiol and progesterone. In male gonads, LH stimulates testosterone production by Leydig cells, and FSH stimulates Sertoli cell proliferation and maintains sperm quality.

Gonadotropin secretion is pulsatile, and release is stimulated by gonadotropin-releasing hormone (GnRH) binding to the anterior pituitary. LH and FSH circulate to target tissues and stimulate sex hormone production. As gonadotropin levels rise, LH and FSH exert negative feedback on the hypothalamus and pituitary to decrease their own production. Sex hormone products also feed back on the hypothalamus and pituitary gland to variably regulate gonadotropin production. Testosterone and estrogen inhibit LH and FSH release by the anterior pituitary, while estradiol may have variable effects on gonadotropin production depending on its plasma concentration, a feature that may be important during various stages of reproduction. High levels of estradiol exert positive feedback on GnRH to promote sustained gonadotropin release, while low levels negatively feedback to inhibit hypothalamic GnRH and pituitary gonadotropin release. Inhibin, a protein produced by ovarian granulosa cells in females and by Sertoli cells in males, inhibits FSH release both by direct feedback on

its production by the pituitary and indirectly by altering GnRH receptor sensitivity. Activin, a protein produced by the ovaries, and dopamine are known stimulators of FSH release. Endogenous opioids have an inhibitory influence on gonadotropin production through alteration of GnRH secretion.

Somatomammotropic Hormones

Growth hormone and prolactin (PRL) are grouped together as the somatomammotropic hormones. Their amino acid sequences are similar, which may account for some common functions.

Growth Hormone As the name suggests, GH regulates growth and development. In young animals, it stimulates growth of connective tissue, long bones, muscles, and endocrine glands. GH is a metabolic counterregulatory hormone, which opposes the actions of insulin and raises glucose by stimulating hepatic gluconeogenesis and impairing glucose uptake in muscle. GH stimulates lipolysis in adipose tissue, which results in increased circulating free fatty acids, and has an anabolic effect on protein synthesis. GH stimulates production of insulin-like growth factor 1 (IGF-1) by hepatocytes. IGF-1 is a primary mediator of the effects of GH.

Growth hormone is a single-chain polypeptide containing two disulfide bridges. The sequence is highly conserved among species; the sequences of canine and feline GH differ by only one amino acid, while those of canine and porcine GH are identical. Receptors for GH have been identified throughout the body, but are found in the highest concentrations in skeletal muscle, liver, adipose tissue, heart, kidneys, lungs, and cartilage. This diffuse distribution in part explains GH's diverse effects. GH receptors are known to have altered sensitivity to various secretagogues throughout life, which aids in preferential growth and development in young, and specialized metabolic function in adults.

Growth hormone secretion is pulsatile, and results from the complex interactions between growth hormone-releasing hormone (GHRH), SS, and peripheral factors (both neural and hormonal). GH release is primarily a reflection of the delivery and binding of hypothalamic GHRH to pituitary somatotropic cells. SS is a known inhibitor of GH secretion, thus high GHRH and low SS levels result in GH release. SS is a more potent inhibitor of GH release than of TSH release.

Insulin-like growth factor 1 is secreted in response to GH, but is also responsive to systemic alterations in energy balance and nutrition. Low levels of IGF-1 stimulate GH release. As GH and IGF-1 levels rise, they feed back on the hypothalamus to decrease GHRH and increase SS secretion, which results in reduced production of GH. Ghrelin, an endogenous ligand produced by enteral cells of the stomach, is a potent GH secretagogue. Other factors known to directly or indirectly influence GH secretion include nutritional states, stress, sex steroids, and exercise. For example, GH secretion is stimulated by alpha-adrenergic agonists and inhibited by beta-adrenergic agonists and hyperglycemia. Estradiol modulates GH levels indirectly via inhibitory effects on SS.

Prolactin Prolactin is involved in the regulation of lactation and reproduction. PRL works together with sex steroids to stimulate mammary gland development and regulate milk production during lactation. Although PRL is secreted in the male, its physiologic role is not yet fully elucidated.

Prolactin is a single-chain polypeptide containing three disulfide bridges. There is significant sequence variation between species. PRL secretion is pulsatile, and stimulated by the hypothalamic hormones prolactin-releasing hormone (PRLH) and TRH. PRL is also released in response to the neural stimulation of suckling during lactation. The definitive identity of PRLH is not yet known, but vasoactive intestinal peptide (VIP) has been suggested. PRL release is inhibited by dopamine, which is also referred to as prolactin-inhibiting hormone. In the regulation of PRL release, the inhibitory component is known to predominate over the stimulatory component.

Upon binding to its receptors in lactotropic cells, dopamine inhibits PRL release. PRL, in turn, acts in a short feedback loop by circulating and binding to PRL receptors on dopaminergic neurons in the hypothalamus. PRL release is also stimulated by oxytocin and angiotensin II, and inhibited by gamma-aminobutyric acid (GABA). Unlike other hypophyseal hormones, PRL is not subject to typical feedback inhibition by target tissue hormone products. Instead, its release is solely regulated through hypothalamic input and the suckling reflex.

Proopiomelanocortin-Derived Peptides

Proopiomelanocortin is a large prohormone which encodes numerous secretory products (Figure 5.2). It is synthesized by corticotropic cells of the anterior pituitary and melanotropic cells of the IL. Proteolytic enzymes hydrolyze POMC into ACTH and beta-lipotropin (beta-LPH). These products are then further cleaved into alpha-MSH, which stimulates melanin production by epithelial cells and leads to darkening of skin, beta-endorphin (an endogenous opioid), and other related peptides. The function of many of these peptides is not yet fully understood and remains under investigation.

Proopiomelanocortin synthesis is under direct neural control by the hypothalamus primarily through inhibitory dopaminergic innervation. Thus, dopamine exerts tonic inhibition of POMC release under normal

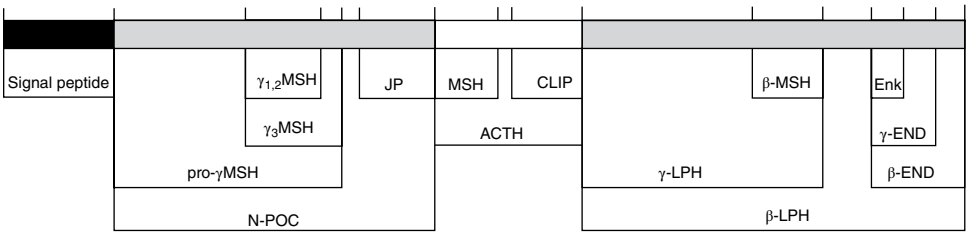

Figure 5.2 Schematic representation of proopiomelanocortin (POMC) and production of ACTH and related peptides. POMC contains four major domains: the signal peptide domain; the N-terminal peptide domain (N-POC) which contains the (pro) gamma-MSH peptide and joining peptide (JP); the ACTH domain which contains melanocyte-stimulating hormone (MSH) and corticotropin-like intermediate lobe peptide (CLIP); and the beta-lipotropin (beta-LPH) domain which generates metenkephalin (Enk) and the endorphin (END) family of peptides. Vertical lines represent potential sites of proteolytic cleavage. *Source*: Mol and Meij 2008. Reproduced with permission of Elsevier.

circumstances. Corticotropin-releasing hormone (CRH) will stimulate POMC production, which results in ACTH release.

Adrenocorticotropic Hormone Adrenocorticotropic hormone is a glycoprotein hormone that regulates the synthesis and release of cortisol. Its binding to adrenal cortical cells stimulates production of glucocorticoids, sex steroids, and, to a lesser extent, mineralocorticoids. ACTH also regulates growth of the adrenal cortex as evidenced by high ACTH causing hypertrophy of the adrenal cortex, and absent ACTH causing atrophy.

Adrenocorticotropic hormone secretion is pulsatile, and stimulated by the hypothalamic hormones CRH and vasopressin. These hormones act synergistically to stimulate ACTH release, but stress will variably modulate their production by the hypothalamus.

Adrenocorticotropic hormone stimulates cortisol release, and as cortisol levels rise, they feed back on the hypothalamus and pituitary to inhibit production of CRH and ACTH, respectively. Hypothalamic dopamine exerts tonic inhibition of ACTH release through dopaminergic neural connections terminating on the IL. Some factors that directly or indirectly influence ACTH release include leptin, vasoactive intestinal peptide (VIP), neuropeptide Y, cholecystokinin (CCK), cytokines such as interleukin-1 and tumor necrosis factor-alpha, serotonin agonists, and beta-adrenergic agonists. Additionally, ACTH release is triggered by exercise and hypoglycemia.

Neurohypophysis

The neural portion of the pituitary is called the *neurohypophysis*, and it is composed of axons that extend downward as a large bundle from the hypothalamus. During embryologic development, the neurohypophysis and hypothalamus both arise from the diencephalon and remain connected through life.

The hormones oxytocin and vasopressin are synthesized by the paraventricular and supraoptic nuclei of the hypothalamus. They are transported to the neurohypophysis through direct neuronal projections, and are stored in secretory vesicles in axon terminals. Upon appropriate neurogenic stimulation, they are released into the general circulation where they travel to distant target tissues and exert a physiologic effect.

Vasopressin; Antidiuretic Hormone, Arginine Vasopressin

Vasopressin (VP) regulates blood volume through alteration of water excretion in the kidneys. It also promotes vascular smooth muscle contraction, and stimulates ACTH release. These diverse effects are mediated by vasopressin receptors: V1 in vascular smooth muscle, V2 in the kidney epithelium, and V3 in the anterior pituitary.

Vasopressin secretion is pulsatile, and hypothalamic production is primarily stimulated when high plasma osmolality (hemoconcentration) or a significant decrease in blood volume (hypovolemia) is detected. In the absence of circulating VP, the epithelial cells lining the distal convoluted tubules and collecting ducts in the kidney are largely impermeable to water. As such, large volumes of dilute filtrate are excreted into the urine. Upon release, circulating VP binds to VP2 receptors and enhances the permeability of water-selective channel proteins (aquaporins) to water in renal epithelial cells. This results in the passive diffusion of water into the interstitial space due to the medullary osmotic gradient, thereby restoring blood volume and suppressing VP production by the hypothalamus.

The binding of VP to V1 receptors in blood vessels results in vasoconstriction through activation of calcium channels (vasopressor effects). VP binding to V3 receptors in the anterior pituitary stimulates ACTH release. The production of VP is stimulated by CRH and angiotensin II, and inhibited by glucocorticoids.

Oxytocin

Oxytocin (OT) regulates lactation and parturition. Similar to VP, OT is produced in hypothalamic nuclei, and transported to the posterior pituitary where it is stored for release. OT release is stimulated by suckling, during lactation, and in response to vaginal or cervical distension. Dopamine and opioids are also known to modulate OT secretion from the posterior pituitary, as well as extrareproductive factors such as stress.

In the uterus, OT binds to its receptors and stimulates the myometrium to contract. The sensitivity of uterine receptors to circulating OT is variable during different stages of reproduction. Receptor sensitivity is reduced during pregnancy, and greatly enhanced at the time of delivery when OT stimulates contraction of uterine smooth muscle and results in expulsion of the newborn. This OT-mediated uterine contraction is further augmented by the presence of estrogen, which increases at parturition. Conversely, OT-mediated uterine contraction is inhibited by progesterone, which is high throughout pregnancy but plummets at parturition.

During lactation, OT release is triggered by suckling. Circulating OT stimulates contraction of myoepithelial cells in mammary gland ducts, which results in milk ejection. As for PRL, its function in the male is not fully understood.

Regulation of the Neuroendocrine System

The neuroendocrine system tightly regulates hormone production by means of feedback mechanisms, which help ensure optimal hormone levels and activity. The hypothalamus and pituitary gland synthesize various regulatory hormones – both releasing and inhibitory in nature – that circulate to target endocrine glands (such as adrenal, thyroid, gonads) and modulate hormone release. These hormones bind to receptors in target tissues to generate a physiologic response, for example GH stimulating growth in long bones. This pathway is referred to as the hormone cascade, and it allows amplification of a signal in a closed system. When sufficient amounts of target hormone are produced, the target hormone exerts feedback on the hypothalamus and pituitary gland to inhibit previous steps in the pathway. Often there is also negative feedback on the hypothalamus by pituitary hormones, a principle referred to as short-loop feedback.

An excellent example of typical feedback regulation is illustrated by the thyroid hormone pathway (Figure 5.3). The hypothalamus produces TRH, which reaches the anterior pituitary via the portal circulation. Here, it stimulates release of TSH, which then is transported in the blood to the thyroid gland where it stimulates production of thyroid hormone. As thyroid hormone levels rise above a certain threshold, there is negative feedback on production of TRH and TSH, which thereby decreases thyroid hormone production. Subsequently, as thyroid hormone levels decay, negative feedback is relieved on the hypothalamus and pituitary, and production of thyroid hormone is once again restored through the hormone cascade. Neuroendocrine regulation predominantly relies on negative feedback, but there are instances when positive feedback is used in which target hormones influence the hypothalamus and pituitary to further augment their own production.

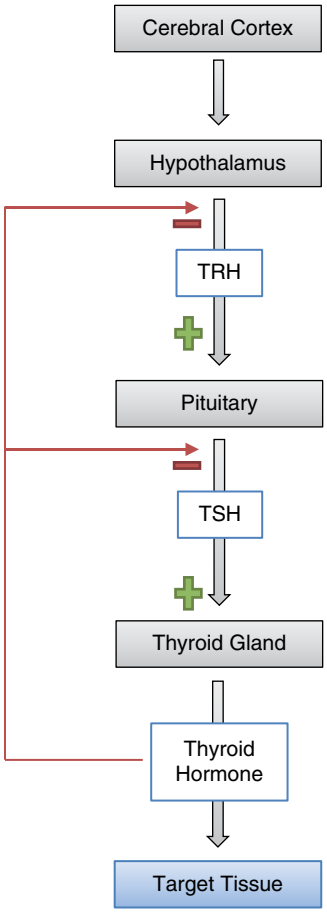

Figure 5.3 Typical feedback control of hormone secretion in the neuroendocrine system. The hypothalamus releases thyrotropin-releasing hormone (TRH) in response to a stimulus. TRH stimulates the anterior pituitary to releases thyroid-stimulating hormone (TSH). TSH targets cells in the thyroid gland to produce thyroid hormone, which circulates to target cells and elicits a response (increase energy expenditure). Thyroid hormone exerts negative feedback on the hypothalamus and pituitary to downregulate TRH and TSH production, respectively. Plus signs indicate stimulation of hormone production and release; minus signs indicate inhibition hormone production and release.

Vascular Supply

The vascular organization of the neuroendocrine system is responsible for the effectiveness of feedback regulation and the hormone cascade. The hypothalamus receives arterial blood from the circle of Willis, while the pituitary gland is supplied by the superior and inferior hypophyseal arteries (branches of the internal carotid artery). The hypophyseal portal circulation connects the hypothalamus with the anterior pituitary, thereby allowing direct transport of hypophysiotropic hormones to their corresponding hypophyseal receptors. Venous blood from the pituitary drains into the cavernous sinus where it enters the systemic circulation to reach target glands and tissues. Short portal veins connect the posterior and anterior lobes of the pituitary. A small portion of pituitary outflow is thought to ascend in retrograde to the hypothalamus where it can directly participate in regulation of hypophyseal hormone production. It is important to note that the blood–brain barrier is incomplete surrounding the portal system, which ensures exposure to circulating hormones emanating from peripheral tissues.

Regulation of Hormone Secretion

Hypothalamus

The hypothalamus is responsible for integrating sensory stimuli from the external environment with input from the internal environment to maintain homeostasis. Therefore, neuroendocrine transduction is regulated not only by hormonal feedback but also by neural input from higher brain centers that convey information about the external environment such as temperature, light, pain, and other sensory stimuli.

In the hypothalamus, cell bodies responsible for hormone synthesis are anatomically intermingled, and there is often redundancy in production of a single hormone by separate hypothalamic nuclei. A single hypothalamic hormone may exert an effect on multiple pituitary hormones, and multiple hypothalamic hormones may influence regulation of a single hypophyseal hormone. This overlap and redundancy throughout the neuroendocrine system allows for a high degree of regulation.

Pituitary Gland

Pituitary hormone regulation is not only under hormonal feedback but is also influenced by central and peripheral neural input, an example of which is illustrated by lactation and nursing. Suckling activates sensory pathways leading to the hypothalamus that trigger release of PRLH and TRH, and inhibit release of dopamine (prolactin-inhibiting hormone), and result in PL secretion by the anterior pituitary. Concurrently, suckling stimulates release of OT by the posterior pituitary, and together PRL and OT stimulate milk production and initiate milk ejection in mammary glands, respectively. Central factors also influence pituitary hormone release, as is seen when on occasion lactating mothers expel a small amount of milk upon the thought of their baby. The images stimulate the cerebral cortex, which results in release of OT and contraction of myoepithelium in mammary gland ducts.

The majority of pituitary hormones are released in a pulsatile manner, therefore regulation of target organs and tissues relies not only on absolute hormone concentrations but also on the frequency and amplitude of hormone pulses.

Feline Acromegaly

David S. Bruyette, DVM, DACVIM (SAIM)

Anivive Lifesciences, Long Beach, CA, USA

Etiology/Pathophysiology and Epidemiology

Feline acromegaly is a disease characterized by excessive growth hormone secretion leading to a wide array of clinical signs caused by the hormones' effects on multiple organ systems. These effects can be divided into two major classes. The first are the catabolic actions of growth hormone that include insulin antagonism, lipolysis, and gluconeogenesis with the net effect of promoting hyperglycemia. The second are the slow anabolic (or hypertrophic) effects of growth hormone, which are mediated by insulin-like growth factors. Growth hormone stimulates production of insulin-like growth factors in several different tissues. Insulin-like growth factor-1 (IGF-1), which is produced in the liver, is thought to be the key factor that facilitates the anabolic effects of growth hormone that are responsible for the characteristic appearance of acromegalic people, dogs, and cats.

Growth hormone is produced in the pars distalis (anterior pituitary), specifically by acidophilic cells, called somatotrophs. The release of growth hormone is regulated by many factors, the most important of which is growth hormone-releasing hormone (GHRH) produced by the hypothalamus. Recently, another hormone, ghrelin, has also been identified as a potent stimulator of growth hormone release. Ghrelin is produced by the stomach and released following ingestion of a meal.

Release of growth hormone is inhibited by the hypothalamic hormone somatostatin as well as by growth hormone and IGF-1 via negative feedback. Feline acromegaly is typically the result of a functional adenoma of the pituitary that releases growth hormone despite negative feedback resulting in excessive growth hormone production and release.

Feline acromegaly, thought to be an uncommon disease until recently, is likely underdiagnosed. Three studies have examined the incidence of acromegaly in the diabetic cat population. A recent study in the United Kingdom measured IGF-1 levels in variably controlled diabetic cats. Of the 184 cases, 59 (32%) had markedly increased IGF-1 concentrations. Eighteen of these 59 cats underwent pituitary imaging, confirming a diagnosis of acromegaly in 17/18 (94%). A second study examined 225 cats with variably controlled diabetes and 40 (17.8 %) had markedly high IGF-1 concentrations. In the largest study to date, of 1222 cats with diabetes, 323 (26.4 %) had IGF-1 suggesting acromegaly and 90% had a pituitary mass upon imaging (CT or MRI). This suggests that 18–32% of diabetic cats may have concurrent acromegaly and acromegaly may be one of the most important predisposing factors to feline diabetes through the induction of insulin resistance.

Etiology

Acromegaly in humans is usually sporadic, but up to 20% of familial isolated pituitary adenomas are caused by germline sequence variants of the aryl-hydrocarbon-receptor interacting protein (AIP) gene. The AIP gene is associated with xenobiotic metabolizing enzymes and endocrine disrupting chemicals in the environment, such as bisphenol A and PBDEs, have been linked to both feline acromegaly and hyperthyroidism. Feline acromegaly has similarities to human acromegalic families with AIP mutations. A recent study sequenced the feline AIP gene, to identify sequence variants and compare the AIP gene sequence between feline acromegalic and control cats, and in acromegalic siblings. A single nonsynonymous single-nucleotide polymorphism (SNP) was identified in exon 1 (AIP:c.9T > G) of two acromegalic cats and none of the control cats, as well as both members of one sibling pair. The region of this SNP is considered essential for the interaction of the AIP protein with its receptor. This sequence variant has not previously been reported in humans. Two additional synonymous

sequence variants were identified (AIP:c.481C > T and AIP:c.826C > T). This was the first molecular study to investigate a potential genetic cause of feline acromegaly and identified a nonsynonymous AIP SNP in 20% of the acromegalic cat population evaluated, as well as in one of the sibling pairs evaluated.

History and Clinical Signs

Feline acromegaly most commonly affects middle-aged to older, male castrated cats. In one study, 13 of 14 cats with acromegaly were males with an average age of 10.2 years. This association may be biased, however, as most cats that are diagnosed with acromegaly present for insulin-resistant diabetes mellitus, which is also more common in older, male castrated cats. Based on available data, there is no known breed association for acromegaly.

Most patients with acromegaly present for insulin-resistant diabetes mellitus (insulin doses greater than 1.5–2.2 units/kg BID) with concurrent weight gain rather than weight loss. Growth hormone has effects on all the tissues in the body and therefore the disease has a range of clinical signs. Physical characteristics of acromegaly include increased body weight, a broadened face, enlarged feet, protrusion of the mandible (prognathia inferior), increased interdental spacing, stertorous breathing, organomegaly, and a poor haircoat. Cardiovascular signs include the presence of a heart murmur, hypertension, arrhythmia, associated with hypertrophic cardiomyopathy. Neurologic disease associated with feline acromegaly is uncommon but can occur with a pituitary macroadenoma. Neurologic signs that have been observed with acromegaly include dullness, lethargy, abnormal behavior, circling, and blindness. Glomerulopathy and secondary renal failure have also been associated with feline acromegaly. Histopathologic evaluation of the kidneys from acromegalic cats has revealed thickening of the glomerular basement membrane and Bowman's capsule, periglomerular fibrosis, and degeneration of the renal tubules. Arthropathy and peripheral (diabetic) neuropathy have been shown to cause lameness in acromegalic cats.

Diagnosis

Diagnosis of feline acromegaly starts with clinical suspicion, using a thorough history, signalment, and clinical signs. Many of the abnormalities in the minimum database of affected cats reflect concurrent diabetes mellitus and include erythrocytosis, hyperglycemia, increased liver enzymes (ALT, ALP), hypercholesterolemia, hyperphosphatemia, hyperglobulinemia, azotemia, glucosuria, ketonuria, proteinuria, and isosthenuria.

Growth hormone concentration is a common diagnostic for acromegaly in humans, but assays specifically for feline growth hormone are not widely available. An assay using ovine GH as the antigen has been validated for use in cats, but is only available in Europe. However, even if an assay were available, growth hormone concentrations alone may not be a reliable diagnostic for acromegaly. Growth hormone production is cyclic and levels may vary throughout the day. A single high value may not necessarily be diagnostic for acromegaly. Additionally, it has been shown that growth hormone may be elevated in nonacromegalic diabetic cats. This may be due to the fact that portal insulin is required for the liver to produce IGF-1. In diabetics being treated with insulin subcutaneously, portal insulin concentrations will remain low, resulting in decreased IGF-1 production and theoretically decreased inhibition of GH release. In addition, GH levels may also not be elevated early in the course of the disease, but later typically increase significantly.

Insulin-like growth factor-1 is the endocrine assay most commonly used to diagnose feline acromegaly and is widely available through the Michigan State University Diagnostic Center for Population and Animal Health (www.animalhealth.msu.edu/Forms/F.ADM.7.pdf). Unlike GH, IGF-1 concentrations are less likely to fluctuate over the course of the day as the majority of IGF-1 is protein bound, giving it a longer half-life in the body. In addition, IGF-1 increases in response to chronically elevated GH concentrations and is thought to be a reflection of GH levels over the previous 24 hours. However, just as with GH, elevations in IGF-1 concentration alone may not be diagnostic for acromegaly. One study found that IGF-1 levels in nonacromegalic cats on long-term insulin treatment (>14 months) had higher levels of IGF-1 than nondiabetics. It was proposed that insulin treatment allowed for beta cell regeneration and increased portal insulin, leading to elevations in IGF-1. A subsequent study evaluating IGF-1 levels in confirmed acromegalics, diabetics, diabetics, and healthy cats found that acromegalic diabetics had significantly higher levels of IGF-1 than diabetics and nondiabetics. This study concluded that IGF-1 was 84% sensitive and 92% specific for diagnosing feline acromegaly. No correlation between long-term insulin use and elevations in IGF-1 concentrations was found in this study.

Diagnostic Imaging

Radiographic findings associated with feline acromegaly are related to the hypertrophic effects of excessive GH. Hyperostosis of the calvarium, spondylosis of the spine, and protrusion of the mandible are common findings.

Periosteal reaction, osteophyte production, soft tissue swelling, and collapse of joint spaces are signs associated with the degenerative arthropathy linked to feline acromegaly. Thoracic radiographs may reveal cardiomegaly (hypertrophic cardiomyopathy) and/or congestive heart failure. Nonspecific signs such as abdominal organomegaly (hepatic, renal, and adrenal) may be revealed by abdominal ultrasound.

Advanced imaging is needed to document the presence of a pituitary macroadenoma. Computed tomography (CT) and magnetic resonance imaging (MRI) are both useful for identifying pituitary masses. However, one study found MRI to be the more sensitive imaging modality. The presence of a pituitary tumor alone is not diagnostic for feline acromegaly as other functional tumors of the pituitary may also result in insulin-resistant diabetes, such as adrenocorticotropic hormone (ACTH)-producing tumors in patients with Cushing disease. Conversely, the absence of a pituitary mass does not rule out acromegaly as there have been reported cases where a patient had a negative MRI but a pituitary mass was identified at necropsy and histopathology confirmed a GH-secreting adenoma.

Histopathology

Histopathology is needed for definitive diagnosis which makes antemortem diagnosis challenging. However, with advancements in surgical procedures such as transsphenoidal hypophysectomy, surgical excisional biopsy is possible. The main histopathologic change associated with acromegaly is acidophil proliferation in pituitary tumors.

Adrenocortical Function Testing

There is no single test for the diagnosis of feline acromegaly. Clinical suspicion based on a thorough history and physical exam is essential. As stated earlier, the most common presenting complaint for patients with acromegaly is insulin resistance with weight gain. The two most common causes of insulin resistance in cats are hyperadrenocorticism and acromegaly. Both of these diseases can be associated with a pituitary mass and bilateral adrenomegaly. As such, all suspected acromegalics should undergo adrenocortical testing via the ACTH stimulation test and/or low-dose dexamethasone suppression test. Normal results on these tests would then be an indication to screen for acromegaly.

Treatment

Medical Treatment

Somatostatin is a hypothalamic hormone that acts on the pituitary to inhibit GH release. Somatostatin analogs are commonly used in human medicine for the treatment of acromegaly and have efficacy rates of 50–60%. The somatostatin analog octreotide has been evaluated in a small number of feline acromegalics with limited success. One study in four cats found no change in GH following treatment. Another study measured the short-term effects of octreotide in five feline acromegalics and found a decrease in growth hormone concentrations for up to 90 minutes. A small study evaluating an octreotide analog (Sandostatin® LAR) showed no benefit in cats treated for 3–6 months.

However, a recent study examined the long-term medical management of acromegaly in cats using pasireotide, a novel somatostatin analog, which had been shown to decrease serum IGF-1 and improve insulin sensitivity in cats with acromegaly when administered as a short-acting preparation. The study used once-monthly administration of long-acting pasireotide (pasireotide LAR) for treatment of cats with acromegaly. Fourteen cats with acromegaly, diagnosed based on the presence of diabetes mellitus, pituitary enlargement, and serum IGF-1 >1000 ng/mL, were enrolled. Cats received pasireotide LAR (6–8 mg/kg SC) once monthly for six months. Fructosamine and IGF-1 concentrations, and 12-hour blood glucose curves (BGCs) were assessed at baseline and then monthly. Product of fructosamine concentration and insulin dose was calculated as an indicator of insulin resistance (Insulin Resistance Index). Eight cats completed the trial. Three cats entered diabetic remission. Median IGF-1 (baseline 1962 ng/mL [range 1051–2000 ng/mL]; month 6 1253 ng/mL [524–1987 ng/mL]; $P < 0.001$) and median Insulin Resistance Index (baseline 812 µmolU/L kg [173–3565 µmolU/L kg]; month 6 135 µmolU/L kg [0–443 µmolU/L kg]; $P = 0.001$) decreased significantly. No significant change was found in mean fructosamine (baseline 494 ± 127 µmol/L; month 6 319 ± 113.3 µmol/L; $P = 0.07$) or mean blood glucose (baseline 347.7 ± 111.0 mg/dL; month 6 319.5 ± 113.3 mg/dL; $P = 0.11$), despite a significant decrease in median insulin dose (baseline 1.5 [0.4–5.2] U/kg; month 6 0.3 [0.0–1.4] U/kg; $P < 0.001$). Adverse events included diarrhea (n = 11), hypoglycemia (n = 5), and worsening polyphagia (n = 2). This initial study indicates that pasireotide LAR has potential as a long-term management option for cats with acromegaly.

Conflicting results with various somatostatin analogs may be related to difference in somatostatin receptor subtypes. Future studies are required to identify the somatostatin receptor subtypes in GH-secreting feline pituitary tumors to determine if they are similar to the ones found in humans.

Dopamine agonists and more recently GH receptor antagonists are also used in human medicine for the treatment of acromegaly. The use of GH receptor antagonists

has not been reported in cats but in humans, response rates have been reported to be as high as 90%. However, it has been noted that the medication has no effect on tumor size and thus would be of no benefit in patients with neurologic signs. A single case study using a dopamine agonist (L-deprenyl) for the treatment of feline acromegaly showed no effect on reducing insulin requirements or clinical signs of disease. In humans, dopamine agonists are typically only 10–20% effective, but are often used in combination with other medications.

Increasing the dosage of insulin to improve glycemic control and clinical signs of diabetes is the most conservative choice for treating insulin-resistant diabetic acromegalics. However, there have been reports that some patients suddenly and inexplicably become sensitized to insulin, resulting in hypoglycemic crises. In one study, several acromegalic cats were euthanized after experiencing hypoglycemic coma.

Surgical Treatment

Surgical removal of the pituitary tumor (adenectomy) is the treatment of choice for acromegaly in human medicine. The procedure can be performed in cats and dogs, usually employing complete removal of the entire pituitary (hypophysectomy).

In veterinary medicine, a transsphenoidal approach is used involving only a small incision through the soft palate and then approaching the pituitary gland through the basisphenoid bone. Complications associated with the surgery include hemorrhage and incision dehiscence. Post surgery, patients are treated with cortisone, L-thyroxine, and desmopressin. The same surgical procedure is also used to treat pituitary-dependent hyperadrenocorticism in both dogs and cats. A study in which seven cats with pituitary-dependent hyperadrenocorticism were treated with transsphenoidal hypophysectomy resulted in five cats showing complete resolution of the disease. Four of these cats had concurrent diabetes mellitus, two of which showed increased insulin responsiveness after surgery.

A few case reports exist for the treatment of feline acromegaly with transsphenoidal hypophysectomy. Prior to surgery, one patient was an insulin-resistant diabetic that was still exhibiting clinical signs despite receiving 25 U of insulin (Levemir® Novo Nordisk) four times per day. Three weeks after surgery, the patient no longer required insulin therapy and up to one year later the patient's IGF-1 and GH concentrations were within normal limits.

In another single case report, a 13-year-old male castrated domestic shorthair was treated for acromegaly with transsphenoidal hypophysectomy. The patient had a history of insulin-resistant diabetes mellitus (15 units of glargine BID) and was diagnosed with acromegaly via elevated IGF-1 (447 nmol/L) and visualization of a pituitary mass on MRI. The diabetes resolved two weeks postoperatively and remained in remission for eight months at which time the patient was euthanized as a result of feline infectious peritonitis.

In more recent studies, hypophysectomy has been offered to owners who presented diabetic cats with confirmed acromegaly (IGF-1 >1000 ng/mL, pituitary mass) to the Royal Veterinary College since 2012. All cats were operated on by one neurosurgeon. Hypophysectomy was performed by manual extirpation using fine surgical tools via a transoral transsphenoidal approach. Cats received intensive peri- and postoperative monitoring of electrolytes, glucose and blood pressure, and were initially administered conjunctival desmopressin (DDAVP), intravenous infusions of insulin and hydrocortisone, before being transitioned to conjunctival DDAVP, oral hydrocortisone and levothyroxine and subcutaneous glargine insulin. In total, 21 diabetic cats underwent hypophysectomy from April 2012 to October 2014 (median, range; age: 10.3 years, 5.4–14.8; pituitary height: 6.0 mm, 4.0–10.6; IGF-1: 1833 ng/mL, 1138 to >2000; fructosamine: 574 µmol/L, 339–1076). Other than mild pelvic limb weakness, no cat displayed overt neurologic deficits prior to surgery. Three (14%) cats died postoperatively. Two cats did not recover from anesthesia and were euthanized within 24 hours; one cat developed septic meningitis and was euthanized 17 days postoperatively. All surviving cats (n = 18) had a reduction of serum IGF-1 and 16 cats (89%) showed IGF-1 normalization (median postoperative serum IGF-1: 38 ng/mL (15–1955), $P < 0.001$). Fourteen of the 18 surviving cats (78%) achieved diabetic remission; the remaining four achieved superior glycemic control with lower insulin dosages (median fructosamine pre- and postoperatively: 692 and 547µmol/L respectively; median insulin dose pre- and postoperatively: 20.5 and 3.5 units/kg/day respectively). Congestive heart failure was encountered as a transient problem in 4/19 cats that recovered from the surgery; all four cases occurred prior to implementing a reduction in volume of intravenous fluid delivered as part of the postoperative protocol. Two cats developed paresis of the left orbicularis oculi muscle, which resolved in the surviving cat. Cardiac arrest occurred in one cat postoperatively at time of jugular catheter placement, which was successfully revived and made an uneventful recovery. One cat developed a left pelvic limb monoparesis, which improved but did not resolve. Palatal wound breakdown was not encountered. This large case series suggests that hypophysectomy as a treatment for feline acromegaly results in a high incidence of diabetic remission and resolution of acromegaly.

An alternative procedure, cryohypophysectomy, has been reported in a small number of cats but the procedure has been less effective and results in a higher complication rate.

Radiation

Radiation therapy is another option for the treatment of feline acromegaly, especially if the tumor is inoperable, the patient is not a suitable candidate for anesthesia, or surgical treatment is not available in the area. In human medicine, radiation therapy is regarded as a second-line treatment as beneficial effects may take years to develop and the patient typically experiences undesired late-term CNS radiation effects.

The majority of studies that have been performed in veterinary medicine focus on radiation treatment of pituitary masses regardless of functional status. There is no standard treatment protocol for pituitary masses in veterinary medicine and varying methods have been used, including both single and multiple dose fractions administering total dosages ranging from 1500 to 4000 cGY. The majority of the cats included in these studies had insulin-resistant diabetes (suspected acromegaly or Cushing disease) and/or neurologic signs. Radiation therapy was shown to be successful in improving insulin resistance and neurologic signs. Neurologic improvement was generally seen within weeks to months and an improved insulin response was seen within the first month, but most patients still required insulin therapy. In cases where repeat imaging was available, a decrease in tumor size was also noted.

Disadvantages of radiation therapy are the early and delayed effects of radiation, repeated anesthesia, and expense. Early effects from radiation therapy include hair loss, skin pigmentation, and otitis externa. Reported late-term side-effects include brain necrosis, tumor regrowth, and visual and hearing impairment.

In one study, 12 cats with pituitary tumors were treated with a coarse fractionated radiation protocol delivering a total dose of 37 Gy in five once-weekly doses. Eight of these cats had insulin-resistant diabetes mellitus secondary to acromegaly. Of these eight cats, five no longer required insulin therapy, two became stable diabetics, and one required less insulin. In addition, 3/4 cats had improved neurologic signs. The mean survival time of cats in this study was approximately 18 months. In another study, 14 cats with confirmed acromegaly and insulin-resistant diabetes were treated with a total dose of 3700 cGy divided into 10 fractions (three per week). Thirteen of the 14 cats had improved insulin responses. The average insulin dosage reduction was approximately 75%. Six of the cats went into complete diabetic remission and at the time the article was written, 3/6 remained in remission. The median survival time of cats in this study was 28 months.

The most promising results with radiation may involve the use of stereotactic radiation therapy (SRT). Fifty-three client-owned cats were referred to Colorado State University for

SRT to treat pituitary tumors causing poorly controlled diabetes mellitus (DM) secondary to acromegaly. Diagnosis of acromegaly was based on history, physical examination, laboratory results, and cross-sectional imaging of the pituitary. Signalment, radiation protocol, insulin requirements over time, adverse effects, and survival were recorded. Median survival time was 1072 days. Of the 41 cats for which insulin dosage information was available, 95% (39/41) experienced a decrease in required insulin dose, with 32% (13/41) achieving diabetic remission. Remission was permanent in 62% (8/13) and temporary in 38% (5/13) cats. Median duration to lowest insulin dose was 9.5 months. Of the treated cats, 14% developed hypothyroidism and required supplementation after SRT. Cats treated with SRT have improved survival time and control of their DM when compared to previously reported patients treated with non-SRT.

Conclusion

Feline acromegaly is likely an underdiagnosed disease in older male cats, especially in patients with insulin-resistant diabetes. There is no single diagnostic test for acromegaly. The diagnostician should use history, clinical signs, laboratory tests (GH and IGF-1), and advanced imaging to arrive at a diagnosis. There are several treatments options, but clinical studies on long-term safety and efficacy are limited and often lack controls. Until more work is done evaluating medical treatments such as somatostatin analogs and growth hormone antagonists, most patients are best treated with either surgery or radiation therapy to control GH levels, improve glycemic control, and improve or prevent the development of neurologic signs.

Pituitary-Dependent Hyperadrenocorticism in Dogs and Cats

David S. Bruyette, DVM, DACVIM (SAIM)

Anivive Lifesciences, Long Beach, CA, USA

Etiology/Pathophysiology and Epidemiology

Pituitary-dependent hyperadrenocorticism (PDH), also known as Cushing disease, is a common endocrine disorder in older dogs though relatively uncommon in cats. This disorder is caused by a pituitary adenoma (PA) that secretes inappropriate amounts of adrenocorticotropic hormone (ACTH), which results in bilateral adrenal hyperplasia and disorderly and excessive production of cortisol by the adrenal gland.

Classification

Basics of Classification

As with all central nervous system tumors, the Tumor–Node–Metastasis (TNM) system used by the World Health Organization does not apply. Current classification systems for PAs in veterinary patients are based primarily on secretory characteristics of the tumor. However, in humans, PAs are currently classified based upon:

- tumor size and degree of invasiveness (Box 7.1)
- tumor endocrine activity (hormone secretion)

or *functional* classification based on immunohistologic findings such as ACTH, thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), etc. immunostaining.

In both humans and animals, pituitary corticotroph adenomas that are responsible for Cushing disease (i.e., PDH) are classified as functional ACTH-secreting PAs (ACTH-PAs).

Further Classification

The World Health Organization classification system for PAs in humans has been refined to include designations for benign adenoma, atypical adenoma, and pituitary carcinoma on the basis of proliferation indices (p53 immunoreactivity, MIB-I Index, mitotic activity) and the absence/presence of metastases.

More comprehensive molecular classification systems based on relevant gene expression have not been systematically used to further characterize pituitary tumors. Similar work to classify canine pituitary tumors both morphologically and functionally is currently under way.

Prevalence

Humans

In humans, PAs are common tumors, with an overall prevalence in the general US population estimated at 16.7%.

- Corticotroph adenomas, comprising functional (ACTH-PAs) and silent corticotroph adenomas, represent approximately 10–15% of all PAs.
- Functional ACTH-PAs are the most common cause of Cushing syndrome (hypercortisolemia from any source), accounting for an estimated 70% of all cases.
- Prevalence of Cushing disease is estimated to be 1.2–2.4 per 1 million people, and affects approximately 12 000 people in the US. This number, however, may be much higher, given that Cushing disease is frequently misdiagnosed and diagnosis is often delayed.

Dogs

Functional ACTH-PAs have a reported incidence of 0.2% in all dogs (1–2 cases/1000 dogs/year), with approximately 100 000 dogs affected yearly in the US. PDH accounts for approximately 85–90% of cases of hyperadrenocorticism, with the remainder of cases resulting from functional adrenal tumors, meal/food-induced cases, occult or atypical disease.

Meal- or food-induced Cushing syndrome is thought to occur as the result of a congenital defect resulting in the aberrant expression of the gastric inhibitory polypeptide

Box 7.1 Classification of pituitary tumors in humans by size and anatomic location

Classification by size based on radiologic findings

Microadenomas	Less than 10 mm diameter
Macroadenomas	Equal to or greater than 10 mm diameter

Classification based on radioanatomic findings

Stage I	Microadenomas (<1 cm) without sella expansion
Stage II	Macroadenomas (≥1 cm); may extend above the sella
Stage III	Macroadenomas with enlargement and invasion of the floor or suprasellar extension
Stage IV	Destruction of the sella

(GIP) receptor in the adrenal cortex. Stimulation of this receptor by GIP, normally released by the stomach in response to a meal, leads to clinical signs of hyperadrenocorticism in younger dogs. Occult hyperadrenocorticism refers to the presence of elevated adrenal steroid concentrations in the absence of clinical signs and has been best described in Scottish terriers with elevated serum alkaline phosphatase (SAP) and vacuolar hepatopathy. Atypical hyperadrenocorticism refers to animals with clinical signs of classic hyperadrenocorticism secondary to excess sex steroid production rather than excessive cortisol secretion.

Pathogenesis

The pathogenesis of pituitary tumors that produce ACTH is becoming more evident based on ongoing studies evaluating gene and protein expression in both humans and dogs. This information will aid our understanding of tumorigenesis and point us toward targeted specific therapies.

Two theories have been put forward to explain the development of an ACTH-producing pituitary tumor (ACTH-PA, corticotrophinoma):

- hypothalamic theory
- monoclonal theory.

Hypothalamic Theory

In this theory, the hypothalamus stimulates corticotrophs through enhanced secretion of corticotropin-releasing hormone (CRH) and vasopressin. In addition, concurrent defects in the pituitary glucocorticoid receptors (GR) on the corticotroph cells lead to decreased negative feedback by cortisol on CRH and ACTH synthesis.

Gene Mutation

Karl and colleagues and Lamberts described a mutation in the gene in humans that encodes the GR, with a reduction in the sites of DNA binding, while maintaining affinity for cortisol. This *de novo* mutation promotes GR resistance that precedes the formation of the corticotrophinoma.

Recent studies by Teshima and colleagues, using trilostane to decrease cortisol, demonstrated pituitary tumor growth as a consequence of a reduction in negative feedback. Their studies on canine ACTH tumor cells suggest that reduced negative feedback might first lead to corticotroph hyperplasia followed by a subsequent somatic mutation that could lead to tumor development.

Dopaminergic Actions

Other possibilities for a hypothalamic theory of PDH include:

- dopaminergic neurodegeneration in aged individuals
- decreased expression of the D2 dopaminergic receptor in the corticotroph cells, resulting in decreased dopaminergic inhibition and subsequent hyperplasia. With this possibility, adenomas would evolve secondary to somatic mutations in hyperplastic cells.

The hypothalamic theory is reinforced by the recurrence of ACTH-producing tumors following surgery or in patients in which no tumor was found on MRI or when exploring the sella. Both of these scenarios suggested stimulation or lack of inhibition of ACTH-producing cells from higher centers (hypothalamus or hippocampus). This hypothesis is also supported by the fact that individuals with chronic stress and greater activation of the hypothalamic–pituitary–adrenal axis show corticotroph hyperplasia.

Monoclonal Theory

The main evidence against the hypothalamic theory is the presence of tumor clonality in the majority of the adenomas studied in humans. The monoclonal theory argues that the adenoma occurs in the pituitary outside of other influences and arises through the somatic mutation of a corticotroph cell, resulting in a tumor clone. This mutation precedes the clonal expansion of the tumor.

It is unknown which mutation(s) result in the development of a tumor. Taking into account microadenomas and macroadenomas, the existence of a variety of corticotrophinomas is suggested. The majority of microadenomas in dogs do not progress to macroadenomas based on the low percentage of dogs that develop such tumors during treatment with adrenolytics or adrenal enzyme blockers. Macroadenomas can display a variety of behaviors, from limited growth and indolent course to more aggressive behavior as seen in human patients with

Box 7.2 Genes and proteins expressed in pituitary tissue in humans with functional ACTH-PAs

Genes

p27Kip1	*Underexpressed* in 4 studies
p16	*Underexpressed* in 2 studies

Nelson syndrome in which the pituitary tumor grows rapidly following bilateral adrenalectomy or suppressive medical therapy.

Gene Origin

In humans with functional ACTH-PAs, studies have identified 43 genes and 22 proteins as overexpressed and 58 genes and 15 proteins as underexpressed compared with normal pituitary tissue (Box 7.2).

In dogs, we are just beginning to learn more about genes and protein expression in patients with PDH. The recent demonstration of expression of somatostatin receptor subtypes and dopamine receptor subtype 2 (D2) in canine corticotroph adenomas offers the possibility for novel medical treatment of PDH with somatostatin analogs and dopamine agonists.

Pituitary Size and Proliferation Markers

The ratio between pituitary height and area of the brain (P/B) has been used to evaluate pituitary size.

- P/B ratio >0.31 indicates an enlarged pituitary
- P/B ratio ≤0.31 indicates a nonenlarged pituitary.

A recent study investigated the expression of proliferation markers Ki-67 and minichromosome maintenance-7 (MCM7) in canine corticotroph adenomas in enlarged and nonenlarged pituitaries, and evaluated their relation to the size of canine pituitary corticotroph adenomas.

- Canine corticotroph adenomas in enlarged pituitaries showed greater proliferation potential compared with adenomas in nonenlarged pituitaries.
- MCM7 expression was significantly greater than Ki-67 expression in canine pituitary corticotroph adenomas.

Thus, MCM7 may be superior to Ki-67 as a proliferation marker in canine pituitary tumors.

Corticotroph and Melanotroph Cell Marker: Tpit

In the pituitary glands of humans and mice, corticotrophs and melanotrophs have a specific marker in common, the *T-box transcription factor* (Tpit or Tbx19), which regulates the late differentiation of corticotrophs and melanotrophs and therefore may contribute to the pathogenesis of corticotroph adenomas.

A recent study in 14 dogs with PDH examined the expression and mutation analysis of Tpit in normal canine pituitary and corticotroph adenomas.

- Tpit was expressed in corticotroph and melanotroph cells of normal and adenomatous canine pituitary, and remained present in nonadenomatous corticotrophs of pituitaries from PDH dogs.
- No tumor-specific mutation in Tpit cDNA from corticotroph adenomas was found; however, a missense polymorphism (see Polymorphism versus Mutation) in the highly conserved DNA-binding domain, the T-box, was discovered in one dog.

The study concluded that Tpit can be used as a reliable marker for corticotroph and melanotroph cells in canine pituitary tissue, but that mutations in the Tpit gene are unlikely to play a major role in pathogenesis of canine corticotroph adenomas.

Corticotroph Differentiation Markers: LIF and LIFR

Leukemia inhibitory factor (LIF) is a cytokine of the interleukin (IL)-6 family that activates the hypothalamic–pituitary–adrenal axis and promotes corticotroph differentiation during development. LIF and leukemia inhibitory factor receptor (LIFR) expression were studied in pituitary glands of control dogs and specimens of corticotroph adenoma tissue were collected from dogs with PDH. The results demonstrated that:

- LIFR is highly co-expressed with ACTH and alpha-melanocyte-stimulating hormone in the control canine pituitary gland and corticotroph adenomas
- there was a strong co-expression of LIFR and ACTH1-24 in the cytoplasm of cells in the pars distalis and pars intermedia of control pituitary tissue. In pituitary glands harboring an adenoma, the cytoplasmic expression of LIFR followed that of ACTH1-24. Nontumorous cells of the pars distalis showed no cytoplasmic staining but did demonstrate nuclear to perinuclear immunoreactivity for LIFR in 10 of 12 tissue specimens from PDH dogs. This nuclear immunoreactivity was not observed in the control pituitary tissues or in the pituitary gland with corticotroph hyperplasia.

Role of ACTH Production and Glucocorticoids

As mentioned earlier, a characteristic biochemical feature of corticotroph adenomas is their relative resistance to negative feedback by glucocorticoids. In a recent study,

gene expression related to ACTH production and secretion and the negative feedback by glucocorticoids in canine corticotroph adenoma was evaluated in pituitary tumors in 10 dogs with Cushing disease. The results demonstrated increased ACTH production and resistance to negative feedback by glucocorticoids in canine corticotroph adenomas.

Therapeutic Role of EGFR

Since tumors in dogs and humans express epidermal growth factor receptor (EGFR), in another study we examined whether EGFR might provide a therapeutic target for Cushing disease.

- In cell cultures from surgically resected human and canine corticotroph tumors, blocking EGFR also suppressed expression of proopiomelanocortin (POMC), the ACTH precursor.
- In mouse corticotroph EGFR transfectants, ACTH secretion was enhanced and POMC promoter activity was increased.

In mice, blocking EGFR activity with gefitinib, an EGFR tyrosine kinase inhibitor:

- attenuated POMC expression
- inhibited corticotroph tumor cell proliferation and induced apoptosis
- decreased both tumor size and corticosterone levels
- reversed signs of hypercortisolemia, including elevated glucose levels and excess omental fat.

These study results indicate that inhibiting EGFR signaling may be a novel strategy for treating Cushing disease.

History and Clinical Signs

Clinical signs, as well as laboratory abnormalities, seen in patients with PDH are secondary to the effects of steroid excess, well recognized, and similar in scope to those seen with exogenous glucocorticoid supplementation (Boxes 7.3 and 7.4).

The clinical signs of polyuria and polydipsia occur as the result of excessive cortisol interfering with pituitary release of antidiuretic hormone (ADH) or the binding of ADH to receptors in the renal tubules. Abdominal distension and thinning of skin occur due to the catabolic effects of cortisol on tissues such as muscle and connective tissue. Hepatomegaly steroid-induced vacuolar hepatopathy also contributes to the "pot-bellied" appearance. The endocrine alopecia mirrors the known distribution of sex hormone receptors in the skin with endocrine alopecias often sparing the head and extremities. Panting occurs in both dogs and humans and is felt to be due to steroid-induced stimulation of ventilator centers in the brainstem. Pyoderma and urinary tract infections reflect the immunosuppressive effects of glucocorticoids. The mechanism(s) behind the steroid induction of calcinosis cutis is poorly understood although the condition does occur with both iatrogenic and spontaneous hyperadrenocorticism and the condition can take months to resolve following resolution of hyperadrenocorticism or withdrawal of the exogenous steroid.

Awareness of PDH has increased over time, resulting in the presentation of patients with only mild clinical signs, clinical signs affecting only one organ system (e.g.,

Box 7.3 Common clinical signs of PDH in dogs and cats

Polyuria and polydipsia
Polyphagia
Abdominal distension
Bilaterally symmetric endocrine alopecia
Panting
Hypertension
Urinary tract infections
Additional dermatologic signs:
– Thin skin
– Pyoderma
– Calcinosis cutis

Box 7.4 Common laboratory findings of PDH

Hematologic abnormalities

"Stress" leukogram (uncommon in cats):
– Neutrophilic leukocytosis
– Lymphopenia
– Eosinopenia
Mild thrombocytosis
Mild erythrocytosis

Serum biochemical abnormalities

Increased serum alkaline phosphatase
Milder increased in alanine aminotransferase
Hypercholesterolemia
Hypertriglyceridemia
Hyperglycemia

Urinalysis

Decreased urine specific gravity <1.018
Proteinuria
Urinary tract infection (even in absence of pyuria and bacteriuria)

polyuria and polydipsia or alopecia), absent clinical signs, or unusual isolated manifestations of the disease.

Diagnosis

Diagnosis of PDH requires incorporating information from the history, physical examination, and routine laboratory tests. Specific endocrine tests and imaging modalities are available to diagnose hyperadrenocorticism (HAC) and distinguish between the various causes of hypercortisolism. No single test is perfect and if the initial screening test is negative and high clinical suspicion of HAC exists, additional tests should be performed. Endocrine evaluation of patients with HAC and nonadrenal illness can be difficult, and it is important to eliminate or manage the concurrent illness before undertaking adrenal function tests.

ACVIM Consensus Statement

In 2012, the American College of Veterinary Internal Medicine (acvim.org) issued a consensus statement addressing the diagnosis of spontaneous canine hyperadrenocorticism, which provides a thorough review of the diagnostic approach to patients with PDH and addresses many common clinical concerns. Access this statement at onlinelibrary.wiley.com/doi/10.1111/jvim.12192/epdf.

Baseline Diagnostics

In all patients being screened for PDH, the following initial diagnostics should be performed prior to endocrine diagnostics.

- Thorough history including prior treatment with systemic or topical glucocorticoids.
- Physical examination.
- Complete routine database, including complete blood count, serum biochemical profile, urinalysis, urine culture, and blood pressure.

These diagnostics are important as the clinical signs of PDH are rarely pathognomonic, and patients are generally older and may have co-morbidities, which affect endocrine function tests and impact therapeutic options and prognosis.

If a patient has a concurrent serious illness, postpone testing until the illness or injury has resolved or been controlled to minimize false-positive test results.

Endocrine Diagnostics

Specific endocrine tests and imaging modalities are available to both diagnose PDH and distinguish between the various causes of HAC (Tables 7.1 and 7.2). No single test is perfect and if the initial screening test is negative and high clinical suspicion of PDH exists, additional

Table 7.1 Diagnostic tests to evaluate patients with suspected PDH

Test	Components	Procedures	Results
Low-dose dexamethasone suppression (LDDS)	Dexamethasone sodium phosphate *or* polyethylene glycol: 0.01–0.015 mg/kg IV[a] (dog), 0.10 mg/kg IV (cat)	Obtain blood samples: 1) Before administration 2) 4 h after administration 3) 8 h after administration	Consult with your reference laboratory for specific reference ranges
ACTH stimulation	Cosyntropin *or* tetracosactrin: 5 µg/kg IV or IM (dog), 0.125 mg IV (cat)	Obtain blood samples: 1) Before administration 2) 60 min after administration	Consult with your reference laboratory for specific reference ranges
Urine cortisol to creatinine ratio (UCCR)[b]	Urine collected from dog in the morning[c]	Have owner collect urine at home for at least 2–3 consecutive mornings; submit an aliquot of the pooled samples to diagnostic laboratory	Consult with your reference laboratory for specific reference ranges

[a] Calculate dose using parent compound.
[b] High UCCRs in dogs without a high degree of clinical suspicion of hyperadrenocorticism should be interpreted cautiously.
[c] Urine collected by the owner is less likely to be influenced by stress; in addition, morning urine is preferred because it usually represents several hours of urine production.
Notes:

- The effect of feeding on LDDS or ACTH stimulation test results is unknown; however, feeding during these tests is not recommended. Fasting before testing is not necessary unless lipemia affects the cortisol assay results (check with your laboratory for specific details).
- In veterinary medicine, the ability of glucocorticoids, progestagens, and ketoconazole to suppress cortisol secretion is known. However, no effect on LDDS, ACTH stimulation, or UCCR has been documented in dogs treated with phenobarbital.

ACTH, adrenocorticotrophic hormone; IM, intramuscular; IV, intravenous.

Table 7.2 Diagnostic tests that differentiate between PDH and ADH

Test	Components	Procedures	Results
Low-dose dexamethasone suppression (LDDS)[a]	Dexamethasone sodium phosphate *or* polyethylene glycol: 0.01–0.015 mg/kg IV[b] (dog), 0.10 mg/kg IV (cat)	Obtain blood samples: 1) Before administration 2) 4 h after administration 3) 8 h after administration	• With LDDS, suppression to <50% baseline in a dog with HAC confirms PDH. • If no suppression with LDDS, cACTH measurement or abdominal ultrasound is recommended. • With LDDS or HDDS, lack of suppression does not confirm AT (approximately 25% of dogs with PDH fail to suppress)
High-dose dexamethasone suppression (HDDS)[a]	Dexamethasone sodium phosphate: 0.1 mg/kg IV[c] (dog), 1.0 mg/kg IV (cat)		
Endogenous ACTH	cACTH	Collect blood into chilled, silicon-coated glass or plastic EDTA tubes. Centrifuge within 15 min (ideally cooled centrifuge). Transfer plasma to plastic tubes and freeze immediately; samples must stay frozen until analysis[d]	Normal or elevated concentrations are consistent with PDH, suppressed values are consistent with AT

[a] LDDS and HDDS results cannot be considered 100% absolute; when imaging and endocrine test results conflict, the latter should be given preference.
[b] Calculate dose using parent compound.
[c] For HDDS, avoid the free alcohol form.
[d] Addition of the protease inhibitor aprotinin prevents ACTH degradation by plasma proteases and greatly facilitates sample handling. Check with your laboratory regarding suitability because, with some assays (i.e., Immulite), aprotinin introduces an artifactual decrease in results.
AT, adrenal tumor; ATCH, adrenocorticotrophic hormone; cATCH, canine adrenocorticotrophic hormone; HAC, hyperadrenocorticism; IV, intravenous.

tests should be performed to determine a definitive diagnosis.

Several endocrine screening tests are available to arrive at a diagnosis of HAC, including:

- low-dose dexamethasone suppression (LDDS)
- ACTH stimulation
- urine cortisol to creatinine ratio (UCCR).

Additional tests may be required to differentiate PDH from other causes of hypercortisolemia, such as endogenous ACTH measurement and advanced imaging.

Initial Endocrine Screening

Low-Dose Dexamethasone Suppression

Low-dose dexamethasone suppression demonstrates decreased pituitary sensitivity to negative feedback from glucocorticoids.

Indications Most consider LDDS the screening test of choice for HAC unless the patient history suggests iatrogenic HAC, in which case ACTH stimulation is preferred.

Sensitivity/Specificity In veterinary medicine, the reported sensitivity and specificity of the LDDS test range from 85% to 100% and from 44% to 73%, respectively.

Test Results Blood samples are obtained (1) before, (2) four hours after, and (3) eight hours after dexamethasone administration (0.01 mg/kg IV). Diagnosis of HAC is based on lack of suppression of cortisol concentration eight hours after dexamethasone administration.

ACTH Stimulation

Adrenocorticotropic hormone stimulation assesses adrenocortical reserve. Sensitivity of ACTH stimulation for all forms of spontaneous canine HAC ranges from 57% to 95%. In dogs with PDH, sensitivity is 80–83%. Specificity ranges from 59% to 93%.

Due to greater purity and quality control, use of synthetic ACTH is recommended. Use of compounded ACTH is discouraged, especially when monitoring patients on adrenolytic agents or adrenal enzyme blockers (see Synthetic versus Compounded ACTH).

Indications Adrenocorticotrophic hormone stimulation is the gold standard for diagnosis of iatrogenic HAC and spontaneous Addison disease (hypoadrenocorticism). A diagnosis of HAC is based on finding an elevated post-ACTH cortisol concentration based on the reference range established by the laboratory.

Sensitivity/Specificity Due to its low sensitivity, it is inferior to LDDS as a screening test for spontaneous HAC. However, many clinicians still use ACTH stimulation because of its convenient study duration of 60 minutes and relative effectiveness in the clinical setting,

especially when combined with abdominal ultrasound evaluation and interpreted in light of the history and physical examination.

Synthetic vs Compounded ACTH Synthetic polypeptides, such as Cortrosyn® (cosyntropin) or Synacthen® (tetracosactrin), contain the biologically active first 24 amino acids of ACTH; however, their potencies have not been compared.

In several studies, after administration of cosyntropin (5 µg/kg or 250 µg/dog IV or IM), peak cortisol concentrations occurred at 60–90 minutes. After administration of 5 µg/kg IV, no difference was detected between 60- and 90-minute cortisol concentrations. Cosyntropin can be reconstituted, divided into aliquots in plastic syringes, and frozen at –20 °C for six months. Whether tetracosactrin can be frozen has not been investigated; according to the manufacturer, store it at temperatures from 2 to 8 °C.

Compounded ACTH products have been evaluated in healthy dogs. Sixty minutes after administration, cortisol concentrations were similar among four compounded products (2.2 U/kg IM) and cosyntropin (5 µg/kg IV). However, at later times, cortisol concentrations varied considerably with the compounded products.

Urine Cortisol to Creatinine Ratio

The UCCR provides an integrated reflection of cortisol production, adjusting for fluctuations in blood concentrations. Determination of basal UCCRs can be performed alone or in tandem with other endocrine testing.

Indications The UCCR can be used as a screening test for hypercortisolemia, although a single positive result should not be overinterpreted. Adding oral dexamethasone suppression to UCCR testing (see later) has the advantage of potentially demonstrating both increased cortisol production and decreased sensitivity to glucocorticoid feedback.

Sensitivity/Specificity When a single, random urine sample is collected in veterinary hospitals, reported sensitivity and specificity of UCCR for diagnosis of HAC range from 75% to 100% and 20% to 25%, respectively. In some dogs, there is considerable day-to-day variation in UCCR results.

However, in dogs with physical and biochemical changes consistent with HAC, when two basal UCCRs were above the cut-off level:

- sensitivity was 99%; 95% confidence interval 94–100%
- specificity was 77%; 95% confidence interval 64–87%.

Evaluation of Pituitary–Adrenal Axis

Evaluation of the pituitary–adrenal axis is indicated in the following circumstances.

- Patients with clinical signs and laboratory findings consistent with PDH and in whom nonadrenal illness has been ruled out or is well controlled.
- Patients in whom an adrenal/pituitary mass or bilateral adrenal hyperplasia has been discovered in conjunction with compatible clinical signs.
- Patients with an incidentally discovered adrenal mass, with adrenalectomy being considered.
- Diabetic dogs with insulin resistance.

Differentiating PDH from ADH: Laboratory Analysis

Given that PDH and adrenal-dependent hyperadrenocorticism (ADH) are the most common forms of HAC, and that their treatment options and prognoses differ, it is important to recommend additional testing to determine the exact etiology of HAC. Several diagnostic modalities are commonly used to differentiate between PDH and ADH.

- Endogenous ACTH
- Dexamethasone suppression
- Dexamethasone suppression with UCCR

Endogenous ACTH

Canine ACTH is secreted from the pituitary gland in an episodic, pulsatile fashion in both healthy dogs and those with PDH. A circadian rhythm has not been convincingly demonstrated, although one study reported higher plasma concentrations of canine ACTH (cACTH) in the late afternoon than in the morning.

Indications Concentrations of cACTH do *not* differ between healthy dogs and those with PDH, and its measurement is not useful to screen for HAC. However, measurement of cACTH is the most accurate stand-alone biochemical test for differentiating PDH from adrenocortical tumor (AT), but the sensitivity of the assay differs with methodology. Normal or elevated concentrations of cACTH are consistent with PDH while suppressed values are consistent with AT.

Sensitivity/Specificity The most common problem with the cACTH assay is poor sensitivity. The largest study of cACTH in dogs with HAC used a two-site solid-phase chemiluminescent immunometric assay (Immulite 2000 Immunoassay System for ACTH; healthcare.siemens.com) and showed excellent discrimination between PDH and AT.

The likelihood of falsely low ACTH values in dogs with PDH is increased by:

- intraassay and interassay variability (increased at lower cACTH concentrations)
- pulsatile ACTH secretion
- inappropriate sample handling allowing ACTH degradation.

Dexamethasone Suppression

Dexamethasone administration in:

- *normal dogs:* causes rapid and prolonged suppression of cortisol secretion
- *patients with an AT:* at any dosage does *not* suppress cortisol secretion
  dogs with PDH:
  - does *not* appropriately suppress ACTH secretion (therefore does not suppress cortisol) when a low dose (0.01 mg/kg) is administered
  - in 75% of dogs with PDH, ACTH and cortisol concentrations decrease when a high dose (0.1 mg/kg) is administered
  - in 25% of dogs with PDH, suppression of ACTH and cortisol does not occur even after administration of higher dosages; in these patients, a large pituitary tumor or tumor developing from the pars intermedia is more likely.

Test Results The largest study evaluating both suppression tests (LDDS and high-dose dexamethasone suppression [HDDS]) included dogs with PDH (n = 181) and ATs (n = 35). With LDDS, criteria for identifying dogs with PDH included:

- four-hour post-LDDS cortisol concentrations below laboratory cut-off *or* <50% of basal cortisol concentration
- eight-hour post-LDDS cortisol concentrations <50% of the basal cortisol concentration *and* greater than the laboratory cut-off.

With HDDS, criteria for cortisol suppression were a four- and/or eight-hour cortisol concentration below the laboratory cut-off *or* <50% of the basal cortisol concentration.

Approximately 75% of dogs with PDH met at least one criterion for suppression on either LDDS or HDDS. Of those with PDH, 88% suppressed with the LDDS and 12% demonstrated suppression with HDDS.

Dexamethasone resistance (i.e., no criteria were met) occurred in all dogs with AT and the remainder (25%) of the dogs with PDH. In another study of 41 dogs with AT, 28 LDDS and 30 HDDS tests were performed, with no suppression seen on any test.

In dogs demonstrating lack of suppression with LDDS, use of endogenous ACTH rather than HDDS is recommended to differentiate PDH from ADH. Since suppression in response to dexamethasone supports a diagnosis of PDH, a dog with dexamethasone resistance can have either AT or PDH.

Dexamethasone Suppression with UCCR

Decreased blood cortisol concentration after dexamethasone administration is reflected in decreased UCCR.

Test Results After the patient's owner/handler collects a morning urine sample on two consecutive days, three doses of dexamethasone (0.1 mg/kg PO) are administered at 6–8-hour intervals, with a third urine sample collected the next morning.

Decrease in the third UCCR to <50% of the mean cortisol basal values is consistent with PDH. Lack of suppression does not confirm AT. In 160 dogs with HAC (49 with ATs, 111 with PDH), the UCCR in 72% of dogs with PDH suppressed to <50% of the basal UCCR, while the other 28% of those with PDH were dexamethasone resistant. In dogs with ATs, maximum suppression was 44% of the baseline sample.

Differentiating PDH from ADH: Imaging

While imaging can be very helpful in differentiating PDH from ADH, it cannot be used to establish a diagnosis of HAC. Moreover, finding normal adrenal glands on imaging studies does *not* rule out HAC.

Radiography

Imaging results may include:

- abdominal distension
- good contrast due to abdominal fat deposition
- hepatomegaly
- bladder distension
- mineralization of bronchi and pulmonary interstitium, and of dermal and subcutaneous tissues in areas predisposed to calcinosis cutis.

A small liver makes HAC unlikely. An AT may be visualized due to either mass effect or tumor calcification.

Adrenal Gland Imaging

Adrenal gland width is the most informative parameter identified on ultrasonography. However, the following may affect correct measurement.

- The long axis of adrenal gland often is misaligned with either the medial or dorsal plane of the body.
- Cross-sectional images may lead to oblique views and miscalculation of glandular dimensions.
- Breed and body size differences.
- Macronodular hyperplasia (a rare form of PDH) and some ATs can be difficult to differentiate.

Test Results In dogs with PDH, ultrasonography reveals normal-sized or enlarged adrenal glands that are typically symmetric; however, mild asymmetry may occur. In dogs with ATs, ultrasonography reveals moderate asymmetry, contralateral adrenocortical atrophy (adrenal width <4–5 mm), destruction of normal tissue architecture, or some combination of these findings.

Ultrasonography can also estimate AT size and possibly vascular or local soft tissue invasion. Although most ATs are unilateral, bilateral tumors may occur and in these patients, endogenous ACTH concentrations should be determined.

Metastasis When an AT has been confirmed, certain thoracic and ultrasonographic findings suggest malignancy.

- Adrenal gland width >4 cm.
- Invasion into the vena cava or adjacent tissues.

However, computed tomography (CT) and magnetic resonance imaging (MRI) are more sensitive techniques to identify vascular invasion and detect metastases.

Adrenalectomy should not be performed without confirming the presence of an AT (and atrophy of contralateral adrenal gland) by abdominal ultrasonography, CT, MRI, or some combination of these. Metastasis can be confirmed by ultrasound-guided biopsy, but differentiating benign from malignant AT often is difficult, even with histopathologic examination.

Pituitary Imaging

Pituitary imaging provides valuable information regarding treatment options and prognosis. Pituitary lesions range from microscopic nests of hyperplastic cells to large tumors. Absence of neurologic abnormalities does not exclude pituitary macrotumors (i.e., tumors that are >1 cm in diameter, extend above the sella turcica, or have a pituitary:brain ratio of >0.31).

Indications Pituitary imaging should be considered for all dogs at the time of PDH diagnosis, especially if hypophysectomy or radiation therapy is being considered. If clinical features suggest a pituitary macrotumor, confirmation requires imaging. Clinical signs of a macroadenoma include disorientation, aimless wandering, severe polyuria/polydipsia, lethargy, hyporexia to anorexia, visual impairment and possibly seizures.

Test Results Because pituitary lesions may be quite small, contrast-enhanced CT and MRI may identify normal-sized pituitary glands in dogs with PDH. However, dynamic contrast-enhanced CT takes advantage of the pituitary gland's blood supply.

- The posterior pituitary gland's blood supply is direct (arterial).
- The anterior pituitary gland's blood supply is mainly indirect via the pituitary portal system.

In dogs with normal pituitary glands, after IV administration of contrast medium, the posterior pituitary gland can be identified first – this phase is called the "pituitary flush." Its absence indicates atrophy due to compression by a pituitary tumor. Displacement or distortion of the flush can be used to identify and localize anterior pituitary microtumors.

Dorsal displacement and decreased signal intensity of the posterior lobe on T1-weighted MRI indicate the presence of a microtumor.

Treatment

In humans, while pituitary surgery is considered the first line of treatment for patients with Cushing disease, medical therapy now plays a more important role in the armamentarium available to patients after failed surgery. Repeat surgery, bilateral adrenalectomy, and pituitary radiation are also frequently employed.

In dogs, medical management is far more common than surgical approaches and generally involves the use of medications directed toward reducing adrenal glucocorticoid production. However, recent work on newer medical and surgical therapies as well as work on emerging treatments provides the clinician with multiple therapeutic options.

Medical treatments can be classified based on their mechanism of action and categorized as (1) adrenal-directed steroidogenesis inhibitors or adrenolytics, (2) centrally acting agents, and (3) glucocorticoid receptor blockers (Box 7.5).

Adrenal-Directed Therapies

In dogs, op-DDD (mitotane, Lysodren®; Bristol Pharmaceuticals), trilostane (Vetoryl®; Dechra Pharmaceuticals) and ketoconazole are the most commonly used agents although several other agents have been used or are under investigation. In cats, mitotane and trilostane are most commonly used.

Mitotane

Mitotane is derived from the insecticide DDT and is a potent adrenocorticolytic agent. The drug causes progressive necrosis of the zona fasciculata and zona reticularis of the adrenal gland and at higher doses may also cause necrosis of the zona glomerulosa. Other effects of mitotane include fatty degeneration, centrilobular

atrophy, and congestion of the liver. Normal dogs and cats are clinically quite resistant to the effects of the drug.

Therapy with mitotane in both dogs and cats is begun at a dose of 50 mg/kg divided q12h. Glucocorticoids are not usually administered concurrently, but a small supply of prednisone should be made available to the owner for emergencies. Mitotane at induction doses is typically administered for 5–10 days, until water consumption decreases to <100 mL/kg/day. It should be discontinued immediately if decreased appetite, depression, diarrhea, or vomiting are observed. At this point, the pet should be reevaluated and an ACTH stimulation test performed. Prednisone treatment (0.2–0.5 mg/kg/day) should be initiated in patients showing clinical signs of hypocortisolemia, until the results of the ACTH stimulation test are known. In patients that are not polydipsic, patients in which water consumption cannot be monitored, and patients in which polydipsia is due to another underlying disease (e.g., diabetes mellitus), mitotane should be administered for a maximum of 5–7 days prior to ACTH stimulation testing.

The goal of treatment is to have both the pre- and postcortisol measurement in the normal resting range (2–6 µg/dL). Maintenance therapy (50 mg/kg q7–10 days) is started once the ACTH stimulation test shows adequate suppression (pre and post less than 5 µg/dL) and prednisone therapy (if necessary) has been discontinued. Failure to use maintenance therapy will result in regrowth of the adrenal cortex and recurrence of clinical signs. Efficacy of maintenance therapy is monitored by an ACTH stimulation test in one month and every 3–4 months thereafter. The dose of mitotane required for long-term maintenance is quite variable (26–330 mg/kg/week).

Reasons for treatment failure include incorrect diagnosis, the presence of an adrenal tumor (although some adrenal tumors will respond well), loss of drug potency due to poor storage or compounding of mitotane, or a need for a higher dose or duration of treatment in some dogs. Side-effects of mitotane include gastric irritation, hypoadrenocorticism, and very occasionally neurologic signs. Mean survival time of 200 dogs treated with mitotane was 2.2 years (range 10 days to 8.2 years).

Trilostane

Trilostane is a synthetic hormonally inactive steroid analog, which is a competitive inhibitor of the 3-beta-hydroxysteroid dehydrogenase system. The drug blocks synthesis of adrenal steroids, including cortisol and aldosterone. Trilostane is rapidly absorbed orally (peak concentrations within 1.5 hours), although suppression of plasma cortisol concentrations is short-lived (<20 hours). The medication should be administered with food (including the days when ACTH stimulation tests are scheduled to be performed) to aid in absorption.

Current recommendations for use of trilostane in dogs are to start at a dose of 1–2 mg/kg q12–24h and then increase or decrease the dose based on evaluation of ACTH stimulation tests performed 4–6 hours after drug administration. While there is no difference in whether the samples are drawn four or six hours post pill, it is important that the same sampling times are used in a given patient. The hormonal endpoints are postcortisol concentration of less than 6–9 µg/dL in conjunction with remission of clinical signs. Twice-a-day therapy at a starting dose of 1–3 mg/kg may result in good control of clinical signs at a lower total daily dose with less risk of adverse effects than higher doses q24h. In addition, BID dosing may be more effective in controlling hypercortisolemia more consistently throughout the day and may be appropriate as a starting dose in dogs with diabetes and other Cushing-related complications.

We have recently evaluated the safety and efficacy of trilostane therapy in 15 cats with PDH at starting doses of 1–2 mg/kg q12–24h. Clinical signs (13 of 15 cats) and ACTH stimulation testing results (13 of 15) improved with trilostane therapy. Diabetes mellitus was reported in 9/15 cases. Insulin requirements decreased by 36% within two months in 6/9 diabetic cats. Median survival

time was 617 days for all cats (range 80–1278 days). Complications included weight loss, urinary tract infections, chronic kidney disease, seizures, and recurrent pancreatitis. Hypocortisolemia was documented in one case. Cause of death occurred as a result of nonadrenal or nondiabetic illnesses (renal failure, seizures [caused by hypoglycemia or unknown]), or lymphoma. Trilostane ameliorates clinical signs of HAC in cats, is tolerated well in the long term, and can lead to improved regulation of diabetes. It should be considered as first-line therapy for cats undergoing medical management of PDH.

Adrenocorticotropic hormone stimulation testing should be performed 10, 30, and 90 days after start of treatment and 30 days after each dose adjustment. Trilostane is well tolerated in most dogs. Adverse effects that are usually mild and self-limiting include diarrhea, vomiting, and lethargy in up to 63% of treated dogs.

The ACTH stimulation test is the monitoring method for patients on trilostane therapy for which we have the most clinical experience and have reliably used for clinical decision making for a decade. However, the correlation of test results with the patient's clinical well-being has been questioned by multiple researchers. As with many endocrine tests, there is not one definitive methodology that can be applied to all patients.

The ACTH stimulation test remains the test of choice in any canine patient found to be clinically unwell by either the owner or the veterinarian. Oversuppression of cortisol production can occur with any medical therapy for hyperadrenocorticism and can develop insidiously or acutely.

Recently in Europe, the cost of cosyntropin has increased significantly. This, along with the multiple publications showing a lack of correlation between the ACTH stimulation test results and patients' clinical well-being, led a group of researchers to investigate the value of examining a single, unstimulated, cortisol result prior to the administration of trilostane.

Procedure/Protocol

1) Owners are instructed to bring their dog to the veterinary hospital prior to receiving the morning dose of trilostane.
2) The owners are then asked questions regarding control of clinical signs, with or without the use of a questionnaire. If any signs of cortisol oversuppression are noted, such as vomiting, anorexia, hyporexia, or lethargy, trilostane is not given, and a baseline cortisol and/or an ACTH stimulation test is performed to rule out hypoadrenocorticism.
3) A serum sample is collected for the measurement of cortisol.

Based on the above literature review, we offer the following recommendations for monitoring canine patients receiving trilostane therapy.

Unwell Dogs, Stressed Dogs, and Dogs With Concurrent Illness

- Perform an ACTH stimulation test.
- Perform an electrolyte panel and evaluate for signs of mineralocorticoid suppression.

Clinically Well and Controlled Dogs (Per Client Questionnaire and/or History)

- Pre-trilostane cortisol <1.4 µg/dL: decrease dose by 10% or perform an ACTH stimulation test.
- Pre-trilostane cortisol 1.4–5 µg/dL: continue current dose.
- Pre-trilostane cortisol >5 µg/dL: reevaluate history and consider splitting dose to twice daily (if currently once daily), or a small dose increase, based on clinical signs.

Clinically Undercontrolled Dogs

- Pre-trilostane cortisol <1.4 µg/dL: reevaluate history and diagnosis; perform an ACTH stimulation test; consult with a specialist.
- Pre-trilostane cortisol 1.4–5 µg/dL: this is currently a gray zone. Depending on the patient, consider splitting the dose to twice daily, if currently on once-daily dosing, or consider a dose increase if >3 µg/dL.
- Pre-trilostane cortisol >5 µg/dL: increase dose frequency (from once daily to twice daily) or dose.

Occasionally, dogs have developed hypoadrenocorticism, which is generally glucocorticoid deficient only, although dogs with evidence of mineralocorticoid deficiency have been reported. Hypoadrenocorticism induced by trilostane is generally reversible, although in rare cases this may take several months, likely because of adrenocortical necrosis. There have been anecdotal reports of acute death shortly after starting trilostane treatment.

Mitotane vs Trilostane

Studies have been performed comparing trilostane with mitotane in dogs with PDH or adrenal tumors. In a retrospective study of dogs treated with either mitotane (n = 25) or trilostane (n = 123), long-term survival was not statistically different between the groups. Median survival in the mitotane group was 708 days (range 33–1399), and in the trilostane group was 662 days (range 8–1971). Of the dogs that died in this study, 11% died due to causes that were attributed to the underlying PDH, and a further 17% died of causes that could have been related to their underlying PDH. In 38% of cases, the cause of death could not be directly attributed to PDH, and in 34% the cause of death was unknown.

Ketoconazole

While ketoconazole was used more frequently in the past, its use now is generally in countries where mitotane and trilostane are not available or when these agents have failed to correct hypercortisolism or resulted in adverse reactions. Its systemic use has recently been restricted or banned in several countries due to the potential of significant hepatoxocity in humans.

Specifically, ketoconazole has been shown to inhibit cholesterol side-chain cleavage enzyme, which converts cholesterol to pregnenolone, 17-alpha-hydroxylase and 17,20-lyase, which convert pregnenolone into androgens, and 11-beta-hydoxylase, which converts 11-deoxycortisol to cortisol.

A paper in 2008 examined the safety and efficacy of ketoconazole in 48 dogs with PDH. Data collected from each record included signalment, clinical signs, results of ACTH stimulation tests before and after treatment with ketoconazole (10 mg/kg PO BID), serum alkaline phosphatase (ALP) and alanine aminotransferase (ALT) activities, dosage of ketoconazole, clinical response, and survival time. Forty-three of 48 (90%) dogs had evidence of clinical improvement during the treatment period. In all dogs, treatment with ketoconazole resulted in significantly lower serum cortisol concentrations as measured before and after ACTH stimulation testing; 69% (33/48) of serum cortisol concentrations measured after ACTH stimulation were within the basal resting range. Serum ALP and ALT activities significantly decreased after treatment with ketoconazole.

Survival time after diagnosis of PDH ranged from 2 to 61 months (mean 26.9 months; median 25 months). Another study evaluating ketoconazole found that after diagnosis, 50% of the dogs died approximately 1.8–2 years (range 0.6–3) after starting therapy.

Several other adrenal steroidogenesis inhibitors have been used in man and at times in dogs.

Aminoglutethemide (Cytadren®; Novartis)

Aminoglutethemide blocks the conversion of cholesterol to pregnenolone by inhibiting the enzyme P450scc and consequently decreases synthesis of all hormonally active steroids. Its use in dogs has been limited. In one study, 10 dogs were diagnosed with PDH based on clinical and laboratory data, adrenal function tests, ACTH stimulation test and UCCR combined with a high-dose oral dexamethasone suppression test, and ultrasonographic evaluation of the adrenal glands. Aminoglutethimide was administered daily at a dose of 15 mg/kg body weight for one month. Median basal cortisol concentration and post-ACTH cortisol concentration one month after treatment were significantly lower than pretreatment values. Complete response was achieved in one dog, and partial response was obtained in three dogs. Severe side-effects of anorexia, vomiting, and weakness occurred in one dog and medication was withdrawn. Two further dogs developed progression of concurrent diseases and medication was stopped in these animals as well. Mild toxicity occurred in four dogs. Moderate to severe elevations in liver enzymes occurred in all dogs. The efficacy of this drug is lower than that observed using mitotane, trilostane and ketoconazole, and adverse effects limit its use.

Metyrapone (Metopirone®; Novartis)

Metyrapone is a pharmacologic agent used in the diagnosis of adrenal insufficiency and occasionally in the treatment of Cushing disease in humans. The primary inhibitory target is 11-beta-hydroxylase and to a lesser extent 17-alpha-, 18-, and 19-hydroxylase. The availability of metyrapone varies by country.

In dogs, it has been used in patients with Cushing syndrome in an attempt to distinguish PDH from a functional adrenal tumor. No reports exist on its use in treating Cushing syndrome in dogs.

Etomidate (Amidate®; Hospira)

Etomidate is a short-acting intravenous hypnotic nonbarbiturate anesthetic agent used for general anesthesia which suppresses steroidogenesis by dose-dependent inhibition of 11-beta-hydroxylase and desmolase. It plays a particular role in human cases with significant biochemical disturbance, sepsis and other serious complications such as severe psychosis, as well as in patients who have acute contraindications to surgery and cannot tolerate oral medications.

Its use in canine surgical patients has been reported revealing adrenal suppression for 2–6 hours following a single bolus injection of 1.5–3.0 mg/kg. Its use as a continuous-rate infusion (CRI) in the management of Cushing syndrome has not been reported.

LCI699 (Novartis)

LCI699 is a potent inhibitor of aldosterone synthase and 11-beta-hydroxylase. The mechanism of action of LCI699 is similar to that of metyrapone, but LCI699 is more potent and has a longer plasma half-life (approximately 4 vs 2 h), which allows for twice-daily dosing. LCI699 is currently under investigation in a Phase III prospective safety and efficacy study in human patients with Cushing disease. No information on its use in canine patients has been reported.

NormoCort (COR-003; Cortendo)

COR-003 is a single 2S, 4R enantiomer of ketoconazole in development as a possible new drug for the treatment of endogenous Cushing syndrome. This 2S, 4R enantiomer of ketoconazole is expected to be a more potent inhibitor of key enzymes in the cortisol synthesis

pathway, and also a less potent inhibitor of a metabolic enzyme, cholesterol 7-alpha-hydroxylase (Cyp7a), than its counterpart. COR-003 is presently in Phase III studies in humans though no information is available regarding its use in dogs.

Pituitary-Directed Therapy

Recent work on somatostatin and dopaminergic receptor changes in humans and dogs with Cushing disease has opened the door to targeted therapy of pituitary tumors. Such therapies result not only in decreased ACTH production but also a reduction in tumor size. Several agents have been studied or are in clinical trials.

Pasireotide (SOM230; Signifor®; Novartis)

Pasireotide is a somatostatin receptor (SSR) ligand with high binding affinity for multiple receptor isoforms (SST1-3 and SST5). SST5 and SST2 are highly expressed in ACTH pituitary adenomas, and animal studies documented that SSR mediates inhibition of cAMP and regulation of ACTH secretion. While SST5 is most commonly overexpressed in humans, SST2 appears to be most common in dogs. Pasireotide has recently been approved for use in humans for the treatment of adult patients with Cushing disease for whom pituitary surgery is not an option or has not been curative.

SOM230 was tested in dogs suffering from Cushing disease (10 animals were treated continuously during six months, and another 10 were treated with three cycles consisting of two months of treatment followed by a two-month rest period). The dose was 0.03 mg/kg SOM230, SC q12h. Clinical and biochemical variables were evaluated at different times: before treatment and at three and six months of treatment. MRI studies at three and six months were performed. A significant decrease in ACTH, urinary cortisol creatinine ratio, adenoma size (magnetic nuclear resonance), and improvement of clinical signs were obtained, without side-effects. In this study, tumor size did not decrease in patients whose tumors were >7 mm, but there was no increase either, and there were variations in the paramagnetic signal intensities, becoming isointense. AtT20 cells treated with SOM230 suppressed proopiomelanocortin (POMC) promoter activity through SSTR2, via the G_i alpha-subunit, and reduced Nur77/Nurr1 transcriptional activity. It was concluded that SOM230, in addition to its well-described antisecretory effects, inhibits, as shown in AtT20 cells, ACTH synthesis at the POMC transcriptional level, an effect mediated mainly through SSTR2, and limits tumor growth. The controlled Cushing disease in the dogs that received the treatment indicates that SOM230 has a potential therapeutic use in dogs suffering from Cushing disease.

We recently evaluated nine client-owned dogs with PDH and macroadenoma in which PDH had been successfully managed with adrenal-directed treatment (trilostane or mitotane). Dogs were given pasireotide (0.03 mg/kg [0.014 mg/lb], SC, q12h) for six months, while adrenal-directed treatment was continued. Physical examination, basic clinicopathologic testing, ACTH stimulation testing, and plasma ACTH concentration measurement were performed before (baseline) and three and six months after treatment began. Measurements of pituitary gland volume and pituitary gland-to-brain ratio were performed via MRI at baseline and six months after treatment began. No dog developed neurologic abnormalities or signs of adverse effects during the study period. No differences from baseline were identified in clinicopathologic values, ACTH stimulation test results, or plasma ACTH concentration at the three- or six-month assessment points. After six months of pasireotide treatment, six dogs had decreases in MRI-measured values, and three had increases. Pasireotide as administered in this study had no noted adverse effects on dogs with PDH and macroadenoma successfully managed with standard treatment. Placebo-controlled, randomized studies are needed to determine whether pasireotide protects from the development of neurologic signs or improves outcome in dogs with pituitary macroadenomas.

As mentioned, while dogs seem to overexpress the SST2 receptor, a recent paper showed no decrease in cortisol concentrations in dogs treated with octreotide, a selective SST2 receptor antagonist.

Cabergoline (Dostinex®; Pfizer)

Cabergoline is a dopamine D2 receptor agonist with a higher affinity and a longer half-life than bromocriptine. In humans, its effectiveness and tolerance in the treatment of prolactinomas and growth-hormone secreting adenomas have been demonstrated. Pivonello described reduction in size of the aggressive corticotroph adenoma, which causes Nelson syndrome, while the antineoplastic effects of cabergoline have been reported in the treatment of nonfunctional tumors of corticotroph cells.

A study with follow-up for over four years was conducted in 40 dogs with PDH that were treated with cabergoline (0.07 mg/kg/week). Out of the 40 dogs, 17 responded to cabergoline (42.5%). A year after the treatment, there was a significant decrease in ACTH (P <0.0001), alpha-MSH (P <0.01), UCCR (P <0.001), and tumor size (P <0.0001) evaluated by nuclear magnetic resonance. Dogs responding to cabergoline lived significantly longer (P <0.001) than those in the control group (ketoconazole). Cabergoline may be useful in 42.5% of dogs with PDH, justifying its use as a treatment especially if a pars intermedia tumor is documented or suspected based on hormonal (elevated MSH) and imaging data.

Selegilene (L-deprenyl)

The monoamine oxidase B inhibitor L-deprenyl, which serves to raise concentrations of dopamine in the brain, has been used to treat hyperadrenocorticism in dogs. The medication appears effective in some patients (20–30%) with pars intermedia disease with few side-effects. Today, the medication is generally used in PDH patients where the cost of monitoring ACTH stimulation tests and electrolytes would prohibit treatment with adrenal enzyme blockers or adrenolytics.

Retinoic Acid

Retinoic acid is an agent that has been shown to inhibit proliferation, invasion, and tumor growth *in vivo* and induces differentiation and apoptosis in different cell types. Some of these effects are mediated by a reduction in binding of the transcription factors AP-1 and Nur77 to their cognate DNA sites; these factors are also essential in the control of the POMC gene, which gives rise to the precursor to ACTH and alpha-MSH. Recently, it was shown that retinoic acid inhibits ACTH secretion both *in vitro* and *in vivo* through an action on POMC gene transcription and also inhibits corticotrophinoma development and proliferation.

A randomized study comparing treatment with 2 mg/kg/day of 9-cis retinoic acid (n = 22) vs 20 mg/kg/day of ketoconazole (n = 20) in dogs with Cushing disease was recently performed. Clinical signs, plasma ACTH and alpha-MSH, UCCR, and pituitary MRI were assessed and compared at different time points for six months. A significant reduction in plasma ACTH, alpha-MSH, and UCCR was seen in the dogs treated with retinoic acid. Pituitary adenoma size was also significantly reduced at the end of treatment. Survival time and all the clinical signs evaluated showed an improvement in the retinoic acid-treated dogs. No adverse events or signs of hepatotoxicity were observed, suggesting that the drug is not only effective but also safe. Retinoic acid treatment controls ACTH and cortisol oversecretion as well as tumor size in dogs with ACTH-secreting tumors, leading to resolution of the clinical signs. This study highlights the possibility of using retinoic acid as a novel therapy in the treatment of ACTH-secreting tumors in humans with Cushing disease.

EGFR Receptor Antagonists

We recently demonstrated that in surgically resected human and canine corticotroph cultured tumors, blocking EGFR suppressed expression of POMC, the ACTH precursor. In mouse corticotroph EGFR transfectants, ACTH secretion was enhanced and EGF increased POMC promoter activity, an effect that was dependent on mitogen-activated protein kinase (MAPK). Blocking EGFR activity with gefitinib, an EGFR tyrosine kinase inhibitor, attenuated POMC expression, inhibited corticotroph tumor cell proliferation, and induced apoptosis. As predominantly nuclear EGFR expression was observed in canine and human corticotroph tumors, we preferentially targeted EGFR to mouse corticotroph cell nuclei, which resulted in higher POMC expression and ACTH secretion, both of which were inhibited by gefitinib.In athymic nude mice, EGFR overexpression enhanced the growth of explanted ACTH-secreting tumors and further elevated serum corticosterone levels. Gefitinib treatment decreased both tumor size and corticosterone levels; it also reversed signs of hypercortisolemia, including elevated glucose levels and excess omental fat. These results indicate that inhibiting EGFR signaling may be a novel strategy for treating Cushing disease and studies in dogs and humans are under way.

Pituitary Surgery

Several groups have described successful use of transsphenoidal hypophysectomy (TSH) as a method of treating PDH in dogs. Recently, we described a technique for transsphenoidal removal of pituitary adenomas in 26 dogs with PDH using a high-definition video telescope. Pituitary tumors were removed using a modification of a transoral transsphenoidal approach. Surgery was observed using a high-definition video telescope (VITOMTM) and localization of the sella was performed by drilling pilot holes in the basisphenoid bone followed by CT. There were no postoperative cerebrospinal fluid leaks, wound dehiscence, or surgical site infections. Overall postoperative mortality was 19%, with no mortality observed in the last 16 dogs, indicating an initial learning curve. Follow-up times ranged from three to 36 months. Sustained tumor control and hormonal remission based on normalized ACTH and UCCR measurements were observed in 20/21 (95%) of dogs at one-year follow-up.

Surgical experience and tumor size are likely important variables in dogs undergoing TSH. The survival rates at one, two, three, and four years in the study by Hanson *et al*. evaluating 181 patients were 86%, 83%, 80%, and 79%, respectively. Disease-free intervals (DFI) were 90%, 77%, 72%, and 68%, respectively.

In our study, one-year survival was 81% (all five deaths occurring within the first five days) with 100% of the surviving dogs in remission at three months and 95% (20/21) in remission at one year. To date, seven dogs have survived >2 years and one dog >3 years.

Another important variable is tumor size. All the dogs in our study had tumors with P/B ratios >0.32 and a median P/B ratio of 0.73. Both the tumor size and extent of removal were typical for this series. Median tumor volume was 820 mm^3, which is nine times larger than the median volume of 89 mm^3 reported by Hanson *et al*. In

that series of 181 dogs with PDH, mean tumor height was 6 mm, mean width 6.2 mm, and mean height 5.4 mm with a median P/B ratio of 0.3.

Forty-three percent of the dogs had a normal P/B ratio. Interestingly, Hanson *et al*. concluded that pituitary size (height) was the most significant predictor of postoperative survival and mortality. In those studies, initial remission of PDH occurred in 85% of dogs with relapse in 28% by three years.

Similarly, Hara *et al*. evaluated outcomes in 25 dogs that had TSH using the protocol of Meij *et al*. Median P/B ratio was 0.38 (range 0.24–0.71) with 24% of dogs having a normal P/B ratio. Initial remission was attained in 84% with 12% of dogs having relapse within four years. Survival at one, two, three, and four years was 92%, 81%, 81%, and 81%. No data on DFI were reported.

Continued experience with surgery for pituitary tumors in both dogs and cats will be important not only in improving survival and DFI, but it will also allow for the continued collections of tumor tissue allowing for additional studies regarding pathogenesis and novel therapies for both man and pets.

Prognosis

With medical treatment, survival time after diagnosis of PDH ranges from two to 61 months (mean 26.9 months; median,25 months). Another study evaluating ketoconazole found that after diagnosis, 50% of the dogs died approximately 1.8–2 years (range 0.6–3) after starting therapy. A recent study evaluated survival times in dogs left untreated for PDH. Median survival time for the trilostane group was not reached (95% confidence interval 443 days–not applicable) and was significantly longer than the 506 days (95% confidence interval 292–564 days; $P = 0.016$) for the untreated group.

Polyuria and Polydipsia

Jennifer L. Garcia, DVM, DACVIM (SAIM)

Houston, TX, USA

Physiology of Water Metabolism

Maintenance of water balance is very tightly regulated between the hypothalamus, pituitary gland, and kidneys. The main hormone involved in this system is arginine vasopressin (AVP) or antidiuretic hormone. AVP is produced in the hypothalamus and stored in the posterior pituitary. The primary stimulus for AVP release is an increase in plasma osmolality sensed by osmoreceptors in the hypothalamus or a decrease in extracellular fluid volume sensed by baroreceptors in the aortic sinus, left atrium, and carotid sinuses. Other factors known to stimulate AVP release include alterations in blood pressure, hypoglycemia, angiotensin II, fever, stress, nausea, pain, exercise, and various drugs, hormones, and metabolic disturbances. *Osmolarity* is the concentration of a solutionin termsof osmoles of solutes per liter of solution. Inveterinary medicine, *osmolarity* is used to estimate the osmolality or tonicityof the extracellular fluid (ECF) space.

Once released into the circulation, AVP binds to receptors on the basolateral surface of cells in the renal distal convoluted tubules and collecting ducts. This initiates insertion of aqueous (aquaporin) channels into the luminal membrane of these cells. The hypertonicity of the renal medulla can then draw free water from the urine filtrate into the distal portion of the nephron, resulting in concentrated urine. Production of concentrated or dilute urine depends on functional kidneys; once greater than two-thirds of nephrons have been lost, the patient will be unable to produce concentrated urine despite the effects of AVP. Decreased concentrating ability may be noted before azotemia is evident on routine laboratory tests.

Etiology/Pathophysiology

Polydipsia is defined as a fluid intake >90–100 mL/kg/day in dogs and >45 mL/kg/day in cats. Patients may be categorized as having primary polydipsia with secondary polyuria or primary polyuria with compensatory polydipsia.

Primary polydipsia may arise from psychogenic causes (such as behavioral or environmental issues), liver disease, neurologic disease, fever, and pain. These patients will often have hyposthenuric urine (1.001–1.005) and have low levels of AVP secondary to excessive thirst and decreased osmolality (285–295 mOsm/kg).

Causes of primary polyuria can be divided into those which result in an osmotic diuresis versus manifestations of diabetes insipidus (DI) in which there is AVP insufficiency or insensitivity.

Osmotic diuresis occurs when an osmotically active solute (e.g., glucose or urea) is present in the glomerular filtrate at a high concentration. This creates a gradient, which impedes passive reabsorption of water in the distal tubules and results in increased water loss. Illnesses such as diabetes mellitus (DM), chronic renal failure, primary renal glycosuria, and postobstructive diuresis can cause polyuria with secondary polydipsia as a result of osmotic diuresis.

Diabetes insipidus can be further categorized as central or nephrogenic. Central DI (CDI) is the less common variant of this disorder and results from a complete or partial deficiency in AVP production. Trauma, infection, congenital anomalies, neoplasia, or idiopathic processes can cause CDI.

Nephrogenic DI (NDI) refers to problems at the level of the kidney, which prevent the patient from being able to concentrate urine appropriately in response to changes in serum osmolality. These patients are insensitive to the antidiuretic effects of AVP and excrete higher than normal amounts of urine (Box 8.1).

Box 8.1 Diseases associated with secondary nephrogenic diabetes insipidus

Renal failure	Hyperadrenocorticism
Hyperglycemia	Hypoadrenocorticism
Hypercalcemia	Hypokalemia
Pyelonephritis	Hepatic disease
Pyometra	Hyperthyroidism (cats)
Leptospirosis (dogs)	Polycythemia
Acromegaly	Neoplasia
Renal medullary solute washout	Drugs (i.e., anticonvulsants, glucocorticoids, diuretics)

Nephrogenic DI can be further classified as primary and secondary. The primary form of NDI is due to an extremely rare congenital structural or functional defect of the kidneys. Secondary NDI is the most common cause of polyuria and polydipsia in veterinary medicine and is due to nonrenal causes, which interfere with the kidneys' ability to respond to AVP.

Signalment

Polyuria and polydipsia (PU/PD) can occur in any breed of dog or cat and at any age. However, certain diseases are associated with specific age groups and breeds. For example, primary polydipsia would be a consideration for a young dog whereas hyperadrenocorticism may be suspected in a middle-aged patient. Reproductive status should also be considered as conditions such as pyometra can result in these clinical signs. In addition, diseases such as Fanconi syndrome have been described in basenjis and Norwegian elkhounds.

History and Clinical Signs

A thorough history is critical when evaluating a patient with polyuria and polydipsia. A recent history of trauma, drug administration, (including topical medications), or environmental change will help narrow the list of differentials. Loss of appetite and lethargy may raise the possibility of liver or renal disease whereas polyphagia may increase the index of suspicion for hyperthyroidism in cats or hyperadrenocorticism in dogs. Diet should be discussed as well as salt content may affect water intake.

Diagnosis

First-Tier Diagnostic Tests

Physical examination findings in patients with PU/PD may be unremarkable or nonspecific. Special attention should be paid to body condition, muscle mass, hydration status, and recent changes in weight. Organomegaly and/or lymphadenopathy may raise suspicion of a neoplastic process. In cats, palpation for thyroid nodules may be useful in evaluating for possible hyperthyroidism. Females should be examined for evidence of vulvar discharge. Pyelonephritis should be suspected in patients with flank or abdominal pain.

Before embarking on a diagnostic work-up for the cause of PU/PD, it is often useful to make sure the problem truly exists. This can be done through a combination of history and evaluation of the urine specific gravity to document isosthenuria or hyposthenuria.

It may also sometimes be useful to ask the owners to quantify water intake at home (remember to discuss access to other sources of water such as ponds, pools, toilets, etc.). Water consumption may vary from day to day so assessing water intake over several days may be necessary. Polydipsia is documented in a patient with a water intake in excess of 100 mL/kg/day for dogs and 45 mL/kg/day in cats.

The urine should also be evaluated for other diagnostic clues.

- *Urine specific gravity (USG)*: Patients with normal renal function who are truly polydipsic should have a USG <1.030 in dogs and <1.035 in cats. If the USG is consistently >1.035, other problems such as incontinence or dysuria should be considered.
- *Glycosuria*: The presence of glucose may be suggestive of diabetes mellitus or, in some cases, primary renal glycosuria.
- *Proteinuria*: In conjunction with a low USG, proteinuria may be seen in patients with hyperadrenocorticism, pyelonephritis, lower urinary tract infection, or glomerulonephritis. A urine culture and/or urine protein:creatinine ratio may be warranted.

Initial diagnostics should also include a complete blood count (CBC), chemistry profile with electrolytes, and a total thyroxine level in middle-aged to older cats. A urine culture should be performed even in the face of an inactive sediment. Patients with underlying diseases such as hyperadrenocorticism or diabetes may be unable to mount an appropriate immune response so pyuria may not be noted. In addition, dilute urine can make it difficult to identify bacteriuria.

These initial tests often provide some direction as to the underlying cause (e.g., presence of azotemia or an elevation in liver values). In dogs, leptospirosis should be considered as a cause of PU/PD in endemic areas even in the absence of liver or renal abnormalities although the exact mechanism for why this occurs is not clearly understood.

The serum sodium concentration may also provide some insight into whether the patient has primary

polydipsia with secondary polyuria or polyuria with compensatory polydipsia.

- Primary polyuria (results in excess loss of free water) > elevated Na concentration > osmoreceptors sense increase in osmolality > trigger thirst response > compensatory polydipsia
- Primary polydipsia (results in excess intake of free water) > decreased Na levels > osmoreceptors sense decrease in osmolality > decrease AVP release > compensatory polyuria

It is important to note, however, that patients with hypoadrenocorticism will have a low sodium level due to mineralocorticoid deficiency despite primary polyuria.

Plasma osmolality can also be used to determine if a patient has primary polydipsia. In clinical practice, this can be estimated by calculating serum osmolality using the following formula:

$$2 \times [Na] + [BUN \text{ in } mg/dL]/2.8 + [Glu \text{ in } mg/dL]/18$$

Low osmolality is suggestive of primary polydipsia and further evaluation for hepatic disease or hyperthyroidism are indicated.

Second-Tier Diagnostic Tests

Further diagnostics will depend on physical and laboratory examination findings. For example, an abdominal ultrasound should be considered for patients with flank/abdominal pain in whom pyelonephritis is suspected. For patients in whom adrenal disease is suspected, an adrenocorticotrophic hormone (ACTH) stimulation test should be considered. It is important to remember that approximately 15% of dogs with pituitary dependent and 40% of dogs with adrenal-dependent hyperadrenocorticism can have a normal ACTH stimulation test. If hyperadrenocorticism is strongly suspected and the dog is otherwise healthy, a low-dose dexamethasone suppression test is a better option.

Other tests that may be considered, depending on laboratory findings, clinical signs, and signalment, include pre- and postprandial bile acids and imaging studies of the chest and abdomen. Imaging will be particularly useful for patients suspected of a neoplastic process and in any patient with hypercalcemia. Abdominal ultrasonography may be useful in looking for masses, enlarged abdominal lymph nodes, or adrenal enlargement.

Modified Water Deprivation Test (WDT) or DDAVP trial

A modified WDT should only be considered for patients in whom more common causes of PU/PD have been ruled out and central DI, primary NDI, or psychogenic polydipsia is strongly suspected. Fortunately, very few cases of PU/PD require performing this test.

In addition to being time-consuming and difficult to perform, for patients with underlying undiagnosed illness, this test is contraindicated and may increase the risk for complications, including death. This test should never be performed in patients who are azotemic or dehydrated. In addition, diseases such as hyperadrenocorticism may show some positive response, thereby complicating the diagnosis or resulting in misdiagnosis.

Steps for Conducting the Modified WDT

Phase 1

Patients that have had PU/PD for a prolonged period of time may have wash-out of their renal medullary concentration gradient and therefore, may be unable to concentrate their urine in the face of water deprivation. For this reason, it is recommended that once the pet's water intake has been quantified, the total amount of water given should be gradually restricted over 3–5 days until the goal of 60–80 mL/kg/day is reached. To avoid prolonged periods of water restriction, the total daily water should be calculated and provided in frequent small portions. A dry food diet should be fed during this phase. This testing will require that the owners pay very close attention to the pet for any signs of illness. Patients with severe polyuria are at increased risk for hypertonic dehydration and hospitalization during this phase of the WDT should be considered. A USG should be measured at the conclusion of this phase in case the patient has already reached a USG >1.030 (supportive of a diagnosis of psychogenic polydipsia) and the WDT is no longer required.

Phase 2

- The patient should be admitted to the hospital for a complete physical examination and assessment of hydration and mentation status.
- An indwelling urinary catheter is placed. The bladder should be emptied completely, and the USG measured.
- A blood urea nitrogen (BUN), creatinine, packed cell volume (PCV), total solids (TS), and electrolytes should be measured.
- Obtain patient's body weight.
- Patient should not have access to food or water.
- Patient should have the following performed every 1–2 hours.
  - Physical examination to assess hydration and mentation
  - Completely empty bladder and check USG
  - Obtain weight
- Every 4–6 hours check BUN, creatinine, PCV, TS, and electrolytes.
- The test should be stopped when *any* of the following occur:

Table 8.1 Currently available DDAVP preparations and common dosages

Preparation	Strength	Dose
Intranasal	100 µg/mL (1 drop = 1.5–4.0 µg desmopressin)	1–2 drops in conjunctival sac one to two times daily Or 2 µg SC one to two times daily (can be administered SC if sterilized through a bacteriostatic filter)
Injectable	4 µg/mL	2 µg SC one to two times daily
Oral	0.1–0.2 mg tablets (each 0.1 mg = approximately 4 µg desmopressin)	0.05–0.2 mg PO twice daily Bioavailability of the oral preparation may be a concern

PO, orally (*per os*); SC, subcutaneously.

- The patient loses 5% of body weight. Maximal stimulation of AVP release occurs at this point but the time required to reach dehydration may be a few hours or up to 12 hours in some patients.
- There is evidence of clinical dehydration or any vomiting, lethargy, or altered mentation is noted.
- Any evidence of azotemia.
- The USG is >1.030.

Phase 3

- If the patient is 5% dehydrated and has not produced an adequately concentrated urine, desmopressin acetate (DDAVP, a synthetic AVP analog) should be administered (see Table 8.1 for a list of desmopressin formulations).
  - Assess mentation and measure weight, BUN, creatinine, PCV, TS, electrolytes.
  - Bladder should be emptied.
  - Administer injectable DDAVP (2-10 µg IV). Alternatively, an intranasal DDAVP formulation may be administered into the conjunctival sac (1–4 drops/dog).
- Empty the bladder in 30 minutes and measure USG. Repeat every 30 minutes for up to two hours until USG >1.015. Bladder should be emptied at each time point. If USG is still below 1.015, empty bladder and measure USG every hour for up to 8 hours. At the conclusion of the test, water can be reintroduced slowly (10-20 mL/kg every 30 minutes for 2 hours).

Interpretation

If the patient achieved an adequate urine concentration during phase 1 of the test, then a diagnosis of primary (psychogenic) polydipsia can be made. AVP secretion and responsiveness are intact.

If concentrated urine was not noted at the end of phase 1, then the patient has primary polyuria – either CDI or primary NDI (causes of secondary NDI should have been ruled out prior to the WDT). Administration of DDAVP differentiates between these two possibilities.

A patient with CDI will achieve an increase in USG (>1.015) after DDAVP administration whereas a patient with NDI will show little to no response. Again, patients with secondary causes of NDI (i.e., hyperadrenocorticism) may also fail to show an elevation in USG after DDAVP administration, which is why it is imperative that secondary causes be ruled out prior to the WDT.

Interpretation may also be complicated in cases of patients with concurrent primary polydipsia and CDI or NDI.

DDAVP Response Test

In cases where more common causes of PU/PD have been ruled out and where there is a high index of suspicion for CDI, a DDAVP response test may be conducted in lieu of a WDT. This can be conducted at home as the owner continues to monitor water intake.

- Measure USG on day 1 and administer DDAVP intranasal preparation (1–4 drops) into the conjunctival sac twice daily for 5–7 days. Alternatively, the owner may administer oral DDAVP (tablet) at a dose of 0.1–0.2 mg every 8 hours for 5–7 days.
- After 5–7 days, the USG is measured again.

Animals with CDI should demonstrate an increase in the USG as well as a decrease in water intake. An animal with NDI or PP will show no response.

Patients with primary polydipsia may continue to drink excessively despite the DDAVP and there is a risk of water intoxication in these patients, which is why appropriate patient selection and owner vigilance are imperative.

Therapy

Treatment will need to address the underlying disorder. For patients with CDI, DDAVP will need to be administered daily. DDAVP can be administered topically in the conjunctival sac or a subcutaneous injection. An oral preparation is also available but may be more costly and has been shown to be less effective than parenteral administration in some patients. See Table 8.1 for recommended dosing schedules.

Regardless of the route of administration, the DDAVP dose should be titrated up gradually as needed to control the PU/PD as the effects last 8–24 hours.

For patients with primary psychogenic polydipsia, gradual water restriction and behavioral modification therapy may be warranted. Consultation with or referral to a behaviorist may be considered.

Canine Hypothyroidism

David S. Bruyette, DVM, DACVIM (SAIM)

Anivive Lifesciences, Long Beach, CA, USA

Etiology/Pathophysiology and Epidemiology

Canine hypothyroidism, while a common endocrinopathy in the dog, may be overdiagnosed due to confusion/inconsistencies in establishing a definitive diagnosis. Hypothyroidism is due to decreased thyroidal production of the thyroid hormones thyroxine (T4) and triiodothyronine (T3). Greater than 90% of cases are primary and are due to acquired immune-mediated destruction of the thyroid gland which is preceded by thyroiditis, idiopathic atrophy or, less commonly, neoplasia. Secondary forms of the disease include thyroid-stimulating hormone (TSH) deficiency, pituitary neoplasia, and cystic Rathke's pouch. Tertiary hypothyroidism with thyrotropin-releasing hormone (TRH) deficiency has not been documented in dogs. Congenital cases have been reported in both dogs and cats.

Hypothyroidism most commonly occurs in young to middle-aged dogs with an average age of 7 years. Dogs with autoimmune disease tend to develop hypothyroidism at a younger age. While thyroid values decrease within the reference range in senior dogs, hypothyroidism is very uncommon and other factors (see later) are likely responsible for the observed decreased thyroid concentrations in euthyroid older patients. Spayed females and neutered males are at increased risk when compared to sexually intact animals. Breed predispositions have been reported for golden retrievers and Doberman pinschers. Thyroiditis is heritable in the beagle, borzoi, golden retriever, Great Dane, Irish setter, Doberman pinscher, and old English sheepdogs. No known environmental factors have been identified.

History and Clinical Signs

As thyroid hormone regulates the metabolic rate and influences the functions of many organs, clinical signs are often nonspecific and insidious in onset. Many other diseases can have similar clinical signs to hypothyroidism, which may lead to an incorrect diagnosis. As such, laboratory testing of thyroid function is often performed as part of the diagnostic work-up in animals with nonthyroidal illness.

Common clinical signs include lethargy, mental dullness, weight gain, exercise intolerance, alopecia, and obesity. Many metabolic, infectious, neoplastic, congenital, degenerative, and inflammatory diseases can cause similar clinical signs and biochemical abnormalities seen with hypothyroidism.

Diagnosis

Laboratory Diagnosis

Thyroxine is the major secretory product of the thyroid while the majority of T3 is derived from extrathyroidal sources. Both T4 and T3 are highly protein bound to serum carrier proteins such as thyroid-binding globulin, transthyretin, and albumin. Only unbound (free) hormone is able to penetrate cell membranes, bind to receptors, and result in biologic activity. Protein-bound hormone acts as a reservoir to maintain steady concentrations of free hormone in the plasma despite rapid alterations in release and metabolism of T3 and T4 and changes in the plasma protein concentrations.

Companion website: www.wiley.com/go/bruyette/clinical

Serum Total T4

Serum T4 is a sensitive (>90–95%) but not specific test (70–75%) for the diagnosis of canine hypothyroidism. The vast majority of dogs with hypothyroidism have a serum T4 below normal, but some normal dogs and those with a variety of other problems may have a low serum T4. A diagnosis of hypothyroidism can be ruled out if the T4 is in the upper 50% of the reference range. Autoantibodies to T4 occur in about 15% of hypothyroid dogs, and these antibodies may falsely increase the serum T4 concentration from below normal into or above the normal range. In-house testing of total T4 is not recommended.

Serum Total T3

Serum T3 concentration is an unreliable test for evaluation of thyroid function.

Serum Free T4 (fT4)

Thyroxine is highly (99.9%) protein bound in the circulation. Protein binding can be altered by many nonthyroidal illnesses and by certain drugs. Measurement of the unbound or free hormone can provide a more accurate assessment of thyroid function in these cases (sensitivity >95%, specificity >97%). The sensitivity of fT4 is equivalent to or slightly better than total T4 in diagnosing hypothyroidism in routine cases. More importantly, fT4 is more specific, particularly when nonthyroidal factors that can influence total T4 are present. Free T4 is less affected by most nonthyroidal illness and drugs, but still can be altered in cases of moderate to severe illness. In addition, fT4 by equilibrium dialysis is not affected by the presence of T4 autoantibodies that will falsely elevate total T4. Measurement of fT4 by equilibrium dialysis should be performed when uncommon clinical signs of hypothyroidism are present, the dog is being treated with a drug that may affect thyroid function, when nonthyroidal illness is present, and if autoantibodies to T4 are detected.

Serum TSH

Primary hypothyroidism results in a decrease in T4 and thus decreased negative feedback on the pituitary gland. In response, the pituitary secretes more TSH and plasma TSH levels increase. In humans, TSH is elevated prior to any decrease of T4 or fT4 outside the normal range. In the dog, TSH concentration is elevated in only 65–75% of cases of hypothyroidism, and thus it lacks sensitivity for use as a screening test. The combination of decreased total T4 or fT4 with an elevated serum TSH is diagnostic of hypothyroidism (specificity >95%). Therefore, a normal TSH does not rule out hypothyroidism, but an elevated TSH combined with a low T4 or fT4 provides a definitive diagnosis.

Diagnosis of Thyroiditis

Antibodies against either T4 or T3 or both are sometimes present in dogs with thyroiditis with or without hypothyroidism. The presence of these antibodies does not indicate that the dog is hypothyroid, but suggests that autoimmune thyroid disease is present. These antibodies frequently cause false elevation of T4 or T3 concentrations that can result in marked elevation of the hormones. Autoantibodies to T4 are present in about 10–15% of hypothyroid dogs.

Dogs with autoimmune thyroiditis may have circulating antibodies to thyroglobulin, the primary protein in the colloid of the thyroid gland. This is not a test of thyroid function but rather a marker for the presence of autoimmune thyroiditis. In one long-term study at Michigan State University, 20% of asymptomatic, antithyroglobulin-positive dogs with normal thyroid function progressed to hypothyroidism in one year. The presence of these antibodies in a dog with borderline laboratory evidence of hypothyroidism and clinical signs supports a diagnosis of hypothyroidism.

Additional Considerations

Breeds

Certain breeds have normal ranges of thyroid hormones that are different from most other breeds. Few have been evaluated but greyhounds have serum total T4 and fT4 concentrations that are considerably lower than most other breeds. Scottish deerhounds, salukis, and whippets also have total T4 concentrations that are well below the mean concentration of dogs in general. Alaskan sled dogs have serum T4, T3, and fT4 concentrations below the reference range of most pet dogs, particularly during periods of intense training or racing.

Time of Day

In one study 50% of normal dogs had a low serum T4 concentration at some time during the day.

Medications

The drugs that are known to commonly alter thyroid function tests are glucocorticoids, phenobarbital, sulfonamides, clomipramine, aspirin, and some other NSAIDs. Glucocorticoids suppress total T4 and sometimes fT4 as well. Phenobarbital causes decreased total T4 and mild increases in TSH. Sulfonamides can induce

overt primary hypothyroidism with clinical signs and thyroid function tests that support the diagnosis. The changes may be reversible when the medication is discontinued. There are dozens of drugs that affect thyroid function and thyroid function tests in humans, so many others likely affect the dog as well.

Nonthyroidal Illness

Illness not involving the thyroid gland can alter thyroid function tests and has been labeled "nonthyroidal illness" or "euthyroid sick syndrome." Any illness can alter thyroid function tests, causing a fairly consistent decrease in total T4 and T3 concentrations in proportion to the severity of illness. Serum TSH concentration is increased in 8–10% of dogs with nonthyroidal illness. Serum fT4 measured by equilibrium dialysis is less likely to be affected, but can also be increased or decreased. However, in dogs with substantial nonthyroidal illness, the fT4 is likely to be decreased. It is recommended that testing of thyroid function be postponed until the nonthyroidal illness is resolved. If this is not possible, measurement of T4, TSH, and fT4 is indicated.

Ancillary Testing

Thyroid Gland Ultrasound

Although rarely necessary, ultrasound of the thyroid glands (by an experienced ultrasonographer) can aid in differentiating dogs with primary hypothyroidism from those with nonthyroidal illness. Thyroid glands of hypothyroid dogs tend to be smaller, less homogeneous, and hypoechoic than those of euthyroid dogs. There is considerable overlap with the ultrasonographic appearance and size of the thyroid glands of euthyroid and hypothyroid dogs. Thyroid ultrasound can only be used to help support a diagnosis of hypothyroidism if the thyroid glands are quite small.

Treatment

Levothyroxine is the only hormone that appears necessary for treatment of hypothyroidism. The frequency of levothyroxine dosing is controversial, and the only study to closely evaluate the response to treatment showed that once-daily treatment is adequate. However, in clinical practice some dogs seem to respond better to twice-daily treatment.

The initial starting dose is 0.02 mg/kg PO q24h. In general, you will never have to exceed 0.8 mg as an initial daily dosage even in very large dogs. If the dog has significant cardiovascular disease, diabetes mellitus, or hypoadrenocorticism, treatment should be instituted at 25% of the standard dose, with the dosage increased by 25% every two weeks based on clinical response and postpill testing. Most dogs show improvement within the first 1–2 weeks, with increased activity, improved attitude, and partial or complete resolution of neurologic signs. The cutaneous manifestations of hypothyroidism may take several weeks to months to resolve.

Posttreatment monitoring may be carried out but clinical response is the most important monitoring tool. Peak T4 concentrations generally occur 4–6 hours after administration of levothyroxine and should be in the high normal to slightly above normal range (40–70 nmol/L). However, the bioavailability of thyroxine ranges from 13% to 87% in the same dog from day to day, bringing into the question the utility of random postpill monitoring of TT4. It is likely more meaningful (though more expensive) to measure TSH (especially if the TSH concentration was elevated pretreatment) or fT4 concentrations after replacement therapy has been started, especially in animals that show a poor clinical response to therapy. Serum TSH concentrations should be in the normal range or undetectable and fT4 concentrations should be in the normal range. Serum concentrations of TSH and fT4 should not be performed until the patient has been on supplementation for at least two weeks. If the patient was initially started on twice-daily therapy, treatment can be reduced to once-daily treatment when a good clinical response has been obtained.

Hyperthyroidism is the most common complication of treatment with levothyroxine, but it is rare in dogs. Clinical signs are similar to those of hyperthyroidism in cats and the diagnosis is confirmed by documenting a substantial elevation of serum T4. Treatment consists of stopping levothyroxine treatment for 2–3 days, then instituting treatment at a lower dose.

Prognosis

Response to therapy should be observed in the first 4–8 weeks post treatment. Improvements in mentation and physical activity may be noted within the first week though some abnormalities, especially dermatologic signs, may take several months to resolve. An absent or incomplete response to therapy may be due to an incorrect diagnosis, poor owner compliance, inadequate dosing, or poor absorption.

Feline Hyperthyroidism

David S. Bruyette, DVM, DACVIM (SAIM)

Anivive Lifesciences, Long Beach, CA, USA

Etiology/Pathophysiology and Epidemiology

Two recent large studies have looked at possible environmental or dietary factors involved in the pathogenesis of hyperthyroidism. One of the studies with a case–control design looked at 100 cats with hyperthyroidism and 163 control cats. The cats' medical records were reviewed and the owners were asked to complete a mailed questionnaire. Data included demographic variables, environmental exposures, and diet to include the preferred flavors of canned cat food. In this study, housing, exposure to fertilizers, herbicides, regular use of flea products, and the presence of a smoker in the house were not associated with an increased risk but cats that preferred fish or liver and giblets flavors of canned cat food had an increased risk. The results suggested that cats that prefer to eat certain flavors of canned cat food may have a significantly increased risk of hyperthyroidism.

In the second case–control study, owners of 379 hyperthyroid and 351 control cats were questioned about their cats' exposure to potential risk factors, including breed, demographic factors, medical history, indoor environment, chemicals applied to the cat and environment, and diet. The association between these hypothesized risk factors and outcome of disease was evaluated. Two genetically related cat breeds (Siamese and Himalayan) were found to have diminished risk of developing hyperthyroidism. Cats that used litter had higher risk of developing hyperthyroidism than those that did not. Use of topical ectoparasite preparations was associated with increased risk of developing hyperthyroidism. Compared with cats that did not eat canned food, those that ate commercially prepared canned food had an approximate twofold increase in risk of disease. When these four variables (breed, use of cat litter, consumption of canned cat food, and use of topical ectoparasite preparations) from the univariate analysis were selected for further, a persistent protective effect of breed (Siamese or Himalayan) was found. In addition, results suggested a 2–3-fold increase in risk of developing hyperthyroidism among cats eating a diet composed mostly of canned cat food and a threefold increase in risk among those using cat litter. In contrast, the use of commercial flea products did not retain a strong association. The results of this study indicate that further research into dietary and other potentially important environmental factors (cat litter) is warranted.

Altered G protein expression was found in thyroid gland tissue from hyperthyroid cats compared to normal control cats. Adenomatous thyroid glands obtained from eight hyperthyroid cats and thyroid glands obtained from four age-matched euthyroid cats were examined for expression of G inhibitory protein (Gi) and G stimulatory protein (Gs). Expression of Gi was significantly reduced in thyroid gland adenomas from hyperthyroid cats, compared with normal thyroid gland tissue from euthyroid cats. Expression of Gs was similar between the two groups. A decrease in expression of Gi in adenomatous thyroid glands of cats may reduce the negative inhibition of the cAMP cascade in thyroid cells, leading to autonomous growth and hypersecretion of thyroxine. What we don't know is what causes the reduction in Gi in hyperthyroid cats. The factors mentioned above in the studies of environmental and dietary risk factors may play a role in altering the G protein expression found in this study.

Oncogenes and the tumor suppressor gene p53 were examined in cats with hyperthyroidism. Formalin-fixed, paraffin-embedded thyroid glands from 18 cats diagnosed with hyperthyroidism were evaluated immunohistochemically for overexpression of the products of oncogenes c-ras (a mitogenic oncogene) and bcl2 (an apoptosis inhibitor) and the tumor suppressor gene p53.

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

Fourteen thyroid glands from euthyroid cats without histologically detectable thyroid lesions were examined similarly as controls. Results from these investigations showed that all cases of nodular follicular hyperplasia/adenomas stained positively for overexpression of c-Ras protein using a mouse monoclonal antihuman pan-Ras antibody. The most intensely positively staining regions were in luminal cells surrounding abortive follicles. Subjacent thyroid and parathyroid glands from euthyroid cats did not stain immunohistochemically for pan-Ras. There was no detectable staining for either Bc12 or p53 in any of the cats. These results indicated that overexpression of c-ras was highly associated with areas of nodular follicular hyperplasia/adenomas of feline thyroid glands, and mutations in this oncogene may play a role in the etiopathogenesis of hyperthyroidism in cats. As with the study on G protein abnormalities, c-ras mutations could either be an initiating cause of hyperthyroidism or simply mediate the effects of an as yet unidentified dietary or environmental initiator.

Alterations in the thyrotropin (TSH) receptor were also examined in cats with hyperthyroidism. The authors used the polymerase chain reaction (PCR) to amplify codons 480–640 of the previously uncharacterized feline thyrotropin receptor (TSHR) gene, and determined the DNA sequence in this transmembrane domain region. They then analyzed single-stranded conformational polymorphisms in thyroid DNA from 11 sporadic cases of feline thyrotoxicosis and leukocyte DNA from two cases of familial feline thyrotoxicosis. They also determined the DNA sequence of this region of the TSHR in five of the cases of sporadic feline thyrotoxicosis and the two familial thyrotoxic cats. The normal feline TSHR sequence between codons 480 and 640 is highly homologous to that of other mammalian TSHRs, with 95%, 92%, and 90% amino acid identity between the feline receptor and canine, human, and bovine TSHRs, respectively. Thyroid gland DNA from 11 cats with sporadic thyrotoxicosis did not have mutations in this region of the TSHR gene. Leukocyte DNA from two littermates with familial feline thyrotoxicosis did not harbor mutations of this region of the TSHR gene. These studies suggested that TSHR gene mutations are likely not involved in feline hyperthyroidism.

Since its first description in 1979, the incidence of hyperthyroidism has dramatically increased, prompting veterinarians and researchers to hypothesize whether exposure to environmental thyroid-disruptor chemicals or other environmental, genetic or dietary factors are involved in the pathogenesis of hyperthyroidism. Potential exposure to several substances has been implicated, including organohalogen compounds such as polychlorinated biphenyls and polybrominated diphenyl ethers, fertilizers, soy isoflavones, bisphenol-A primarily released from "pop-top" canned cat food lids, and consumption of commercial canned food. One theory as to why the number and percentage of unexpected outliers becomes accelerated over the age of 9 years is that it may take several years of exposure to such environmental, dietary, and genetic factors before they express themselves clinically and hyperthyroidism ensues, although this topic requires further investigation.

History and Clinical Signs

With time, we have seen both an increase in the diagnosis of hyperthyroidism and a decrease in the severity of the clinical signs associated with thyrotoxicosis. This is most likely due to an increased awareness on the part of the pet owner and the veterinarian as well as the increased use of T4 concentrations as an integral part of routine feline health screening. We have also seen additional work on some of the less obvious manifestations of hyperthyroidism such as hypertension which may be clinically silent and/or present initially with ocular signs, as well as the effects of hyperthyroidism on the cardiovascular and renal system (to be discussed later).

As stated earlier, the clinical signs associated with hyperthyroidism have been decreasing in severity over the years (Box 10.1). A paper examined the electrocardiographic and radiographic changes seen in hyperthyroid cats today versus those seen 10–12 years ago. Two populations (1992–1993 and 1979–1982) of confirmed hyperthyroid cats were compared to determine whether the incidence of certain cardiovascular specific manifestations of feline thyrotoxicosis had experienced similar changes. Sinus tachycardia, which is the most commonly recognized cardiac manifestation of feline thyrotoxicosis, was not as prevalent in the 1993 group when compared to the 1982 group. This was also true for the finding of an increased R-wave amplitude on lead II electrocardiography. Both groups had a similar low incidence of atrial and ventricular dysrhythmias; however, the 1993 group had a significantly higher occurrence of right bundle branch block. Thoracic radiographs were deemed necessary in a larger proportion of the 1982 group compared to the 1993 group. Although there were

Box 10.1 Clinical signs of feline hyperthyroidism

Weight loss and poor hair coat
Aggressive or "cranky" behavior
Periodic vomiting
Polyuria and polydipsia
Increased appetite, activity, restlessness, and heart rate
Occasionally, difficulty breathing, weakness, and depression

no significant differences in radiographically defined cardiac size between the two groups, a larger number of cats in the 1982 group had evidence of congestive heart failure. These findings suggest that feline hyperthyroidism is being diagnosed earlier and with less severe clinical signs than when studied a decade ago.

Diagnosis

Diagnosis most often is based on the presence of one or more typical clinical signs and increased serum total thyroxine (T4) concentration. However, up to 10% of all hyperthyroid cats and 40% of those with mild disease have serum T4 values within reference range. The diagnosis of hyperthyroidism should not be excluded on the basis of a single normal serum T4 value, especially in a cat with typical clinical signs, a palpable thyroid nodule and serum T4 in the upper half of the normal range. In these cases, serum free T4 (fT4), measured by equilibrium dialysis, may provide an alternative means of diagnosing hyperthyroidism in cats with normal serum total T4 values. Studies document that up to 20% of sick euthyroid cats can have increased fT4 concentration. Therefore, it is most appropriate and reliable to interpret the two values together. Mid-to-high reference range total T4 and increased fT4 concentration are consistent with hyperthyroidism. In contrast, low total $T4_4$and increased fT4 values are usually associated with nonthyroidal illness. In cases where a strong index of suspicion exists for hyperthyroidism and test results are equivocal, thyroid imaging can be of benefit.

Treatment

Once hyperthyroidism has been diagnosed, all management options (thyroidectomy, radioactive iodine, antithyroid drugs, nutritional management) should be discussed with pet owners. All options can be ≥90% effective for controlling hyperthyroidism when used appropriately. The selected management option will differ for each cat based on several considerations (Table 10.1). Radioactive iodine therapy is considered the gold standard for treatment of hyperthyroidism but most pet owners currently opt for medical management. Until recently, this included oral or transdermal antithyroid drugs. Now nutritional management using a limited-iodine food is another option for cats with hyperthyroidism.

Radioactive Iodine

Radioiodine treatment is often considered the best option for many hyperthyroid cats because:

- it has the potential to eliminate a benign thyroid tumor or abnormal thyroid tissue with a single treatment
- it treats extrathyroidal thyroid tissue, which may occur in 10–20% of hyperthyroid cats
- no general anesthesia is required
- reported side-effects are minimal.

Cats should be stable prior to radioiodine therapy; those with clinically significant cardiovascular, renal, gastrointestinal, or endocrine (e.g., diabetes mellitus) disease may not be very good candidates, especially because of the time necessary for boarding after treatment.

Table 10.1 Advantages/disadvantages of options for managing cats with hyperthyroidism

Option	Advantages	Disadvantages
Thyroidectomy	Cures current tumor	High initial costs Requires anesthesia Hospitalization required Risk of postoperative hypocalcaemia **Irreversible**
Radioactive iodine	Cures current tumor Single treatment Effective for ectopic tissue Side-effects uncommon	High initial costs Limited availability Hospitalization required **Irreversible**
Antithyroid drugs	Routinely available Reversible Costs spread over time	Not curative (controls T4 and signs) Daily administration needed Drug side-effects
Limited-iodine food	Routinely available Reversible Costs spread over time	Not curative (controls T4 and signs) Cat can only eat a single food

After administration, radioactive iodine is actively concentrated by the thyroid gland and has a half-life of eight days. It emits both beta-particles and gamma-radiation; the beta-particles are responsible for the majority of tissue destruction, but are only locally destructive, traveling a maximum of 2 mm. Therefore, no significant damage to adjacent parathyroid tissue, atrophic thyroid tissue, or other cervical structures is expected. The main limitation to widespread use of radioactive iodine is the requirement for special licensing and the isolation of the cat for variable periods after treatment. This can range from several days to several weeks depending on state or local radiation regulations and the dose administered.

The goal of treatment is to restore euthyroidism with the smallest possible single dose of radioactive iodine, while avoiding development of hypothyroidism. Controversy exists as to the best method of calculating the optimum dose for individual cats. Based on the majority of reported cases, posttreatment hypothyroidism is transient and generally uncommon (2–7% of cases); even fewer cats have clinical signs or appear to require thyroid hormone replacement. However, up to 30% (50 of 165 cats) were hypothyroid three months after radioactive iodine therapy in one study; of these, 56% (19 of 34 hypothyroid cats with available information) had clinical signs of hypothyroidism and 52% (23 of 44 cats) were given thyroid hormone supplementation. Thyroid hormone replacement may be needed in some cats, especially those with concurrent kidney disease, since hypothyroidism has been associated with azotemia and decreased survival time in previously hyperthyroid cats. Owners should be advised of this possibility, particularly if their motivation is to avoid long-term oral medication.

Antithyroid Drugs

Antithyroid drugs (e.g., methimazole, carbimazole) are commonly used for treatment of hyperthyroidism in cats. If administered appropriately, they reliably inhibit the synthesis of thyroid hormones and thereby lower serum thyroid hormone concentrations. These drugs do not affect the thyroid gland's ability to trap inorganic iodide or release preformed hormones. They are widely recommended to stabilize hyperthyroid cats prior to surgery and are the only drugs that can be used chronically for management of hyperthyroidism. Almost all cats are potential candidates unless thyroid carcinoma is suspected.

Antithyroid drugs used most often in cats include methimazole and carbimazole; both can be given orally or formulated for transdermal application. Custom formulation of transdermal products may increase the expense of therapy and stability of the product is not guaranteed. Results of a recent prospective study conducted in New Zealand showed that once-daily treatment for 12 weeks with transdermal methimazole in a novel lipophilic vehicle was as effective as twice-daily carbimazole administered orally.

While many cats have been successfully managed long term with antithyroid drugs, it is important to monitor for potential side-effects that have been associated with their use. In the study with the largest number of cats, 18% had side-effects associated with methimazole; a more recent study revealed that 44% of 39 cats had side-effects. In 44 cats receiving carbimazole for one year, 44% had associated side-effects, with gastrointestinal signs (decreased appetite, vomiting, diarrhea) being most common. In another study, 13% of 39 cats treated with carbimazole experienced side-effects. It is difficult to determine what percentage of side-effects are caused by the drug versus something else such as concurrent disease.

Most adverse reactions occur within the first few weeks to months after beginning therapy and include depression, inappetence, vomiting, and self-induced excoriations of the head and neck (facial pruritus). Gastrointestinal signs are less common with transdermal administration of methimazole. Mild to serious hematologic complications, including agranulocytosis and thrombocytopenia either alone or concurrently, and more rarely immune-mediated hemolytic anemia may also occur. Hepatic toxicity with marked increases in bilirubin concentration and hepatic enzyme activities has been described in less than 2% of cats treated with methimazole. Cessation of therapy is required if either serious hematologic or hepatic reactions develop. Serum antinuclear antibodies develop in approximately 50% of cats treated with methimazole for longer than six months, usually in cats on high-dose therapy (>15 mg/day). Although clinical signs of a lupus-like syndrome have not been reported, decreasing the daily dosage is recommended.

Nutritional Management

Production of thyroid hormone requires uptake by the thyroid gland of sufficient amounts of iodine, which is provided by dietary intake. The only function for ingested iodine is for thyroid hormone synthesis. This observation led to the hypothesis that limiting dietary iodine intake could be used to control thyroid hormone production and potentially manage hyperthyroidism in cats. After more than a decade of research and development, a limited-iodine therapeutic food (Hill's® Prescription Diet® y/d™ Feline) containing <0.3 ppm (mg/kg) iodine on a dry matter basis (DMB) is now available as an option for managing cats with hyperthyroidism.

Three studies were designed to determine the magnitude of iodine control necessary to return newly diagnosed cats to a euthyroid state; the maximum level of dietary iodine that maintains cats in a euthyroid state; and the effectiveness of a therapeutic food formulated based on the previous studies to control naturally occurring hyperthyroidism in cats. In summary, results of these studies demonstrated that a food with 0.17 or 0.32 ppm iodine (DMB) maintained normal thyroid hormone concentrations in hyperthyroid cats, helping to further define the range of iodine effective for managing hyperthyroidism.

After confirming the diagnosis and performing a thorough patient evaluation, nutritional management should be discussed along with other options for managing hyperthyroidism. If selected as the management option, gradual transition to the limited-iodine food over at least seven days is recommended. It is very important to counsel owners so they understand that success of nutritional management depends on the limited-iodine food being the sole source of nutrition for their cat.

The first recheck evaluation should be done four weeks after completing the transition to y/d Feline (i.e., once the cat has eaten y/d exclusively for four weeks) and as a minimum should include physical examination and measurement of T4, BUN, serum creatinine, and urine specific gravity. All cats should have decreased T4 concentrations compared with baseline and many will have returned to normal by the four-week evaluation. Clinical improvement including weight gain, improved hair coat, and decreased tachycardia/cardiac murmur also may be noted by the first evaluation. Clinical signs should continue improving by the next reevaluation at eight weeks and most cats will be euthyroid. Some require slightly longer to become euthyroid but it is expected that 90% will have normal T4 concentrations if the limited-iodine food is their sole source of nutrition.

If euthyroidism is not achieved within 4–12 weeks, a thorough history is indicated to confirm that only the limited-iodine food is being fed.

Managing Hyperthyroid Cats with Concurrent Kidney Disease

Chronic kidney disease (CKD) and hyperthyroidism are more likely to be diagnosed in older cats so it is not surprising that many hyperthyroid cats have CKD. Untreated hyperthyroidism complicates the diagnosis of CKD because it is associated with increased glomerular filtration rate (GFR) and therefore often masks biochemical markers of CKD. Regardless of the therapeutic modality (methimazole, surgical thyroidectomy, or radioiodine), decreased GFR, increased serum urea and creatinine concentrations, and development of overt clinical signs of kidney disease have been reported after successful treatment of hyperthyroidism. The presence of underlying CKD may affect the prognosis; one study documented a shorter survival time in hyperthyroid cats with azotemia. However, two recent studies comparing survival of cats that developed azotemia with those that did not after treatment of hyperthyroidism found no significant difference between the two groups if cats did not become hypothyroid post treatment.

The reported occurrence of azotemia after treatment of hyperthyroidism ranges from 15% to 49%. Iatrogenic hypothyroidism has been reported to decrease GFR in human patients. Posttreatment iatrogenic hypothyroidism has been reported in cats after radioiodine therapy and bilateral thyroidectomy, which constituted the predominant therapeutic modalities in previous studies. In one recent study, cats with iatrogenic biochemical hypothyroidism were almost twice as likely to develop azotemia post treatment as euthyroid cats. The hypothyroid cats with azotemia had shorter survival times than those without azotemia, whereas, consistent with previous reports, there was no difference in survival times of euthyroid cats with or without azotemia.

It is not possible to consistently predict which cats will develop overt CKD after treatment of hyperthyroidism or have progression of their kidney disease. This should be considered when deciding on treatment options, particularly those that are irreversible (thyroidectomy, radioactive iodine). Regardless of the option selected for managing hyperthyroidism, it is important to remember that the only intervention shown to improve quality of life and prolong survival time in cats with naturally occurring CKD is feeding a therapeutic renal food. Until the recent availability of limited-iodine food, nutritional recommendations have not generally been considered for hyperthyroid cats without azotemia. In cats with compromised renal function but without azotemia (IRIS Stage 1), the decrease in GFR associated with normalizing serum T4 levels may be sufficient to prevent effective clearing of protein metabolic by-products (BUN and creatinine) when dietary intake of protein and phosphorus is high. This could contribute to the occurrence of post-therapy azotemia in hyperthyroid cats.

Prognosis

Although older studies report survival times of two years after diagnosis, more recent data show that cats without concurrent CKD have a median survival of 5.3 years. Untreated hyperthyroidism is a progressive disease that can lead to significant morbidity and mortality. Morbidity and mortality in well-managed hyperthyroid cats are more strongly influenced by the presence and severity of the co-morbid disease than the hyperthyroidism itself.

Hypoadrenocorticism in Dogs and Cats

Patty Lathan, VMD, DACVIM (SAIM)

Mississippi State University, College of Veterinary Medicine, Mississippi State, MS, USA

Hypoadrenocorticism in Dogs

Etiology/Pathophysiology

Primary hypoadrenocorticism (Addison disease, HOAC) results from the destruction of >90% of the adrenal cortex. Clinical signs are due to both cortisol and aldosterone deficiency in the majority of patients, although some patients only have signs of cortisol deficiency (atypical hypoadrenocorticism).

Aldosterone is the major mineralocorticoid secreted by the outermost layer of the adrenal cortex, the zona glomerulosa. Its main activities are the conservation of sodium and water, and excretion of potassium and hydrogen ions (acid), from the distal renal tubules. Aldosterone secretion is primarily regulated by the renin-angiotensin-aldosterone system, but secretion can also be stimulated by hyperkalemia. In patients with hypoadrenocorticism and subsequent aldosterone deficiency, hyperkalemia, hyponatremia, and hypovolemia are common.

Cortisol is the major glucocorticoid produced by the innermost layers of the adrenal cortex, the zonae fasciculata and reticularis. Its functions include stimulation of gluconeogenesis and erythropoiesis, suppression of the inflammatory response, and maintenance of gastrointestinal mucosal integrity. Cortisol also helps the body deal with stress. In dogs with HOAC, cortisol deficiency often results in lethargy, gastrointestinal signs, hypoglycemia, and anemia.

Cortisol release is regulated by the hypothalamic-pituitary-adrenal axis (HPAA). During times of stress (emotional, physiologic, other), corticotropin-releasing hormone (CRH) is secreted from the hypothalamus, and stimulates the release of adrenocorticotropic hormone (ACTH) from the pituitary gland. ACTH then stimulates cortisol secretion from the adrenal cortex. Cortisol has a negative feedback effect on both the pituitary and hypothalamus, such that ACTH and CRH production are decreased when adequate cortisol concentrations are present.

Most naturally occurring cases of primary hypoadrenocorticism in dogs are idiopathic, likely due to immune-mediated destruction of the adrenal cortex. Rarely, infiltration of the adrenal cortex by fungus, neoplasia, other granulomatous disease, or amyloidosis has been reported. Trauma, hemorrhage, and infarction may also lead to Addison disease, as can drugs used to treat hyperadrenocorticism. Although proper use of mitotane usually leads to necrosis of only the zonae fasciculata and reticularis, improper monitoring, or use in a particularly sensitive patient, can result in destruction of all three layers of the cortex, causing both cortisol and aldosterone deficiency. Trilostane is an enzyme inhibitor that decreases cortisol concentrations, but also decreases aldosterone concentrations to a lesser extent. It can lead to cortisol deficiency and, occasionally, aldosterone deficiency. Additionally, trilostane has been reported to cause idiosyncratic adrenocortical necrosis, resulting in both cortisol and aldosterone deficiency.

Secondary hypoadrenocorticism can be caused by either a pituitary lesion, resulting in ACTH deficiency, or iatrogenically. Iatrogenic secondary hypoadrenocorticism is caused by abrupt cessation of exogenous glucocorticoids following long-term use. Long-term use of glucocorticoids suppresses production of ACTH. Without the trophic effects of ACTH, the zonae fasciculata and reticularis atrophy. When the exogenous glucocorticoid is abruptly discontinued (not tapered), ACTH production occurs, but the adrenal cortex is atrophied and incapable of producing adequate amounts of cortisol. Thus, signs of cortisol deficiency occur. Aldosterone deficiency is not present in cases of secondary hypoadrenocorticism, since ACTH has little regulatory control of aldosterone production.

Companion website: www.wiley.com/go/bruyette/clinical

Epidemiology

Hypoadrenocorticism affects approximately 1/2000 dogs. Dogs with other immune-mediated endocrinopathies, such as hypothyroidism and diabetes mellitus, are at increased risk.

Signalment

Young to middle-aged female dogs are predisposed to Addison disease, although dogs at any age may be affected, with some studies revealing a more equal distribution between sexes. Poodles of all sizes, West Highland white terriers, Great Danes, bearded collies, Portuguese water dogs, Leonbergers, and Nova Scotia duck-tolling retrievers (NSDTRs) are predisposed. Notably, NSDTRs may develop clinical signs at a very young age (as young as 2 months). Heritability has been proven in standard poodles, bearded collies, and NSDTRs.

History and Clinical Signs

The clinical manifestation of hypoadrenocorticism is highly variable in presenting complaint, chronicity, and severity. Whereas some dogs present with chronic signs, others present acutely, in an "Addisonian crisis." The pathophysiology for chronic and acute hypoadrenocorticism is the same, and these presentations represent a continuum of disease progression. If not diagnosed and treated early in the course of disease, dogs with chronic signs may present in crisis.

Addison's disease often causes vague, nonspecific clinical signs that can be confused with other diseases, thus its nickname "The Great Pretender." Nonspecific signs such as lethargy, inappetence, and weight loss occur in most patients. A waxing and waning pattern, with exacerbations following stressful events or improvement following fluid or steroid administration, is often noted.

Gastrointestinal signs, including vomiting and diarrhea, are common and likely due to the loss of "trophic" effects of cortisol on the gastrointestinal mucosa. Melena and/or hematochezia, and abdominal pain, may be reported by the owners or found on rectal examination. Exacerbation or onset of gastrointestinal (GI) signs following a stressful event is often reported in dogs later diagnosed with Addison disease, so HOAC should be considered in patients with recurrent "stress colitis," particularly if accompanied by other GI signs, lethargy, or weakness.

Renal loss of sodium and water, and the resulting decreased renal medullary concentration gradient due to hyponatremia, sometimes lead to polyuria and polydipsia. Rarely, seizures due to hypoglycemia occur, and HOAC should be ruled out in all dogs with unexplained hypoglycemia.

Less common clinical signs include generalized or hindlimb muscle weakness, megaesophagus (ME), and muscle cramping. The etiology of these abnormalities is unclear, but is probably due to aberrant neuromuscular function caused by deranged electrolyte concentrations and/or hypocortisolemia. Muscle weakness can be severe, and the patient may present for inability to rise. Generalized debility could explain the weakness, but some of these dogs are specifically weaker in the hindlimbs. Regurgitation due to ME is a rare presentation for hypoadrenocorticism, but since the ME usually resolves with appropriate treatment, HOAC should be ruled out in all cases of ME.

Hair loss or a change in hair coat color are observed occasionally in dogs with hypoadrenocorticism, but the cause is unknown. Hypothyroidism should be ruled out in these patients following initial management of HOAC.

Approximately 30% of dogs with Addison disease present in hypovolemic shock, or Addisonian crisis. In addition to the aforementioned clinical signs, especially vomiting, diarrhea, and GI bleeding, these dogs sometimes experience collapse and/or severe generalized weakness. Classic signs of hypovolemic shock are usually present, including weak pulse, pale mucous membranes, and prolonged capillary refill time. Some dogs are also hypothermic. Heart rate is variable. Whereas most hypovolemic non-Addisonian dogs are tachycardic (>160 bpm), patients in an Addisonian crisis often have a normal to decreased heart rate. This is due to the effects of hyperkalemia on cardiac conduction. The presence of a decreased or normal heart rate in a patient in hypovolemic shock ("relative bradycardia") should raise suspicion of hyperkalemia and hypoadrenocorticism. In patients with cardiac changes associated with hyperkalemia, rapid treatment and correction are critical for the survival of the patient.

Gastrointestinal bleeding, including melena and hematochezia, is frequently seen during crisis. It may be present initially or appear within 2–3 days of presentation. Progressively decreasing hematocrit during treatment should increase suspicion of melena, and the possibility of GI bleeding should not be excluded despite the absence of melena or hematochezia on the initial examination. Hospitalization is recommended until the hematocrit stabilizes or increases. GI blood loss is occasionally severe enough to require blood transfusion.

Diagnosis

Since dogs with HOAC often present with nonspecific signs, most of the diagnostics are performed early in the work-up, prior to significant suspicion of hypoadrenocorticism. A complete blood count, serum biochemistry analysis, and urinalysis should be performed in each

patient with clinical signs consistent with hypoadrenocorticism. Electrolyte analysis must be included in the minimum database, as sodium and potassium abnormalities are often the first specific indicators of HOAC, and electrolyte disturbances are common in patients with gastrointestinal signs of any etiology, and need to be addressed during treatment.

Serum Biochemistry, Urinalysis, and Complete Blood Count

Most dogs with HOAC are hyperkalemic and hyponatremic at diagnosis. Dogs with "atypical" hypoadrenocorticism are not (see Atypical Hypoadrenocorticism later). Potassium concentrations usually remain below 8 mEq/L, but may be as high as 11 mEq/L. Sodium concentrations are usually 120–140 mEq/L, but may be as low as 100 mEq/L. Some dogs present with one abnormality without the other (e.g., hyponatremia without hyperkalemia). Hypochloremia follows hyponatremia in about half the patients. Metabolic acidosis is also common, due to the inability to excrete H+ ions from the distal tubule.

Electrolyte abnormalities are not always detected early in the course of the disease, and may appear as disease progresses. Emphasis is sometimes placed on calculation of the Na+/K+ ratio. The lower the sodium and the higher the potassium concentration, the lower the ratio. Although lower ratios make HOAC more likely, a high ratio does not rule it out, and dogs with low ratios do not always have HOAC. Therefore, the utility of the ratio is questionable. Any dog with hyponatremia and/or hyperkalemia should be considered a suspect for HOAC, regardless of the ratio.

Most patients experience some degree of azotemia, with increased BUN (90% of dogs) and creatinine (65%). This is due to a combination of decreased renal perfusion from hypovolemia, and GI blood loss (increased BUN). Phosphorus is usually increased, as well. Although the azotemia is primarily pre-renal in nature, most dogs with HOAC have a urine specific gravity <1.030 (often <1.020), which is more dilute than expected with pre-renal azotemia alone. For this reason, and the presence of hyperkalemia and hyponatremia, some Addisonian patients are initially misdiagnosed with acute kidney injury (AKI). Given the difference in prognosis and treatment, clinicians must consider HOAC in every suspected AKI patient, especially if the dog has a history of gastrointestinal signs. Severe azotemia caused by HOAC usually resolves quickly following appropriate rehydration. Primary renal damage is possible with prolonged hypovolemia, but most Addisonian patients recover renal function. Conversely, patients with AKI take much longer or never improve. Additionally, significant hyperkalemia and hyponatremia rarely occur in polyuric AKI patients, but often occur in anuric and oliguric AKI dogs. Addisonians may initially present with physiologic oliguria (appropriately decreased urine production in the face of hypovolemia and/or dehydration). However, rehydration results in polyuria. Thus, if a hypovolemic, azotemic, hyperkalemic, hyponatremic dog has significant improvement of attitude and becomes polyuric upon rehydration, HOAC should be strongly considered as a differential diagnosis.

Hypocholesterolemia and hypoalbuminemia occur in approximately 10% and 15% dogs with HOAC, respectively. Both might be due to decreased hepatic production and GI malabsorption. GI blood loss exacerbates the hypoalbuminemia in some cases.

Hypoglycemia is present in about 15% of HOAC dogs, probably due to decreased gluconeogenesis and increased insulin sensitivity. It is usually subclinical, but occasionally can be severe enough to result in seizures. Thus, hypoadrenocorticism should be a differential diagnosis in adult dogs with unexplained hypoglycemia.

Total and ionized hypercalcemia occurs in about 30% of Addisonians. It is not usually the presenting complaint, but HOAC should be considered a differential diagnosis in hypercalcemic patients.

Increased alanine aminotransferase (ALT), alkaline phosphatase (ALP), and aspartate aminotransferase (AST) are also frequently seen (20–30%) in HOAC dogs, possibly secondary to hepatic hypoperfusion and cholestasis.

At diagnosis, about 30% of Addisonian dogs are anemic. This increases to 70% following rehydration. It is usually a mild normochromic, normocytic, nonregenerative anemia, and GI blood loss should be suspected in patients with severe anemia. The lack of a stress leukogram (neutrophilia, lymphocytosis, monocytosis, and eosinopenia) in a sick dog is suggestive of HOAC. Occasionally, lymphocytosis and eosinophilia occur (10%), but neutropenia is rare.

Diagnostic Imaging

Diagnostic imaging is not required to diagnose HOAC in most patients, but abdominal imaging is often performed in the initial work-up of patients with gastrointestinal signs. Imaging is recommended, however, in Addisonian patients that do not respond to appropriate therapy. These patients may have concurrent disease or HOAC due to infiltrative disease (e.g., neoplasia or fungal disease invading the adrenal cortex).

In patients with primary idiopathic HOAC, abdominal radiographs and ultrasound may reveal a small liver, consistent with hypovolemia. Adrenal gland length and thickness might be smaller than in normal dogs, but the overlap in adrenal size between normal and HOAC patients does not allow definitive differentiation. Thoracic radiographs

often reveal nonspecific signs of hypovolemia, including microcardia. Megaesophagus is seen infrequently.

Electrocardiogram

Additional diagnostics for patients that present in hypovolemic shock include blood pressure measurement and electrocardiography. ECG abnormalities are caused by hyperkalemia. Although rigid criteria associating specific ECG findings with specific potassium concentrations do not exist, cardiac effects are rarely seen when K+ <7.0 mEq/L, and frequently observed when K+ >9 mEq/L (and may be fatal). With increasing severity of hyperkalemia, ECG changes may include increased T-wave amplitude ("spiked" T wave), shortened Q-T interval, decreased P-wave amplitude, prolonged P-R interval, absent P-wave, severe bradycardia, and asystole. Bizarre QRS complexes, including ventricular tachycardia and ventricular fibrillation, may also occur. Patients with ECG abnormalities require immediate interventions to prevent progression to a fatal arrhythmia.

Endocrine Diagnostics

The ACTH stimulation test is required for definitive diagnosis of hypoadrenocorticism. A baseline cortisol concentration alone can help rule out the diagnosis of HOAC, but cannot be used to definitely diagnose it.

During an ACTH stimulation test, a supraphysiologic dose of ACTH is administered, and the cortisol concentration is measured 1–2 hours later. In a dog with normally functioning adrenal glands, ACTH should cause a significant increase in cortisol concentration. In HOAC dogs, minimal to no increase in cortisol will occur.

To perform an ACTH stimulation test, a baseline serum sample is first obtained. Then, 1 µg/kg (up to 250 µg/dog) of synthetic ACTH (cosyntropin or tetracosactrin) is administered intravenously. One hour later, another serum sample is obtained. Cortisol concentration is then measured in both pre- and post-ACTH serum samples.

Protocols for the ACTH stimulation test vary when testing for HOAC or hyperadrenocorticism. The use of compounded ACTH gel is not recommended for the diagnosis of hypoadrenocorticism, due to inconsistent results. Additionally, since dogs with HOAC are often hypovolemic, intramuscular administration of ACTH is not recommended.

The diagnosis of HOAC requires a post-ACTH cortisol concentration <2 µg/dL (55 nmol/L), with a post-ACTH cortisol concentration >2 µg/dL ruling out the diagnosis. Rarely, dogs with HOAC have a post-stimulation cortisol between 2 and 3 µg/dL. Note that this test does not differentiate between primary, secondary, and iatrogenic Addison disease. However, iatrogenic HOAC, due to long-term administration of glucocorticoids, should be identified based on historical findings.

Administration of glucocorticoids prior to an ACTH stimulation test can interfere with and/or cause decreased response to the test. Most synthetic glucocorticoids, including prednisone and methylprednisolone, cross-react with the cortisol assay, which can result in falsely increased cortisol concentrations. Dexamethasone and triamcinolone do not. Thus, if a steroid is given just prior to the test, dexamethasone is recommended. Other short-acting glucocorticoids (such as prednisone) should be withheld for 12–24 hours prior to the test. Longer-acting glucocorticoids, such as methylprednisolone acetate, should be withheld for at least four weeks prior to the test to avoid cross-reactivity.

Administration of glucocorticoids decreases endogenous ACTH concentrations, which causes atrophy of the adrenal cortex (fasciculata and reticularis). A blunted cortisol response during the ACTH stimulation test is expected in patients that have received glucocorticoids (oral, parenteral, or topical) within a month of the test, or longer if longer-acting glucocorticoids (such as methylprednisolone acetate) have been administered. A post-stimulation cortisol between 2 µg/dL and 5 µg/dL is often the result of recent steroid administration and not hypoadrenocorticism.

One way to save money with ACTH stimulation tests is to freeze the unused portion of a vial of cosyntropin. Cosyntropin can be frozen in plastic syringes (not glass, as it binds to ACTH) for up to six months. The use of a frost-free freezer is not recommended, as the effect of the freeze/thaw cycles on the ACTH is unknown.

A baseline cortisol concentration is a less expensive way to rule out hypoadrenocorticism. Since the cortisol concentration in almost any patient with HOAC is <2 µg/dL, a baseline cortisol concentration of >2 µg/dL rules out the diagnosis in most dogs. However, if the patient has a baseline cortisol concentration <2 µg/dL, an ACTH stimulation test is required for definitive diagnosis of HOAC.

For the definitive diagnosis of primary hypoadrenocorticism, a potential alternative to the ACTH stimulation test is the cortisol-to-ACTH ratio (CAR). Since dogs with HOAC have low cortisol concentrations and high ACTH concentrations (due to lack of negative feedback), the CAR is significantly lower in patients with hypoadrenocorticism than in normal dogs or dogs with nonadrenal illness (Lathan et al, 2014, *JVIM*). Unfortunately, there is some overlap between dogs with Addison's and dogs with non-adrenal illness (Boretti et al, JVIM, 2015). Thus, at this time, the CAR cannot be recommended for definitive diagnosis of HOAC when synthetic cosyntropin is available.

Therapy

Acute Management

Patients with hypoadrenocorticism fall along a continuum of disease. While some patients present in hypovolemic shock with severe hyperkalemia, most are less critical, but require intravenous fluids and other supportive therapy. The most severe cases (true Addisonian crises) will be discussed in this section.

The initial goal of treatment of Addisonian crisis is to correct hypovolemia, hyperkalemia and associated arrhythmias, hypoglycemia, and acidosis. Aggressive intravenous fluid resuscitation is the top priority. In addition to correcting hypovolemia, it also helps treat hyperkalemia, hyponatremia, hypochloremia, and acidosis. One-third of a shock bolus of crystalloids is given initially, and response is assessed based on heart rate, pulse quality/blood pressure, capillary refill time, and mental status. Additional fluids are then given as necessary.

Historically, 0.9% NaCl has been recommended as the fluid of choice, since it contains sodium and chloride but no potassium. However, Normosol-R®, Plasma-Lyte A®, and/or lactated Ringer's solution (LRS) are preferred by some clinicians, since they are more alkalinizing than saline, thus correcting acidosis more efficiently. Although they contain a small amount of potassium, these crystalloids still allow for correction of hyperkalemia via dilution and increased renal perfusion. Hydroxyethyl starch can also be used in conjunction with crystalloids for more rapid fluid resuscitation, at a dosage of 5–10 mL/kg.

Sodium concentration should not be increased by more than 0.5 mEq/kg/h, as myelinolysis may occur with more rapid correction. Thus, hypertonic saline should not be used to treat an Addisonian crisis. Normosol-R, Plasma-Lyte A, and LRS all have lower sodium concentrations than 0.9% saline (140 mEq/L, 140 mEq/L, 130 mEq/L, and 154 mEq/L, respectively). Their use is sometimes preferred in patients with severe hyponatremia, as they are less likely to increase the serum sodium concentration as rapidly as 0.9% saline.

Hyperkalemia is often the most life-threatening consequence of HOAC, and must be addressed immediately. Mild to moderate hyperkalemia usually responds to fluid therapy alone. However, severe hyperkalemia (>9 mEq/L) and/or hyperkalemia accompanied by life-threatening arrhythmias (severe bradycardia, absent P-waves, idioventricular rhythm) require specific therapy.

Calcium gluconate is given for its cardioprotective effects, allowing time for fluids and other therapies to take effect. However, it does not directly decrease the potassium concentration. A dosage of 0.5–1.5 mL/kg of 10% calcium gluconate is given slowly over 15 minutes, while monitoring the ECG. Rapid administration may cause additional arrhythmias, such as shortened Q-T interval and more severe bradycardia.

Intravenous regular insulin helps drive the potassium intracellularly. Dosages of 0.2–0.5 U/kg regular insulin are administered, followed by 2 g of dextrose (diluted to 25% in an isotonic crystalloid) per unit of insulin administered. Dextrose should then be added to the intravenous fluids (e.g., 0.9% saline or LRS) to produce a 1.25–2.5% dextrose solution, and blood glucose should be monitored. Generally, 5% dextrose alone (D5W) should not be given, as it becomes hypotonic and enters the interstitial space once the dextrose is metabolized.

Hypoglycemia is uncommon, but should be treated with an IV dose of 1 mL/kg of 25–50% dextrose in a 1:1 solution of dextrose and 0.9% saline. Maintenance fluids should then be supplemented with dextrose to make a 1.25–5% dextrose solution.

Glucocorticoid deficiency is responsible for the hypoglycemia, gastrointestinal signs, and general debility of patients in crisis, and may also contribute to hypotension. Supplementation should be instituted after the life-threatening issues (hypovolemia, hyperkalemia, and hypoglycemia) have been initially addressed. Dexamethasone sodium phosphate (0.25 mg/kg IV) is recommended, since it does not cross-react with the cortisol assay. Since it has approximately eight times the glucocorticoid activity of prednisone, this is equivalent to 2 mg/kg of prednisone, or 10 times the physiologic dose. Higher doses previously recommended (such as 2 mg/kg) are excessive and unnecessary. Hydrocortisone sodium succinate (0.5 mg/kg/h), cortisol acetate (1 mg/kg), and prednisolone sodium succinate (2 mg/kg) can also be used. However, since they cross-react with the cortisol assay, they should not be given until after the ACTH stimulation test.

Additional supportive therapy is provided as necessary. Dogs with gastrointestinal signs are given gastroprotectants, including proton pump inhibitors (omeprazole or pantoprazole, which can be given IV) and sucralfate. Due to potential bacterial translocation from the GI tract, dogs with significant GI signs may be given prophylactic antibiotics (such as ampicillin), but this is controversial. Packed red cell or whole blood transfusion is occasionally necessary in dogs with severe GI blood loss.

Frequent reassessment of patients is necessary following initial stabilization. Fluid rates should be adjusted to correct dehydration and azotemia. The ECG should be reassessed until arrhythmias resolve. Electrolyte concentrations should be rechecked following initial stabilization, and then every 6–12 hours until potassium and sodium concentrations normalize.

Intravenous fluids are continued until the dog is able to eat and maintain hydration on its own, and

mineralocorticoid supplementation (fludrocortisone or DOCP) is provided following definitive diagnosis of HOAC. Dexamethasone should be continued at a dose of 0.15–0.2 mg/kg/day until prednisone can be given orally. Prednisone is then started at 0.5 mg/kg BID. Following discharge of the patient, prednisone is usually tapered to approximately 0.5 mg/kg per day, and then decreased based on clinical signs, as discussed in chronic management.

Most patients in Addisonian crisis respond quickly to treatment (within hours), although more severely debilitated patients may take 2–3 days to demonstrate dramatic improvement. Dogs are usually discharged 3–5 days after initial presentation.

Chronic Management

Chronic therapy for hypoadrenocorticism consists of life-long glucocorticoid and mineralocorticoid supplementation to replace the missing cortisol and aldosterone.

Mineralocorticoids are given to correct hyperkalemia, hyponatremia, and hypochloremia. Either a monthly injection or a twice-daily pill can be used. Desoxycorticosterone pivalate is a long-acting, injectable mineralocorticoid. It is initially administered at a dose of 2.2 mg/kg, subcutaneously or intramuscularly, every 25 days. Electrolyte concentrations are then measured two weeks and 25 days following the first injection. The 14-day measurement helps determine whether the dose is sufficient, whereas the 25-day recheck confirms that the interval is acceptable. If hyperkalemia and/or hyponatremia are present, the dose (14-day recheck) is increased by 10–15%, or the interval is decreased by two days (25-day recheck). The author usually increases the dosing interval by 2–3 days each month, measuring the electrolytes before each injection to ensure that they are within reference range, until the interval reaches 30–31 days, for owner convenience. Most dogs also do not require the entire 2.2 U/kg, and since DOCP is expensive, the dose can be decreased by approximately 10% per month, measuring electrolytes immediately prior to each injection to ensure that the electrolyte concentrations are still acceptable. The author usually starts with 1.5 mg/kg and rarely decreases below 1 mg/kg/month. Clients *must* understand that using lower doses leaves room for less error and requires tight adherence to the dosing schedule. Owners must be warned not to prolong the dosing interval to save money without veterinary advice; this often results in Addisonian crisis, which is significantly more expensive to treat than a single injection of DOCP.

Following stabilization of DOCP dose, electrolytes should be measured every 3–6 months. Dogs receiving DOCP injections must also receive a glucocorticoid, as DOCP has no glucocorticoid activity.

Side-effects of DOCP are uncommon, but polyuria/polydipsia (PU/PD) has been reported. This is usually due to concurrent prednisone administration. However, PU/PD is occasionally reported to be worse immediately following DOCP injection, and to improve throughout the month. In these cases, prolonging the dose interval or decreasing the dose, while monitoring electrolytes, may result in improvement.

Fludrocortisone is a shorter-acting oral mineralocorticoid that is available in 0.1 mg pills. The starting dose is 0.01 mg/kg twice daily. Electrolytes are measured in one-week increments until they are within the reference range. If hyponatremia and/or hyperkalemia are present, the dose is increased by 0.05–0.1 mg/day. If hypernatremia and/or hypokalemia are present, the dose is decreased. Once the dose has normalized, electrolyte concentrations are rechecked every 3–6 months. The dose often increases during the first 1–2 years of therapy. Since fludrocortisone has some glucocorticoid activity, only approximately 50% of dogs need additional glucocorticoids long term. However, all dogs are started on concurrent prednisone therapy at initial diagnosis, which is then tapered as necessary.

Polyuria, polydipsia, polyphagia, and panting are the most commonly reported side-effects of fludrocortisone therapy. Most of these are due to the glucocorticoid properties of fludrocortisone, and resolve when the patient is switched to DOCP.

DOCP is available in two veterinary-approved products (Zycortal®, Dechra; Percorten-V®, Elanco). Fludrocortisone is available through human pharmacies.

Glucocorticoids are used to control the nonspecific and gastrointestinal signs associated with hypoadrenocorticism, and prednisone is most frequently used. All dogs receiving DOCP need glucocorticoid supplementation, and about 50% of dogs taking fludrocortisone will need additional glucocorticoid supplementation long term. The physiologic dose of prednisone is 0.1–0.25 mg/kg/day, although many dogs (particularly larger breeds) do well on 0.05 mg/kg/day or less. The dose is tapered to effect, based on the clinical signs. If the dog has any gastrointestinal signs or continues to display vague clinical signs, the dose is increased. If PU/PD, polyphagia, or panting occur, the dose needs to be decreased. Remember that the dose is adjusted based on clinical signs, and that an ACTH stimulation test is never required to monitor patients with primary hypoadrenocorticism.

During times of stress, the prednisone dose is usually increased by 2–4 times (two times is usually sufficient).

"Stressful" situations include physiologic and emotional stress, such as when a dog goes to the veterinary clinic for electrolyte rechecks, when new visitors are in the household, when the dog goes hunting (if applicable), and when the dog has a concurrent illness. The increased dose is usually started the morning before the stress begins, and continued for a day or two following the end of the stressful event. Astute clients are usually able to identify when their dog needs additional prednisone, and adjust the dose appropriately. However, some clients need frequent reminders, particularly when they present for electrolyte evaluation.

Prognosis

With appropriate treatment and monitoring, the prognosis for dogs with naturally occurring hypoadrenocorticism is excellent. Dogs enjoy a good quality of life, and may participate in normal activities, as long as they are provided with additional prednisone as needed. Consistent medication and patient monitoring must be stressed to owners, as poor medication compliance or prolonging the treatment interval for DOCP, without veterinary approval, may lead to Addisonian crisis.

Atypical Hypoadrenocorticism

Etiology/Pathophysiology

Atypical hypoadrenocorticism refers to hypoadrenocorticism with clinical signs attributable to cortisol deficiency only; electrolyte concentrations are within reference range. At this time, the etiology is unknown. Individual cases may result from different etiologies. In some cases, partial immune-mediated destruction of the adrenal cortex occurs, sparing the zona glomerulosa and aldosterone synthesis. Occasionally, this is an early manifestation of "typical" hypoadrenocorticism, and the glomerulosa is eventually destroyed, leading to concurrent electrolyte abnormalities. In other cases, dogs may actually be aldosterone deficient but able to compensate and maintain normal electrolyte concentrations. The compensatory mechanisms are unclear, but aldosterone deficiency has been documented in patients with normal electrolyte concentrations.

Secondary hypoadrenocorticism, due to ACTH deficiency, results in signs of cortisol deficiency without electrolyte abnormalities, as well. However, secondary HOAC can be identified by low to nonexistent ACTH concentrations. Dogs with atypical HOAC have normally functioning pituitary glands, and usually increased ACTH concentrations.

Epidemiology

Atypical hypoadrenocorticism is an uncommon form of hypoadrenocorticism. However, due to its vague clinical signs and lack of electrolyte abnormalities on serum biochemistry, it is likely underdiagnosed.

Signalment

The signalment for atypical HOAC is similar to that of typical HOAC. Young to middle-aged dogs are predisposed, as are poodles, West Highland white terriers, Great Danes, and NSDTRs. However, any breed of any age may be affected.

History and Clinical Signs

Historical findings and clinical signs associated with atypical HOAC are similar to those in typical HOAC. Addisonian crisis does not usually occur with atypical HOAC, partially because hyperkalemia and hyponatremia are not present. Nonspecific signs such as weight loss, lethargy, and anorexia predominate, while gastrointestinal signs such as vomiting and diarrhea are also common. Atypical HOAC should always be considered in dogs with chronic GI signs, especially if they are more common when the dog is stressed (such as "stress colitis"). Seizures secondary to hypoglycemia and megaesophagus are uncommon, but atypical HOAC should remain on the rule-out list for dogs with megaesophagus and hypoglycemia, even if they have normal electrolyte concentrations. PU/PD may also be reported in dogs with atypical HOAC.

Diagnosis

Dogs with atypical HOAC may have many of the same clinicopathologic abnormalities as dogs with typical HOAC, except for hyperkalemia, hyponatremia, and hypochloremia. Although mild to moderate azotemia is possible, it is less common and less severe than in typical HOAC. Anemia and hypoalbuminemia are more common in dogs with isolated cortisol deficiency, likely because typical Addisonians are more hemoconcentrated (hypovolemic) than atypical Addisonians. Hypocholesterolemia is also common, and hypoglycemia can also occur and result in seizures.

Definitive diagnosis of atypical hypoadrenocorticism relies upon the ACTH stimulation test, and is interpreted the same way as with typical hypoadrenocorticism. A more economical way to rule out atypical HOAC is to measure the baseline cortisol; patients with cortisol >2-3 µg/dL do not have the disease. However, if the baseline cortisol is <2 µg/dL, an ACTH stimulation test is necessary for diagnosis. Although atypical HOAC is uncommon, it is easily treated and has a good prognosis. Thus, testing is indicated in patients with unexplained GI signs, lethargy, and weight loss.

Patients with both atypical HOAC and secondary HOAC have similar clinical signs of isolated cortisol deficiency. Endogenous ACTH concentrations should be measured to differentiate between secondary and primary hypoadrenocorticism. High concentrations indicate that the patient has primary HOAC (due to lack of cortisol's negative feedback on the pituitary), whereas low to unmeasurable concentrations are consistent with secondary HOAC. If secondary HOAC is diagnosed, imaging of the brain is recommended, to rule out a pituitary/hypothalamic lesion; however, a distinct anatomic lesion may not be identified.

Therapy

Therapy for atypical HOAC consists of glucocorticoid replacement, usually with prednisone, given at 0.1–0.25 mg/kg/day. Some patients do well on even lower dosages, particularly big dogs. The author has used dosages as low as 0.03 mg/kg/day. The goal is to administer enough prednisone to control the clinical signs of HOAC, while not causing steroid side-effects. Additional prednisone (2–4 times the normal dose) is recommended during times of stress.

Approximately 10% of dogs with atypical hypoadrenocorticism develop signs of mineralocorticoid deficiency (electrolyte abnormalities) weeks to months after the initial diagnosis (usually within one year). It is impossible to predict which dogs will develop electrolyte abnormalities, so reevaluation of the electrolytes is recommended at one and three months following initial diagnosis, and then every six months thereafter.

Prognosis

Prognosis for atypical hypoadrenocorticism is excellent, provided that the owners continue to administer medication as recommended. Almost all patients die of disease unrelated to hypoadrenocorticism.

Hypoadrenocorticism in Cats

Etiology/Pathophysiology

Hypoadrenocorticism is rare in cats. Most cases are idiopathic, but suspected to be due to immune-mediated destruction of the adrenal cortex. Neoplastic infiltration and abdominal trauma have also been reported to cause HOAC in cats. Concurrent glucocorticoid (cortisol) and mineralocorticoid (aldosterone) deficiency occurs in most cats, and isolated glucocorticoid deficiency ("atypical" hypoadrenocorticism) is rare. Secondary iatrogenic hypoadrenocorticism can result from glucocorticoid or progestogen (megesterol acetate) administration, but this is uncommon. In cases of secondary iatrogenic HOAC, the administered glucocorticoid or progestogen causes decreased ACTH production from the pituitary gland. Decreased ACTH production results in atrophy of the zonae fasciculata and reticularis, leading to decreased cortisol production. Since ACTH is not required for the synthesis of aldosterone from the zona glomerulosa, electrolyte abnormalities do not occur.

Epidemiology

Hypoadrenocorticism is rare in cats, with fewer than 50 cases reported in the literature.

Signalment

Unlike in dogs, there are no sex, age, or breed predispositions. Affected cats range in age from 1.5 to 14 years. The majority of reported cases have been domestic short- or long-haired cats, but two British shorthair cats have also been reported.

History and Clinical Signs

Clinical signs and historical findings are similar to those described in dogs. The signs may be chronic (months) or acute (several days), and may wax and wane. Owners may note improvement following treatment with fluids and/or glucocorticoids. The most commonly reported signs include lethargy, inappetence, and weight loss. Vomiting, PU/PD, and constipation can also occur. In contrast to dogs, diarrhea has not been reported.

Physical examination usually reveals depression, weakness, dehydration, and hypothermia. About half of the cats present in hypovolemic shock, characterized by prolonged capillary refill time and weak femoral pulse. Collapse, ataxia, bradycardia, and abdominal pain are less common.

Diagnosis

Clinicopathologic findings in cats with HOAC are similar to those in dogs with HOAC. Hyponatremia and hyperkalemia are almost always present, although one may occur without the other. Most cats are also hypochloremic, azotemic, and hyperphosphatemic. Although the azotemia is usually prerenal, most Addisonian cats have a urine specific gravity <1.030. Hypercalcemia, hypoglycemia, and acidemia are less common than in Addisonian dogs, but can be severe. Alanine aminotransferase, alkaline phosphatase, and bilirubin may be mildly increased. Complete blood count may reveal mild anemia and lymphocytosis; alternatively, lack of a stress leukogram (neutrophilia

and lymphopenia) in a stressed cat should raise suspicion for HOAC.

Diagnostic imaging is not necessary to diagnose HOAC, but is often performed as part of the diagnostic work-up prior to suspicion for HOAC. Thoracic radiographs may reveal pulmonary hypoperfusion or microcardia due to dehydration; abdominal imaging is usually unremarkable. The ECG may reveal bradycardia, but the other classic ECG abnormalities (spiked T-wave, decreased R-wave, and absent P-wave) are less consistent in hyperkalemic cats, though the reason for this is unclear.

Definitive diagnosis of HOAC in cats relies upon an ACTH stimulation test. A serum sample is taken prior to administering 5 µg/kg cosyntropin (or tetracosactrin), which is given intravenously. A poststimulation sample is collected one hour later. The diagnosis of HOAC is consistent with a poststimulation cortisol concentration of <2 µg/kg.

Measurement of endogenous ACTH concentrations can help determine whether an Addisonian cat with normal electrolyte concentrations has primary or secondary HOAC. High concentrations are consistent with primary disease. Low concentrations are expected in cats with secondary disease.

Therapy

Treatment of feline HOAC is similar to treatment of canine HOAC. Intravenous crystalloid fluids (0.9% NaCl, LRS or Plasma-Lyte A) should be administered to cats in Addisonian crisis. One-third of a shock dose (40–60 mL/kg) is given, and then the patient is reassessed. Dexamethasone (0.15 mg/kg BID) is given intravenously until oral prednisolone is tolerated. Prednisolone is started at 1 mg/kg/day, and slowly tapered to 0.1–0.2 mg/kg/day following discharge. Two to four times the dose should be given when the cat experiences stress (going to the veterinarian, visitors in the house, concurrent illness).

Mineralocorticoid supplementation can be provided using either desoxycorticosterone pivalate (DOCP, 2.2 mg/kg every 25 days) or fludrocortisone (0.05–0.1 mg/cat, SID–BID). Dosage adjustments are made based on electrolyte concentrations, as described for dogs.

Prognosis

Cats in Addisonian crisis tend to respond to treatment more slowly than dogs, and may require 3–5 days for significant improvement. Long-term prognosis for cats with hypoadrenocorticism is good, provided that the owners continue to administer medication and monitor as directed.

Hyperaldosteronism in Cats

Etiology/Pathophysiology

Primary hyperaldosteronism (PHA) results from excessive aldosterone production by the zona glomerulosa of the adrenal cortex, and usually leads to clinical signs related to hypokalemia and/or systemic hypertension. Unilateral adrenocortical tumors are the most common cause; carcinomas are more common than adenomas. Bilateral adenomas occur rarely. Idiopathic adrenal hyperplasia ("non-tumorous hyperaldosteronism"), characterized by bilateral micronodular hyperplasia of the zona glomerulosa, is reported less frequently than the tumorous forms. However, since definitive diagnosis requires histopathologic confirmation, and these cats are treated medically instead of surgically, idiopathic adrenal hyperplasia is likely underdiagnosed.

Aldosterone is the most important endogenous mineralocorticoid in dogs and cats. It primarily acts on the principal cells of the distal tubules and collecting ducts in the kidney, stimulating sodium and water reabsorption (thus expanding the vascular volume), and promoting potassium and acid excretion.

Aldosterone is regulated by the renin-angiotensin-aldosterone system (RAAS). Decreased renal perfusion pressure and decreased delivery of sodium to the distal tubules stimulate the release of renin from juxtaglomerular cells. Renin cleaves angiotensinogen, produced by the liver, into angiotensin I. Angiotensin I is then converted to angiotensin II by angiotensin converting enzyme. Angiotensin II then stimulates aldosterone synthesis via the activity of aldosterone synthase. Hyperkalemia also has a direct stimulatory effect on aldosterone secretion, with ACTH contributing to a lesser degree.

Secondary hyperaldosteronism ("hyperreninemic hyperaldosteronism") results from increased renin produced in response to reduced arterial blood volume, such as occurs with congestive heart failure, renal failure, and liver failure. Primary hyperaldosteronism, however, is due to autonomous secretion of aldosterone from the zona glomerulosa, and is associated with low plasma renin activity. It is sometimes referred to as "hyporeninemic hyperaldosteronism" for this reason.

In addition to expected consequences of hyperaldosteronism, such as hypokalemia and hypertension, some cats with PHA develop progressive renal disease. There is evidence that aldosterone itself mediates vascular fibrosis and inflammation, resulting in glomerular sclerosis, hyaline arteriolar sclerosis, tubular atrophy, and interstitial fibrosis. Thus, in azotemic patients with

hypokalemia and/or hypertension, determining whether hyperaldosteronism is primary (PHA) or secondary (hyperreninemic hyperaldosteronism) can be a diagnostic challenge.

Epidemiology

Primary hyperaldosteronism is rare. However, because several of the diagnostic findings associated with PHA are also associated with chronic kidney disease, PHA is likely underdiagnosed.

Signalment

Middle-aged to older cats are predisposed (median age 13 years; range 5–20 years), but there does not appear to be a sex or breed predisposition.

History and Clinical Signs

The most common clinical signs are associated with hypokalemia and systemic arterial hypertension; polyuria, polydipsia, weight loss, and a palpable abdominal mass may also be noted (Box 11.1). Hypokalemic myopathy can be acute or chronic in onset and clinical signs can be mild or severe. Affected cats often have cervical ventroflexion, a plantigrade stance, difficulty jumping, and/or severe weakness. Forelimb stiffness followed by acute collapse and dysphagia have also been reported. Whereas most cats with PHA caused by adrenocortical tumors present for hypokalemic myopathy, fewer of the cats with idiopathic adrenal hyperplasia display this clinical feature.

Ocular changes due to hypertension are more common with idiopathic adrenal hyperplasia, and may include retinal detachment and sub- and intraretinal and intravitreal hemorrhages. Cats with these lesions usually present for acute-onset blindness, hyphema, and/or mydriasis (Figure 11.1). Subclinical retinal lesions are often identified in cats with myopathy, as well.

Box 11.1 Clinical findings in cats with hyperaldosteronism

Due to hypokalemia:
- Cervical ventroflexion
- Plantigrade stance
- Difficulty jumping
- Weakness

Due to hypertension (systolic BP >180 mmHg):
- Ocular changes
- Acute blindness
- Hyphema
- Mydriasis

Polyuria/polydipsia

Figure 11.1 A 13-year-old male neutered domestic shorthair presented for acute blindness due to severe hypertension (>250 mmHg, as measured by Doppler). Note the mydriasis with complete bullous retinal detachment and retinal hemorrhages. *Source:* Photo courtesy of Martin Coster, DVM, MS, DACVO.

Diagnosis

The diagnostic evaluation of a cat for PHA includes blood pressure measurement, complete blood count, serum biochemistry, urinalysis, imaging, and specific hormone testing. Cats with idiopathic adrenal hyperplasia are more likely to be hypertensive, with a median systolic blood pressure of 210 mmHg (range, 185–270 mmHg) in one study. Median systolic BP in cats with neoplasia was 185 mmHg (range, 160–250 mmHg) in another study. Hypertension is often difficult to control in cats with PHA, and PHA should be suspected in cats with refractory hypertension.

The CBC does not usually reveal any significant abnormalities in patients with PHA. Moderate to severe hypokalemia is often evident on the serum biochemistry profile, although not all cats with PHA are hypokalemic. Significant signs of hypokalemic myopathy are not usually obvious until potassium concentrations decrease to less than 2.5 mmol/L, but this is variable. Creatine kinase is markedly increased in cases of hypokalemic myopathy. Hypernatremia is uncommon, likely because of dilution from volume expansion.

Some cats with PHA are also mildly to moderately azotemic, and often develop progressive renal disease as a consequence of PHA. This is more common in cats with idiopathic adrenal hyperplasia. Determining whether hyperaldosteronism is a consequence of chronic kidney disease, or vice versa, can be difficult and relies on measurement of plasma renin activity, which is not readily available in the US. Interestingly, phosphorus concentration is often at the lower end of the reference range and does not become increased with progressive azotemia in cats with PHA. The reason for this is unclear but may be

related to hypersecretion of parathyroid hormone. Hypercalcemia is also present in some of these cats. Urine specific gravity is variable at the time of PHA diagnosis, ranging from 1.010 to 1.040 (mean 1.029).

Concurrent diseases reported in cats with PHA include hyperthyroidism, diabetes mellitus, and hyperprogesteronism. Thus, additional testing is prudent if a patient with suspected PHA has clinical signs that cannot be explained.

Since PHA caused by adrenocortical tumors and adrenal hyperplasia has different treatment recommendations, abdominal and thoracic imaging is recommended. Thoracic radiographs can help identify pulmonary metastases. Abdominal ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI) can be used to visualize the adrenal glands and potential extension of a tumor into the caudal vena cava. Reported ranges for unilateral adrenocortical tumors range from 1–3.5 × 1–2.5 cm on US. The contralateral adrenal may not be seen, or may appear normal. CT and/or MRI is often used preoperatively to assess invasion of the caudal vena cava. In cats with bilateral adrenal hyperplasia, adrenal glands may be thickened, partially mineralized, or normal upon US examination. Unfortunately, imaging is not always definitive. Pulmonary metastases and caval invasion may be missed, bilateral disease may be present when unilateral disease is suspected, and an identified adrenal mass may be nonfunctional or producing something other than aldosterone, such as progesterone, cortisol, or catecholamines.

The gold standard for diagnosis of PHA is the aldosterone:plasma renin activity ratio, since aldosterone concentration should be increased with concurrent decrease in plasma renin activity (PRA), resulting in an increased ratio. However, measurement of PRA is difficult and inconsistently commercially available, limiting the utility of the ratio.

The plasma aldosterone concentration (PAC) is the most widely available test for confirmation of hyperaldosteronism. It is increased in all reported cases of PHA due to adrenocortical carcinomas or adenomas, but may only be mildly increased or within reference range in cats with adrenocortical hyperplasia. Additionally, an increased PAC does not differentiate between primary and secondary hyperaldosteronism. Measurement of the PAC:PRA ratio is useful in cases in which PAC is within reference range, and when clinical information does not differentiate between primary and secondary hyperaldosteronism (e.g., adrenal glands are of normal size and/or azotemia is present).

Adrenocorticotropic hormone stimulation testing is not usually necessary for the diagnosis of PHA. However, suppression testing is used to diagnose PHA in people. In a small study in cats, an oral fludrocortisone suppression test helped to differentiate some cases of PHA from other causes of arterial hypertension. Fludrocortisone was administered (0.05 mg/kg q12h) for four days, and urine was collected to measure the urine aldosterone to creatinine ratio (UACR) prior to the first dose, and the morning after the last evening dose of fludrocortisone. All of the non-PHA cats had >50% suppression of the UACR, while only 3/9 of the PHA cats had >50% suppression of the pretest UACR. This test has its limitations, including the availability of urine aldosterone measurement, but may be useful in PHA suspects with PAC within reference range.

Therapy

Initial treatment of PHA is aimed at controlling hypertension and hypokalemia and medical stabilization is recommended prior to adrenalectomy for adrenal tumors. Spironolactone is a competitive aldosterone receptor antagonist that helps control both hypertension and hypokalemia. The starting dose is 2 mg/kg q12h but this dose may be increased to 4 mg/kg q12h. Spironolactone has been reported to cause facial dermatitis in Maine Coon cats treated for hypertrophic cardiomyopathy, but this has not been reported in cats with PHA. Amlodipine, a calcium channel blocker, is given at 0.625–1.25 mg/cat q12–24h, to help control hypertension. Potassium gluconate is administered at a dose of 2–6 mEq PO q12h to alleviate hypokalemia. While adjusting medication doses, blood pressure and potassium concentration should be measured weekly. Myopathy is expected to resolve, although normokalemia may not be achieved. Hypertension usually resolves with appropriate therapy, but the vision loss is almost always permanent.

Patients with idiopathic adrenal hyperplasia should be treated medically. Following medical stabilization, adrenalectomy is ideal for patients with unilateral adrenocortical neoplasia. However, surgery is associated with a high mortality rate (30% in one study), particularly if the vena cava is affected. Additionally, some owners have financial limitations that prohibit surgery, and some cats have concurrent conditions or metastasis. If the owner elects not to pursue surgical therapy, medical management can be pursued long term.

The most common complication associated with adrenalectomy is hemorrhage; in one study, 4/10 cases experienced intraoperative or perioperative hemorrhage. One patient was stabilized with autotransfusion and another laparotomy, but the other three patients were euthanized following failed attempts at surgical hemostasis.

Postsurgical monitoring includes blood pressure and potassium monitoring, at least daily for 2–3 days. Amlodipine and spironolactone are discontinued postoperatively, and potassium supplementation is tapered until the potassium concentration normalizes.

Prognosis

Cats with unilateral adrenocortical neoplasia that survive the perioperative period have good long-term survival (up to 1803 days); patients with adenocarcinomas appear to have the same prognosis as cats with adenomas. Medically managed cats have reported survival times from several months to years. The prognosis for cats with adrenocortical hyperplasia is not well defined, but most cats eventually succumb to chronic kidney disease.

Diabetes Mellitus in Dogs and Cats

Jacquie S. Rand, BVsc, DVSc, MANZVS, DACVIM (SAIM)

School of Veterinary Science, University of Queensland, Gatton, Queensland, Australia; Australian Pet Welfare Foundation, Kenmore, Queensland, Australia

Etiology/Pathophysiology

Glucose is the primary source of energy in the body. Blood glucose concentrations are tightly controlled by a feedback system of endocrine hormones. Insulin is produced by the pancreatic beta-cells in response to increased blood glucose, and promotes storage of glucose, fatty acids, and amino acids as glycogen, fat, and protein. Insulin promotes uptake of glucose into most body cells for use, promotes storage of glucose as glycogen in liver and muscle, and inhibits gluconeogenesis. Cortisol, glucagon, epinephrine, and growth hormone oppose the actions of insulin, promoting catabolism of stored carbohydrate into glucose, stored triglycerides into free fatty acids and ketone bodies, and stored protein into amino acids. Because they oppose insulin's effects, these four hormones are called "counterregulatory hormones" (Table 12.1).

Diabetes mellitus is a disease characterized by hyperglycemia and associated clinical signs. It is classified into four broad types in human and veterinary medicine.

- Type 1 diabetes is a result of immune-mediated beta-cell destruction, usually leading to an absolute insulin deficiency. The majority of neutered diabetic dogs have type 1 diabetes, but this form appears to be very rare in cats. The etiology of type 1 diabetes in dogs is multifactorial, and likely involves genetic factors and poorly understood environmental factors, which trigger beta-cell injury and inflammation. In type 1 diabetes, following nonspecific beta-cell injury, autoimmunity then propagates continued destruction of beta-cells, preventing regeneration after injury. Factors which trigger the gastrointestinal immune system are implicated in human type 1 diabetes, and in dogs, pancreatitis is a potential triggering factor. As in humans, there is a seasonal influence, with the incidence peaking in winter. Environmental factors such as chronic insulin resistance secondary to glucocorticoid administration or obesity, and diseases which antagonize insulin's actions would be expected to hasten onset of clinical signs when superimposed on a reduced capacity to secrete insulin as a result of immune-mediated beta-cell destruction.
- Type 2 diabetes is characterized by insulin resistance with concomitant beta-cell dysfunction. In developed countries, the majority of feline diabetics are type 2. Insulin resistance is multifactorial and associated with genetic factors, obesity, physical inactivity, male gender, and glucocorticoid steroids. Beta-cell destruction is initiated and propagated by a variety of factors, not yet fully understood, that lead to a decline in insulin secretory capacity. When the increased demand to produce insulin as a result of insulin resistance is superimposed on beta-cell dysfunction, chronic hyperglycemia ensues. Chronic hyperglycemia is toxic to beta-cells and in turn causes injury and death of the beta-cells, reducing insulin production even further.
- "Other specific types of diabetes" includes most other forms in companion animals, including drug-induced diabetes (usually steroid use), endocrinopathies that antagonize insulin action (acromegaly, hyperadrenocorticism), or exocrine pancreatic disease. Chronic pancreatitis is the most common cause of canine diabetes in this category, accounting for approximately 30% of cases. Approximately 25–30% of poorly controlled diabetic cats have acromegaly.
- Gestational diabetes is not a significant cause of diabetes in companion animals in the US, as most companion animals are desexed. Pregnancy and diestrus are associated with increased progesterone concentrations, which uniquely in the bitch stimulate the mammary glands to produce growth hormone. Both hormones oppose insulin's glucose lowering effects, leading to periodic insulin resistance in intact female dogs, and diestrus-associated diabetes. Concurrent obesity would be expected to exacerbate this insulin resistance.

Table 12.1 Effects of insulin and counterregulatory hormones on carbohydrate metabolism

Hormone	Effect on carbohydrates
Cortisol	Increases blood glucose • ↓ Glucose uptake by cells • ↑ Gluconeogenesis • ↑ Glycogenolysis • Inhibits insulin
Glucagon	Increases blood glucose • ↑ Gluconeogenesis • ↑ Glycogenolysis • Inhibits insulin
Epinephrine	Increases blood glucose • ↑ Gluconeogenesis • ↑ Glycogenolysis
Growth hormone	Increases blood glucose • ↓ Glucose uptake by cells • ↑ Gluconeogenesis
Insulin	Decreases blood glucose • ↑ Glucose uptake by all cells except liver, brain, red blood cells • ↑ Glycogen formation • ↓ Gluconeogenesis, glycogenolysis

Epidemiology

Diabetes mellitus is the most common disorder of the endocrine pancreas in dogs and cats. The incidence in dogs is approximately 0.13%, and the incidence in cats is approximately 0.5%, depending on the study population, and is influenced by geographical location and type of veterinary practice (referral or primary accession).

Signalment

Diabetes mellitus is a disease of middle-aged to older companion animals, with peak prevalence of 7–12 years of age in dogs and 10–13 years in cats. Intact female dogs and male cats are predisposed. Various breeds of cat and dog are overrepresented, and predisposed breeds vary with geographic area. For example, in the USA, dog breeds at increased risk include miniature schnauzer, Samoyed, and miniature poodle, whereas in the UK, in addition to miniature schnauzer and Samoyed, breeds more commonly seen include Tibetan, cairn, border and Yorkshire terriers and Labrador retrievers. In cats, Burmese are overrepresented in Australia, New Zealand and the UK, and in the USA, Maine Coon, domestic longhair, Russian blue and Siamese. Norwegian forest cats and Burmese are at increased risk in Scandinavia.

History and Clinical Signs

Diabetes is characterized by hyperglycemia resulting from insufficient insulin production or function. Hyperglycemia causes the hallmark clinical signs of polyuria, polydipsia, polyphagia, and weight loss that distinguish diabetes. Some dogs and up to 50% of cats present with decreased appetite. Other clinical signs include hepatomegaly, lethargy, cataract formation (dogs), and diabetic neuropathy (mainly cats). Signs are usually slowly progressive over weeks to months.

Polyuria and Polydipsia

Relative or absolute insulin deficiency in diabetes causes reduced blood glucose uptake by liver, muscle, and adipose tissues, and unchecked glucose production in the liver, which result in hyperglycemia. In the glomerulus of the kidney, nearly all the blood glucose is passively filtered into the ultrafiltrate. In the proximal tubule of the kidney, receptors are capable of resorbing only a fixed amount of glucose from the ultrafiltrate. This fixed amount is called the renal threshold, and is approximately 200 mg/dL in dogs and 250–290 mg/dL in cats. When the amount of glucose in the blood exceeds this renal threshold, glucose remains in the ultrafiltrate, acting as an osmotic diuretic and causing polyuria and compensatory polydipsia.

Polyphagia

Animals with uncomplicated diabetes mellitus may have an increased appetite. This is governed by central mechanisms, including increased hunger triggered by nutrient loss (predominantly glucose), and lack of insulin-mediated uptake of glucose into cells of the satiety center, which normally inhibits hunger.

Weight Change

Obesity is a common co-morbidity in middle-aged and senior diabetic dogs and cats. It reduces insulin sensitivity, and when superimposed on beta-cell loss from any cause, will hasten onset of hyperglycemia and clinical signs. However, untreated diabetes mellitus leads to weight loss, due to malassimilation of nutrients absorbed from the gut, and urinary loss of glucose and amino acids. Dogs in which pancreatitis is either a complicating co-morbidity or a cause of their diabetes may later progress to exocrine pancreatic insufficiency (EPI), which exacerbates weight loss, and may be first evident as increased frequency of defecation.

Hepatomegaly

Insulin promotes storage of lipid in adipose tissue. Relative or absolute lack of insulin promotes lipid catabolism into fatty acids, which are transported to the liver. The liver uses this excess of fatty acids to produce and store triglycerides (lipids), leading to hepatic lipidosis and hepatomegaly. In the diabetic liver, excess fatty acids are also used for gluconeogenesis, which worsens hyperglycemia, and are converted into ketone bodies, which cause ketoacidosis.

Cataracts

The pathogenesis of cataracts in diabetics is multifactorial and incompletely understood. The enzyme aldose reductase catalyzes the conversion of glucose to sorbitol, and the enzyme sorbitol dehydrogenase catalyzes the conversion of sorbitol to fructose. In the eye, the formation of sorbitol occurs more rapidly than its degradation into fructose. In the diabetic eye, a large amount of sorbitol is produced and acts as an osmotic agent within the lens fibers, drawing water into the lens, leading to lens swelling, lens fiber collapse, and ultimately cataract formation.

Lens-induced uveitis is common in diabetic dogs due to the rapid onset of the cataracts. Lens-induced uveitis occurs when the lens becomes swollen and the stretched lens capsule allows leakage of cataract lens proteins into the anterior and posterior chambers. This, in turn, causes iris and ciliary body vasculitis, resulting in serum protein leakage into the aqueous humor and prostaglandin release from the iris, which continue the uveitis.

Diabetic cataracts are found in 80% of diabetic dogs within 16 months (Figure 12.1). Diabetic cats are rarely clinical for cataracts, though recent studies suggest that mild diabetes-associated lens opacity is more common than previously thought. Topical administration of

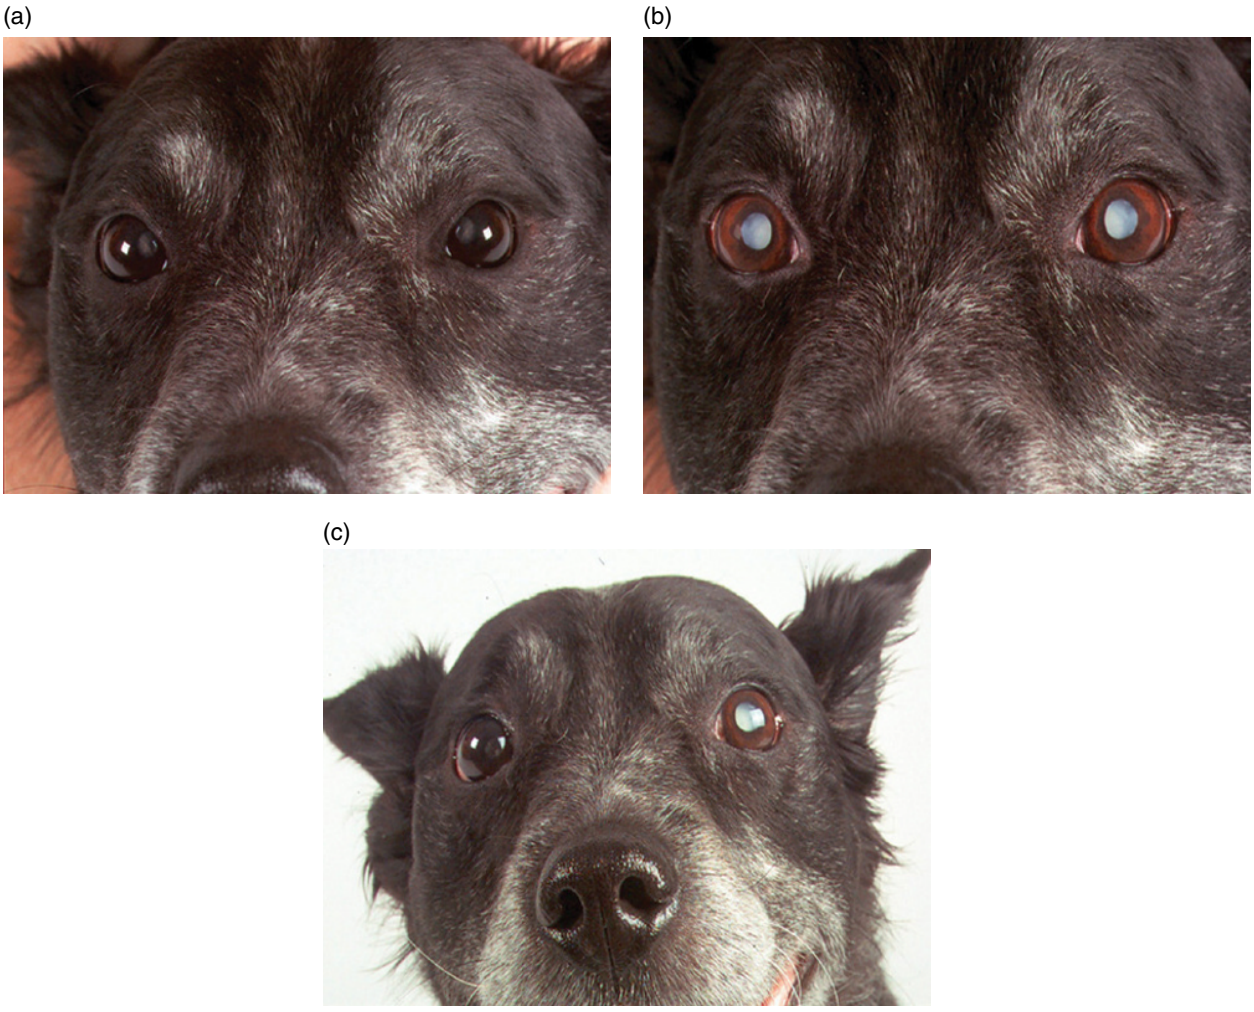

Figure 12.1 Diabetic cataracts in a dog. (a) An 11-year-old cross-bred dog photographed shortly after diagnosis of diabetes mellitus. (b) The same dog three months later. Diabetic cataracts had developed rapidly and the owners reported sudden vision loss. aldose reductase inhibitors three times daily retards progression of ocular changes.

Diabetic Neuropathy

The majority of diabetic dogs, cats, and people have microscopic evidence of nerve injury, including demyelination, remyelination, and axonal degeneration. However, less than 50% of cats with diabetes mellitus have clinical neuropathy with hindlimb paraparesis, a plantigrade stance, and decreased ability to jump, as well as reduced reflexes and proprioceptive deficits (Figure 12.2). Weakness and muscle wasting are present in 50% of diabetic cats. Clinical diabetic neuropathy is rarely recognized in dogs.

Diagnosis of Diabetes Mellitus

Diagnosis of diabetes mellitus is based on demonstration of persistently increased blood glucose concentration, and is typically associated with glucosuria and classic clinical signs of polyuria and polydipsia. In dogs, blood glucose concentrations above the renal threshold of 200 mg/dL (11 mmol/L) are considered diabetic. In humans and cats, blood glucose concentrations persistently above normal but below that considered diabetic (>117 to < 180 mg/dL; >6.5 to <10 mmol/L) are associated with increased risk of developing diabetes and considered prediabetic in cats. Persistent hyperglycemia of ≥180 mg/dL (10 mmol/L) should be considered diabetic, but it will only be accompanied by clinical signs once it exceeds the renal threshold of 250–290 mg/dL (14–16 mmol/L). Stress hyperglycemia and postprandial hyperglycemia may complicate diagnosis of diabetic hyperglycemia in cats.

The presence of elevated plasma fructosamine (approximately >400 µmol/L; reference range varies by laboratory) or glycated hemoglobin (A1c) (reference range depends on assay used) in symptomatic pets with hyperglycemia and glucosuria helps confirm the diagnosis of diabetes mellitus. However, fructosamine is not consistently increased above the reference range in cats until blood glucose is approximately >300 mg/dL (>17 mmol/L), making it unsuitable for differentiating stress hyperglycemia from diabetes when blood glucose is 300 mg/dL (17 mmol/L) or less. In contrast, unpublished data suggest the new Baycom A1c is more sensitive at distinguishing transient hyperglycemia secondary to stress from persistent hyperglycemia of diabetes or prediabetes. Fructosamine is formed when blood glucose irreversibly binds plasma proteins (mainly albumin). Fructosamine concentration is roughly proportional to the average blood glucose concentration over the preceding 7–14 days, which is the half-life of albumin in dogs and cats. Therefore, while a single blood glucose measurement reflects blood glucose at one moment in time, fructosamine is used as an indicator of blood glucose over a longer period of time and is used to document persistent hyperglycemia. Similarly, glycated hemoglobin is formed when blood glucose irreversibly binds hemoglobin (especially hemoglobin A1), and its concentration reflects the average blood glucose concentration over approximately 70 days (erythrocyte lifespan).

A new test (Baycom A1c) validated for cats is available, and may be useful for differentiating cats with blood glucose in the normal range from those with a persistent mild hyperglycemia, for example prediabetic cats with glucose concentrations of 130–180 mg/dL (7.2–9.9 mmol/L) or cats with subclinical diabetes (>180 mg/dL up to the renal threshold of 250–290 mg/dL; >10 mmmo/L to 14–16 mmol/L).

In cats, stress hyperglycemia may be confused with diabetic hyperglycemia on initial presentation. Stress hyperglycemia is usually (but not always) lower than diabetic hyperglycemia, with median blood glucose in stressed cats around 305 mg/dL (16.9 mmol/L) with a wide range (126–505 mg/dL; 7–28.1 mmol/L). Median blood glucose in newly diagnosed diabetic cats is around 475 mg/dL (26.4 mmol/L) with a wide range of 180–1100 mg/dL (10–61. mmol/L) that overlaps with the range of stress hyperglycemia. Diabetic hyperglycemia and glucosuria will be persistent over time, and will always be accompanied by typical clinical signs if blood glucose is above the renal threshold. In contrast, stress hyperglycemia typically resolves in 3–4 hours but may take 24 hours in a very few cats. Therefore, in most cats, an easy way to rule out persistent hyperglycemia of diabetes or prediabetes, is to test a repeat sample from the ear after the cat has been sitting quietly in a cage for 4 hours; in the majority of cats with stress hyperglycemia, blood glucose will be <117 mg/dL (6.5 mmol/L).

Fructosamine is most often normal in cats with stress hyperglycemia, but elevated in diabetic cats that have been markedly hyperglycemic (≥360 mg/dL; 20 mmol/L) for at least 3–5 days. However, a normal fructosamine concentration does not rule out prediabetes or diabetes associated with more moderate hyperglycemia, whereas Hb1c appears more sensitive. Home blood glucose monitoring with a meter calibrated for feline blood may also assist in identifying prediabetic cats with persistent mild elevation of glucose (>117–162 mg/dL; 6.5–9 mmol/L).

A typical work-up for dogs or cats with suspected diabetes mellitus will include a complete blood count, chemistry profile with electrolytes, urinalysis, and urine culture via sterile collection. Some veterinarians routinely use fructosamine or, less commonly, glycated hemoglobin to document persistent hyperglycemia. In dogs, if hypothyroidism or hyperadrenocorticism is suspected, it is best tested after diabetes is regulated, because of the effect of poorly regulated diabetes on interpretation of tests. In intact female dogs, measurement of serum progesterone may also be helpful; elevated progesterone levels in diestrus or pregnancy increase secretion of growth hormone, a counterregulatory hormone, leading to insulin resistance. In cats, a total T4 and feline leukemia virus/feline immunodeficiency virus (FeLV/FIV) test is warranted. Middle-aged to older cats with polyuria/polydipsia, polyphagia, and weight loss should be screened for diabetes mellitus and hyperthyroidism, as the diseases cause similar clinical signs, and may occur concurrently. For patients with atypical or additional clinical signs, consider a thyroid panel (total or free T4 and thyroid-stimulating hormone), insulin like growth factor (IGF-1), trypsinogen-like immunoreactivity (TLI), pancreatic lipase immunoassay (PLI), cobalamin and folate, adrenal function testing, thoracic and abdominal radiographs, and abdominal ultrasound as indicated based on the patient's history and clinical exam findings. Cats with diabetes and blood glucose above the renal threshold have weight loss, and cats with a stable weight or weight gain should be tested for acromegaly. If IGF-1 is in the normal range, but clinical signs are consistent with acromegaly, test again after 6 weeks of insulin therapy.

Therapy

Nearly all veterinary patients with diabetes mellitus are managed with a combination of insulin therapy, diet, and weight management.

Human and veterinary insulins are categorized both by onset and duration of action, and by protein source. Based on onset and duration of action, insulins are short acting, intermediate acting, and long acting. Short-acting insulins are generally used in hospital for intensive blood glucose control, while intermediate- and long-acting insulins are used both in hospital and at home for long-term, daily glycemic control. Based on protein source, insulins are human, human analog (synthetic insulin that is altered from the natural form but retains biological function), bovine, or porcine. Porcine and canine insulin have an identical amino acid sequence, while bovine and feline insulin differ by just one amino acid.

Traditionally, veterinarians have managed canine and feline diabetes with a variety of veterinary or human insulins (Table 12.2). Veterinary insulins include porcine lente (Vetsulin/Caninsulin®, Merck), and protamine zinc human recombinant insulin (ProZinc®, Boehringer Ingelheim Vetmedica). Human insulins or insulin analogs include human-origin lente (no longer available), neutral protamine Hagedorn (isophane, NPH, various manufacturers), glargine (Lantus®, Sanofi-Aventis), detemir (Levemir®, Novo Nordisk), glargine 300 U/mL (Toujeo, Sanofi-Aventis) and degludec (Tresiba®, Novo Nordisk). Premixed combinations of short-acting lispro (Eli Lilly) or aspart (Novo Nordisk) insulin with longer-acting protamine insulin are also available as intermediate-acting insulins (Humalog® Mix 75/25 and Novolog® 70/30, respectively).

The goals of treatment in canine diabetes include resolution of polyuria, polydipsia and abnormal body condition, while avoiding clinical hypoglycemia, diabetic ketoacidosis, urinary tract infections, and other complications through excellent glycemic control. In dogs, American Animal Hospital Association guidelines recommend the use of porcine lente, PZI, or NPH insulins, and a complete and balanced diet that lacks simple carbohydrates.

A stable routine for meals, snacks, and exercise is crucial for good glycemic control; frequent changes in type of food or amount fed should be avoided (Box 12.1). The best diet for diabetic dogs is yet to be determined. Diets recommended include high-fiber/restricted-fat diets, which as a consequence are high in carbohydrate (>45%), and diets with moderate fiber and restricted carbohydrate (<30% metabolizable energy [ME]), which as a consequence are higher in fat and protein. High-fiber diets may help to delay glucose absorption from the gastrointestinal tract and reduce postprandial hyperglycemia. A number of prescription canine diabetic diets are available with increased fiber, although most have carbohydrate levels >45% ME. If used with NPH insulin, these high-fiber diets may exacerbate postprandial hyperglycemia in some dogs, because peak gastrointestinal glucose absorption occurs after peak insulin action, and in these cases are better fed 1–2 hours after insulin administration. High-fiber/moderate-fat diets may cause

Table 12.2 Insulin types used in companion animal medicine and their characteristics

Brand name	Product	Manufacturer	Concentration	Origin	Size
Intermediate acting					
Humulin N	NPH	Eli Lilly	U-100	Human	10 mL vial 3 mL pen

Box 12.1 Dosing protocol for dogs on lente, NPH, glargine or detemir

- Starting dose is 0.5 U/kg administred BID for NPH, lente (Caninsulin/Vetsulin, Merck) and glargine (Lantus, Sanofi-Aventis) insulin in dogs. Note starting dose for dogs on detemir (Levemir, Novo Nordisk) is 0.125 µ/kg BID. Dogs are on average four times more sensitive to detemir than other insulin.
- Home blood glucose monitoring is recommended using a meter calibrated for dog blood. Continuous or flash glucose monitoring systems are also very useful for assessing duration of action and adjusting insulin dose, but they measure interstitial blood glucose and are not calibrated for dogs. Their accuracy for determining actual nadir blood glucose concentration is poor.
- In the intitial stabilization phase, reassess dogs weekly. Feed a prescription diet formulated for diabetic dogs and keep amount fed and type of diet constant on a daily basis. Low carbohydrate is best when using lente, glargine or determir. Adjust amount of energy fed to achieve and maintain ideal body weight. If excessive weight loss occurs with a diabetic diet, swap to a premium maintenance diet with low carbohydrate and moderate fiber content.
- Increase insulin dose when the nadir (lowest) glucose concentration is >145 mg/dL (8 mmol/L) and when the blood glucose measurements obtained just prior to the morning and evening insulin injection are both ≥180 mg/dL (10 mmol/L).
- Do not change insulin dose when the nadir is 90–145 mg/dL (5–8 mmol/L) and when the blood glucose measurements just prior to the morning and evening insulin injection are both ≥180 mg/dL (10 mmol/L).
- Decrease insulin dose either when the nadir is <90 mg/dL (5 mmol/L) or when at least one of the blood glucose measurements just prior to the morning and evening insulin injection is <180 mg/dL (10 mmol/L).
- Once the dog is well controlled, the target nadir glucose concentration can be lower, e.g., 70–110 mg/dL (4–6 mmol/L).
- Assessment of the dog's clinical signs determines the magnitude of the change in insulin dose. When clinical signs of uncontrolled diabetes (water drunk >70 mL/kg/day, ketonuria, or lethargy) are present, increase insulin dose by 20% rounded down to the nearest unit. When dog has shown no clinical signs during the preceding 2 weeks, insulin dose adjust by 1 unit. Similarly, when reducing dose, adjust down by 1 unit if no clinical signs, but by 20% if signs of hypoglycemia.
- The protocol for serial blood glucose evaluation comprises administration of the dog's usual meal and insulin dose in the morning and 12 hours later at night and blood glucose measurement with a portable glucose meter every 2 hours for 12 hours beginning immediately prior to the morning insulin injection and meal until immediately before the next insulin injection.

Results of serial blood glucose concentration testing determine whether the insulin dose should be increased, left unchanged, or decreased. Be conservative with dose increases because severe clinical hypoglycemia kills dogs.

- Dogs are considered to have stable glycemic control when the following criteria are all met over 2 months: (a) fluctuation of insulin dose by 1 unit or less, (b) water drunk <70 mL/kg/day, (c) stable body weight, and (d) absence of ketonuria. The period required to achieve stablization ranges from 3 to 10 months (median 7 months).
- If duration of action of NPH or lente insulin apprears to be substantially less than 12 hours and signs of poor control persist, try detemir if the dog is >5–10 kg (note lower dose with detemir). If insulin sensitivity is normal, dosing dogs weighing <5–10 kg can be problematic with detemir. If necessary, it can be diluted with saline or sterile water or a special diluting solution from the manufacturer. Alternatively, glargine 300 U/ml (Toujeo) appears to be useful in some poorly controlled dogs and is best combined with a low carbohydrate diet.

significant weight loss in some diabetic dogs, and thus are not suitable for most lean or underweight dogs. A variety of commercially available, nonprescription grain-free diets are available which are lower in carbohydrate and higher in protein and fat, but have not yet been used in clinical trials with diabetic dogs. Dietary fat restriction (<30% ME) should be considered for diabetic dogs with concurrent chronic pancreatitis or persistent hypertriglyceridemia. It is usually recommended that insulin be given within one hour of a meal and in most cases, for convenience, it is given at the time of insulin injection.

The primary goal of treatment in feline diabetes is to obtain remission; that is, maintenance of euglycemia without the need for insulin therapy or oral hypoglycemic drugs. Remission is possible in 80% or more of newly diagnosed feline diabetics if managed to achieve normal or near normal blood glucose concentrations soon after diagnosis. Probability of remission is increased when a low-carbohydrate (<15% ME), high-protein diet (Hills® m/d, Purina® DM, or others) is used in combination with long-acting insulins such as glargine or detemir administered twice daily. Lower remission rates are reported using PZI or porcine lente insulin or when a moderate-carbohydrate diet is fed. Rapid institution of excellent glycemic control, ideally in conjunction with home monitoring, contributes to remission, while institution of tight control six months or more after diagnosis is associated with significantly lower rates of remission (84% versus 34%) (Box 12.2). Because remission often occurs within 4–8 weeks of therapy if cats are managed optimally, weight loss is not a major factor in achieving remission but it is critically important for maintaining remission. Eating does not need to be coordinated with insulin administration, especially if a low-carbohydrate diet and long-acting insulin are used. Type and amount of food and snacks should be consistent each day, and snacks must be low carbohydrate.

Exogenous Insulin Resistance

Insulin resistance means decreased sensitivity to endogenous or exogenous insulin. Endogenous insulin resistance is a major factor in the pathogenesis of type 2 diabetes in cats, when superimposed on reduced beta-cell function. Insulin resistance should be investigated in dogs or cats when insulin therapy does not have the expected effect – animals are consistently hyperglycemic despite insulin doses of greater than 1–1.5 units of insulin per kg body weight *per dose* (not per day).

Insulin resistance may incorrectly be diagnosed when insulin is stored, handled or administered improperly. It can also be misdiagnosed when duration of insulin action is too short to maintain good glycemic control and results in marked hyperglycemia prior to each insulin injection, despite increasing dose. Hyperglycemia following a hypoglycemic episode is often attributed to a rebound phenomenon associated with secretion of counterregulatory hormones, termed a Somogyi phenomenon. However, evidence for this pathogenesis as a cause of hyperglycemia following hypoglycemia is lacking in veterinary and human medicine. This pattern of hypoglycemia followed by marked hyperglycemia is a relatively rare occurrence in cats treated with glargine or detemir (1.5% of blood glucose curves), and inadequate duration of insulin action should be suspected rather than attributing the hyperglycemia to a rebound effect and associated insulin resistance. Persistent hyperglycemia also causes insulin resistance which likely explains why insulin dose, after an initial increase over 1–2 months in newly diagnosed animals, typically decreases over a similar period in both dogs and cats which remain insulin dependent.

Acromegaly is a syndrome of excess growth hormone production, which typically causes profound endogenous insulin resistance. It is rare in dogs, and caused by mammary tissue oversecretion. It is relatively common in cats, with at least 25–30% of poorly controlled diabetic

Box 12.2 Home blood glucose monitoring protocol for glargine or detemir using a preinsulin blood glucose concentration measured using a glucometer calibrated for feline blood, used in a feline-only practice for the last 8 years

Newly diagnosed diabetics (<2 months insulin therapy)

Blood glucose concentration >235 mg/dL (>13 mmol/L)	Increase the dose by 0.5 IU
Blood glucose concentration 126–235 mg/dL (7–13 mmol/L)	Keep the dose the same
Blood glucose concentration 72–<126 mg/dL (4–<7 mmol/L)	Decrease the dose by 0.5 IU
Blood glucose concentration <72 mg/dL (<4 mmol/L)	Do not give insulin and call the clinic to discuss

Longer-term diabetics (>2 months insulin therapy)

Blood glucose concentration >450 mg/dL (>25 mmol/L)	Increase the dose by 1 IU
Blood glucose concentration 270–450 mg/dL (15–25 mmol/L)	Increase the dose by 0.5 IU
Blood glucose concentration 108–<270 mg/dL (7–<15 mmol/L)	Keep the dose the same
Blood glucose concentration 90–<126 mg/dL (5–<7 mmol/L)	Decrease the dose by 0.5 IU
Blood glucose concentration <90 mg/dL (<5 mmmo/L)	Do not give insulin and call clinic to discuss, check for remission depending on dose

If using a glucometer calibrated for human blood, decrease target glucose concentration by 20% (approximately 18 mg/dL; 1 mmol/L).
Source: Adapted from Rand 2017.

cats subsequently shown to have acromegaly, and is caused by pituitary oversecretion. Cats that have poor glycemic control despite adequate or increased insulin doses should have insulin-like growth factor (IGF) measured and, if possible, brain imaging. Occasionally, diabetic cats with acromegaly are not insulin resistant at the time of diagnosis, but this is atypical. Hyperadrenocorticism causes clinically significant endogenous insulin resistance and is more common in dogs than cats. Approximately 1 in 20 dogs with hyperadrenocorticism develops diabetes.

Clinically significant insulin resistance occurs when concurrent disease causes upregulation of glucocorticoids, epinephrine, glucagon, and other counterregulatory hormones. Any concurrent infection or inflammatory disease, endocrine or cardiac disease, or neoplasia can contribute to insulin resistance. In dogs, common concurrent diseases that can contribute to insulin resistance include hyperadrenocorticism, acute pancreatitis, urinary tract infection, neoplasia, hypothyroidism, kidney disease, severe obesity, and oral infection. In cats, common concurrent diseases include pancreatitis, hepatic lipidosis, cholangiohepatitis, urinary tract infection, kidney disease, hyperthyroidism, acromegaly, inflammatory bowel disease, obesity, oral infection, and heart disease.

Diabetic Ketoacidosis

Diabetic ketoacidosis is a form of decompensated diabetes mellitus in which cells use free fatty acids as an energy source, because they cannot access glucose due to absolute or relative insulin deficiency. In the presence of elevated glucagon and other counterregulatory hormones, free fatty acids are broken down into ketoacids. As ketoacids and glucose accumulate in the blood, metabolic disturbances occur, which can be profound and life-threatening, and include dehydration, hypovolemia, elevated anion gap, metabolic acidosis, electrolyte disturbances, azotemia, elevated liver enzymes, hyperlactatemia, and clinical signs of vomiting and anorexia. Treatment involves rehydration and the use of short- and long-acting insulins to reduce ketone production and establish euglycemia.

Hyperosmolar hyperglycemic state is another syndrome of decompensated diabetes mellitus. It is characterized by profound hyperglycemia greater than 600 mg/dL (33.3 mmol/L) and hyperosmolality >320 mOsm/kg, with a normal pH and no or mild ketonemia or ketonuria. It is less common than diabetic ketoacidosis. In the classic form, animals are not ketotic or acidotic, but mixed forms occur with severe hyperosmolality, compounded by ketoacidosis.

Prognosis

Improved diets, insulin types, and the availability of home monitoring have led to improvements in canine and feline diabetes management in recent years. Most important of these is diabetic remission, thought to be attainable in 80% or more of newly diagnosed feline diabetics if managed to achieve normal or near normal blood glucose concentrations. Current data on prognosis that incorporates recent improvements in management are lacking. Older data suggest that in diabetic animals managed with

insulin therapy, median survival time from diagnosis is 2–3 years for dogs and 1.5 years for cats. Prognosis is likely better for cats that undergo diabetic remission.

Approximately 25–30% of cats relapse and require insulin to control blood glucose, and this increases with duration of remission. A small proportion of cats (approximately 22%) achieve a second remission, but most remain insulin dependent. Factors predisposing to diabetes such as obesity and corticosteroid administration are likely also important factors associated with relapse.

Intermittent home blood glucose is recommended for cats in remission to detect deteriorating glycemic status. Cats with impaired fasting glucose (>117 mg/dL and <180 mg/dL; >6.5 mmol/L and <10 mmol/L) or impaired glucose tolerance are at increased risk of relapse. Diabetic cats in remission with fasting blood glucose >135–162 mg/dL (>7.5–9 mmol/L) when measured after overnight hospitalization or at home, and blood glucose >250 mg/dL (>14 mmol/L) three hours after a glucose tolerance test (using 1 g/kg glucose IV) have an 86% probability of relapsing within nine months. In contrast, no cat with normal fasting glucose and normal glucose tolerance became diabetic again during the follow-up period (17–37 months). A low-carbohydrate diet should continue to be fed during remission.

Conclusion

Diabetes mellitus is a common endocrinopathy in middle-aged and older dogs and cats. The disease results from insulin deficiency. Most dogs have type 1 diabetes mellitus from immune-mediated pancreatic destruction, and most cats have type 2 diabetes mellitus from a combination of beta-cell failure and insulin resistance associated with obesity, inactivity, breed, and other factors.

Diagnosis is made by the demonstration of persistent hyperglycemia and glucosuria along with typical clinical signs of polyuria, polydipsia, and others.

Treatment is with exogenous insulin administration and an appropriate diet, and involves frequent blood glucose monitoring (ideally, home blood glucose monitoring), appropriate dose adjustment, and a stable daily schedule, together with elimination of factors that promote insulin resistance. In cats, diets that are low in carbohydrate assist with glycemic control. Complications include diabetic ketoacidosis, cataracts (dogs), muscle wasting, plantigrade stance (cats), and urinary tract infections. The treatment goal for diabetic dogs is to resolve clinical signs and achieve ideal body condition while avoiding complications and blood glucose extremes. The primary treatment goal for diabetic cats is diabetic remission and maintenance of euglycemia without the need for insulin therapy. Diabetic remission is achievable in 80% or more of newly diagnosed diabetic cats managed to achieve normal or near normal blood glucose. For cats that remain insulin dependent, goals of therapy are resolution of clinical signs while avoiding life-threatening hypoglycemia. Cats that remain poorly controlled with insulin doses above 1U/kg BID should be tested for acromegaly.

Hypoglycemia in Patients without Diabetes Mellitus: Evaluation and Management

Rhett Nichols, DVM, DACVIM (SAIM)

Antech Diagnostics, Farmingdale, NY, USA

Hypoglycemia is defined as a blood glucose concentration of <60 mg/dL (3.3 mmol/L). Because of the effectiveness of defense mechanisms against falling glucose concentrations, hypoglycemia is an uncommon clinical event in nondiabetic adult dogs and cats, although two exceptions are xylitol toxicity and babesiosis caused by *Babesia canis rossi* in the dog. However, hypoglycemia does occur with regularity in neonates, toy and miniature breed dogs less than 6 months of age without portosystemic vascular anomalies (PSVA), and young dogs with PSVA. In addition, hypoglycemia is a very common complication in insulin-treated diabetic dogs and cats; the incidence of owner-reported "occasional" hypoglycemic episodes ranges from 35% to 40%. Although animals with diabetes are not spared the risk for the same hypoglycemic disorders as those without diabetes, the vast majority of their hypoglycemic episodes are the result of diabetes treatment. Furthermore, because the pathophysiology of hypoglycemia in diabetes is distinct, and the diagnostic and management approaches are different for pets without diabetes, this chapter will only address the evaluation and management of hypoglycemia in patients without diabetes mellitus. In addition, insulin-secreting pancreatic endocrine tumors, more commonly known as insulinomas, will be covered in Chapter XX.

Maintenance of Normal Glucose Concentrations in Healthy Dogs and Cats

Cell function and metabolism are dependent on energy sources delivered via the circulation. There are two major sources of energy: meals (ingested carbohydrates, proteins, and fat) and glucose that is produced by the liver. The liver initially produces glucose by the breakdown of stored glycogen (glycogenolysis). As glycogen stores are depleted, glucose levels are augmented by gluconeogenesis. The whole process of gluconeogenesis is quite complex and is dependent on certain substrates such as amino acids and free fatty acids mobilized from muscle and adipose tissue. In addition, a normally functioning endocrine system is also necessary to maintain glucose homeostasis and prevent hypoglycemia. Insulin is the dominant glucose-lowering hormone. It suppresses endogenous glucose production and stimulates glucose utilization. The glucose-raising or counterregulatory hormones include epinephrine, glucagon, growth hormone (GH), and cortisol. These increase hepatic glucose production by stimulating glycogenolysis and gluconeogenesis and also inhibit glucose utilization by tissues.

Because the brain cannot synthesize glucose, store glycogen, or use physiologic circulating concentrations of alternative fuels effectively, maintenance of brain function, and ultimately survival, requires a continuous supply of glucose from the circulation. That, in turn, requires maintenance of the plasma glucose concentration within the physiological range because blood-to-brain glucose transport is a direct function of the arterial plasma glucose concentration. Glucose counterregulatory mechanisms effectively prevent or rapidly correct hypoglycemia. These critical physiologic defenses include a decrease in insulin secretion as glucose levels decline within the physiologic range; an increase in glucagon secretion; or, in its absence, an increase in epinephrine secretion, both occurring as glucose levels decline just below the physiologic range. In addition, increased cortisol and GH secretion are involved in the defense against prolonged hypoglycemia. If these defense mechanisms fail, blood glucose levels will continue to fall, and as a result, insulin secretion is virtually completely suppressed at glucose levels <60 mg/mL.

In essence, hypoglycemia develops when the sum of glucose utilization from the circulation (largely by the

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

brain but also by the renal medulla, red blood cells, and insulin-sensitive tissues, such as muscle) exceeds the sum of glucose delivery into the circulation (from ingested carbohydrates and hepatic and renal glucose production).

Clinical Signs of Hypoglycemia

Clinical hypoglycemia is a blood glucose level low enough to cause symptoms, including impairment of brain function. For example, values below 50 mg/dL (2.8 mmol/L) are often accompanied by symptoms, but values below the lower end of the normal reference range may not be. Hence clinical hypoglycemia, which is also referred to as "the hypoglycemic syndrome," is not defined by hypoglycemia alone, but according to Whipple's triad – hypoglycemia accompanied by symptoms that are relieved by the administration of glucose or by feeding.

Symptoms of hypoglycemia are categorized as neuroglycopenic (lack of glucose supply to the brain) or autonomic (largely the result of the sympathoadrenal discharge triggered by hypoglycemia). The neuroglycopenic signs range from lethargy, weakness, ataxia, and unusual behavior to seizures and coma. Clinical signs resulting from stimulation of the sympathoadrenal system include restlessness, muscle tremors, and hunger. Clinical manifestations are dependent on the duration and severity of hypoglycemia. For example, in healthy people, symptoms of hypoglycemia develop at a mean plasma glucose concentration of 55 mg/dL. However, people with recurring fasting hypoglycemia appear to tolerate low blood glucose levels (e.g., <40 mg/dL) for prolonged periods without exhibiting clinical signs. This adaptive process to chronic severe hypoglycemia also occurs in animals.

Etiology/Pathophysiology

Identification of randomly obtained or a fasting blood glucose concentration below 60 mg/dL is cause for concern in dogs or cats. Although this finding is not always diagnostic of organic disease, normal dogs and cats have consistently been shown not to have blood glucose concentrations decline below this level. Therefore, once artifactual hypoglycemia has been ruled out as a possible cause, organic disease is a likely cause of persistent hypoglycemia. Failure in any one of the key steps in the production or conservation of glucose may result in hypoglycemia and clinical signs of hypoglycemia. The many causes of hypoglycemia and a list of differential diagnoses are given using the acronym DAMN IT scheme for diagnosis (Box 13.1).

Box 13.1 DAMN IT diagnosis mnemonic

D	=	Degenerative or Developmental
A	=	Anomalous or Autoimmune
M	=	Metabolic, Mechanical, or Mental
N	=	Nutritional or Neoplastic
I	=	Inflammatory, Infectious, Ischemic, Immune-mediated, Inherited, Iatrogenic, or Idiopathic
T	=	Traumatic or Toxic

Artifactual Hypoglycemia

Artifactual hypoglycemia, also called pseudohypoglycemia, is not a clinical syndrome but rather a result of artifactually low blood glucose concentration *in vitro*, mainly in the presence of leukocytosis, polycythemia, or both. In dogs, it has been reported that the glucose concentration in whole blood kept at room temperature can decrease by as much as 10 mg/dL/h. Presumably, this decrease in glucose concentration is due to continuing utilization of glucose by cells present in the blood. Therefore, whole blood obtained for glucose determination should be centrifuged within an hour after collection, separated and refrigerated or frozen to minimize artifactual lowering of blood glucose concentration. In addition, the practice of measuring glucose in whole blood immediately after collection using portable hand-held glucometers specifically designed and manufactured for measuring human blood glucose, while quick and convenient, is less accurate than measurements by an accredited veterinary laboratory. Because dogs, cats, and humans have different ratios of glucose between the plasma and red blood cells, if a portable hand-held glucometer is used to determine the blood glucose, it is recommended to use the AlphaTRAK® glucometer (Abbott Animal Health) which is calibrated specifically for dogs and cats.

Another cause of artifactual hypoglycemia is laboratory error. Incorrect values can occur with any assay and therefore, it is always wise to confirm a finding of hypoglycemia by evaluating another blood sample before more sophisticated or extensive studies are performed.

Other less common causes of pseudohypoglycemia are seen with the following conditions.

- Leukemias (e.g., chronic lymphocytic leukemia) and benign forms of leukocytosis (e.g., leukemoid reactions).
- Chronic hemolytic anemia accompanied by a high (>3%) nucleated red blood cell count.

- Polycythemia vera: an 87% decrease in blood glucose levels over four hours has been reported.
- Hypovolemic shock: poor capillary circulation leads to increased glucose transit time, promoting increased glucose extraction by the tissue. Capillary blood sampling from the ear or paw pads is low compared to central venous glucose levels which are normal.

Congenital Hepatic Disease: Portosystemic Vascular Shunts, Microvascular Dysplasia, and Glycogen Storage Disease

The most common congenital cause of hepatic-induced hypoglycemia is portosytemic vascular anomalies (PSVA). PSVA is really an "umbrella term" which includes dogs with extrahepatic shunting (PSVA-E) or intrahepatic shunting (PSVA-I). In addition, many small-breed dogs with PSVA have concurrent microvascular dysplasia (MVD). The prevalence of hypoglycemia in dogs with PSVA varies from 5% to 10%. The hypoglycemia associated with PSVA is presumably caused by chronic hepatic hypoperfusion which leads to insufficient glycogen stores and inadequate hepatocellular function to support gluconeogenesis.

Signalment

There is no gender predilection while the average age at presentation is 1.5 years for PSVA-E and 1.0 year for PSVA-I, although dogs can be as young as 1 month or as old as 12 years. Significant difference in body weight between PSVA-E and PSVA-I correlates with the long-recognized propensity for PSVA-E to occur in small-breed dogs and PSVA-I to occur in large-breed dogs. Breed prevalence for PSVA-E implicates high risk in the Yorkshire terrier and several other small breeds including shih tzu, Maltese, pug, miniature schnauzer, West Highland white terriers, bichon frise, miniature and toy poodles, Havanese, cairn terriers, silky terriers, and mixtures of these breeds. The most prevalent breed with PSVA-I is the Labrador retriever, followed by mixed-breed dogs and Siberian huskies.

History

Historical features of PSVA include pediatric hypoglycemia, small body stature (runt of the litter), episodic inappetence, vomiting, salivation, polyuria and polydipsia, and signs associated with ammonium biurate urolithiasis (hematuria, stranguria, and pollakiuria). Neurobehavioral signs of hepatic encephalopathy may be unapparent or may include ataxia, obsessive circling, and head pressing.

Laboratory Findings

In a cohort of 610 dogs with PSVA at Cornell University, no dog with a portosystemic shunt was undetected when tested with paired serum bile acids. Therefore, the most reliable tests for detection of a portosystemic shunt are paired fasting and postprandial bile acid (100% detection), 80% demonstrate low protein C activity (this test reflects the severity of shunting), >60% show microcytosis, low total protein and cholesterol, and a urine specific gravity <1.025, and biurate crystalluria occurs in approximately 33% and 22% of PSVA-E and PSVA-I respectively. It is important to remember that usually, biopsy alone cannot differentiate PSVA and MVD and that MVD alone is not associated with signs of illness (e.g., clinical hypoglycemia).

Other Diagnostics

Imaging studies are needed to differentiate PSVA-E from PSVA-I and MVD and are important for surgical and medical treatments. These include transsplenic microbubble studies, transsplenic and colorectal technetium-99m scintigraphy. However, the gold standard of imaging studies is contrast multisector CT imaging and three-dimensional image reconstruction, which provides optimal comprehensive information for diagnosis and surgical planning for PSVA.

Treatment

It is inarguable that optimal therapy for symptomatic PSVA is shunt attenuation. However, it is important to remember that all symptomatic PSVA dogs will benefit from medical management, yet all dogs do not require all forms of therapy. For example, a wide spectrum of PSVA patients at Cornell University have been managed medically with survival outcome and survival duration no different than for shunt ligation.

Glycogen Storage Diseases

Glycogen storage diseases (GSD) are rare congenital hepatic disorders in which hypoglycemia results from the inability to convert glycogen to glucose because of the absolute or relative deficiency of the enzymes necessary for the breakdown of glycogen stores in the liver. Type III GSD (Cori disease), a deficiency of amylo-1,6-glucosidase, was documented in puppies with massive hepatomegaly caused by glycogen accumulation, failure to thrive, and muscle weakness. Type I GSD (von Gierke disease) has been documented in the Maltese breed. This uncommon disorder is a deficiency of glucose-6-phosphatase caused by a defect in the glucose-6-phosphatase gene. Affected puppies develop progressive hepatomegaly characterized by diffuse hepatocellular vacuolization, tremors, weakness, and neurologic signs when hypoglycemic. Biochemical abnormalities include fasting hypoglycemia, hypercholesterolemia, hypertriglyceridemia, and elevated uric acid levels. Confirmatory

tests include histologic evaluation of liver biopsies and specific enzyme assays that are rarely performed in veterinary medicine. And lastly, GSD type IV has been documented in a family of Norwegian forest cats. It leads to death as a result of perinatal hypoglycemic collapse or late juvenile-onset neuromuscular degeneration.

Idiopathic Causes of Liver-Associated Hypoglycemia in Young Animals: Neonatal and Juvenile Hypoglycemia

Neonatal Hypoglycemia

The blood glucose concentration in the healthy neonate falls during the first few hours after birth because of the loss of continuous transplacental infusion of glucose. Thereafter, the neonate is dependent on glycogenolysis and gluconeogenesis to maintain euglycemia between feedings. Limited glycogen stores, small muscle mass, and lack of adipose tissue as alternative energy sources place the neonate at risk for hypoglycemia. That said, the ill neonate should always be evaluated for hypoglycemia, especially if sepsis, toxic milk syndrome, or starvation is suspected or hypothermia is noted. Orally administered glucose or frequent bottle feeding can help correct or prevent hypoglycemia.

Juvenile Hypoglycemia

Hypoglycemia of toy and miniature breed dogs younger than 6 months of age is common. Deficiency of gluconeogenic precursors such as the amino acid alanine or an age-related transient malfunction or deficiency of enzymes responsible for gluconeogenesis is implicated in this syndrome. Insufficient food supply of any cause such as starvation or gastrointestinal disturbances may cause hypoglycemia within 24 hours of fasting. In addition, underlying conditions such as PSVA that cause anorexia or impaired liver function may contribute to the precipitation of this syndrome. Many of these puppies have a history of being recently purchased along with a recent change in environment and diet. Presenting signs may include weakness, depression, vomiting and diarrhea with or without intestinal parasites, ataxia, stupor, and seizures. Similar forms of juvenile hypoglycemia have not been well documented in kittens.

Treatment and Prognosis

Intravenous administration of a 20% or 50% dextrose solution (0.8 mL to 0.2 mL per 100 g body weight respectively) is indicated if there are neurologic signs. If the pup can take the glucose solution orally, this is administered at regular intervals until appetite returns. The small amounts of food are given at two-hour intervals. If tube feeding is needed, oral rehydration is guided by electrolyte measurements. Clinical improvement occurs rapidly following glucose administration. The prognosis is good if hypoglycemia is corrected before brain damage occurs. The risk of developing hypoglycemia decreases with increasing age and body weight.

Nonislet Cell Tumor-Induced Hypoglycemia

Hypoglycemia can be a manifestation of neoplastic disease. Tumors related to the occurrence of hypoglycemia can, as a general rule, be divided into three groups. First, tumors can produce excess insulin such as pancreatic insulinomas or ectopic insulin-producing tumors. Second, hypoglycemia can be caused by tumor-related factors such as destruction of the liver by massive tumor infiltration. And lastly, there is now convincing evidence that secretion of insulin-like growth factor (IGF)-2 and incompletely processed IGFs (e.g., pro-IGF-2 or "big"-IGF-2) causes hypoglycemia in humans. This mechanism has also been documented in a few cases of hypoglycemia in dogs. Nonislet cell tumor-induced hypoglycemia (NICTH) can arise in virtually every benign and malignant tumor. However, it mainly occurs in patients with solid tumors of mesenchymal (e.g., leiomyosarcoma, fibrosarcoma) and epithelial origin (e.g., hepatoma, hepatocellular carcinoma), but rarely in patients with tumors of hematopoietic or neuroendocrine origin. The most frequent nonpancreatic tumors associated with hypoglycemia are leiomyoma, leiomyosarcoma, hepatoma, hepatocellular carcinoma, and tumors with extensive hepatic metastasis.

Pathophysiology

Understanding the cause of hypoglycemia with NICTH involves a brief review of the IGF system. The IGF system is composed of two IGF ligands (IGF-1 and IGF-2) and two IGF receptors: the IGF-1 receptor (IGF1R) and IGF-2 receptor (IGF2R). Both IGF-1 and IGF-2 are structurally and functionally related to insulin but the glucose-lowering effect of IGFs is 10 times lower than that of insulin, although in healthy human subjects the serum concentration of IGFs is about 1000 times higher than insulin. The crucial event in the development of NICTH seems to be overexpression of the IGF-2 gene by the tumor. NICTH is characterized by recurrent fasting hypoglycemia and is associated with the secretion of precursors of IGF-2 ("big"-IGF-2) by the tumor.

Diagnosis

Dogs with hypoglycemia caused by NICTH are usually brought to the veterinarian with clinical signs of hypoglycemia, or hypoglycemia may be noted on a biochemical profile in an asymptomatic patient during a wellness exam. The diagnosis of a nonislet cell tumor requires a

thorough physical examination, thoracic and abdominal radiographs, abdominal ultrasonography, and histopathologic examination of the tumor, which is often located in the abdominal cavity.

Treatment

The long-term therapeutic strategies in NICTH involve complete removal of the tumor or reduction of the tumor mass. In order to treat hypoglycemia, a short-term beneficial effect is best achieved with (continuous) parenteral administration of glucose and dietary guidelines. Glucocorticoids, at least in humans, seem to be the most effective form of medical therapy in terms of long-term relief from hypoglycemia by stimulating glyconeogenesis and suppressing, although not in all cases, the production of "big"-IGF-2. In addition, moderate to high doses of glucocorticoids may cause shrinkage of the tumor.

Hypoadrenocorticism

Incidence

Hypoadrenocorticism should always be on the rule-out list for hypoglycemia. Of 506 dogs diagnosed with hypoadrenocorticism at UC Davis Veterinary Medical Teaching Hospital, 116 (25%) were hypoglycemic at the time of diagnosis. Interestingly, however, clinical signs attributable to hypoglycemia appear to be uncommon. In this cohort of cases, hypoglycemic seizures and other clinical signs that may have been caused by hypoglycemia, such as ataxia and disorientation, were observed in only 30 dogs (6%).

Pathophysiology and Treatment

With glucocorticoid deficiency, glucose production by the liver (i.e., gluconeogenesis) is decreased and the sensitivity of insulin receptors in peripheral tissues is increased. In tandem, these factors predispose the animal with adrenal insufficiency to hypoglycemia. That said, the blood glucose concentration should always be measured in a dog suspected or known to have hypoadrenocorticism. A 2.5–5% dextrose infusion, usually added to lactated Ringer's or normal saline solution, should be administered as soon as hypoglycemia is documented in addition to glucocorticoid replacement therapy. If the pretreatment serum sodium and potassium concentrations are normal, mineralocorticoid replacement is not necessary over the short term, and may never be indicated in some dogs with adrenal insufficiency (atypical hypoadrenocorticism). These dogs, despite low serum aldosterone concentrations, are able to maintain normal serum sodium and potassium levels for reasons that are unclear.

Critical Illness and Hypoglycemia: Renal Failure, Acquired Liver Disease, Sepsis, and Virulent Babesiosis

Renal Failure

Renal failure is associated with hypoglycemia in critically ill diabetic and nondiabetic human patients, but the impact of renal failure on the blood glucose concentration is unpredictable in dogs and cats. In most cases, the blood glucose concentration is normal. However, hyperglycemia may develop as a result of uremic-induced carbohydrate intolerance and insulin resistance in a dog or cat with impaired insulin secretion; this phenomenon has been referred to as "pseudodiabetes." Alternatively, renal failure may induce hypoglycemia.

Several mechanisms for the development of hypoglycemia during renal insufficiency have been proposed. These include reduced renal gluconeogenesis and decreased caloric intake related to inappetence. Normally, renal gluconeogenesis may supply as much as 45% of new glucose during prolonged starvation. Additional defects in glucose homeostasis occur in renal insufficiency, including an increased insulin half-life related to decreased renal degradation or excretion of insulin, impaired hepatic glycogenolysis and gluconeogenesis, inadequate glucose counterregulatory responses, or a combination of these factors. It should be emphasized that hypoglycemia is rarely the cause of death in the critically ill patient with renal failure and is considered more a marker for multisystem failure than a cause of mortality.

Acquired Hepatic Dysfunction

Hypoglycemia has been associated with a wide spectrum of liver diseases in people. These disorders include everything from type 1 glycogen storage disease, cirrhosis, viral hepatitis, procainamide-induced hepatitis, cholecystitis, and metastatic infiltration to fulminant liver failure after cardiac arrest. In dogs and cats, hypoglycemia often results from severe destruction of the liver from bacterial infection, hepatotoxins, neoplasia, and chronic fibrosis/cirrhosis with the development of acquired portosystemic shunts. The underlying cause of hypoglycemia results from inadequate amounts of functional liver tissue for optimal gluconeogenesis and glycogen storage to maintain normal blood glucose levels.

The diagnosis of acquired liver dysfunction is usually quite straightforward. Common CBC, serum biochemical profile and urinalysis abnormalities may include microcytosis, low serum albumin, BUN and cholesterol concentrations, elevated serum bilirubin levels, elevated paired serum bile acid concentrations, ammonium biurate crystals in the urine, radiographic evidence of abnormal liver size, and/or ultrasonographic changes consistent with abnormal echotexture or liver size. A liver biopsy is

necessary to determine the exact cause of the liver disorder and may help guide specific treatment options such as the selective use of antibiotics, glucocorticoids, copper chelation, ciclosporin, lactulose, and dietary therapy.

Sepsis-Induced Hypoglycemia

Systemic illness caused by microbial (usually bacteria) invasion of normally sterile parts of the body is referred to as sepsis. Sepsis plus organ dysfunction or hypoperfusion is termed severe sepsis. And severe sepsis accompanied by hypotension is termed septic shock.

Impaired glucose homeostasis has been well documented in patients with sepsis. Hyperglycemia is the most common blood glucose abnormality seen early in the course of bacterial sepsis. In preterminal sepsis, profound hypoglycemia may occur because of hyperinsulinemia, increased tissue uptake of glucose, and the failure of hepatic glucose production. It is postulated that sepsis-related hypoglycemia is a manifestation of nonspecific inflammatory responses mediated by high levels of cytokines, including tumor necrosis factor and interleukin-6.

The signs and symptoms of sepsis are highly variable. They are influenced by the virulence and "bioburden' (the amount) of the organism, the portal of entry (e.g., skin, gut, urinary tract) and host susceptibility (the young and very old and patients with weakened immune systems are most at risk). Patients with sepsis can present with a fever or hypothermia and CBC findings may show a leukocytosis with a left shift or leukopenia. Common causes of sepsis-induced hypoglycemia include parvovirus infection, prostatic and liver abscesses, pyothorax, pyometra, hemorrhagic gastroenteritis, and gram-negative bacteremia. The diagnosis of sepsis-induced hypoglycemia is often one of suspicion or identification of an infection based on history, physical examination and CBC findings, and other diagnostics such as bacterial cultures, radiography and ultrasonography, and resolution of hypoglycemia after initiation of antibiotic therapy.

Virulent Babesiosis

Hypoglycemia has been identified as a life-threatening metabolic complication in almost 20% of severely ill dogs suffering from babesiosis caused by *Babesia canis rossi*. This highly virulent subspecies of *Babesia canis* is endemic only to South Africa. Clinical signs include pale mucous membranes, depression, tachycardia, tachypnea, anorexia, weakness, splenomegaly, and fever. The clinical signs are attributed to tissue hypoxia resulting from anemia and a concomitant systemic inflammatory response syndrome caused by marked cytokine release. The severe form of the disease is characterized by hemolytic anemia and severe acid–base derangements, with secondary multiple organ failure and complications such as acute renal failure, hepatopathy with marked icterus, hypoglycemia, acute respiratory distress syndrome, cerebral pathology, and additional immune-mediated erythrocyte destruction. Mortality is around 12%. A feature of the disease is that, in contrast to babesiosis in other domestic species, pups and immature dogs are also severely affected. Only one case of *Babesia canis rossi* has been reported in a dog in the United States and that was a dog imported from South Africa.

Several contributing factors have been implicated as causes of the hypoglycemia. These include increased peripheral requirement for glucose during febrile and critical illness, obligatory demands of the parasites that use glucose as their major fuel, hyperinsulinemia, failure of hepatic gluconeogenesis and glycogenolysis, and increased glucose consumption by anaerobic glycolysis because of tissue hypoxia.

Blood glucose concentration should ideally be measured in all dogs requiring inpatient treatment for babesiosis, but is mandatory in collapsed dogs, puppies and dogs with severe anemia, vomiting, or icterus. Many dogs have probably been misdiagnosed with cerebral babesiosis in the past, and hypoglycemia should be suspected in any dog with coma or other neurologic signs. Response to treatment with selected antibabesial compounds such as imidocarb dipropionate, atovaquone, azithromycin, clindamycin, and doxycycline is variable, and intravenous dextrose does not reliably improve glycemic status or survival.

Persistent Hyperinsulinemic Hypoglycemic Syndrome

In humans, persistent hyperinsulinemic hypoglycemia of infancy (PHHI) represents the most common cause of hyperinsulinism in neonates and children; currently, many authors prefer the term congenital hyperinsulinism (CHI). Severe recurrent hypoglycemia associated with an inappropriate elevation of serum insulin defines CHI. This disturbance of the normal relationship between glucose concentration and insulin secretion is caused by a variety of genetic mutations. If left untreated, CHI can lead to brain damage or death secondary to severe hypoglycemia. Although it was initially thought to affect only infants and children, numerous cases have been reported in adults of all ages but at a much lower incidence. CHI is often poorly responsive or unresponsive to medical management, necessitating 95% or near-total pancreatectomy.

Recently, a persistent hyperinsulinemic hypoglycemic syndrome, not associated with sepsis or insulinoma, was diagnosed in two dogs. Both dogs were less than 12 months of age. The clinical signs in these dogs were similar; hypoglycemic-induced seizures unresponsive to

intravenous glucose administration and anticonvulsant therapy. The owners of these dogs chose euthanasia because of poor response to therapy and poor prognosis. Blood was cultured from one dog using a special enrichment PCR media to rule in or rule out an infection caused by a fastidious bacteria; *Bartonella hensalae* was amplified and sequenced from this dog's blood. In the other dog, *Bartonella kohlerae* was amplified and sequenced retrospectively from paraffin-embedded tissue. Despite isolating *Bartonella* spp. from both dogs, it is unclear whether *B. hensalae* and *B. kohlerae* contributed to the pathogenesis of this unusual and rare hypoglycemic syndrome. That said, persistent hyperinsulinemic hypoglycemic syndrome should be suspected in any young dog with hypoglycemia refractory to intravenous glucose. Moreover, until more is known about the cause of this syndrome, testing and treating for *Bartonella* should be a diagnostic and therapeutic consideration.

Xylitol Toxicity

Xylitol exposure, even in small amounts, can cause hypoglycemia and severe liver damage in dogs. Xylitol is a 5-carbon sugar alcohol that is used primarily as an artificial sweetener that has less than two-thirds of the calories of most sugars. The two major sources of xylitol exposure are food and dental or medical products. Initially, exposure to xylitol in dogs was from "sugar-free" chewing gums. However, with demands from human diabetic patients, particularly because of the popularity of Atkins-like "low-carb" diets, many foods now contain xylitol. A large number of low-carbohydrate foods, including breads, candies, gums, and deserts, have xylitol as the sweetener of choice. Xylitol has a wide margin of safety in mammals with the exception of dogs. Oral exposures as low as 0.1 mg/kg have induced hypoglycemia in the dog, and levels of 0.5 mg/kg have resulted in hepatotoxicity in some dogs. For example, one piece of Trident gum contains 0.22 g of xylitol and the popular breath mint Ice Breakers contains 1 g of xylitol per piece and therefore, nine pieces of Trident or two Ice Breaker pieces could potentially cause xylitol toxicity in a 20 kg dog. The literature reports no cases of xylitol toxicity in cats.

Prevalence

Recently, there has been a rapid increase in the number of products containing xylitol. According to the ASPCA Animal Poison Control Center (APCC), the number of reported xylitol exposures in dogs has been increasing steadily and exponentially over the past few years. In 2007, theAPCC began to log xylitol cases. That year, the center received 1764 calls about xylitol. In 2012, the figure was 3184. The number of products containing xylitol has been steadily rising over the last few years, with a resultant surge in xylitol cases reported to the APCC.

Clinical Signs and Laboratory Abnormalities

In laboratory experiments, xylitol directly stimulates insulin synthesis and secretion within 30 minutes after ingestion. However, in clinical cases, the onset of clinical signs varies based on the form of xylitol used in the product ingested. The powder used in candies and mints is absorbed quickly and signs can be seen in 30 minutes. Gum must be chewed to release the xylitol. If the gum is swallowed whole it leaches into the stomach, and the onset of clinical signs can be delayed 8–18 hours. Vomiting is often the first symptom. Clinical signs can include ataxia, depression, dilated pupils, and seizures (related to hypoglycemia), and lethargy, inappetence, vomiting, and diarrhea (related to liver failure). Laboratory abnormalities initially include hyperinsulinemia, hypoglycemia, hypophosphatemia, hypokalemia, and increased AST and ALT concentrations. Dogs that do not exhibit hypoglycemia immediately after ingestion of xylitol may still develop acute liver failure. These dogs may develop severe signs 24–72 hours later.

Diagnosis

The diagnosis of xylitol toxicity is made by history of exposure, clinical signs, and serum biochemical abnormalities consistent with xylitol poisoning. Because the serum half-life of xylitol is about two minutes and there is rapid progression of the toxic effect, testing for xylitol in the blood is not realistic.

Treatment and Monitoring

Blood glucose levels should be determined initially and monitored at least every four hours for 24 hours or longer, as indicated. Liver enzyme levels and prothrombin time/partial thromboplastin time (PT/PTT) should be monitored every 24 hours for 48–72 hours. It is not uncommon to have a transient elevation in ALT (300–800) very quickly after ingestion. Electrolyte status and packed cell volume (PCV) should also be monitored regularly.

- There is no antidote for xylitol toxicity.
- Induce emesis if the xylitol ingestion is recent.
- Use of activated charcoal is of limited efficacy with xylitol because it is not effective at binding xylitol.
- IV fluid support: important to restore or maintain hydration, treat hypoglycemia, and prevent or treat disseminated intravascular coagulation (DIC). Patients with normal blood glucose levels should receive a 2.5% dextrose solution.
- Hypoglycemia caused by xylitol toxicity is usually responsive to IV dextrose solutions. Refractory cases

may be treated with glucagon or dexamethasone. Feeding small frequent meals may be beneficial in helping to manage hypoglycemia.
- Use antiemetics and gastrointestinal protectants as needed.
- Avoid drugs that are metabolized by the liver.
- Antibiotics may be indicated in acute liver failure cases to treat concurrent infection (clavamox or amoxicillin, ampicillin, cephalexin, or cefadroxil with metronidazole).

Duration of Treatment and Prognosis

The length of treatment depends on the severity of clinical signs**.** Treatment for cases without liver involvement may last 1–3 days. Treatment should continue until glucose levels are normal. Treatment of cases with liver involvement may last weeks. The prognosis for patients that only develop hypoglycemia is good. Prognosis for patients who develop liver failure is guarded and depends on the severity of the disease. Typically, there are no lingering medical issues once liver problems have been successfully resolved.

Diagnostic Approach to Disorders Associated with Hypoglycemia

After confirming the finding of hypoglycemia, the history (including exposure to insulin, sulfonylureas, or xylitol), signalment, physical exam findings, and a careful review of available laboratory data guide the evaluation. This information will either provide clues to the cause of hypoglycemia or exclude hypoglycemia caused by acknowledged drugs or toxins, critical illnesses, hormone deficiencies, or a nonislet cell tumor. A test of adrenocortical function is reasonable although hypoadrenocorticism is not commonly found as a cause of hypoglycemia in dogs in the absence of other clinical clues. Nonislet cell tumor hypoglycemia is often associated with a large, clinically apparent mesenchymal tumor (e.g., leiomyoma and leiomyosarcoma) as well as epithelial tumors that are associated with the liver (e.g., hepatoma or hepatocellular carcinoma).

As part of the signalment, age of the animal can be quite useful in narrowing down the long list of rule-outs for hypoglycemia. For example, hypoglycemia in a puppy or kitten is often idiopathic in origin or related to starvation, PSVA, or sepsis. In young adult dogs, hypoglycemia is usually caused by hepatic insufficiency, hypoadrenocorticism, or sepsis. And in older dogs, hepatic insufficiency, insulinoma (see Chapter XX), nonislet cell tumor-induced hypoglycemia, hypoadrenocorticism, and sepsis are the most common causes of hypoglycemia.

The results of routine and specialized tests can also be quite helpful diagnostically. For example, dogs with adrenal insufficiency without the classic electrolyte changes of hyperkalemia and hyponatremia often have hypoalbuminemia, hypocholesterolemia and a resting cortisol <2 µg/dL, although an ACTH response test is required for a definitive diagnosis. Paired fasting and postprandial serum bile acids are diagnostic for virtually all dogs with a portosystemic shunt, and CBC findings which include a neutrophilic leukocytosis with a left shift in a hypoglycemic febrile dog or cat are highly suggestive of sepsis.

When the cause of the hypoglycemic disorder is not evident in a seemingly well adult dog, serum glucose and insulin concentrations should be measured during an episode of spontaneous hypoglycemia to rule out an insulinoma. The key pathophysiologic feature of endogenous hyperinsulinism (e.g., an insulinoma) is the failure of insulin secretion to fall to very low rates as blood glucose concentrations fall to hypoglycemic levels.

Canine Autoimmune Polyglandular Syndromes

Deborah Greco, DVM, PhD, DACVIM (SAIM)

Desert Veterinary Specialists, Palm Desert, CA, USA

Many endocrine disorders, such as lymphocytic thyroiditis, hypoadrenocorticism, and type 1 diabetes mellitus, have an autoimmune basis. When endocrine immune disorders occur in the same individual, they are known as autoimmune polyglandular syndromes (APS). These syndromes (APS) can be further divided into APS type 1 (diabetes mellitus, ectodermal mucositis, etc.), APS type 2 (hypoadrenocorticism, hypothyroidism, etc.), and APS type 3 (liver cirrhosis plus endocrinopathies). The combination of hypoadrenocorticism and hypothyroidism is called Schmidt syndrome after the pathologist who described concurrence of these two diseases in human beings. Autoimmune polyglandular syndrome type 2 is the only one that has been described in dogs.

Etiology and Pathophysiology

Polyendocrine gland failure or autoimmune polyglandular syndrome, the most common form of which is APS type 2, has been well documented in humans. Autoimmune polyglandular syndrome type 2 is defined as the occurrence of two or more of the following disorders in the same individual: adrenal insufficiency, primary hypothyroidism, type 1 diabetes mellitus (DM), primary hypogonadism (premature ovarian failure, immune-mediated orchitis), myasthenia gravis, megaesophagus, immune-mediated hemolytic anemia (IMHA), immune-mediated thrombocytopenia (ITP), hypoparathyroidism, hypopituitarism, and celiac disease.

Circulating organ-specific autoantibodies are commonly present in APS type 2. Environmental factors combined with an HLA-associated genetic predisposition are thought to trigger the process. Cell-mediated immune abnormalities in the type 2 syndrome include defects and alterations of cell surface markers, but the most consistent abnormality is a functional defect leading to a decrease in suppressor T cell activity. Approximately 45% of all human patients with idiopathic (autoimmune) adrenal insufficiency will develop one or more additional endocrinopathies (usually hypothyroidism).

The genetics of APS has been studied extensively in human beings. APS 2 is inherited as an autosomal dominant trait in humans associated with the presence of human leukocyte antigens (HLA). In families where this syndrome has been documented in several individuals, the inheritance of major histocompatibility loci haplotype correlates most strongly with the disease. Many individuals with this haplotype have circulating organ-specific autoantibodies directed against cytochrome P450 without clinical signs of disease. Recently, one study found that a higher proportion of dogs with hypoadrenocorticism were P450scc autoantibody positive when compared to hospital controls (24% vs 1%). Lymphocytic and plasmacytic destruction of the affected endocrine glands may be documented histologically.

Hypoadrenocorticism is the most common initial endocrinopathy observed in polyendocrine gland failure in dogs and is usually followed by the development of hypothyroidism. However, type 1 diabetes combined with immune-mediated thyroid disease (Hashimoto thyroiditis) is also a common combination of immune endocrinopathies in humans and has been described in dogs. Studies show that 45–50% of humans with adrenal insufficiency associated with polyendocrine gland failure (onset 20–30 years) develop a second endocrinopathy. The most common second endocrinopathy, primary hypothyroidism, develops 10–20 years after the first endocrinopathy.

In a retrospective of 225 cases of canine hypoadrenocorticism, 4% of the dogs (n = 9) also suffered from hypothyroidism, two dogs had concurrent IDDM and hypoadrenocorticism, and one had concurrent hypoadrenocorticism, hypothyroidism, IDDM, and hypoparathyroidism. Another retrospective of 45 dogs with

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

adrenal insufficiency reported four with concurrent hypothyroidism, one dog with concurrent IDDM and one dog with concurrent primary gonadal hypoplasia. A single case of type 2 APS has been described in a middle-aged female dog presenting in a hypothyroid crisis; treatment of the hypothyroid state resulted in precipitation of the hypoadrenocorticism. The presence of serum autoantibodies to thyroid and adrenal tissue was observed in this dog as evidence of APS type 2.

History and Clinical Signs

Most of the dogs in reported studies were diagnosed with hypoadrenocorticism initially and the mean age of onset of the disease was in young adulthood. Dogs are usually diagnosed with a second endocrinopathy approximately one year after the first endocrinopathy.

A familial tendency was observed in one study where two dogs were mother and daughter and one dog had a sibling with hypoadrenocorticism. Hypoadrenocorticism is inherited in several breeds, including standard poodles, West Highland white terriers, Nova Scotia duck tolling retrievers, Portuguese water dogs, and Leonbergers; however, there may be different DLA haplotypes depending on breed. There is a distinct breed predisposition for primary hypothyroidism with golden retrievers, Doberman pinschers, Irish setters, miniature schnauzers, dachshunds, cocker spaniels, and beagles. Diabetes mellitus (type 1a), which has an autoimmune basis, is seen with increased frequency in Samoyeds, Tibetan terriers, Australian terriers, keeshonds and several other breeds. In fact, one study showed that the DLA-DRB1*009/DQA1*/DQB1*008 haplotype was associated with DM in certain breeds (Samoyed, Tibetan, and cairn terriers) and that the DLA-DQA1*001 allele is also associated with hypothyroidism in dogs, suggesting a common susceptibility allele for canine immune-mediated endocrinopathies.

A decreasing insulin requirement is often the earliest sign of adrenal insufficiency in a patient with type 1 diabetes mellitus secondary to APS in human beings. In contrast, dogs with concurrent hypothyroidism and IDDM often have increasing insulin requirements; hypothyroidism may cause insulin resistance resulting from lipid abnormalities or other factors.

The most common presenting complaints for hypoadrenocorticism as the initial diagnosis include lethargy, collapse, vomiting, weight loss, weakness, ataxia, anorexia, bradycardia, megaesophagus, and diarrhea. Clinicopathologic features include hyponatremia, hypercholesterolemia, hyperkalemia, hypochloremia, azotemia, hypocalcemia, and hypercalcemia.

In dogs diagnosed with hypoadrenocorticism as the initial endocrinopathy, thyroid evaluation is often performed because of continued lethargy despite adequate mineralocorticoid replacement therapy, persistent hyponatremia, hypercholesterolemia, dermatologic disease, bradycardia, obesity, and heat-seeking behavior. In cases of combined DM and hypothyroidism, diabetes mellitus insulin resistance is usually the reason for thyroid testing.

Diagnosis and Prognosis

In two studies, dogs with concurrent diabetes and hypothyroidism showed significantly lower serum sodium concentration and had significantly higher fasting serum cholesterol compared with nonhypothyroid diabetic dogs; similarly, dogs with hypoadrenocorticism combined with hypothyroidism exhibited significantly lower sodium and higher serum cholesterol than dogs with hypoadrenocorticism alone. These two chemistry abnormalities are highly suggestive of hypothyroidism in a dog with otherwise well-regulated hypoadrenocorticism or in a poorly regulated diabetic dog. Severe hyponatremia (<120 meq/L) is a sign of Schmidt syndrome in humans. Thyroid testing should be performed in diabetics dogs that exhibit poor glucose regulation, persistent hyponatremia and hypercholesterolemia, obesity or weight gain, lethargy, dermatologic disease, and regurgitation.

Resting serum cortisol concentration is often subnormal (<2 µg/dL) in dogs that suffer from APS 2 that manifests as hypoadrenocorticism and all will show inadequate response to adrenocorticotropic hormone (ACTH) stimulation. Endogenous ACTH levels should be increased due to primary adrenal insufficiency and loss of negative feedback to the pituitary gland. One reported case of Schmidt syndrome (APS 2) had evidence of lymphocytic adenohypophysitis in addition to adrenalitis and thyroid gland atrophy; immune-mediated pituitary disorders have been reported in humans as well. Mean basal thyroxine (T4) and free T4 levels are usually low to low normal and endogenous thyroid-stimulating hormone (TSH) is usually elevated in dogs with multiple endocrinopathies resulting from APS.

Therapy

Treatment of multiple endocrinopathies consists of specific hormone replacement. For dogs with hypoadrenocorticism, treatment with fludrocortisone (0.018 mg/kg PO q24h) or deoxycorticosterone pivalate (DOCP) (1 mg/kg IM monthly) should be initiated first, followed by levothyroxine therapy (22 µg/kg once or twice daily PO). One should be aware that aggressive levothyroxine therapy might precipitate a life-threatening adrenal crisis

in a patient with APS so starting once daily would be suggested. When the hypothyroid and hypoadrenal states occur concurrently, the rate of clearance of cortisol and cholesterol is reduced due to low serum thyroxine concentrations. When thyroid supplementation is initiated, cortisol clearance increases suddenly without a compensatory increase in cortisol synthesis because of destruction of adrenal tissue. As a result, thyroid therapy may precipitate an adrenal crisis. Hence, one should assess adrenal function prior to initiation of levothyroxine therapy in animals with suspected multiple endocrinopathies. In dogs with diabetes mellitus and hypothyroidism, one must balance the insulin dose with the levothyroxine therapy. A reduction of 25% of the insulin dose is recommended when starting levothyroxine at 22 µg/kg BID. In dogs with hypoadrenocorticism and diabetes mellitus, the insulin dose will need to be gradually increased as supplementation with glucocorticoids (0.22 mg/kg PO q24h) and DOCP will cause insulin resistance.

Conclusion

In summary, multiple endocrine deficiencies occur with a low incidence in dogs with hypoadrenocorticism, hypothyroidism, IDDM, and perhaps hypoparathyroidism. This syndrome appears to be similar to APS 2 of human beings. Veterinarians should be aware of some of the features, such as persistent hyponatremia and hypercholesterolemia, which may indicate the presence of multiple endocrinopathies in the same individual. Dogs with hypoadrenocorticism that exhibit inadequate response to therapy, persistent hypercholesterolemia and hyponatremia despite normalization of serum potassium, dermatologic disease, and/or bradycardia should be evaluated for thyroid function. Diabetic dogs that exhibit inadequate glycemic control associated with persistent hyponatremia, hypercholesterolemia (>500 mg/dL), obesity and dermatologic disease should also be tested for hypothyroidism.

Cardiovascular Disease

15

Approach to the Patient with Suspected Cardiovascular Disease

Ingrid Ljungvall, DVM, PhD, DECVIM-CA (Cardiology) and Jens Häggström, DVM, PhD, DECVIM-CA (Cardiology)

Department of Clinical Sciences, Swedish University of Agricultural Sciences, Uppsala, Sweden

Suspicion of cardiac disease in dogs and cats may arise due to information obtained from owner complaints and/or physical findings. Unfortunately, most of the common clinical signs of heart disease are not specific for heart disease. Likewise, heart disease may occur concurrently with other disease, making it unclear whether the clinical signs are due to cardiac disease or something else. The approach to the patient with suspected cardiovascular disease is therefore to obtain as much information as possible in order to make a correct diagnosis.

Signalment

Signalment information is the first step in the clinical work-up of a patient with suspected heart disease as some diseases are more commonly seen in specific types of animals. However, this type of data is only supportive in nature, and does not provide sufficient evidence for a definite diagnosis. The signalment data should include information concerning age, species, breed, sex, and geographic location.

Age

Age can provide valuable information in a patient with suspected cardiac disease; congenital heart disease, which is defined as a heart defect present at birth, is more likely in young pets. However, congenital heart disease may remain undiscovered in middle-aged or old dogs and cats not previously examined by a veterinarian. Acquired heart disease, defined as a heart condition developing after birth, is most frequently found in middle-aged and old dogs and cats, although its presence in a younger individual cannot be excluded. For both dogs and cats, presence of cardiac neoplasia is more common in older individuals. Extracardiac disease may affect the heart by causing myocyte damage in dogs and cats of any age.

Species and Breed

Some specific heart diseases, both congenital and acquired, are more commonly identified in individuals of certain breeds compared to others (see separate disease chapters), which supports a genetic background for these disorders.

Sex

Very little is known concerning the effect of sex on the prevalence of congenital heart disease in dogs and cats. In most studies, no sex predilection has been reported. However, sex appears to affect the prevalence of the most common forms of acquired heart disease in dogs (myxomatous mitral valve disease [MMVD] and dilated cardiomyopathy [DCM]) and cats (cardiomyopathy). Males appear affected at an earlier age in both cats and dogs, which leads to a slightly higher proportion of affected individuals at a given age and a higher cause-specific mortality. The reason for this influence of sex is unknown.

Geographic Location

Information concerning the geographic origin of the pet is important because the prevalence of certain congenital and acquired heart diseases differs between continents, countries, and even within countries. Again, this likely reflects different gene pools within breeds, but it underlines the importance of interpreting results of disease prevalence with caution. It is also important to obtain information about where the animal has lived geographically because some diseases, for example parasitic diseases (e.g., dirofilarosis), are prevalent in certain areas but nonexistent in others.

Case History and Owner Complaints

A thorough medical history provides important information and is an integral part of the cardiovascular examination. The questions may vary depending on the nature of the animal's health problem. Information obtained from the owner interview and findings at the physical examination are used to formulate a problem list, which can be used in the decision to pursue further clinical testing.

Dogs and cats with heart disease can present with clinical signs related to the heart condition but also, the pet can be completely free of signs of disease and the only reason for the cardiac examination is an incidental finding of a heart murmur or arrhythmia. Common owner complaints for a pet with heart disease include increased respiratory rate (tachypnea), difficulty of breathing and changed respiratory pattern (dyspnea), coughing (unusual in cats), abdominal distension (ascites), fainting (syncope), tongue and mucous membrane cyanosis, weight loss, and weakness and exercise intolerance. These signs of heart disease can be grouped into four main categories:

- respiratory abnormalities caused by left-sided congestive heart failure (CHF)
- exercise intolerance, weakness, wasting, and syncope caused by low cardiac output
- abdominal distension caused by right-sided CHF
- cyanosis caused by reduced oxygenation of peripheral blood.

Unfortunately, none of these signs is specific for heart disease, and may be caused by a wide variety of disorders.

Dyspnea, Tachypnea, and Cough

The most common sequela of heart disease in dogs and cats is left-sided CHF. The increased pulmonary venous pressure leads to pulmonary congestion and edema formation, causing respiratory signs such as dyspnea, tachypnea, and cough (unusual in cats). Dyspnea may appear in many different forms in pets with heart disease. In working dogs, an experienced owner might note a changed respiratory character during and/or after work at an earlier stage of disease. However, many dogs and cats do not exercise in this intense manner, which means that owners do not observe changed respiration until it is apparent at rest (at a comparably advanced stage).

In general, the respiratory rate gradually increases followed by a worsening of dyspnea, but the respiratory signs may develop at different rates in different diseases and individuals. Accordingly, it is useful to have the owner monitoring the respiratory rate at home in an animal at risk for developing CHF. Dogs and cats without decompensated CHF have in general a sleeping/resting respiratory rate of <30/min. As a general rule, long-standing (weeks or months) respiratory signs that have not worsened over time speak against CHF. Respiratory signs, with or without cough, while lying down or asleep, a phenomenon called nocturnal dyspnea/coughing, are common early signs of left-sided CHF. The severity of dyspnea can range from mild, with only minimal changes in breathing pattern and respiratory rate, to severe life-threatening dyspnea, when the pet is unwilling to lie down (orthopnea), usually with respiratory rates >50/min. The owner often describes changed breathing sounds in animals with severe pulmonary edema. Cats with left-sided CHF frequently develop pleural effusion alone or in addition to pulmonary edema, and these cats can exhibit a paradoxical breathing pattern.

Dogs presenting with left-sided decompensated CHF may present with cough. Cough is not commonly associated with CHF in cats, and owner complaints of coughing in cats should raise the suspicion of other respiratory disease. In dogs, there is also a problem distinguishing cough caused by other diseases, such as small bronchial disease and tracheal collapse, from cough associated with pronounced cardiomegaly with or without CHF. There is no definitive way of distinguishing cardiac from noncardiac cough in dogs. A noncardiac cough is more frequently nonproductive, loud and "honky," whereas cough caused by left-sided CHF can be softer and may have a more productive "wet" character, in particular in large dogs with DCM where co-existing respiratory disease is less common.

Exercise Intolerance, Weakness, Wasting, and Syncope

Variable degrees of weakness and exercise intolerance often develop in dogs and cats with heart disease. However, exercise intolerance can be difficult to assess in cats. Weakness and exercise intolerance can occur as a consequence of a reduced cardiac output resulting in reduced peripheral perfusion with reduced oxygen and nutrient delivery to skeletal muscles.

Weakness, exercise intolerance, and syncopal events can develop due to pulmonary hypertension or cardiac arrhythmia, intermittent or sustained, in dogs and cats with heart disease. Pets with sustained bradycardia or tachycardia are often weak even at rest and exhibit significant exercise intolerance. In cases of intermittent arrhythmia, the owner often describes a rapid change in the dog's behavior, consciousness, or postural tone. Defecation and urination can accompany these events. Even though syncope can occur in dogs and cats with heart disease, it is not specific for heart disease or heart failure, which underlines the importance of obtaining an accurate and detailed case history.

In dogs with CHF and a chronic reduction of peripheral perfusion, a loss of body weight may be apparent. Sequential measurements of body weight over time can be useful to identify subtle weight loss. However, identification of weight loss may be problematic if loss of muscle mass is masked by concurrent fluid retention.

Abdominal Distension

Abdominal distension can be caused by a wide variety of diseases, both cardiac and noncardiac in origin. In heart disease, abdominal distension is the result of right-sided CHF leading to congestion of abdominal organs (such as the liver) and transudation of fluid into the abdominal cavity. This usually occurs slowly, and remains unnoticed by the owner until quite advanced stages. In other conditions, such as pericardial effusion, the ascites may develop more rapidly.

Cyanosis

Cyanosis is defined as a blue to blue-gray discoloration of the mucous membranes as the result of increased concentration of deoxygenated hemoglobin. It can be evident on physical examination and also described by the owner. Discoloration of the tongue and mucous membranes is a common complaint of owners suspecting heart disease in their pet, but can be difficult to identify or replicate at the clinic. Additionally, cyanosis can be difficult to identify because of pigmentation of the skin and mucous membranes. Cyanosis in veterinary patients is usually associated with severe left-sided CHF or congenital heart disease. In case of severe left-sided CHF, other significant signs of disease always accompany the cyanosis. In some cases of congenital heart disease leading to right-to-left shunting of blood, some animals can have reduced exercise capacity, pelvic limb weakness and frequently have to sit down during play or exercise. Depending on the degree of shunting, some of these animals can be cyanotic at rest but the cyanosis becomes more apparent with physical exercise.

Physical Examination

A thorough physical examination is the foundation for the clinical work-up in dogs and cats with suspected heart disease. The examination includes general inspection and observation (e.g., attitude, body condition, mobility, degree of anxiety, and respiratory pattern), and a thorough physical examination to identify abnormalities in other organ systems. The cardiovascular examination includes evaluation of the peripheral circulation (mucous membranes), systemic veins (jugular veins), peripheral arterial pulses, the precordium (left and right chest wall over the heart), palpation of abdomen to identify ascites, and auscultation of heart and lungs.

Mucous Membranes

The mucous membrane color and capillary refill time are used to evaluate peripheral perfusion. The mucous membranes of the oral cavity are usually used for this purpose, but also ocular and caudal (vaginal or preputial) membranes can be examined. Preferably findings of caudal membranes should be compared with findings in the oral cavity. Findings of bluish discoloration are suggestive of cyanosis (see earlier), darkish red is suggestive of erythrocytosis, and pale membranes are suggestive of anemia and/or decreased perfusion. Capillary refill time (CRT) is conducted to evaluate peripheral perfusion. While commonly performed, CRT is a comparably insensitive method to detect abnormal perfusion.

Systemic Veins

The jugular veins should be inspected in cases with suspected heart disease, and clipping or wetting of the fur may be required to visualize these vessels. Distension or pulsations of the jugular veins, while the animal is sitting with the neck moderately extended, are indicative of increased systemic venous pressure (right-sided CHF) or occlusion (most commonly neoplasia or thrombosis) of the vessel at the level between the right heart and the jugular vein. Because there is no valve between the right atrium and the systemic veins, changes in pressure in the right atrium are transmitted within the systemic veins, and can be caused by right atrial contractions at high systemic venous pressure or tricuspid regurgitation. Sometimes, the carotid arterial pulse is transmitted through the soft tissues, mimicking a venous pulsation (so-called false venous pulsations). Differentiation between true and false venous pulsations can be obtained by applying pressure to the jugular vein at a level slightly below the area of the pulsation. If the pulsation disappears, it is a sign of true venous pulsation; if it continues, it is a sign of false venous pulsation.

Peripheral Arterial Pulsations

The strength and quality of the femoral arterial pulses are subjectively assessed by simultaneous palpation of both femoral arteries in a standing animal. Sufficient pressure should be placed on the vessels to occlude them, so that pulsation is no longer palpable. The pressure is then slowly released until maximal pulsation is evident.

This subjective evaluation provides information on the pulse pressure (i.e. the difference between systemic arterial peak systolic and diastolic pressures) and potential presence of various heart diseases.

The quality of pulses in the two limbs should be compared, particularly in cats. Absent femoral arterial pulse in one or both limbs may be indicative of arterial thromboembolism. The femoral artery should be palpated simultaneously with cardiac auscultation to detect heartbeats that do not produce pulses. Arrhythmias can cause the heart to contract before it is properly filled with blood, producing variable pulses or pulse deficits.

Palpation of the Precordium

The precordium is evaluated by placing palms and fingers on each side of the thorax over the cardiac ostia (Figure 15.1). Normally, the cardiac contraction (precordial impulse) is best felt on the left side of the thorax over the apical area. Changes in cardiac size and shape, or space-occupying thoracic masses can cause a shift of the location of the precordial impulse. A weak impulse can be caused by obesity, hypovolemia, thoracic masses, pleural or pericardial effusion, or pneumothorax. Increased precordial impulse can be caused by hyperkinetic conditions such as stress or anemia or conditions characterized by cardiac volume overload and cardiomegaly, such as severe MMVD or DCM. Severe valvular regurgitation or stenosis can cause palpable "buzzing" vibrations called a *precordial thrill*. The intensity of the auscultated heart murmur is always greatest over the area of the thrill.

Evaluation of Fluid Accumulation

Right-sided CHF leads to accumulation of fluid in body cavities, most commonly in the abdomen. The abdomen should therefore be palpated for ballottement and the presence of fluid accumulation (ascites). Mild ascites is difficult to detect, whereas moderate to severe ascites is comparably easy to detect. Pleural effusion is more difficult to detect and thoracic radiography or centesis is often required to obtain a definite diagnosis. The limbs should also be inspected for the presence of peripheral edema, although this is an extremely unusual finding in dogs and cats with heart disease.

Auscultation

Cardiac auscultation is an important component of the physical examination in dogs and cats with suspected cardiac disease. An exact diagnosis can seldom be established based solely on cardiac auscultation, but optimal auscultation technique can substantially narrow down the list of differential diagnoses. Auscultation allows assessment of heart rate, rhythm, and presence of abnormal sounds, such as murmur, click, and additional heart sounds.

Auscultation should be performed in a quiet environment, and background noise should be minimized. The animal should preferably be standing on all four limbs during cardiac auscultation as abnormal sounds, which can easily be mistaken for heart murmurs, can arise in a recumbent animal due to rubbing of the heart against the chest wall. Furthermore, localization of the area of origin of different cardiac sounds is more easily achieved in a

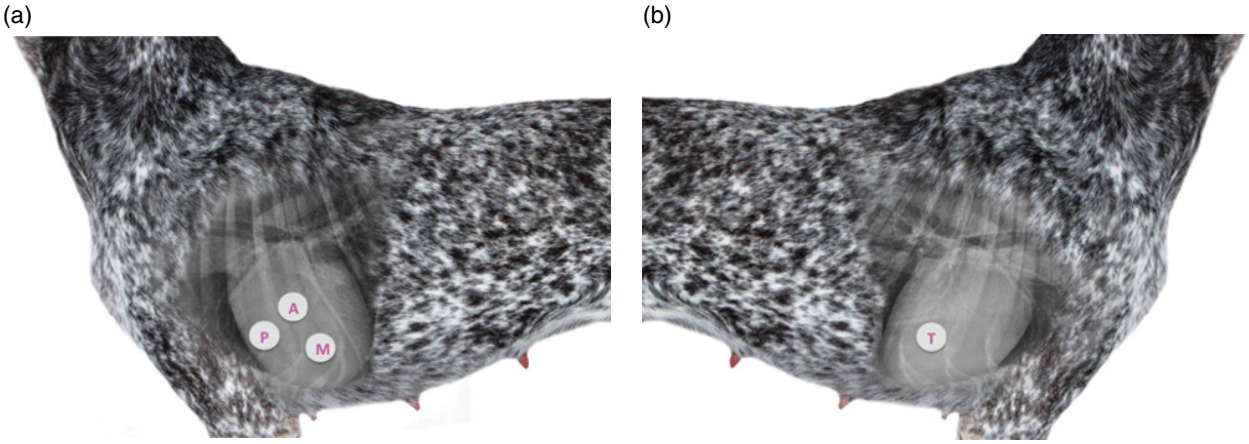

Figure 15.1 Principal areas of cardiac auscultation in dogs. The valve relationships are the same in cats, whereas intercostal space (ICS) guidelines differ slightly for cats and are, accordingly, mentioned in parentheses. Because of the small size of the feline heart, murmurs in cats are often described as sternal versus parasternal, basilar versus apical, and left versus right. (a) Left hemithorax: M = mitral valve area: 5th (cat: 5th–6th) ICS at the costochondral junction. A = aortic valve area: 4th ICS (cat: 2nd–3rd ICS) just above the costochondral junction. P = pulmonic valve area: 2nd–4th (cat: 2nd–3rd) ICS just above the sternum. (b) Right hemithorax: T = tricuspid valve area: 3rd–5th (cat: 4th–5th) ICS near the costochondral junction.

standing animal. The entire cardiac area should be auscultated thoroughly. The areas of auscultation of the heart are shown in Figure 15.1.

The areas of the ventral thorax adjacent to the sternum should always be auscultated in cats, as murmurs and gallop rhythms often are heard best at this location. If needed, the animal's mouth should be manually gently closed for brief periods of time as panting can generate referred sounds, which can be mistaken for murmurs. Evaluation of heart sounds and murmurs is often difficult in purring cats. The purring can be stopped by quickly occluding a nostril, by placing the cat in the proximity of a running tap, by holding cotton wool soaked in alcohol near the cat's nose, or by blowing short bursts of air into the face of the cat. Breathing sounds, especially in cats, can be mistaken for sounds originating from the heart, and differentiating heart sounds from breath sounds can be facilitated by watching the cat's breathing pattern while simultaneously ausculting the heart.

Heart Rate and Rhythm

Dogs in CHF are likely to be tachycardic, although the degree of tachycardia may be modest. Tachycardia in CHF patients results from parasympathetic withdrawal and increased sympathetic tone. Cats in decompensated CHF may present with normal, increased or decreased heart rate. Healthy dogs have either a regular heart rhythm or a respiratory sinus arrhythmia where the heart rate increases during inspiration and decreases during expiration due to changes in vagal tone. This phenomenon can be exaggerated, particularly in the presence of respiratory disease. Dogs presenting with respiratory sinus arrhythmia are unlikely to be in decompensated CHF with pulmonary edema. Healthy cats normally have a regular heart rhythm, and the finding of respiratory sinus arrhythmia in cats warrants further examination of potential respiratory disease. Other arrhythmias in dogs and cats, such as the detection of premature beats or long periods of asystole, can indicate presence of heart disease, and further diagnostic tests such as an electrocardiogram are then indicated.

Heart Sounds and Murmurs

Two heart sounds are normally audible in healthy dogs and cats. The first heart sound (S1), which is heard loudest at the heart apex, occurs concurrently with closure of the atrioventricular valves, whereas the second heart sound (S2), which is heard loudest at the heart base, occurs concurrently with closure of the semilunar valves. The intensity of heart sounds is influenced by many factors, such as auscultation technique, body condition, and presence of cardiac disease. Heart sound intensity can be decreased in animals affected by obesity, pericardial or pleural effusions, space-occupying lesions (such as thoracic masses), diaphragmatic hernias, shock, bradycardias, or severely affected myocardial function. The intensity of S2 is commonly dampened in dogs with severe MMVD. Heart sound intensity can be increased in animals with increased sympathetic tone, cardiac enlargement, or in those with narrow chest conformation. Intensity of heart sounds often varies from beat to beat in animals affected by cardiac arrhythmias, such as atrial fibrillation and ventricular tachycardia.

In dogs and cats, the presence of S3 and/or S4 signifies a gallop heart sound (tripling or quadrupling of the heart sounds, resembling the canter of a horse), and is generally an indication of myocardial disease in dogs and cats. The S3 (ventricular gallop) occurs early in diastole, and is associated with rapid ventricular filling during early diastole into a ventricle with decreased compliance, and is typically heard in dogs with conditions characterized by ventricular volume overload, such as DCM, MMVD or patent ductus arteriosus (PDA). The S4 (atrial gallop) occurs later in diastole, and is associated with vigorous atrial contractions in animals with conditions characterized by increased resistance to ventricular emptying or impaired ventricular compliance. This typically occurs in disorders with ventricular concentric hypertrophy, such as in cats with hypertrophic cardiomyopathy (HCM) or systemic hypertension. The S4 can also be present in dogs with third-degree atrioventricular (AV) block, dogs with ruptured chordae tendineae, or even in healthy cats due to decreasing ventricular compliance with age. The S3 and S4 can be superimposed in animals with tachycardia (most commonly in cats), resulting in one additional diastolic sound called a summation gallop.

Systolic clicks are transient, mid to late systolic sounds, which are higher in frequency than gallop sounds and are mainly heard in dogs with abnormal AV valve leaflet movement, such as mitral valve prolapse in dogs affected by mild MMVD. Clicks occurring in early systole can be associated with abnormal valve leaflet movement or great vessel dilation in dogs with aortic or pulmonic stenosis.

Murmurs are auditory vibrations caused by high-velocity and turbulent blood flow through the heart and vessels. Murmurs can be characterized by timing within the cardiac cycle, anatomic location, radiation area, intensity (loudness), frequency (pitch), and shape of vibration pattern (which is visualized by phonocardiography). Most cardiovascular diseases in dogs and cats result in systolic murmurs, which most commonly start immediately after the S1, but they can also start later in systole. Systolic murmurs can last for only a portion of the systole (early, mid or late systolic murmurs), throughout systole from the end of S1 to the beginning of S2

(holosystolic murmur), or, rarely, throughout systole from the beginning of S1 to the end of S2 (pansystolic murmur). Diastolic turbulent blood flow is rare in dogs and cats, and can be relatively difficult to detect. Diastolic murmurs most commonly start immediately after the S2. Continuous murmurs last throughout systole and diastole. The most common heart disease associated with a continuous murmur is PDA where the murmur commonly peaks in intensity at the time of the S2.

Point of maximum intensity (PMI) of a murmur is commonly the location over the thorax where the murmur is loudest, and can serve as a guide to the origin of the murmur. The PMI is associated with a particular valve region (i.e., pulmonic, aortic, mitral, tricuspid). The small size of the feline heart makes it difficult to distinguish the different valve areas on the thorax. Accordingly, localization of murmurs in cats is often described as sternal versus parasternal, base versus apex, and left versus right. The areas of auscultation of the heart in dogs are shown in Figure 15.1. The area of murmur radiation refers to how widely the murmur can be heard from the PMI, and generally increases with increasing turbulence.

Table 15.1 Classification of murmur intensity

	Grade	Description
Low-intensity murmurs	Grade 1	A very soft, barely audible murmur localized to a small area
	Grade 2	A soft murmur, heard immediately, localized to a small area
Moderate-intensity murmurs	Grade 3	A moderately loud murmur, evident at more than one location
	Grade 4	A loud murmur that radiates considerably to other areas, but without a consistent palpable precordial thrill (vibrations created by turbulence within the heart through the chest wall)
High-intensity murmurs	Grade 5	A loud murmur that radiates considerably to other areas, accompanied by a palpable precordial thrill
	Grade 6	Very loud murmur that radiates considerably to other areas, accompanied by a palpable precordial thrill, and is audible without the use of a stethoscope or when the stethoscope is slightly lifted off the thoracic wall

Murmurs are traditionally graded on a scale of 1–6. However, evidence exists that a four-grade scale can be used for some heart diseases without losing clinically important information (Table 15.1).

For some cardiac diseases, such as MMVD and aortic/pulmonic stenosis, grading of murmurs serves as a rough estimate of disease severity. However, a lack of agreement exists between severity of cardiac disease and murmur grade for other conditions, such as for ventricular septal defects, dilated or restrictive cardiomyopathy (DCM/RCM), and feline cardiomyopathies. Although the majority of dogs with heart disease have an audible murmur, it is important to remember that some cardiac diseases (such as pericardial diseases, cardiac neoplasia, DCM, atrial septal defects [ASD], right-to-left shunting PDA, and primary myocardial diseases in cats) do not necessarily produce blood flow turbulence and an audible murmur (Table 15.2).

Presence of a heart murmur does not always signal structural cardiac disease as murmurs in cats and dogs can also arise due to other physiologic processes. Physiologic murmurs tend to be fairly quiet (grade 1/6–3/6), and may vary in intensity with changes in heart rate. Mild dynamic right ventricular outflow tract obstruction is a common cause of murmurs in healthy cats in stressful situations such as examination at a veterinary hospital. Puppies and kittens may have "innocent" physiologic murmurs assumed to arise due to large stroke volumes relative to the size of their great vessels and/or due to physiologic anemia. These murmurs usually disappear before approximately 5 months of age. Murmurs may also be created in an anemic animal due to the combination of decreased blood viscosity and increased stroke volume. High-output diseases, such as chronic renal disease and hyperthyroidism, can also give rise to a systolic murmur due to increased velocity of the ejected blood. Finally, murmurs are common in fit dogs with athletic hearts, where the murmurs are caused by mild mitral/tricuspid valve insufficiency and/or a large stroke volume into the aorta.

Respiratory Auscultation

Normal respiratory sounds differ in frequency (pitch), intensity (loudness), and timing along different parts of the animal's upper and lower respiratory tract. Normal lung sounds are comparably soft sounds heard louder on inspiration than expiration, whereas normal sounds auscultated over the trachea are much louder and higher pitched and heard well on both inspiration and expiration. Based on location and sound characteristics, normal lung sounds are commonly termed vesicular, bronchial, or bronchovesicular, even though the term "vesicular" incorrectly implies that sounds are made in the vesicles (alveoli) of the lung.

Auscultation of the lungs of a cardiovascular patient may reveal abnormal sounds superimposed on normal

Table 15.2 Simplified table for presumptive diagnosis of murmur origin in common heart conditions

Point of maximal intensity	Timing	Associated heart conditions	Cause of murmur	Sound quality
Left heart base	Systolic	Physiologic or innocent murmurs	Turbulence in aorta/pulmonary artery	Soft or musical. Crescendo-decrescendo
		Aortic and pulmonic stenosis (tetralogy of Fallot)	Turbulence in aorta/pulmonary artery	Soft to harsh (depending on disease severity). Crescendo-decrescendo
		Atrial septal defect	Turbulence in pulmonary artery	If present, soft. Crescendo-decrescendo
	Diastolic	Aortic and pulmonic regurgitation	Turbulence in left or right ventricle	Soft, blowing (barely audible). Decrescendo
Left axillary region/left heart base	Continuous (systole and diastole)	Left to right shunting patent ductus arteriosus (PDA)	Turbulence in the main pulmonary artery	"Machinery" sound of varying intensity throughout the cardiac cycle. Crescendo-decrescendo in systole peaking at S2
Left heart apex	Systolic	Mitral regurgitation (secondary to myxomatous mitral valve disease, mitral dysplasia, etc.)	Turbulence in the left atrium	Soft (blowing), musical, or harsh, depending on disease severity. Decrescendo or plateau shaped
Right heart apex	Systolic	Tricuspid regurgitation (secondary to myxomatous tricuspid valve disease, tricuspid dysplasia, pulmonary hypertension, etc.)	Turbulence in the right atrium	Soft to harsh depending on disease severity. Decrescendo if mild in intensity, plateau shaped when moderate/severe in intensity
Right heart base (cranially near the sternum)	Systolic	Ventricular septal defects (left to right shunting)	Turbulence in the right ventricle/right ventricular outflow tract	Harsh and plateau shaped (occasionally varying conformation throughout systole)
Parasternal (cats)	Systolic	Left ventricular outflow tract obstruction with or without mitral regurgitation (commonly caused by hypertrophic cardiomyopathy)	Turbulence in the left ventricular outflow tract, sometimes accompanied by turbulence in the left atrium if systolic anterior motion (SAM) is present	Soft to harsh, crescendo-decrescendo
	Systolic	Dynamic right ventricular outflow tract obstruction (DRVOTO) (commonly stress-induced or caused by hemodynamic alterations)	Turbulence in the right ventricular outflow tract	Soft crescendo-decrescendo

lung sounds. Auscultation of dogs and cats presenting with pulmonary edema often reveals harsh lung sounds, or high-frequency crackles at the end of inspiration. Crackles are interrupted, nonmusical, crepitant sounds, which in general are associated with conditions in which some airways are closed. Crackles should not be considered pathognomic for pulmonary edema as primary respiratory disease can also produce crackles. Wheezes, which are high-frequency musical sounds of longer duration associated with narrowing of an airway, can also be heard in animals with pulmonary edema. Animals can present with interstitial pulmonary edema without any abnormal auscultatory sounds other than increased bronchovesicular sounds due to hyperpnea.

Attenuated or absent bronchovesicular sounds can be due to pleural effusion or shallow breathing. Animals with pleural space disease, such as pleural effusion in cats in decompensated CHF, often present with a paradoxical respiratory pattern with prominent abdominal wall movements. Thoracic auscultation in these animals may reveal dull lung sounds, muffled heart sounds, or an auscultable fluid line.

Imaging in Cardiovascular Disease

Valérie Chetboul, DVM, PhD, DECVIM-CA (Cardiology)

National Veterinary School at Alfort, Maisons-Alfort, France

The diagnosis of canine and feline heart diseases as well as that of heart failure is predominantly based on thoracic radiography associated with standard transthoracic echocardiography, also called conventional echocardiography. In the late 1980s, the miniaturization of transesophageal probes led to the use of transesophageal echocardiography especially for analyzing specific abnormalities or for monitoring surgical and interventional techniques. During the last decade, newer imaging modalities such as tissue Doppler imaging, strain and strain rate imaging, and speckle tracking echocardiography have been introduced in veterinary cardiology, allowing an accurate assessment of myocardial performance, deformation, and synchrony. The following chapter provides an overview of these imaging techniques and their application in clinical settings, with particular emphasis on the two most commonly used in practice: thoracic radiography and conventional echocardiography.

Cardiac Radiography

Although most radiographic findings are not specific and therefore do not lead to an accurate definitive diagnosis of a given heart disease, thoracic radiography remains a key complementary examination to detect heart enlargement, assess the presence or absence of congestive heart failure, and distinguish between respiratory and cardiovascular diseases.

Normal Thoracic Radiography

Heart and thoracic vessels should be systematically evaluated on at least two good-quality views taken during inspiration – the dorsoventral view and a lateral view. Ventrodorsal views may also be used, but dorsoventral views usually provide a better definition of caudal pulmonary vessels and of the hilar area than the ventrodorsal view, and therefore allow a better assessment of cardiogenic pulmonary edema, particularly in the canine species. Additionally, dorsoventral views are often better tolerated than ventrodorsal views in the case of dyspnea. Ventrodorsal views, which are most often associated with a more central position of the heart within the thorax, may sometimes be used to complement the dorsoventral view to detect small volumes of pleural effusion and to better assess specific lung lesions.

In both canine and feline species, the heart shape is most often relatively ovoid with a pointed ventral apex. Nevertheless, several noncardiac factors (Table 16.1) can influence heart size and shape, including respiratory phase, pericardial fat accumulation (Figure 16.1), age and, most of all, breed (see details below and Figure 16.2). All these are important to take into consideration, as they may be a source of misinterpretation of cardiomegaly.

Lateral Views

Either right or left lateral views may be performed. Nevertheless, as some variations may exist according to positioning of the patient, the same lateral projection should be used to ensure a reliable comparison of radiographic findings over time in sequential radiographs.

On lateral views, the heart, which is located between the third and sixth intercostal spaces, tends to "lie" more on the sternum in cats than in dogs, and in older cats (>7 years old) more than in younger cats (Figure 16.3). The maximum heart width (or maximum cranial–caudal diameter) is usually around two intercostal spaces in the cat and between 2.5 and 3.5 intercostal spaces in the dog, with breed variations (Figures 16.2 and 16.3). For example, the heart in "barrel-chested" dogs tends to be more globular, with a greater sternal

Table 16.1 Main noncardiac-related factors able to induce cardiac silhouette changes on thoracic radiographs

Factors	Radiographic change
Age	
Young age (dog)	Heart tends to be larger relatively to the thoracic cavity size than that of adult dogs
Old age (cat)	Heart of cats >7 years old tends to have a more horizontal orientation on lateral views, with a prominent aortic arch on lateral, DV, and VD views
Breed	See Table 16.2, text, and Figure 16.2
Patient positioning	Chest rotation can increase the apparent heart base size and that of the left atrium
Respiration phase	
Expiration	The heart appears wider than in inspiration with increased sternal contact (therefore potentially mimicking right heart enlargement)
Body condition score	
Overweight	Pericardial and mediastinal fat accumulation can mimic cardiomegaly (Figure 16.1)
Cachexia	Cachexia can be associated with a small cardiac silhouette (microcardia)
Hypovolemia	Hypovolemia is associated with microcardia and small vessels (pulmonary vessels and caudal vena cava)
Lung, mediastinal, pleural and sternal diseases	
Lung parenchymal and mediastinal mass lesions	Such lesions can modify position and axis of the heart and can also obscure cardiac margins ("positive silhouette" sign). The cranial cardiac silhouette may also be masked by the thymus in puppies
Lung atelectasis	Atelectasis can cause a mediastinal shift and therefore can modify position and axis of the heart
Sternal deformations (congenital or acquired)	Such lesions can modify position and axis of the heart

DV, dorsoventral; VD, ventrodorsal.

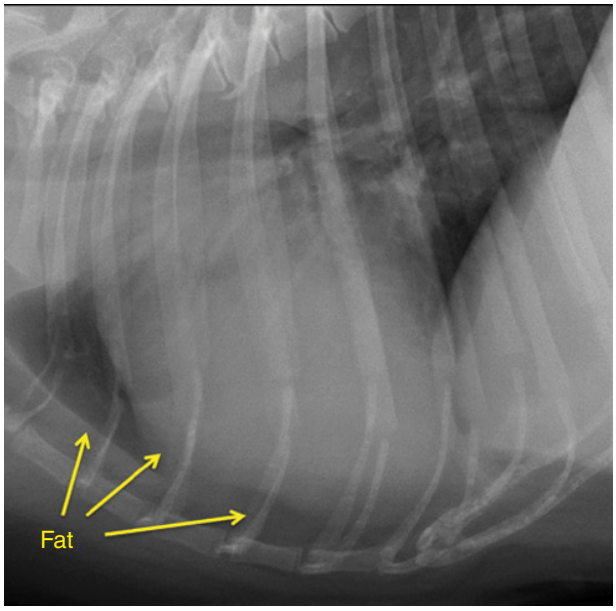

Figure 16.1 Lateral thoracic radiograph of an obese dog. The cardiac silhouette appears falsely enlarged owing to mediastinal and pericardial fat accumulation. Fat, which is characterized by slightly lower density than the heart, is clearly seen ventrally to the heart. *Source:* Medical Imaging Unit, ENVA.

contact than that of narrow- and deep-chested dogs, which appears elongated with a more vertical orientation (Figure 16.2).

Right heart chambers are approximately positioned cranially and left chambers caudally to the line drawn from the tracheal bifurcation to the apex (base–apex axis). Both atrial chambers are located dorsally and the ventricular chambers ventrally to the line drawn perpendicular to the base–apex axis and running along the ventral border of the caudal vena cava (Figure 16.4).

The vertebral heart score (VHS) may be used to objectively assess heart size, and to confirm and determine the severity of cardiomegaly in both cats and dogs (Figure 16.5). The mean ± SD canine VHS is 9.7 ± 0.5 vertebrae (range: 8.5–10.6). Nevertheless, VHS values are influenced by breed-dependent heart shape and size, thoracic conformation (long *versus* short thorax), and thoracic vertebrae abnormalities such as hemivertebrae. For example, abnormal thoracic vertebrae have recently been shown to be associated with a significant increase of VHS in the bulldog and Boston terrier. Such breed-dependent variations of VHS (Table 16.2) represent a limitation of the vertebral heart-size method in the dog. Nevertheless, the VHS system is easy to use and may be helpful to objectively compare heart size in sequential radiographs.

Feline VHS seems to be less subject to variations than canine VHS, with normal values of 7.5 ± 0.3 vertebrae.

Dorsoventral View

As in the lateral views, the normal canine cardiac shape varies widely among breeds, with a wider and more rounded cardiac silhouette in barrel-chested

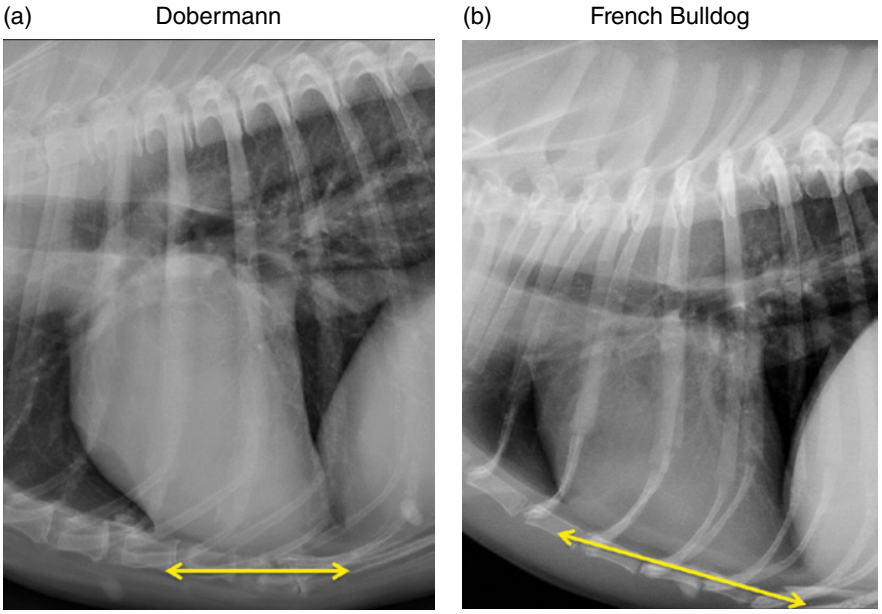

Figure 16.2 Lateral thoracic radiographs of two normal dogs from different breeds (a: Doberman; b: French bulldog). Both cardiac shape and size vary markedly between the two dogs. Note the elongated upright orientation of the Doberman's heart and the wider silhouette, with a greater sternal contact (*double arrows*) and a more horizontal orientation, of the bulldog's heart. *Source:* Medical Imaging Unit, ENVA.

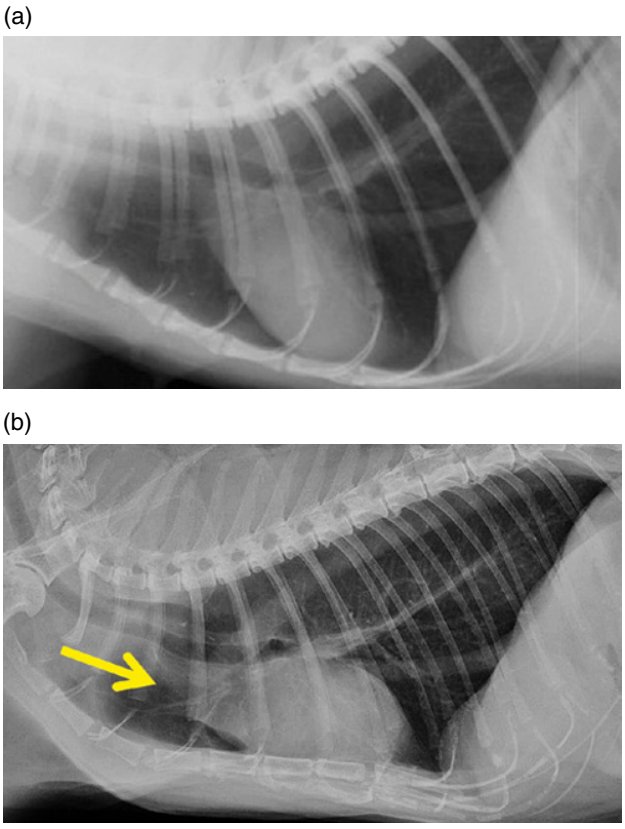

Figure 16.3 Lateral thoracic radiographs of two normal cats, one young adult cat (a) and one 15-year-old cat (b). Compared to the young adult cat, note the more horizontal orientation of the heart and the prominent aortic arch (*arrow*) in the aged cat. *Source:* Medical Imaging Unit, ENVA.

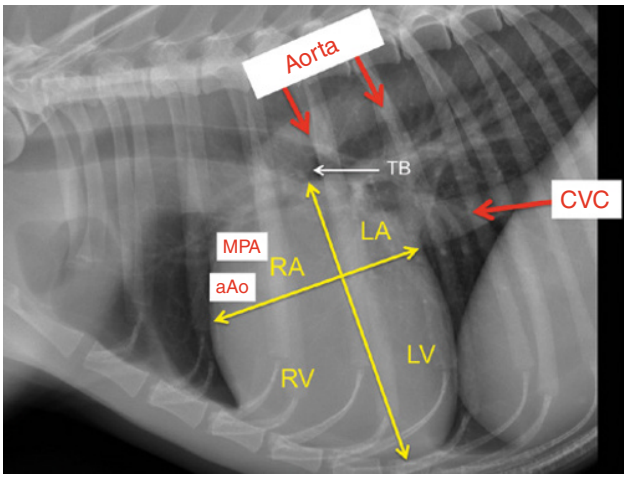

Figure 16.4 Lateral thoracic radiograph of a normal dog showing the approximate location of the four cardiac chambers, the tracheal bifurcation (TB) and the main thoracic vessels. aAo, ascending aorta; CVC, caudal vena cava; LA, left atrium; LV, left ventricle; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle. *Source:* Medical Imaging Unit, ENVA.

dogs than in narrow-chested and deep-chested dogs. The maximum canine heart width is usually less than 65% of the thorax width at the same level. The maximum feline heart width is less than one half of the thorax width, with a prominent aortic arch in aged animals.

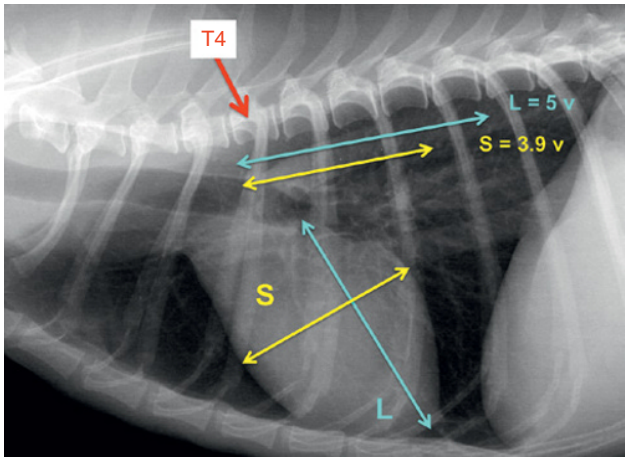

Figure 16.5 Calculation of the vertebral heart score (VHS) from a thoracic lateral radiograph in a normal mixed-breed dog. The cardiac long-axis dimension (L) represents the combined size of the left atrium and the left ventricle, and is measured from the cardiac apex to the base where it intersects the tracheal bifurcation. The cardiac short-axis dimension (S) is perpendicular to L, and is measured at the point of maximum cardiac width, which usually corresponds to the point at which the cardiac silhouette intersects the ventral border of the caudal vena cava (as shown here). S therefore includes left and right cardiac chambers in the region of the coronary groove. L and S cardiac dimensions are then transposed on the vertebral column and recorded as the corresponding number of vertebrae (v), as measured caudally from the cranial edge of the fourth thoracic vertebra (T4). These values are summed to calculate the VHS. As in the present case, L is equal to 5 v and S to 3.9 v, the VHS value is 8.9 v, which is within normal ranges (8.5–10.6 v according to Buchanan *et al*., *J Am Vet Med Assoc* 1995; **206**: 194–9). *Source:* Medical Imaging Unit, ENVA.

A clock face analogy can be used to approximately localize the normal cardiovascular structures responsible for the cardiac silhouette (Figure 16.6). This clock face analogy can help in identifying the origin of bulges and deformations of the cardiac silhouette associated with heart diseases.

The VHS can also be calculated on the dorsoventral view as follows: sum of cardiac long-axis (distance from cardiac apex to base) and short-axis dimensions (perpendicular to the long-axis measurement at the maximum cardiac width) assessed in vertebrae beginning with the cranial edge of the fourth vertebra on the lateral radiograph. The feline VHS on the dorsoventral view is 8.1 ± 0.45 vertebrae. Also in the cat, the maximum short-axis cardiac dimension on the dorsoventral view, compared with the thoracic spine beginning at the cranial edge of the fourth vertebra on the lateral chest radiograph, is usually less than four vertebrae.

Common Abnormal Cardiac Radiographic Patterns

Congenital and acquired heart diseases can be responsible for generalized or localized cardiac enlargement associated with changes in the intrathoracic blood vessels. The main cardiac causes responsible for left, right and global heart enlargement are presented in Table 16.3 and in Figures 16.7–16.12.

Left Heart Diseases (Figures 16.7–16.10)

Left Atrial Enlargement

On lateral views, left atrial enlargement is characterized by:

- straightening of the dorsocaudal part of the cardiac silhouette
- dorsal elevation of the caudal portion of the trachea and tracheal bifurcation (carina)
- separation of the normally superimposed caudal main bronchi owing to a disproportionate dorsal elevation of the latter (with a more dorsal position of the left bronchus as compared to the right).

On the dorsoventral view, left atrial enlargement is characterized by:

- bulging of the cardiac silhouette in the 2–3 o'clock position (Figures 16.7b and 16.9b) owing to the enlargement of the left auricular appendage (dog and cat) and the left atrium (cat)
- the presence of a round soft tissue opacity covering the caudal part of the cardiac silhouette, with lateral displacement of the mainstem bronchi in the case of marked left atrial dilation in the dog (Figures 16.7b and 16.8c).

Similar abnormal patterns are detected on the ventrodorsal view.

Left Ventricular Enlargement

On lateral views, left ventricular enlargement is characterized (Figures 16.7a, 16.7c, 16.8a, 16.10a) by:

- a "taller" heart with straightening of the caudal part of the cardiac silhouette
- dorsal elevation of the trachea, carina, and mainstem bronchi.

On the dorsoventral view, left ventricular enlargement is characterized by:

- elongation and enlargement at the 3–6 o'clock position of the cardiac silhouette (Figure 16.8c)
- broadening and rounding with a possible shift to the right of the cardiac apex.

Similar abnormal patterns are detected on the ventrodorsal view.

Table 16.2 Examples of vertebral heart score (VHS) values assessed on lateral thoracic radiographs in normal dogs. For calculation of VHS, see Figure 16.5. SD, standard deviation.

Animals	VHS value (mean ± SD vertebrae)	Comments	*References*
All breed dogs (n = 100)	**9.7 ± 0.5**		*1. Buchanan JW, et al. J Am Vet Med Assoc 1995;206:194–9*
Boston terrier (n = 19)	**11.7 ± 1.4**	VHS assessed on right lateral views – 74% of dogs had a VHS >2SD above the VHS of reference #1 (9.7 ± 0.5)	*2. Jepsen-Grant K, et al. Vet Radiol Ultrasound 2013;54:3–8*
Bulldog (n = 30)	**12.7 ± 1.7**	VHS assessed on right lateral views except for 1 dog – 93% of dogs had a VHS >2SD above the VHS of reference #1 (9.7 ± 0.5)	*2. Jepsen-Grant K, et al. Vet Radiol Ultrasound 2013;54:3–8*
Dachshund (n = 29)	**9.7 ± 0.5**	VHS assessed on right lateral views – 7% of dogs had a VHS >2SD above the VHS of reference #1 (9.7 ± 0.5)	*2. Jepsen-Grant K, et al. Vet Radiol Ultrasound 2013;54:3–8*
Lhasa apso (n = 18)	**9.6 ± 0.8**	VHS assessed on right lateral views – 6% of dogs had a VHS >2SD above the VHS of reference #1 (9.7 ± 0.5)	*2. Jepsen-Grant K, et al. Vet Radiol Ultrasound 2013;54:3–8*
Pomeranian (n = 18)	**10.5 ± 0.9**	VHS assessed on right lateral views except for 1 dog – 50% of dogs had a VHS >2SD above the VHS of reference #1 (9.7 ± 0.5)	*2. Jepsen-Grant K, et al. Vet Radiol Ultrasound 2013;54:3–8*
Pug (n = 30)	**10.7 ± 0.9**	VHS assessed on right lateral views – 43% of dogs had a VHS >2SD above the VHS of reference #1 (9.7 ± 0.5)	*2. Jepsen-Grant K, et al. Vet Radiol Ultrasound 2013;54:3–8*
Shih tzu (n = 30)	**9.5 ± 0.6**	VHS assessed on right lateral views – 0% of dogs had a VHS >2SD above the VHS of reference #1 (9.7 ± 0.5)	*2. Jepsen-Grant K, et al. Vet Radiol Ultrasound 2013;54:3–8*
Yorkshire terrier (n = 30)	**9.9 ± 0.6**	VHS assessed on right lateral views – 13% of dogs had a VHS >2SD above the VHS of reference #1 (9.7 ± 0.5)	*2. Jepsen-Grant K, et al. Vet Radiol Ultrasound 2013;54:3–8*
All breed dogs (n = 63) *Right lateral recumbency* *Left lateral recumbency*	**9.8 ± 0.6** **9.5 ± 0.8**	VHS was significantly larger in right than in left lateral recumbency	*3. Greco A, et al. Vet Radiol Ultrasound 2008;49:454–5*
Beagle (n = 19) *Right lateral recumbency* *Left lateral recumbency*	**10.5 ± 0.4** **10.2 ± 0.4**	VHS was significantly larger in right than in left lateral recumbency	*4. Kraetschmer S, et al. J Small Anim Pract 2008;49:240–3*

Cavalier King Charles (n = 20)	**10.6 ± 0.5**	Right lateral thoracic radiographs	*5. Lamb CR, et al. Vet Record 2001;148:707–11*
German Shepherd dog (n = 20)	**9.7 ± 0.7**	Right lateral thoracic radiographs	*5. Lamb CR, et al. Vet Record 2001;148:707–11*
Rottweiler (n = 38)	**9.8 ± 0.1**		*6. Marin L, et al. Vet Radiol Ultrasound 2007;48:332–4*
Greyhound (n = 42)	**10.5 ± 0.1**	VHS was significantly higher in greyhounds than in rottweilers	*6. Marin L, et al. Vet Radiol Ultrasound 2007;48:332–4*

Left-Sided Congestive Heart Failure

In the case of left-sided congestive heart failure, prominent pulmonary veins owing to venous congestion are seen, particularly in the hilar area (as they enter the left atrium) on lateral views. The pulmonary vein diameter appears greater than that of the corresponding arteries. This asymmetry is easiest to detect for cranial vessels on lateral views (where the pulmonary veins are ventral to the accompanying arteries), and for caudal vessels on the dorsoventral view (where the pulmonary veins are medial to the accompanying arteries).

Radiographic signs of left-sided congestive heart failure also include visualization of mild to severe interstitial, peribronchial to alveolar pulmonary opacity

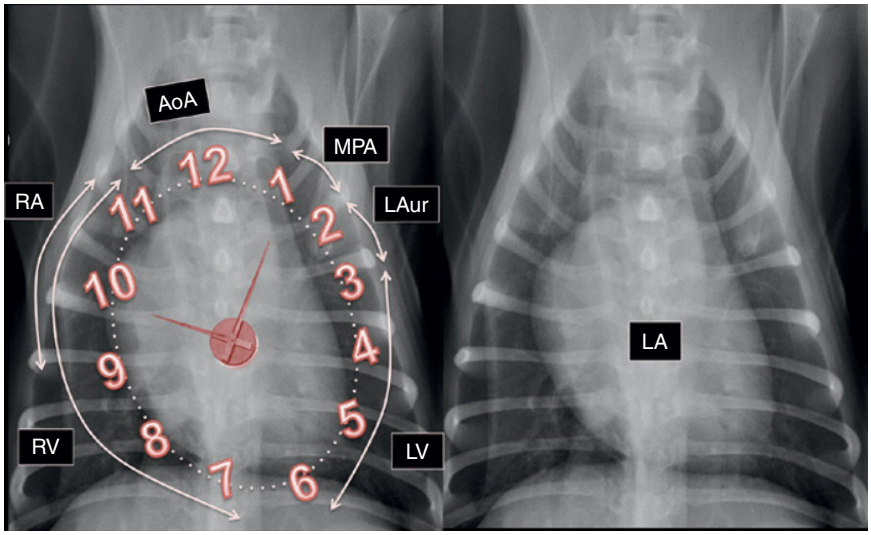

Figure 16.6 Clock face analogy (a) applied to the canine cardiac silhouette (b) on the dorsoventral view. The aortic arch (AoA) approximately extends from 11 o'clock to 1 o'clock, the main pulmonary artery (MPA) from 1 o'clock to 2 o'clock, the left ventricle (LV) from 3 o'clock to 6 o'clock, and the right ventricle (RV) from 6–7 o'clock to 11 o'clock (with a superimposition with the RA between 9 and 11 o'clock). In cats and dogs, enlargement of the left auricular appendage (Laur) contributes to a deformation of the cardiac silhouette between 2 and 3 o'clock. In the cat, the body of the left atrium (LA) also extends from 2 to 3 o'clock, whereas in the dog the LA is rather superimposed over the caudal part of the cardiac silhouette (b). *Source:* Medical Imaging Unit, ENVA.

(Figures 16.7c, 16.10a and 16.10b) due to pulmonary edema. Cardiogenic pulmonary edema is typically more pronounced in the dorsal perihilar area on lateral views in the dog, with a bilateral distribution on the dorsoventral view in both species. In some instances, it can be asymmetric in the dog, with the right lung fields more severely affected than the left. In the case of alveolar edema, the alveolar spaces are filled with fluid. The margins of the pulmonary vessels are therefore totally obscured and air bronchograms (corresponding to black air-filled bronchi surrounded by white radiopaque lung tissue) are detected.

Right Heart Diseases

Right Atrial Enlargement

On lateral views, right atrial enlargement is characterized by:

- enlargement of the dorsocranial part of the cardiac silhouette (Figure 16.11a)
- dorsal elevation of the trachea over the cranial portion of the heart (less commonly).

On the dorsoventral view, right atrial enlargement is characterized by bulging of the cardiac silhouette in the 9–11 o'clock position.

Right Ventricular Enlargement

On lateral views, right ventricular enlargement is characterized (Figures 16.7c and 16.11a) by:

- increased sternal contact, with widening and increased convexity of the cranioventral heart margins
- elevation of the apex from the sternum and, in the case of severe enlargement, dorsal elevation of the caudal vena cava as well.

On the dorsoventral view, right ventricular enlargement is characterized (Figure 16.11b) by:

- broadening and rounding of the cardiac silhouette at the 6–7 to 9–11 o'clock position with a reverse-D appearance
- a shift to the left of the cardiac apex in the case of severe enlargement.

Similar abnormal patterns are detected on the ventrodorsal view.

Right-Sided Congestive Heart Failure

Thoracic radiographic signs of right-sided congestive heart failure include visualization of right heart enlargement associated with widening of the caudal vena cava (whose normal diameter is usually approximately that of the descending thoracic aorta) and interlobar pleural fissures secondary to pleural effusion (with lung collapse and rounded pulmonary borders in severe cases).

Extrathoracic radiographic signs include hepatomegaly (extension of the liver caudally to the last rib with abnormally round margins and caudal displacement of the stomach) and ascites, which is characterized by abdominal distension and increased fluid opacity with loss of intraabdominal details.

Specific Radiographic Signs Associated with Heart Diseases

The main specific radiographic signs associated with heart diseases are presented in Table 16.3 and in Figures 16.7 to 16.12.

Table 16.3 Generalized or localized heart enlargement on thoracic radiographs: main cardiac causes, associated radiographic signs, differential diagnosis

Type of heart enlargement	Main causes	Potential associated radiographic signs	Differential diagnosis
Left heart enlargement			
Left atrial and/or ventricular enlargement	**Congenital heart diseases:** mitral dysplasia with mitral valve regurgitation, significant left-to-right shunting due to VSD and PDA, subaortic stenosis and/or aortic insufficiency **Acquired heart diseases:** hypertrophic and restrictive cardiomyopathy (cat), degenerative mitral valve disease (dog), mitral or aortic valve endocarditis, dilated cardiomyopathy, cardiomyopathy secondary to systemic arterial hypertension and hyperthyroidism (cat)	**Enlargement of the aortic arch** in the case of PDA, subaortic stenosis and systemic arterial hypertension **Increased pulmonary artery prominence and increased pulmonary vessels (veins and arteries)** in the case of VSD and PDA with significant left-to-right shunting **Increased pulmonary veins** in cases with **left-sided congestive heart failure** (see text)	Pulmonary mass and/or adenopathy in the hilar area (left atrial enlargement)
Isolated left atrial enlargement	**Congenital heart diseases:** mitral valve stenosis		
Right heart enlargement			
Right atrial and/or ventricular enlargement	**Congenital heart diseases:** tricuspid dysplasia with tricuspid regurgitation, significant left-to-right shunting due to ASD, pulmonic stenosis and/or pulmonic insufficiency (rare), tetralogy of Fallot **Acquired heart diseases:** degenerative tricuspid valve disease, arrhythmogenic right ventricular cardiomyopathy, pulmonary arterial hypertension (main causes: dirofilariosis, angiostrongylosis, respiratory diseases, pulmonary embolism, reversed-shunting congenital defects, etc.)	**Increased caudal vena cava** on lateral views in cases of **right-sided congestive heart failure** (see text) **Enlargement of the main pulmonary artery (post-stenotic dilation) with decreased pulmonary vasculature** in the case of pulmonic stenosis **Enlargement of the main pulmonary artery, abnormal pulmonary arteries (tortuous, larger than their accompanying veins)** in the case of pulmonary hypertension **Pulmonary infiltrates** in the case of dirofilariosis, pulmonary embolism, respiratory diseases, etc.	Tracheobronchial adenopathy and cranial mediastinal mass (including heart base tumor)
Isolated right atrial enlargement	**Congenital heart disease:** tricuspid stenosis **Acquired heart disease:** right atrial neoplasia (hemangiosarcoma)		
Generalized heart enlargement	Severe left and/or right heart diseases Pericardial effusion, peritoneal-pericardial hernia Intracardiac mass (tumor) "Athletic heart"	Globoid cardiac silhouette in the case of pericardial diseases, with gas-containing structures within the pericardial sac and loss of outline between the ventral diaphragmatic surface and the caudal ventral cardiac silhouette in the case of peritoneal-pericardial hernia	

ASD, atrial septal defect; DV, dorsoventral; PDA, patent ductus arteriosus; VD, ventrodorsal; VSD, ventricular septal defect.

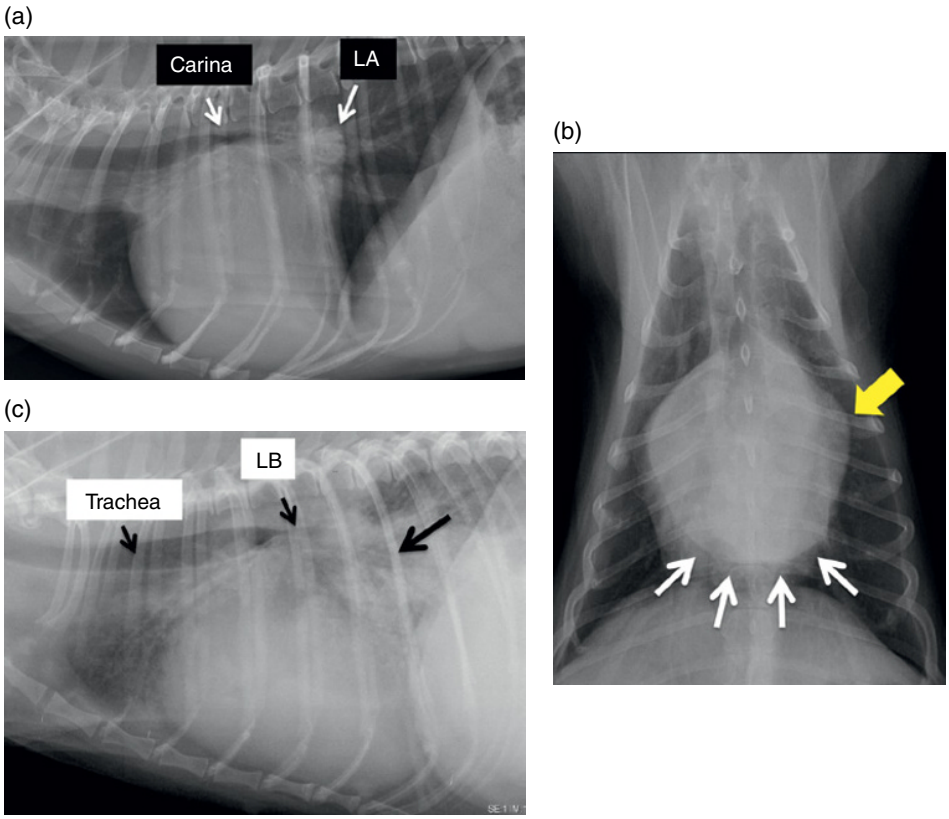

Figure 16.7 Thoracic radiographs of three different dogs with compensated (a,b) and decompensated (c) degenerative mitral valve disease. (a) A marked left atrial enlargement (LA) is seen on this lateral radiograph. Note the tracheal and carina dorsal elevation as well as the straightening of the caudal part of the cardiac silhouette, suggesting left ventricular dilation as well. (b) On this dorsoventral view, enlargement of the left auricular appendage produces a bulge (*large arrow*) at the 2–3 o'clock position. Additionally, the dilated LA body (*thin arrows*) creates a "mass effect" in the dorsocaudal region of the cardiac silhouette. (c) This lateral radiograph shows diffuse cardiogenic pulmonary edema that is more severe in the caudodorsal perihilar area (*arrow*). Left heart enlargement is responsible for dorsal elevation of the intrathoracic trachea, carina, and left main bronchus (LB). Note also the abnormal increased sternal contact of the heart, suggesting right ventricular enlargement (which was further confirmed to result from pulmonary arterial hypertension). *Source:* Medical Imaging Unit, ENVA.

Conventional Echocardiography

Over the last 30 years, standard transthoracic echocardiography has become a major imaging tool for the diagnosis, management, and follow-up of canine and feline heart diseases, allowing noninvasive assessment of heart morphology (ventricles, atria, cardiac valves, auricular appendages) and function, as well as examination of the anatomy of the proximal great vessels.

General Principles and Technique

Conventional echocardiography combines 2D and M-mode imaging. M-mode echocardiography provides one-dimensional views of the heart, while 2D echocardiography displays cross-sectional or 2D cardiac images (in transverse and longitudinal planes) moving in real time. M-mode echocardiograms display motion over time of the various tissue interfaces crossed by the linear M-mode ultrasound beam. Currently, the 2D mode is always used to guide accurate placement of the M-mode cursor, which appears as a vertical line on 2D echocardiograms. M-mode echocardiography has a much higher spatial and temporal resolution than 2D echocardiography, and therefore allows recording of the motion of subtle cardiac structures.

Transthoracic 2D and M-mode echocardiography can be performed on animals in lateral recumbency or in standing position, as the measurements obtained in both positions show similar variability. Some animals may not tolerate a recumbent position because of discomfort or dyspnea, making the standing position easier and more suitable. Placing the patient in lateral recumbency decreases lung interference but, on the other hand, may increase stress in nervous animals.

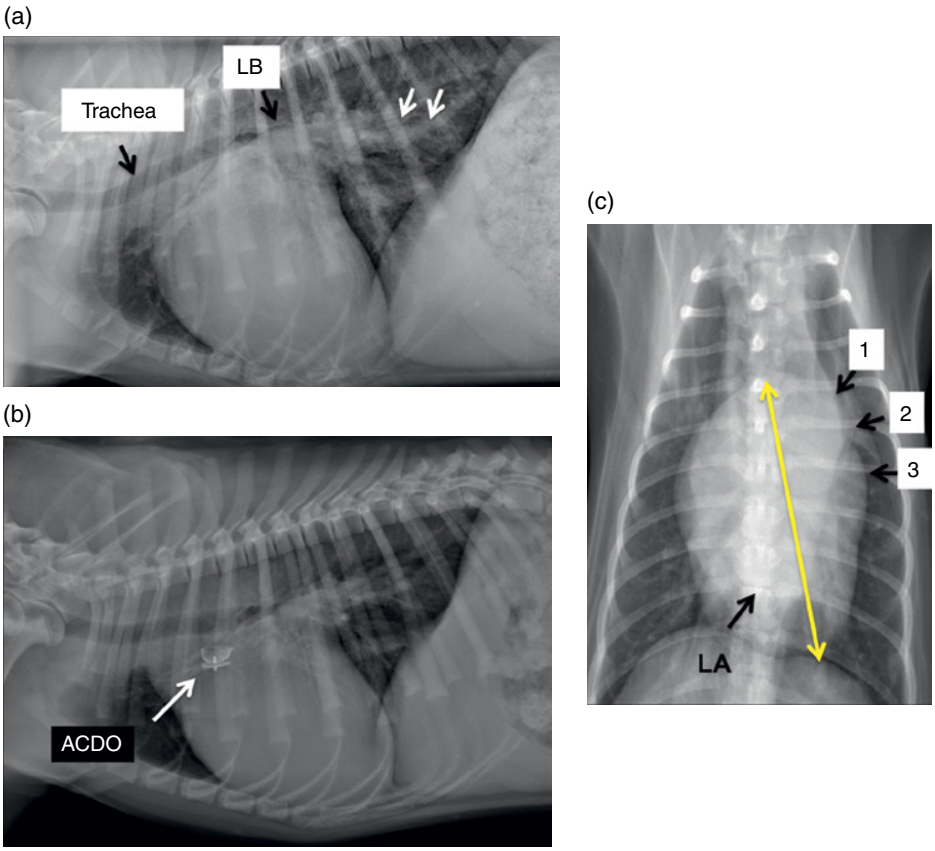

Figure 16.8 Thoracic radiographs of two dogs with patent ductus arteriosus (PDA). (a,b) Lateral radiographs of the same dog (German shepherd) respectively before and 24 hours after surgery (placement of an Amplatz canine duct occluder, ACDO). Note the marked generalized heart enlargement on (a), with dorsal elevation of the intrathoracic trachea, carina, and left main bronchus (LB), associated with vascular congestion (*arrows*) due to overcirculation of the lung field, and interstitial edema in caudal lungs. After ACDO placement (b), heart size (width and height) has decreased and vascular congestion disappeared. (c) Dorsoventral radiograph of a Cavalier King Charles spaniel with PDA before surgical closure. Note the elongated cardiac silhouette (*double arrow*), the heart base enlargement (including 1: descending aorta, 2: main pulmonary artery, 3: left auricular appendage), and the increased opacity caudally to the tracheal bifurcation, corresponding to the dilated left atrium (LA) superimposed over the caudal cardiac silhouette. *Source:* Medical Imaging Unit, ENVA.

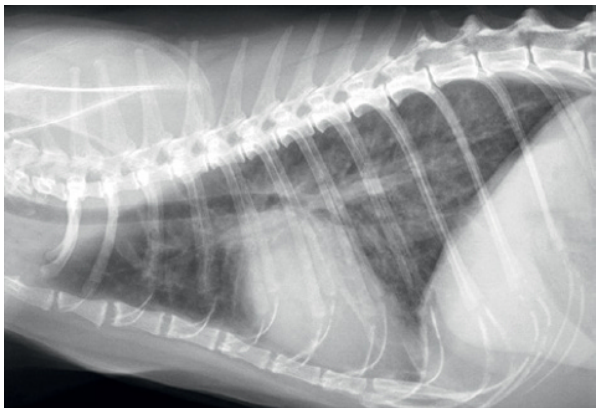

When patients are echoed in a recumbent position, a special scanning table with a cutout is needed, and images are obtained from beneath the table through the table hole. The standing position does not require a specific scanning table, as the animal is gently restrained against an assistant to keep its position stable. For both animal positions, the transducer is placed on the thoracic wall in an intercostal space over the precordial impulse area, close to the sternum, to obtain parasternal views. However, subcostal (or subxiphoid) views may sometimes be used for Doppler assessment of the aortic outflow (as they may provide a better Doppler beam alignment than parasternal views).

In most cases where manual restraint is sufficient, sedation is avoided as it can alter systolic function and may affect cardiac dimensions.

Most animals do not require clipping of hair over the area of contact on the thoracic wall (more than 90% of the patients at our unit are not clipped for conventional echocardiographic examinations or for advanced ultrasound techniques, such as tissue Doppler imaging). Acoustic gel helps to provide an optimal air-free contact between the probe and the thoracic wall.

High-frequency transducers are characterized by low penetrating power but high resolution. Conversely, low-frequency transducers are characterized by high penetrating power but low resolution. In canine and feline cardiology, transducer frequencies are usually between 2.5 and 12 MHz. Transducer frequencies are commonly adjusted during a single echocardiographic examination, depending on the location and size of the cardiovascular structures tested. As most commercially

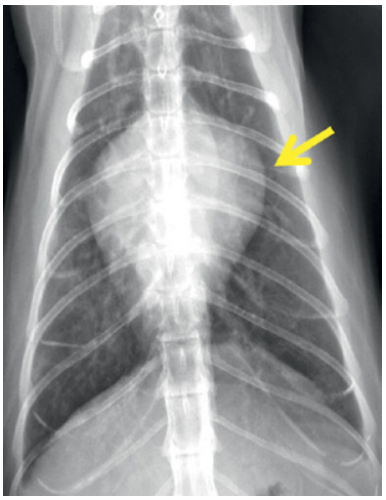

Figure 16.9 Thoracic radiographs of a cat with left-sided congestive heart failure secondary to hypertrophic cardiomyopathy. Note on the lateral view the mild convexity of the caudal heart border and the increased cranial–caudal diameter associated with mild but diffuse interstitial pulmonary edema (a). On the dorsoventral view (b), the dilated left atrium (*arrow*) associated with the pointed appearance of the left apex (owing to concentric left ventricular hypertrophy) creates a "Valentine-shaped" heart silhouette. *Source:* Medical Imaging Unit, ENVA.

available transducers have a wide frequency bandwidth, frequencies can be changed while using the same probe.

If possible, the ultrasound machine's ECG should be connected to the patient during the echocardiographic examination, in order to detect potential arrhythmias and study the correlation between electrical and mechanical events.

Standard 2D Echocardiographic Views and Measurements

A variety of standardized 2D transverse and sagittal echocardiographic views have been defined from the right and left parasternal positions. Transverse views, also called short-axis views, are obtained with the 2D ultrasound plane perpendicular to the long axis of the heart. Conversely, sagittal views, also called long-axis views, are obtained from short-axis views by rotating the transducer 90° counterclockwise, so that the 2D ultrasound plane becomes parallel to the long axis of the heart.

Main Parasternal Short-Axis Views

The three most commonly used 2D transverse echocardiographic views are the right parasternal transventricular short-axis view (Figure 16.13), the right parasternal transmitral short-axis view (Figure 16.14), and the right parasternal transaortic short-axis view (Figure 16.15).

The right parasternal transventricular short-axis view (Figure 16.13a) provides transverse visualization of the two ventricular cavities, and is therefore used to assess left (Figures 16.13b and 16.13c) and right (Figure 16.13d) ventricular changes in size and shape. This view is also commonly used to obtain M-mode echocardiograms at the ventricular level.

The right parasternal transmitral short-axis view (Figure 16.14) allows visualization of the mitral valve leaflets within the left ventricular cavity, and is therefore commonly used to obtain M-mode echocardiograms at the mitral valve level.

The right parasternal transaortic short-axis view (Figure 16.15a) provides transverse visualization of the heart base, with the ascending aorta visible as a circle in the middle of the sector image. This view is commonly used to calculate the left atrium/aorta ratio, and to therefore allow detection of left atrial dilation (Figure 16.15b, Tables 16.4 and 16.5). This view is also used to evaluate the right ventricular outflow tract as well as the pulmonary cusps (Figure 16.15c). A slight rotation of the transducer provides a short-axis view of the heart base optimized for the pulmonary arteries, which is useful for observing heartworms or blood clots within the pulmonary arteries (Figure 16.15d) and for detecting indirect signs of pulmonary arterial hypertension (Figure 16.15e). A similar view can be obtained from the left parasternal position.

Main Parasternal Long-Axis Views

Two 2D sagittal echocardiographic views can be obtained from the right side of the thorax – the right parasternal long-axis four- and five-chamber views (Figures 16.16 and 16.17, respectively). The right parasternal long-axis four-chamber view provides clear visualization of the atrial septum and the atrioventricular valves, and is therefore useful for the diagnosis of

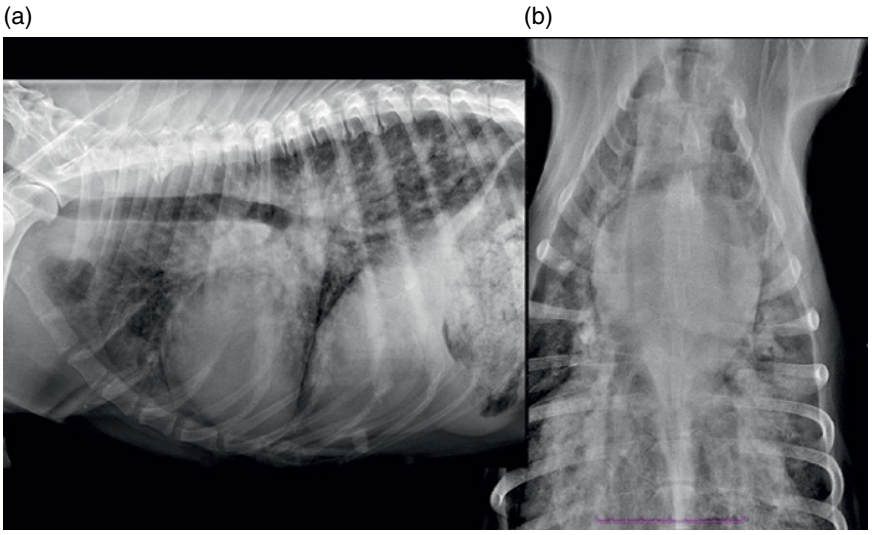

Figure 16.10 Thoracic radiographs of a Doberman with acute left-sided congestive heart failure secondary to dilated cardiomyopathy. Note the tracheal and carina dorsal elevation as well as the straightening of the caudal part of the cardiac silhouette, suggesting left heart enlargement on the lateral view (a). Diffuse patchy interstitial and alveolar opacities consistent with cardiogenic pulmonary edema are also present. They are symmetrically distributed in the right and left lung fields on the dorsoventral view (b). *Source:* Medical Imaging Unit, ENVA.

atrial septal defects (Figure 16.16b) and mitral valve lesions (Figure 16.16c).

The right parasternal long-axis five-chamber view is commonly used to examine the left ventricular outflow tract, the mitral valve leaflets, and the junction between the interventricular septum and the anterior aortic wall in order to respectively diagnose left ventricular outflow tract obstruction (Figure 16.17b), mitral valve lesions (Figure 16.17c), and ventricular septal defects (Figure 16.17d).

Long-axis four- and five-chamber views can also be obtained from the left parasternal position (2D left apical or caudal four- and five-chamber views; Figure 16.18).

The left apical four-chamber view provides good visualization of the ventricular inflow tracts and is therefore used to assess mitral and tricuspid diastolic inflows. It may also be used to calculate end-diastolic and end-systolic left ventricular volumes (Box 16.1).

The end-diastolic left ventricular length can also be measured from the left apical four-chamber view and the index of sphericity can then be calculated (this index is defined as the end-diastolic left ventricular length / left ventricular diameter assessed by M-mode at end-diastole; normal values are usually >1.65). The main use of the left apical five-chamber view is for the Doppler assessment of systolic aortic outflow.

Standard M-Mode Views and Measurements

The two most commonly used M-mode echocardiograms are obtained at the ventricular level and the mitral valve level (Figure 16.19). The M-mode echocardiogram obtained at the ventricular level is used to measure left ventricular end-diastolic and end-systolic diameters, left ventricular free wall thickness and interventricular septal thickness at end-diastole and at end-systole (which correspond to the onset of qRs and end of T-wave, respectively, on concomitant ECG tracing), in order to detect and quantify left ventricular alterations (Figure 16.20a and 16.20b). The left ventricular fractional shortening can then be calculated to indirectly assess the transverse systolic myocardial function (Figure 16.19a; see also Tables 16.4 and 16.5). The M-mode echocardiogram obtained at the ventricular level can also be used to measure right ventricular dimensions (end-diastolic diameter and end-systolic myocardial wall thickness).

E point to septal separation (up to 5–8 mm in the dog, depending on the size of the animal) can be measured from M-mode echocardiograms obtained at the mitral valve level. This distance increases in the case of severely reduced systolic left ventricular function. The same M-mode view may be used to detect systolic anterior motion of the mitral valve, which is commonly associated with obstructive forms of feline hypertrophic cardiomyopathy (Figure 16.20c).

Conventional Doppler Echocardiography

Conventional Doppler echocardiography allows detection and analysis of blood flows within the cardiovascular system. The conventional Doppler examination consists of locating blood flows within the cardiac chambers and vessels, as well as assessing their direction, velocity, and duration. This technique is also used to differentiate normal laminar flows from abnormal nonlaminar (or turbulent) flows. Additionally, flow volumes and pressure

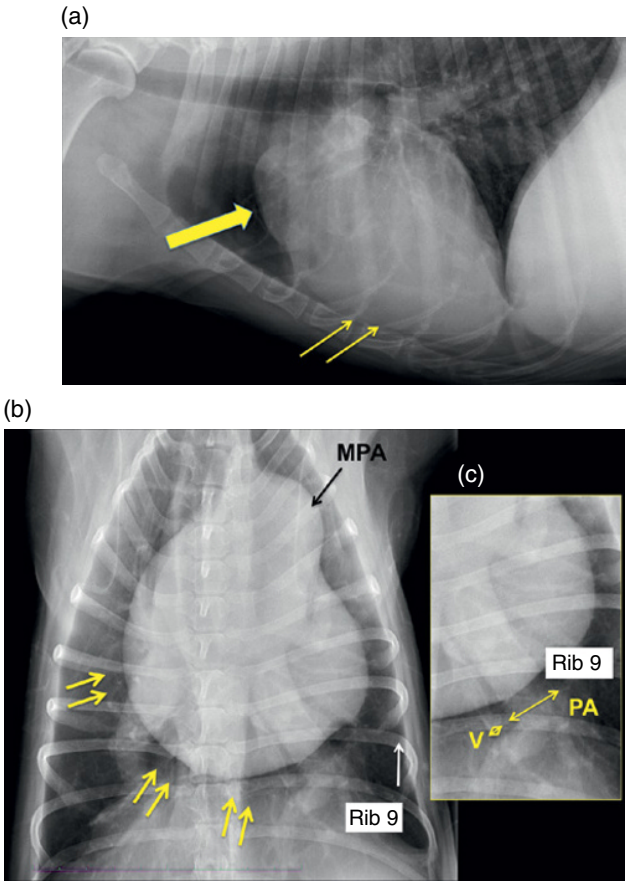

Figure 16.11 Thoracic radiographs of two dogs with marked right heart enlargement resulting from severe pulmonic stenosis (a) and pulmonary arterial hypertension secondary to a large reversed ventricular septal defect (b,c). (a) Note on this lateral view the increased sternal contact of the cranial cardiac margin (*small arrows*) consistent with right ventricular enlargement, as well as protrusion of the dorsal cranial margin of the cardiac silhouette (*large arrow*) owing to both right atrial dilation and enlargement of the main pulmonary artery. The pulmonary vasculature is also slightly diminished. (b) On this dorsoventral view, right ventricular enlargement is characterized by a rounded right heart border bulging to the right (approximately between 6 and 9 o'clock; *arrows*) and a leftward shift of the cardiac apex, leading to a reverse-D appearance. Note also the marked prominence of the main pulmonary artery (MPA) between 1 and 2 o'clock and the enlarged peripheral pulmonary arteries (PA), compared with the pulmonary veins (V, see details on (c)), which indicates pulmonary arterial hypertension. Width of peripheral pulmonary arteries should be similar to that of the corresponding pulmonary veins and should not be larger than the ninth rib diameter at the crossing point between the two. *Source:* Medical Imaging Unit, ENVA.

gradients across valves or between cardiac chambers can be estimated from velocity Doppler data using specific equations. Conventional Doppler echocardiography complements 2D and M-mode echocardiography by providing accurate cardiovascular hemodynamic information, and has now supplanted invasive techniques such as cardiac catheterization for the diagnosis of most human and animal heart diseases. Advanced ultrasound imaging techniques beyond the scope of this chapter are summarized in Box 16.2.

Basic Principles

Conventional Doppler echocardiography is based on the Doppler principle, discovered by Christian Doppler in the 19th century, which states that a moving structure (e.g., blood cells) reflects the incident ultrasound beam back to the transducer with a higher or lower frequency than the original transmitted frequency depending on whether the structure is, respectively, moving toward or away from the transducer. This difference between transmitted and received frequencies, also called the Doppler shift or frequency shift, is directly related to the velocity of the reflecting moving structures, which can thus be deduced from the frequency shift analysis.

The recorded frequency shift (and therefore the calculated flow velocity) also depends on the cosine of the intercept angle (θ) between the ultrasound beam and blood flow path. Therefore, whichever Doppler mode is used, the incident ultrasound beam must be perfectly parallel to the blood flow path ($\theta = 0°$), otherwise the blood flow velocity will not be assessed correctly, that is, it will be underestimated as compared to the actual velocity.

As frequency shift values are usually within the hearing range of the human ear, an audible signal can be simultaneously associated with spectral Doppler tracings of flow velocities. Listening to this Doppler audio signal is particularly useful in practice to help in aligning the ultrasound beam parallel to blood flow: the louder the audible signal, the higher the Doppler shift, the smaller the intercept angle θ, the better the alignment between blood flow and the ultrasound beam.

Standard Doppler Modes

Standard Doppler echocardiography includes different complementary modes, spectral Doppler modes and color-flow Doppler mode (see examples on Figures 16.21–16.23). Each mode has specific advantages and limitations, of which the observer must be perfectly aware in order to avoid misinterpretation of the recorded Doppler signals.

Spectral Modes: Pulsed-Wave and Continuous-Wave Doppler Modes

The two main spectral Doppler modes are pulsed-wave (PW) and continuous-wave (CW) Doppler modes.

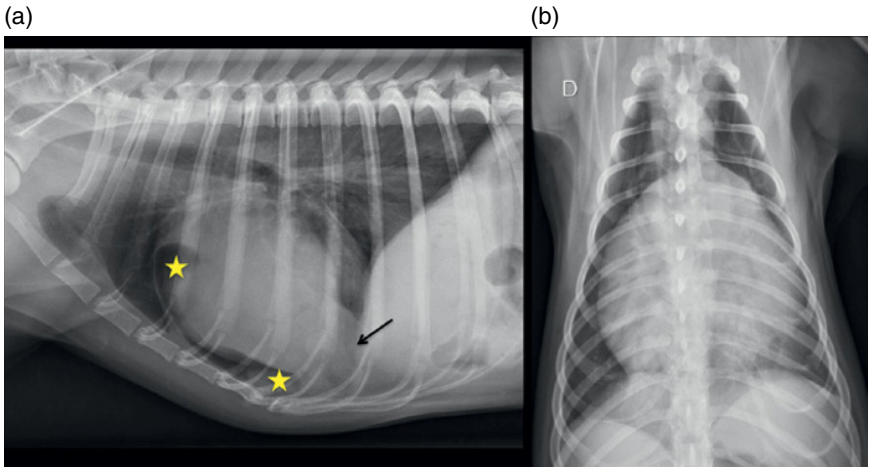

Figure 16.12 Lateral (a) and ventrodorsal (b) thoracic radiographs of a dog with a peritoneal-pericardial diaphragmatic hernia. Note the marked enlargement and the globoid shape of the heart on both views, overlap of the diaphragmatic and caudal heart borders (*arrow*), associated with a small liver and gas-filled intestinal loops (*stars*), that are superimposed on the cardiac silhouette because of their pericardial location. *Source:* Medical Imaging Unit, ENVA.

With these spectral Doppler modes, blood flow velocities (expressed in m/s) are displayed over time in a region of interest, that is, either all along a linear axis (or cursor line) for the CW Doppler mode or in a specific site, also called a sample gate or sample volume, for the PW Doppler mode. The position of the CW Doppler cursor as well as the location and size of the PW sample volume are carefully selected by the observer on 2D echocardiographic views. Whichever spectral Doppler mode is selected, the velocity profiles are displayed as positive (i.e., above the baseline) or negative (i.e., below the baseline), when blood cells respectively move toward or away from the transducer.

The CW mode uses two transducer elements, one continuously emitting and the other continuously receiving ultrasound waves. Because this emission–reception process is continuous, there is no loss of blood flow information and therefore no maximum limit for velocity measurements. Velocities higher than 8 m/s can thus be measured. Conversely, the PW mode uses only one transducer element which discontinuously emits short bursts of ultrasound waves at a given frequency (pulse repetition frequency, PRF = number of pulses per second), and receives reflected ones only at a given time and for a limited duration. This pulsed emission–reception process explains why the main limitation of the PW Doppler mode is its inability to measure high velocities: there is a maximum value for PW velocity recording, also called the Nyquist limit. When blood flow velocities exceed the Nyquist limit, an aliasing artifact occurs, characterized by a reversal of the velocities (Figure 16.24). The maximum velocity that can be recorded without aliasing is usually around 1.5–2.5 m/s. Its value depends on both the transducer frequency and the sample gate depth: the lower the transducer frequency and the lower the sample gate depth, the higher the maximal velocity that can be recorded.

Nevertheless, the advantage of the PW Doppler mode is that blood flows can be analyzed at very specific locations, whereas with the CW Doppler mode it is impossible to determine the accurate location of recorded blood flow velocities on the line of interrogation.

Color Flow Doppler Mode

The color flow Doppler mode provides a color-coded map of the velocity and direction of blood flows, which is superimposed in real time on black-and-white 2D-mode images. Blood flow velocities towards the transducer are coded in red whereas those away from the transducer are coded in blue (Blue Away, Red Toward or "BART"), with lighter colors for higher velocities. Many ultrasound systems also use variance color maps, adding green to the above-mentioned colors when the tested flow is turbulent.

As color flow imaging provides numerous color sites of flow information, it may be considered as a form of PW Doppler mode with numerous sample gates located on many scan lines. It therefore suffers from the same limitation, the aliasing artifact, which occurs when blood flow velocities exceed the Nyquist limit. This artifact is characterized by a color reversal (blue instead of red, red instead of blue). The maximum value for color-coded velocity without aliasing is dependent on blood flow depth and transducer frequency, as with the PW Doppler mode.

Normal Transvalvular Flows

General Characteristics

Transvalvular flows include two arterial flows (pulmonary and aortic flows) and two atrioventricular flows (mitral and tricuspid flows). These four flows are typically laminar, which means that all blood cells are moving in the same

direction and at approximately the same velocity throughout the entire cardiac cycle. Normal PW Doppler transvalvular flow profiles therefore appear as hollow (Figures 16.21c, 16.21d, 16.22b, 16.22c, 16.23c), because the blood flow velocities in the selected sample gate are very similar. Conversely, normal CW Doppler flow profiles appear as completely filled because of the various velocities recorded all along the CW scan line (Figure 16.21b).

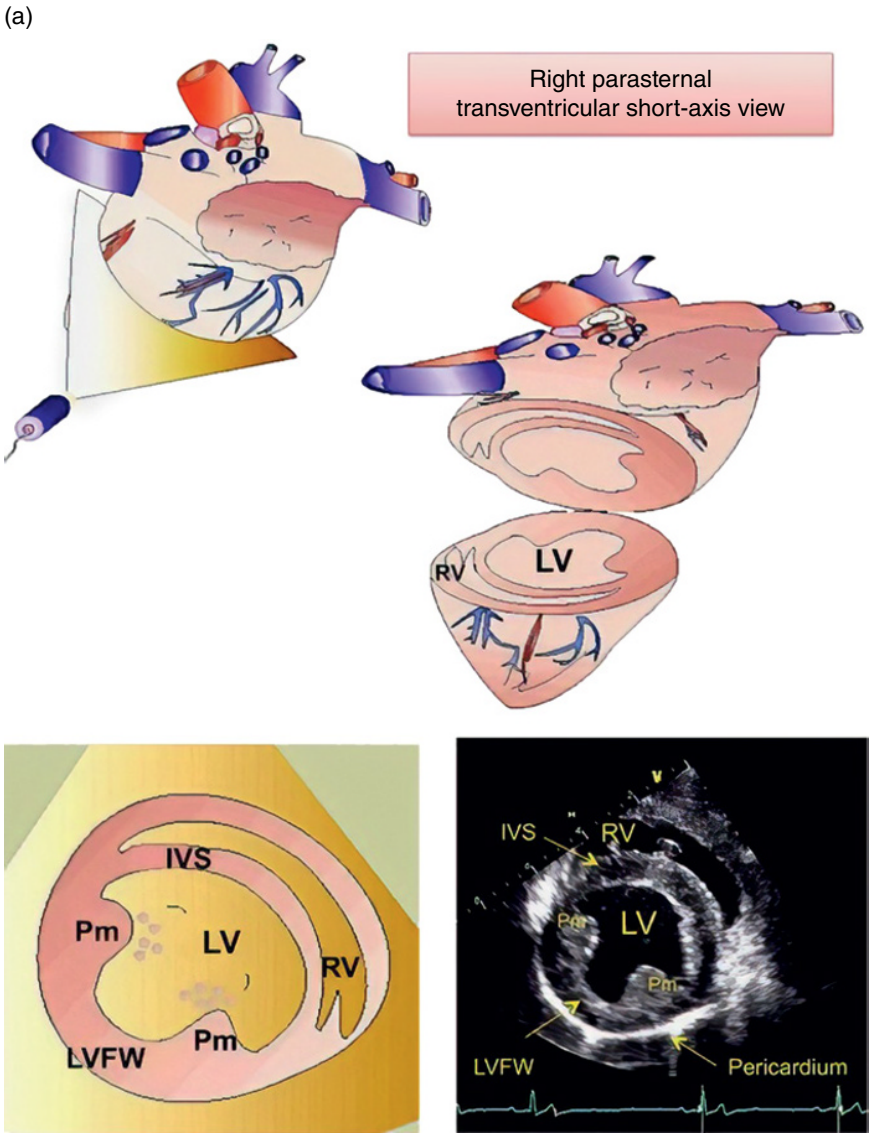

Figure 16.13 Two-dimensional right parasternal transventricular short-axis view in a normal dog (a) and in three dogs with heart diseases (b–d). (a) The top image shows spatial orientation of the ultrasound beam, with the transducer placed on the right side of the thorax. As shown on the middle image, the ultrasound plane goes first through the right ventricle (RV) and then the left ventricle (LV). Therefore, the real-time two-dimensional right parasternal transventricular short-axis view shows the crescent-shaped RV at the top of the sector image and the mushroom-shaped LV below, with the curved interventricular septum (IVS) between the two. Note the two symmetric papillary muscles (Pm) within the LV cavity and the left ventricular free wall (LVFW) at the bottom of the image. *Source:* Tessier-Vetzel D and Chetboul. In Chetboul *et al.* 2005. (b) In this dog with dilated cardiomyopathy, the right parasternal transventricular short-axis view taken in early systole shows an abnormal dilated and rounded (instead of mushroom-shaped) LV with thin myocardial walls and atrophied left Pm. (c) Unlike (b), in this dog with lipid storage myopathy and associated hypertrophic cardiomyopathy, note the reduced LV cavity, the hypertrophied myocardial walls and left Pm, associated with hyperechoic focal lesions (*arrows*) due to myocardial fibrotic remodeling. (d) In this dog with pulmonic stenosis, the IVS and the RV myocardial wall (RVW) are severely thickened. Note also the hypertrophied right Pm, the flattened IVS, and the reduced LV cavity.

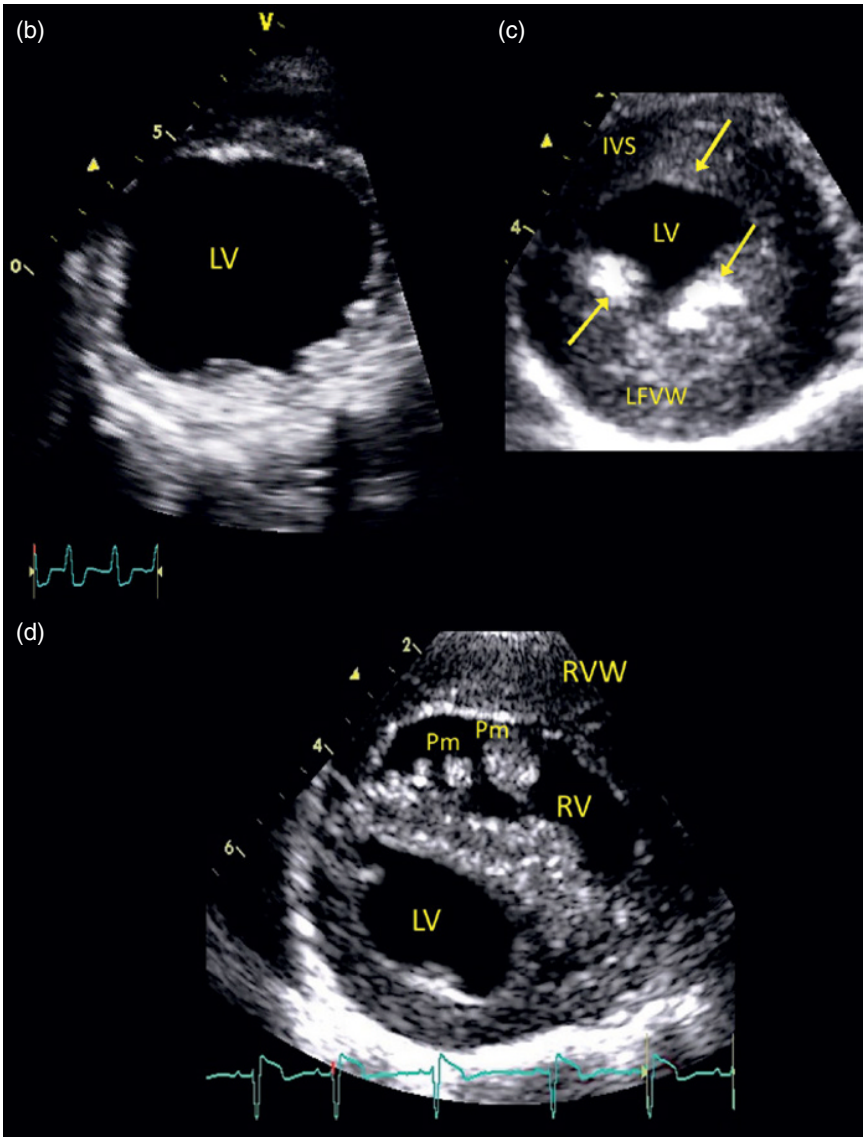

Figure 16.13 (Continued)

Normal Pulmonary and Aortic Systolic Flows

Pulmonary flow is assessed from the right or left parasternal transaortic short-axis views, whereas the left apical five-chamber view and the subcostal view are commonly used to analyze aortic flow. The subcostal view sometimes provides a better alignment than the left apical five-chamber view for imaging aortic outflow.

Both arterial flows are systolic (starting from the qRs complex and lasting until the end of the T-wave) and move away from the transducer. Pulmonary and aortic systolic flows are therefore encoded in blue with color flow Doppler mode, and the corresponding CW and PW systolic flow profiles are negative, with a symmetric or asymmetric appearance, respectively (Figures 16.21 and 16.22).

Peak arterial flow velocities are usually less than 2 m/s (Tables 16.4 and 16.5). Nevertheless, owing to left ventricular outflow tract morphology or high sympathetic tone, the laminar aortic flow profiles of some normal dogs may show higher peak values (between 2 and 2.5 m/s).

Normal Mitral and Tricuspid Diastolic Inflows

Mitral and tricuspid inflows are both assessed from left parasternal views (the left parasternal apical, or caudal, four-chamber view and the left parasternal cranial view optimized for right cavities, respectively).

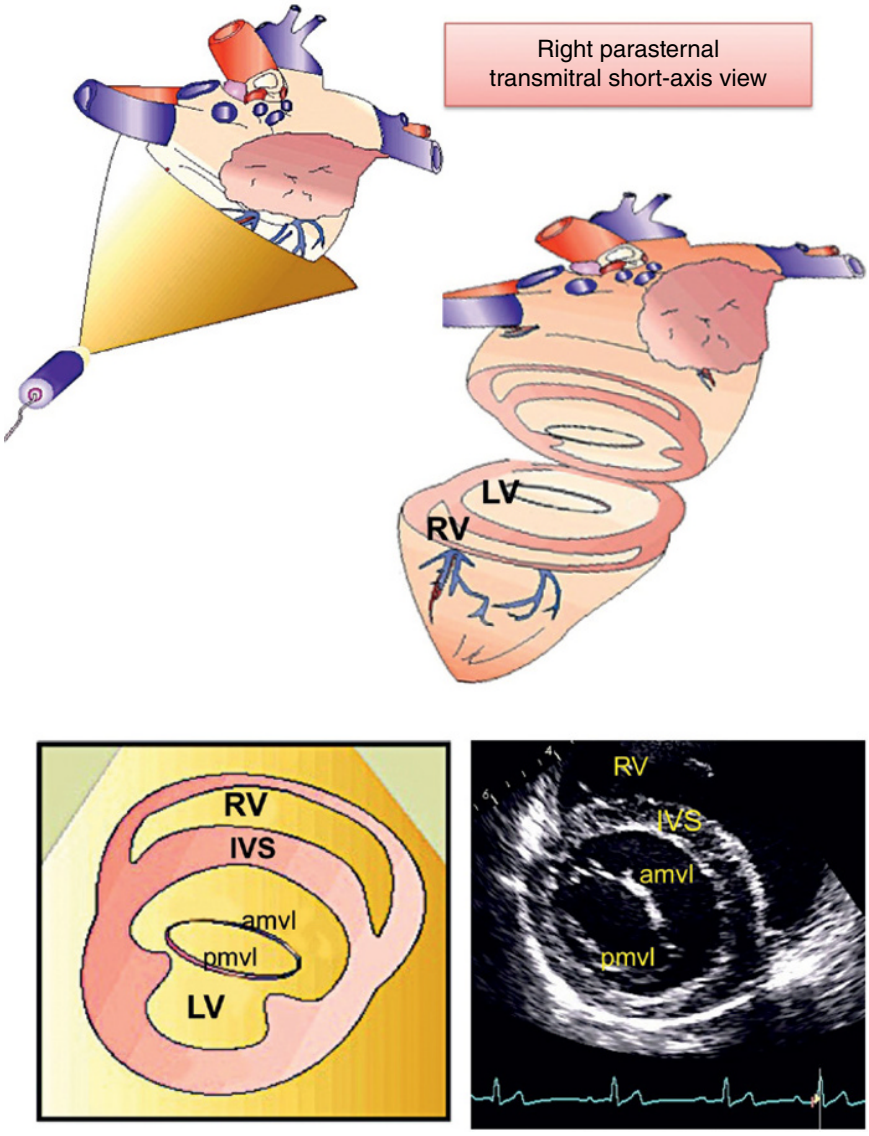

Figure 16.14 Two-dimensional right parasternal transmitral short-axis view. The top image shows spatial orientation of the ultrasound beam, with the transducer placed on the right side of the thorax. As shown on the middle image, the ultrasound plane goes first through the right ventricle (RV) and then the left ventricle (LV) at the mitral valve level. Therefore, the real-time two-dimensional right parasternal transmitral short-axis view shows the crescent-shaped RV at the top of the sector image and the rounded LV below, with the curved interventricular septum (IVS) between the two, and the two mitral valve leaflets within the LV cavity. amvl and pmvl: anterior and posterior mitral valve leaflets, respectively. *Source:* Tessier-Vetzel D and Chetboul. In Chetboul *et al*. 2005.

Unlike the above-described arterial flows, mitral and tricuspid flows are both diastolic (starting from the end of the T-wave and ending at the beginning of the qRs complex) and move toward the transducer. They are therefore encoded in red using the color flow Doppler mode, and the corresponding CW and PW diastolic flow profiles are positive, with a similar biphasic appearance (Figure 16.23) owing to an early rapid ventricular filling wave (E) and a late filling wave (A) resulting from atrial contraction. Peak early and late diastolic flow velocities are usually less than 1.5 m/s in dogs and cats (Tables 16.4 and 16.5), with an E/A ratio >1 except for healthy aged animals (as E/A ratio decreases with age). If the heart rate increases, E and A waves can fuse in a single summated signal, and this is commonly observed in the feline species.

(a)

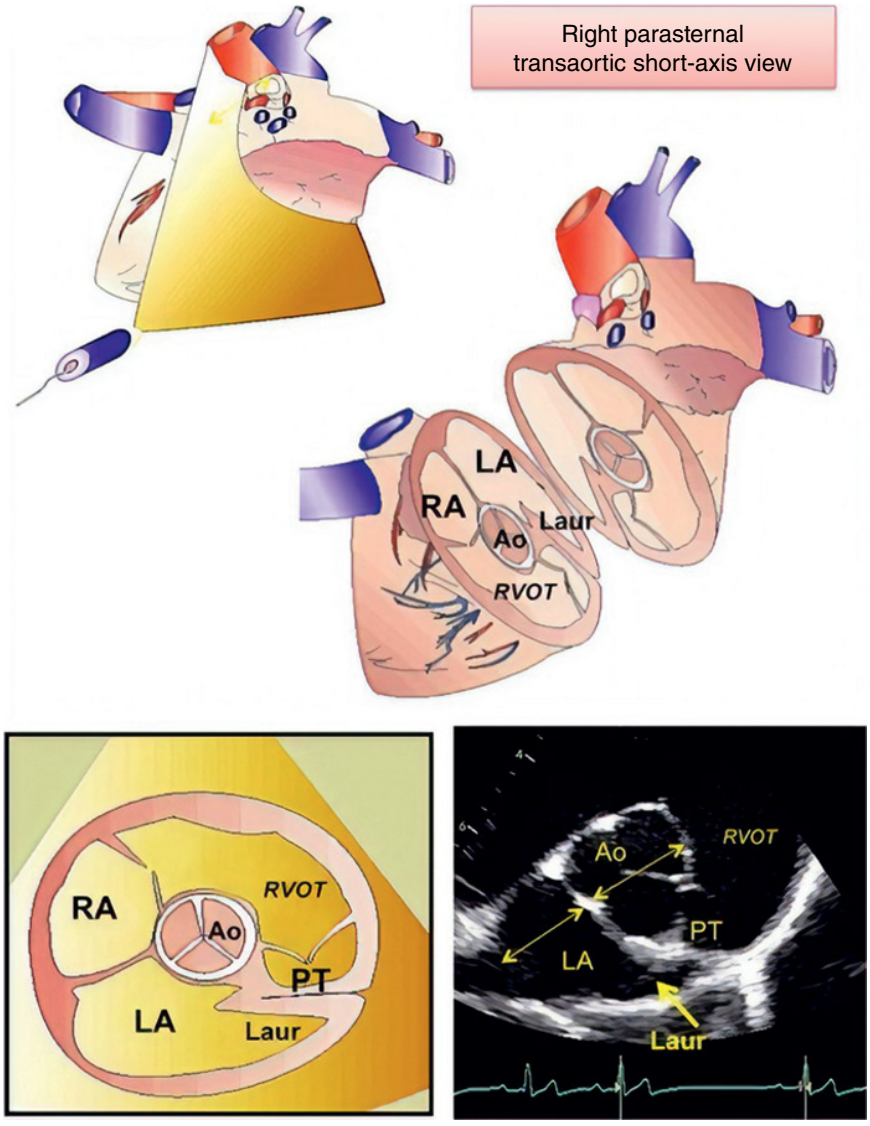

Figure 16.15 Two-dimensional right parasternal transaortic short-axis view in a normal dog (a) and in four dogs with heart diseases (b–e). (a) The right parasternal transaortic short-axis view is a transverse view of the heart base. The top image shows spatial orientation of the ultrasound beam, with the transducer placed on the right side of the thorax. As shown on the middle image, the ultrasound plane goes first through the right cavities including the right ventricular outflow tract (RVOT) and the right atrium (RA), then the aorta (Ao), and lastly the left atrium (LA). Therefore, the real-time two-dimensional right parasternal transaortic short-axis view shows the RVOT at the top of the sector image with the RA on the left, the circular-shaped Ao including the more or less visible aortic cusps at the center (appearing like the Mercedes car insignia), and the LA with the left auricle (Laur) at the bottom of the image. Note also the pulmonary trunk (PT) at the bottom right of the image. Measurements of the Ao and LA diameters can be obtained from this view, as follows: the internal short-axis Ao diameter is measured along the commissure between the noncoronary and left coronary aortic valve cusps, and the LA is measured in a line extending from and parallel to the commissure between the noncoronary and left coronary aortic valve cusps (*double arrows*). The LA/Ao ratio is then calculated (see Tables 16.4 and 16.5). *Source:* Tessier-Vetzel D and Chetboul. In Chetboul *et al*. 2005. (b) In this dog with end-stage degenerative mitral valve disease, the right parasternal transaortic short-axis view shows severe dilation of the LA and a markedly enlarged Laur (*arrow*). (c) In this dog with valvular pulmonic stenosis, the right parasternal transaortic short-axis view taken in systole shows thickened immobile pulmonic cusps (*arrow*) remaining in the center of the PT (instead of being "pushed" against the PT walls). (d) In this dog with severe heartworm infestation, the right parasternal transaortic short-axis view optimized for the pulmonary arteries shows several worms within the PT as well as the right and left pulmonary arteries (RPA and LPA, respectively). Heartworms appear as linear echoes (*arrow*) including two parallel lines separated by a thin hypoechoic line. (e) (same view as (d), taken in diastole) In this dog with severe pulmonary arterial hypertension associated with a right-to-left PDA, note the severe RPA, LPA and PT dilation (compared with the Ao) and the abnormal doming of the pulmonic cusps (*arrow*).

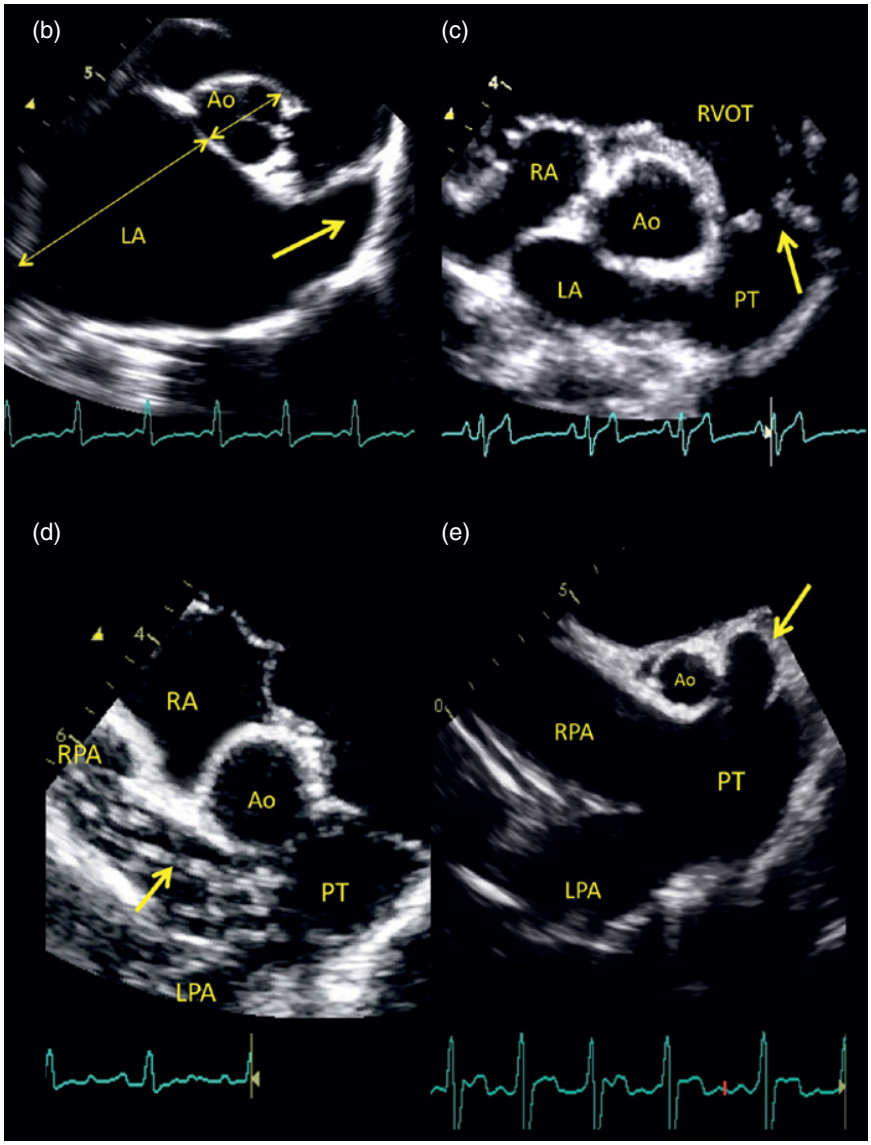

Figure 16.15 (Continued)

Physiologic Regurgitations

Many healthy dogs display trivial to mild physiologic regurgitations of the pulmonary and tricuspid valves. Physiologic systolic tricuspid regurgitation is also common in cats. Such physiologic regurgitations are commonly used to noninvasively assess pulmonary arterial pressure, and thus diagnose pulmonary arterial hypertension (see example in Figure 16.25). High regurgitant jet velocities of the tricuspid valve (>2.5 m/s in the absence of pulmonic stenosis) and the pulmonary valve (>2.0 m/s at end-diastole), detected by CW Doppler mode, are usually considered diagnostic for systolic and diastolic pulmonary arterial hypertension, respectively.

Standard Quantitative Doppler Echocardiographic Measurements

Conventional Doppler echocardiography using spectral Doppler modes provides accurate assessment of the direction and peak velocity (m/s) of blood flows. These velocity measurements can be used to estimate the maximum pressure gradients (ΔP in mmHg) across valves or between cardiac chambers with the modified Bernoulli equation:

$$\Delta P = 4 \times V^2$$

where V is the peak velocity (m/s) of blood flow distal to the orifice assessed by spectral Doppler modes.

Table 16.4 Standard echocardiographic and pulsed-wave Doppler data obtained from 100 healthy dogs of various breeds

Variable	Mean ± SD	Range
Heart rate (beats/min)	109 ± 20	70–171
Fractional shortening (%)	36.2 ± 3.5	30.1–49.0
Left atrium/aorta ratio at end-diastole (2D method)	0.90 ± 0.11	0.52–1.13
Systolic peak aortic flow velocity (m/s)	1.29 ± 0.22	0.92–1.88
Systolic peak pulmonary flow velocity (m/s)	1.05 ± 0.19	0.50–1.50
Mitral E wave velocity (m/s)	0.87 ± 0.13	0.58–1.17
Mitral A wave velocity (m/s)	0.61 ± 0.12	0.39–0.86
Mitral E/A ratio	1.46 ± 0.35	0.92–2.72
Tricuspid E wave velocity (m/s)	0.72 ± 0.11	0.50–0.98
Tricuspid A wave velocity (m/s)	0.43 ± 0.09	0.29–0.70
Tricuspid E/A ratio	1.75 ± 0.34	1.09–2.80

Mitral E/A ratio	1.5±0.3	1.1–2.9
Time parameters		
Isovolumic relaxation time (ms)	43±9	34–56
Heart rate (beats/min)	184±33	100–261

Source: Chetboul V, Carlos Sampedrano C, *et al.* Quantitative assessment of velocities of the annulus of the left atrioventricular valve and left ventricular free wall in healthy cats by use of two-dimensional color tissue Doppler imaging. *Am J Vet Res* 2006; **67**: 250–8.

Several indices of diastolic function can also be calculated. These include the mitral E/A ratio, E wave deceleration time, and the isovolumic relaxation time (time interval between end of aortic flow velocity and onset of transmitral flow), which is an index of active myocardial relaxation (Figure 16.23e).

Lastly, the volume of blood flowing through an orifice can be estimated by multiplying the area under the spectral Doppler curve (velocity time integral) by the cross-sectional orifice area assessed on 2D echocardiographic images.

Common Abnormal Flow Patterns

Abnormal Pulmonary Flow Patterns

Alterations in Systolic Pulmonary Flow

The most common causes of abnormal systolic pulmonary flow patterns are pulmonary arterial hypertension and congenital pulmonic stenosis.

Elevated pulmonary arterial pressures may induce an abnormal asymmetric PW Doppler pulmonary velocity profile with a short acceleration time and a delayed deceleration time, similar to the normal aortic flow profile. A midsystolic notch (Figure 16.26a) may also be seen, most commonly in the case of severe pulmonary arterial hypertension (prevalence of notched pulmonary velocity profiles of 38% for systolic pulmonary arterial pressures >40 mmHg). Peak systolic flow velocity may also be diminished.

Pulmonic stenosis is responsible for an increase in systolic pulmonary flow velocity (Figures 16.26b and 16.26c), which can be assessed without aliasing artifact using the CW Doppler mode (Figure 16.26c).

When the PW Doppler mode is used, the velocity spectrum is broadened, as the flow is turbulent (instead of laminar). Measurement of peak velocity using the CW Doppler mode and subsequent calculation of the maximum systolic pressure gradient across the stenotic lesion provides an accurate and noninvasive estimate of lesion severity (Figure 16.26c). Pulmonic stenosis is considered as severe when the pressure gradient across the stenotic orifice exceeds 80–100 mmHg. Color flow Doppler mode shows narrowing of the color-coded systolic pulmonary flow map, and is therefore useful to accurately localize the stenotic lesion (Figure 16.26b).

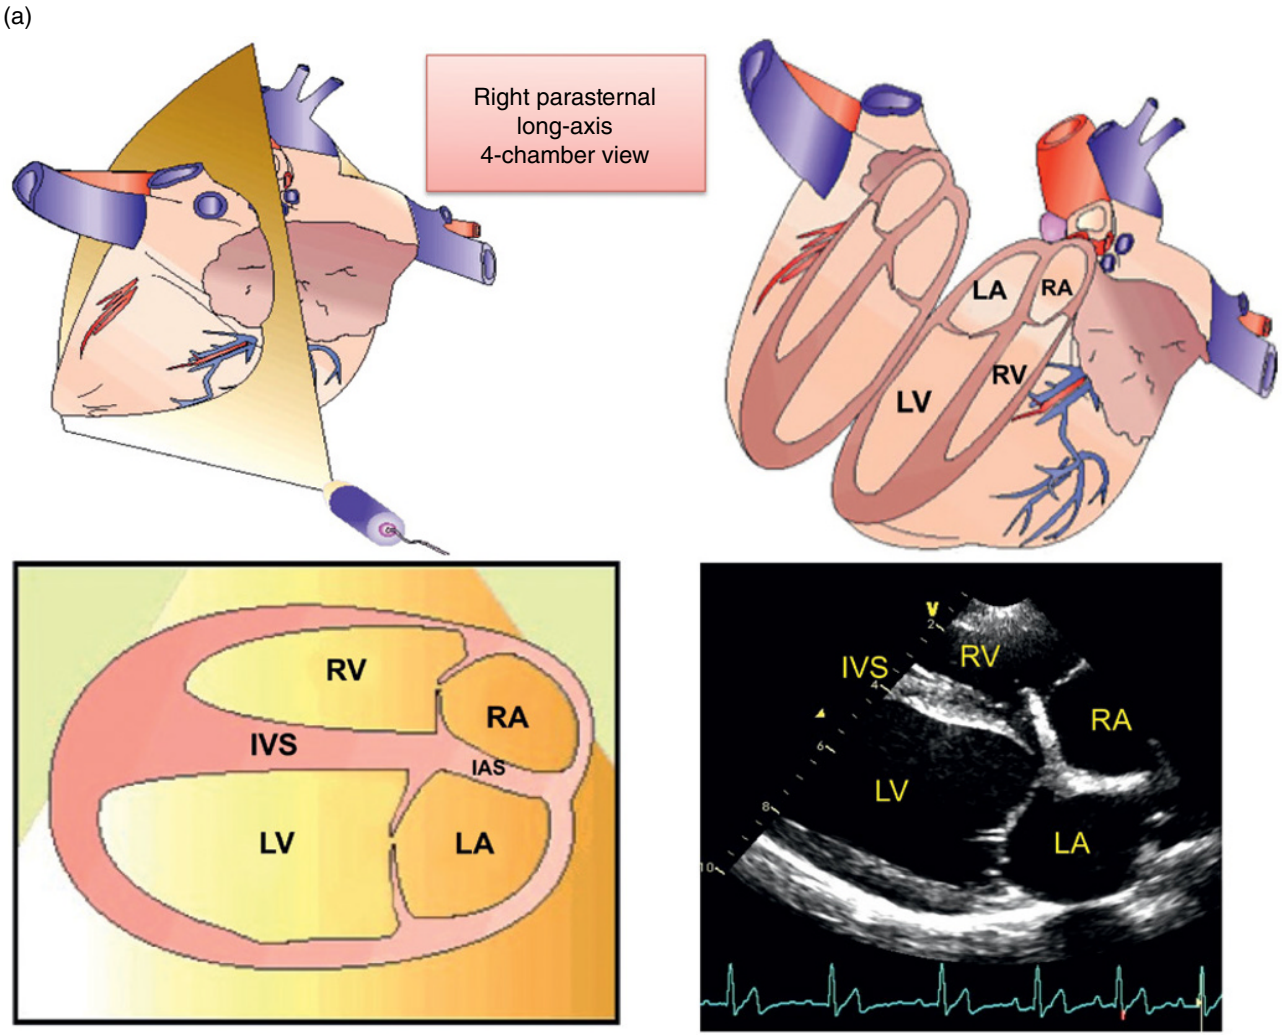

Figure 16.16 Two-dimensional right parasternal long-axis four-chamber view in a normal dog (a) and in two dogs with heart diseases (b,c). (a) The top image on the left shows spatial orientation of the ultrasound beam, with the transducer placed on the right side of the thorax. As shown on the top image on the right, the ultrasound plane goes first through the two right cavities, i.e., the right ventricle (RV) and the right atrium (RA), then the two left cavities, i.e., the left ventricle (LV) and the left atrium (LA). Therefore, the real-time two-dimensional right parasternal long-axis four-chamber view shows the RV and the RA separated by the tricuspid valve at the top of the sector image, and the LV and the LA separated by the mitral valve below. The interventricular septum (IVS) and interatrial septum (IAS) are also clearly seen. *Source:* Tessier-Vetzel D and Chetboul. In Chetboul *et al*. 2005. (b) In this dog presenting with exercise intolerance, a large defect (*arrow*) is located in the middle of the IAS (ostium secundum type atrial septal defect). (c) Two-dimensional right parasternal long-axis four-chamber view obtained in systole from a dog with degenerative mitral valve disease and chordae tendinae rupture. A portion of the ruptured chordae tendinae (*arrow*) still attached to the prolapsed anterior mitral valve leaflet is seen within the severely enlarged LA.

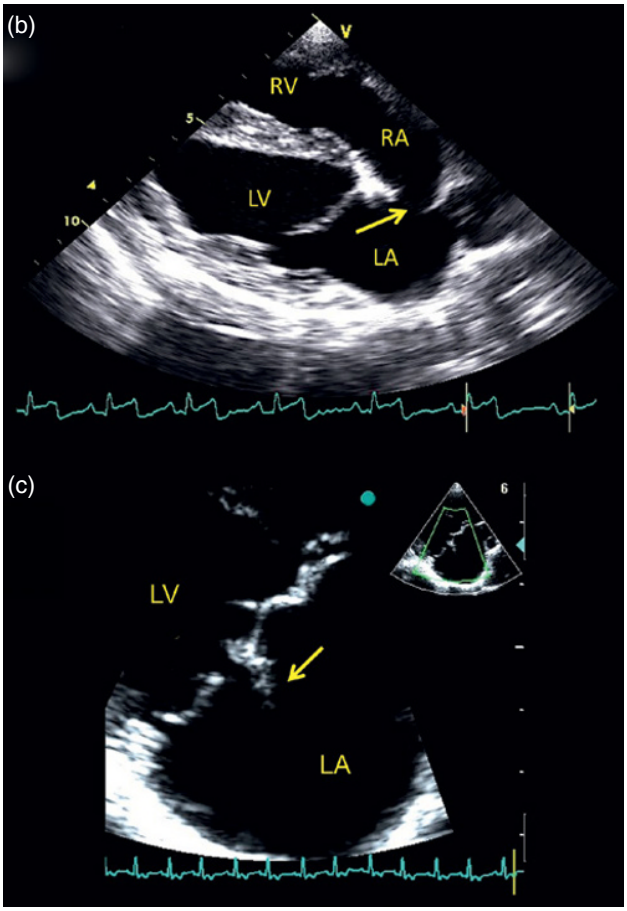

Figure 16.16 (Continued)

Nonphysiologic Pulmonary Regurgitations

Pulmonary regurgitation is often associated with congenital pulmonic stenosis, because of the abnormally thickened and irregular pulmonary leaflets (Figure 16.26c). Its severity may be mildly to moderately increased in patients with pulmonary stenosis that have undergone balloon valvuloplasty. In contrast, pulmonary regurgitation caused by infectious endocarditis is a very rare condition.

Physiologic diastolic pulmonary regurgitation becomes turbulent as well as of increased velocity, duration and extension in the case of diastolic pulmonary hypertension (see Figure 16.25 and above paragraph).

Abnormal Aortic Flow Patterns

Alterations in Systolic Aortic Flow

Aortic stenosis may result from infectious endocarditis. However, the two most common causes of systolic aortic flow obstruction in the dog and cat are congenital aortic stenosis and obstructive hypertrophic cardiomyopathy, respectively. Whatever the cause, aortic stenosis produces an accelerated turbulent systolic aortic flow, with similar spectral and color flow Doppler characteristics to those described for pulmonic stenosis (Figure 16.27).

Aortic Insufficiency

Common causes of aortic insufficiency include infectious endocarditis, congenital abnormal aortic valve (most often in association with subaortic stenosis), and degenerative valvular disease. Color flow Doppler mode criteria indicating severe aortic regurgitation are large insufficiency jet size, compared to the left ventricular outflow tract, and high extension of the diastolic jet within the left ventricle, that is, beyond the mitral leaflets tips. Severe aortic insufficiency also causes a rapid deceleration of the diastolic Doppler CW signal, owing to the marked decrease in the diastolic pressure gradient across the abnormal aortic valve over time. Examples of mild and severe aortic regurgitation jets are presented in Figures 16.27c and 16.28.

Abnormal Mitral Flow Patterns

Alteration in Diastolic Transmitral Inflow

Alteration in left ventricular diastolic function may induce transmitral inflow changes, including delayed relaxation and restrictive transmitral flow patterns (Figures 16.29a and 16.29b). Impaired relaxation may cause lower E wave velocity and higher A wave velocity (E/A <1), as well as prolonged isovolumic relaxation time, reduced flow acceleration time, and prolonged deceleration time (Figure 16.29a). However, in the case of delayed relaxation associated with increased left atrial pressure and left ventricular stiffness, the transmitral inflow may be normal (also called the "pseudonormal" transmitral flow pattern). The restrictive filling pattern is characterized by a shortened isovolumic relaxation time, a tall narrow mitral E wave, and a small A wave (Figure 16.29b).

Diastolic transmitral inflow is also altered in the case of congenital or acquired (endocarditis) mitral stenosis (Figures 16.29c and 16.29d).

In dogs with degenerative mitral valve disease, a high-velocity E wave (>1.5 m/s) suggests elevated left atrial pressure and therefore severe mitral regurgitation.

Mitral Regurgitation

One of the methods commonly used to assess mitral regurgitation severity in dogs with mitral valve dysplasia or degenerative mitral valve disease consists of

calculating the maximal ratio of the regurgitant jet area signal to left atrium area (ARJ/LAA ratio) using color flow Doppler mode (Figure 16.30). The major advantage of this color Doppler mapping method is the rapidity and ease of data acquisition. Nevertheless, this technique presents several limitations: the maximal value for the ARJ/LAA ratio is 100%, which precludes accurate discrimination between dogs with "significant" mitral regurgitation. Additionally, the ARJ/LAA ratio may be influenced by several factors including systemic arterial blood pressure, left atrial pressure, and spatial orientation of the regurgitant jet. Note that it may also be possible to quantify (rather than "semi-quantify") mitral valve regurgitation (in mL) using another Doppler technique, called the Proximal Isovelocity Surface Area (PISA) or flow convergence method.

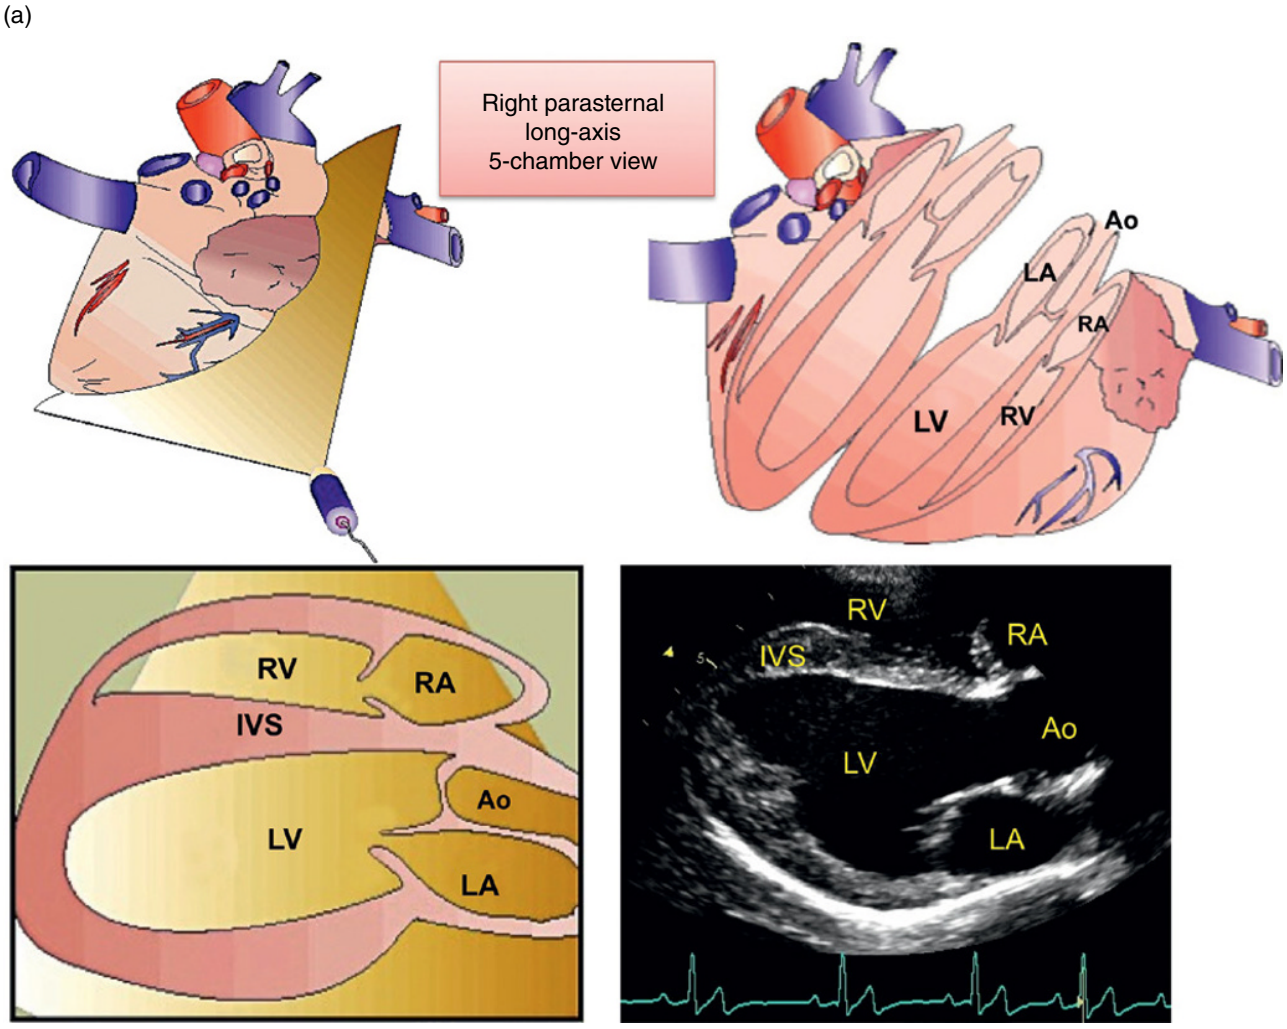

Figure 16.17 Two-dimensional right parasternal long-axis five-chamber view in a normal dog (a) and in three dogs with heart diseases (b–d). (a) The top image on the left shows spatial orientation of the ultrasound beam, with the transducer placed on the right side of the thorax. As shown on the top image on the right, the ultrasound plane goes first through the two right cavities, i.e., the right ventricle (RV) and the right atrium (RA), then the aorta (Ao), and the two left cavities, i.e., the left ventricle (LV) and the left atrium (LA). Therefore, the real-time two-dimensional right parasternal long-axis five-chamber view shows the RV and the RA separated by the tricuspid valve at the top of the sector image, the LV and the LA separated by the mitral valve below, and a long-axis image of the Ao too. The interventricular septum (IVS) is continuous with the anterior aortic wall. *Source:* Tessier-Vetzel D and Chetboul. In Chetboul *et al*. 2005. (b) A muscular bulge of the IVS into the LV outflow tract (*arrow*) creating outflow obstruction is clearly visible in this boxer dog with subvalvular aortic stenosis. (c) In this dog suffering from bacterial endocarditis, large vegetative lesions (*arrow*) are visible on the mitral valve leaflets. (d) In this dog presenting with exercise intolerance, a large ventricular septal defect (*arrow*) is seen just below the aortic valve. Note also the markedly enlarged right pulmonary artery (RPA).

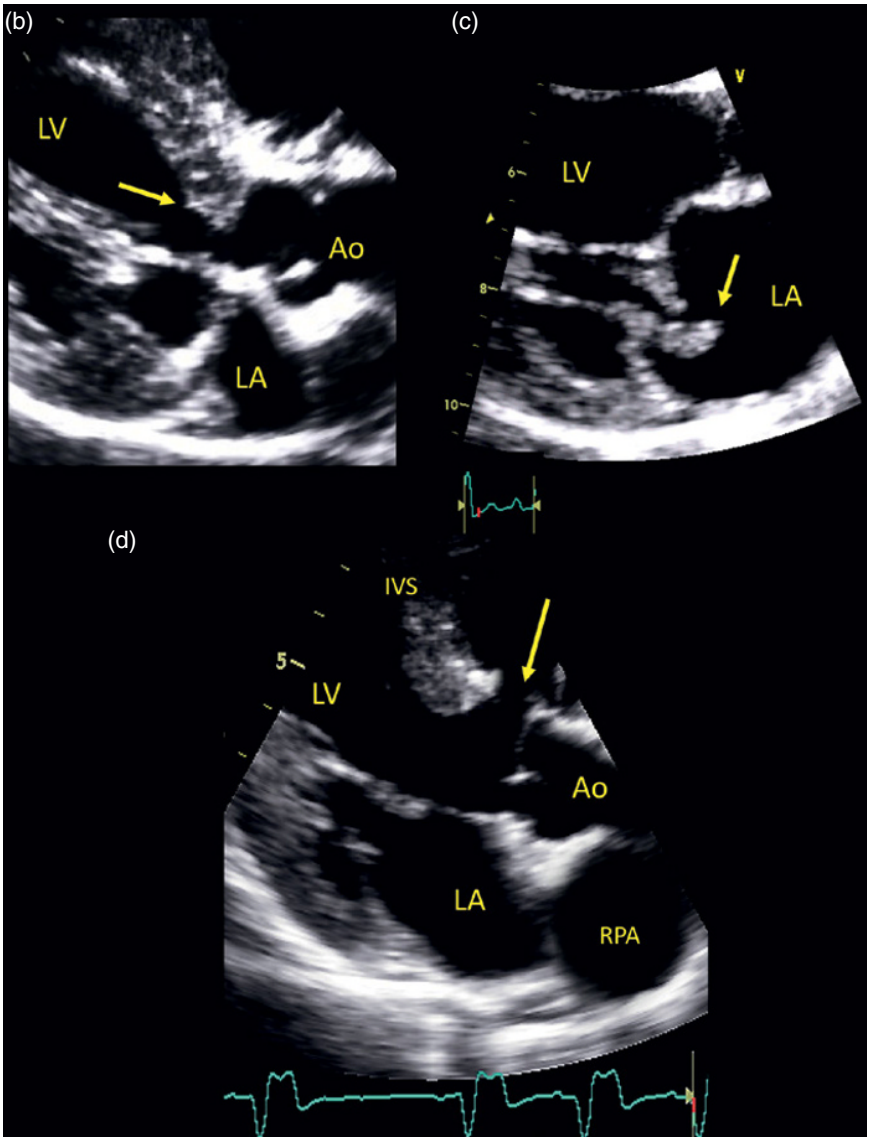

Figure 16.17 (Continued)

Abnormal Tricuspid Flow Patterns

Abnormal tricuspid flow patterns are similar to those described above for mitral inflow. In the case of systolic pulmonary hypertension, tricuspid regurgitation demonstrates increased velocity, duration, and extension. The CW Doppler recording of this high peak systolic tricuspid regurgitant velocity can be used to calculate the systolic right ventricle-to-right atrium pressure gradient across the tricuspid valve by applying the modified Bernoulli equation. The systolic pulmonary arterial pressure (equivalent to the systolic right ventricular pressure in the absence of pulmonic stenosis) is then calculated by adding the estimated right atrial pressure (5, 10 or 15 mmHg in patients with a normal sized right atrium, a dilated right atrium, or right-sided congestive heart failure, respectively) to the systolic right ventricle-to-right atrium pressure gradient.

Nonvalvular Abnormal Flows

Patent Ductus Arteriosus

Color flow Doppler shows the turbulent jet flowing from the ductus into the pulmonary trunk throughout the cardiac cycle (Figure 16.31a). Continuous-wave Doppler mode confirms continuous systolic and diastolic turbulent flows of high velocity into the pulmonary artery (>5 m/s in systole, around 4 m/s in diastole), and allows estimation of the aorta–pulmonary artery pressure gradient (Figure 16.31b). When the pulmonary

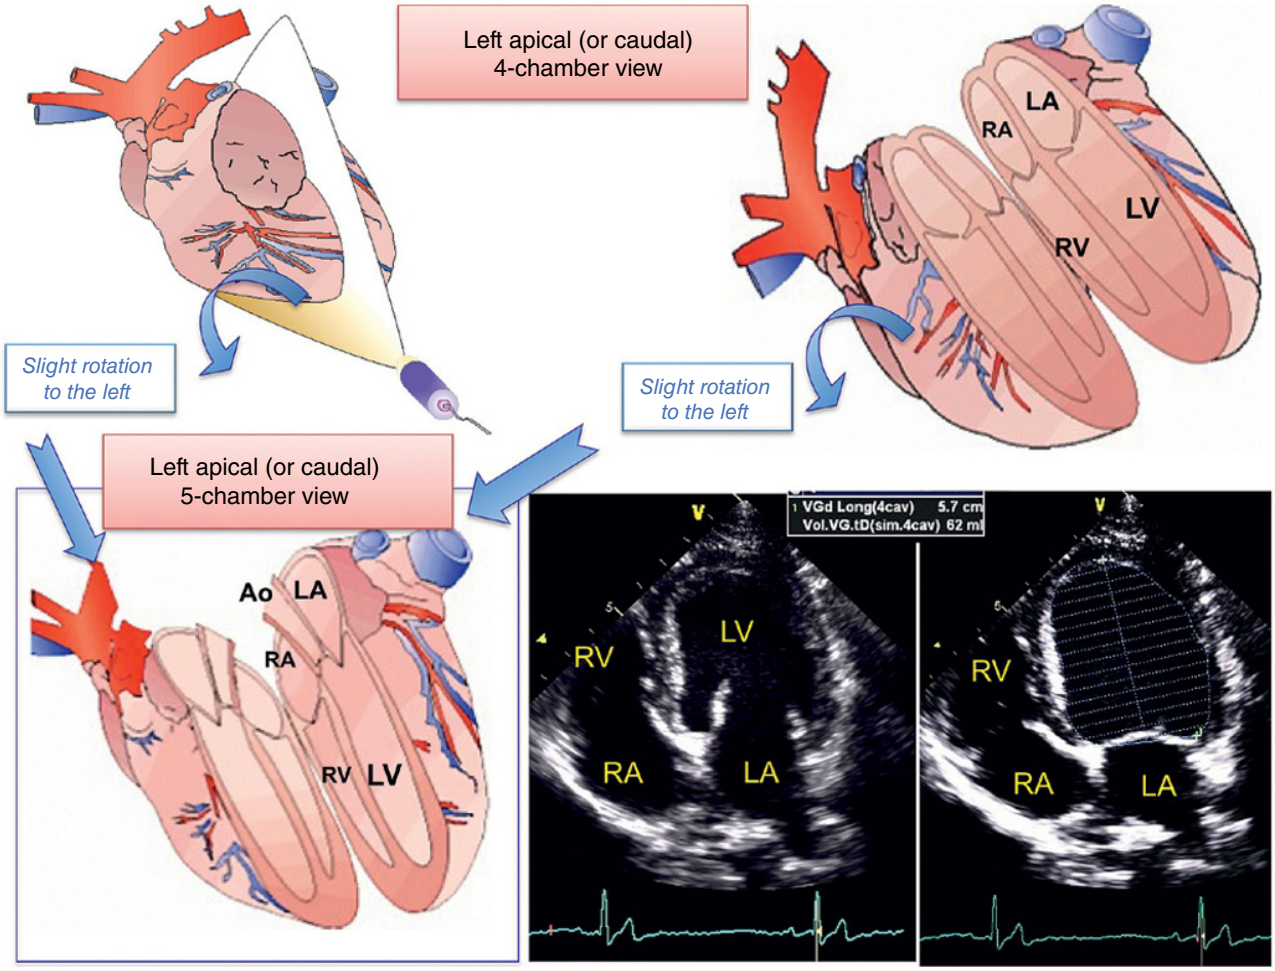

Figure 16.18 Two-dimensional left apical (or caudal) four- and five-chamber views. The top image on the left shows spatial orientation of the ultrasound beam, with the transducer placed on the left side of the thorax, to obtain the left apical four-chamber view. As shown in the top image on the right, the ultrasound plane goes first through the apex, then the right (RV) and left (LV) ventricles, and lastly the left and right atrial cavities (LA and RA, respectively). Therefore, the real-time two-dimensional left apical four-chamber view shows the apex and the two ventricles at the top of the sector image, and the two atrial cavities below, with the mitral valve opened during diastole and closed from end-diastole to end-systole (middle and right bottom images, respectively). The left apical four-chamber view can be used to measure maximum end-systolic and end-diastolic LV length as well as LV volumes. An example of calculation of end-diastolic LV volume using the Simpson's derived method of discs is provided on the bottom right image. The endocardial border has been traced and closed around the mitral annulus, thus delimiting the end-diastolic LV area. The end-diastolic LV volume, considered as the summation of parallel cylinders, whose diameters are derived from endocardial border tracing, is then automatically calculated using a specific software (62 mL). Another method, also called the length-area method, relies on the following simple formula: LV volume = $0.85A^2/L$, where A is the LV area, and L is the LV length measured on the same view. From the left apical four-chamber view, a slight rotation of the transducer to the left allows visualization of the left ventricular outflow tract and a long-axis image of the aorta (Ao), thus defining the left apical five-chamber view (bottom image on the left). See also Figures 16.22 and 16.27 as examples for use of the latter view. *Source:* Tessier-Vetzel D and Chetboul. In Chetboul *et al*. 2005.

Box 16.1 Measurement of ventricular volumes

Echocardiography can be used to measure ventricular volume using a variety of methods, including the Simpson's derived method of discs or length-area method (see explanation in the legend of Figure 16.18). The left ventricular ejection fraction (expressed as a percentage) can then be calculated according to the following formula: 100*(EDV-ESV)/EDV, with EDV and ESV corresponding to the end-diastolic and end-systolic left ventricular volumes. The end-systolic volume index, defined as the end-systolic left ventricular volume divided by the body surface area, may be used as an index of systolic myocardial function.

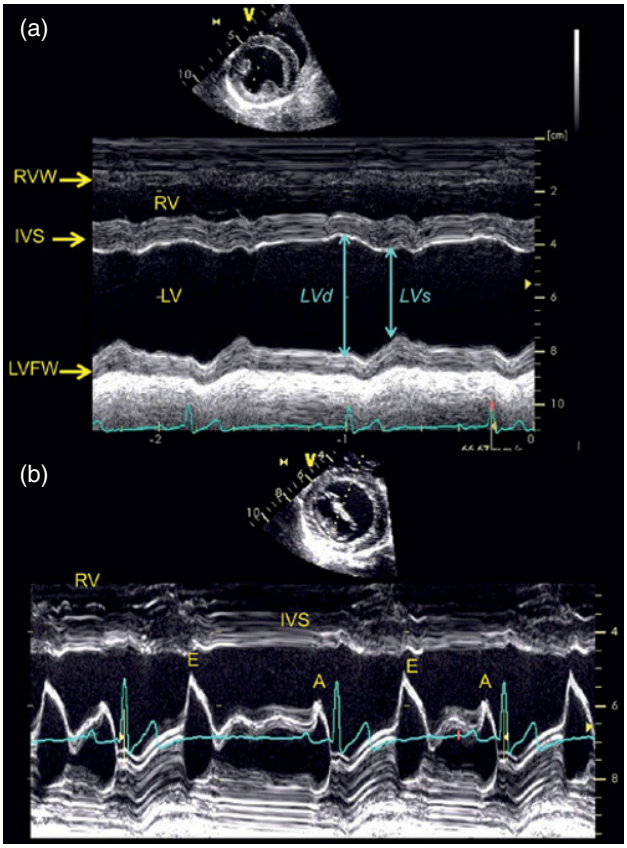

Figure 16.19 M-mode echocardiograms obtained from two normal dogs at the ventricular level (from the right parasternal transventricular short-axis view, (a)) and the mitral valve level (from the right parasternal transmitral short-axis view, (b)). (a) This ventricular M-mode echocardiogram displays the right ventricular myocardial wall (RVW) and the right ventricular cavity (RV) at the top of the image, the left ventricle (LV) and the LV free wall (LVFW) below, with the interventricular septum (IVS) between the two ventricular cavities. The M-mode cursor is placed perpendicular to the IVS and the LVFW between the two left papillary muscles. The LV end-diastolic (LVd) and end-systolic (LVs) diameters can be measured (*double arrows*), and the left ventricular fractional shortening (expressed in percentage and defined as the difference between the LVd and LVs divided by LVd) can then be calculated. (b) This M-mode echocardiogram at the mitral valve level shows the M-shaped motion of the anterior mitral valve leaflet during diastole. The E point and the smaller A point represent the maximum valve opening during the rapid ventricular filling phase and the atrial contraction, respectively. Closure of the mitral valve occurs after atrial contraction, at end-diastole.

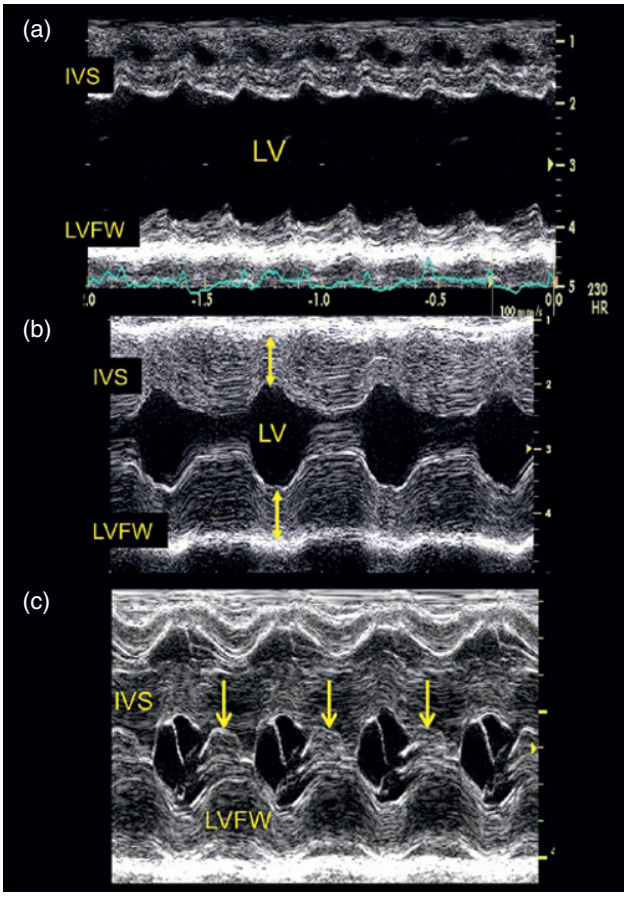

Figure 16.20 Abnormal M-mode echocardiograms obtained from three cats with heart diseases at the ventricular level (a,b) and the mitral valve level (c). (a) In this cat with taurine deficiency-induced dilated cardiomyopathy, the ventricular M-mode echocardiogram shows marked dilation of the left ventricular cavity (LV) with almost no difference between the end-diastolic and end-systolic LV diameters. (b) This ventricular M-mode echocardiogram in a Maine Coon cat with hypertrophic cardiomyopathy shows severe symmetric hypertrophy (end-diastolic interventricular septum and LV free wall >6 mm, double arrows). (c) This M-mode echocardiogram obtained at the mitral valve level in a cat with hypertrophic cardiomyopathy shows a significant systolic anterior motion of the mitral valve (*arrows*), which is characterized by an abnormal mitral valve septal contact during diastole, leading to LV outflow tract obstruction. IVS, interventricular septum; LVFW, left ventricular free wall.

vascular resistance increases, lower velocities are recorded across the ductus.

Septal Defects (Figures 16.31c and 16.31d)

Color flow Doppler echocardiography associated with spectral Doppler modes may identify small defects that cannot be visualized on 2D mode images. High-velocity flow across the ventricular septal defect (>5 m/s) associated with normal peak systolic pulmonary flow velocity is indicative of "restrictive" ventricular septal shunt, that is, hemodynamically not significant, with conservation of the left ventricle–right ventricle pressure gradient (at least 100 mmHg). Flow velocities across the atrial septal defect are typically low (<1 m/s), as the left atrium–right atrium pressure gradient is only several mmHg (Figure 16.31d).

Box 16.2 Advanced ultrasound techniques

Tissue Doppler imaging

Tissue Doppler imaging (TDI) is a relatively recently developed ultrasound technique which allows the quantification of regional myocardial function from measurements of myocardial velocities in real time (Figure 16.32). The 2D color TDI has been shown to be repeatable and reproducible in the awake cat and dog, and is more sensitive than 2D and M-mode echocardiography in detecting myocardial dysfunction of different etiologies in these species, even when overt myocardial changes are absent. This technique may therefore be used for the early detection of systolic and diastolic myocardial alterations associated with dilated or hypertrophic cardiomyopathies, and may be particularly useful in the case of equivocal 2D and M-mode results.

Strain and strain rate imaging

Strain and strain rate imaging are two quantitative TDI-derived imaging techniques, allowing measurement of myocardial segmental deformation (contraction or stretching) and rate of deformation, respectively (see Figure 16.32). Myocardial strain represents the deformation of a myocardial segment over time, and is expressed as the % change from its original dimension. Myocardial strain rate (expressed in s^{-1}) is the temporal derivative of strain, and therefore describes the rate of myocardial deformation. Strain and strain rate imaging therefore offer a direct evaluation of regional intrinsic active myocardial function.

Speckle tracking echocardiography

Two-dimensional speckle tracking echocardiography is the most recently developed ultrasound technique allowing quantitative assessment of regional myocardial function (Figure 16.33). This non-Doppler technique is based on identification and frame-by-frame tracking of speckle patterns created within the myocardium on routine 2D gray-scale echocardiographic images and subsequent assessment of myocardial motion (myocardial tissue velocity, strain and strain rate, and also LV rotation). One of its major advantages, compared to Doppler-based techniques (TDI or TDI-derived techniques), is its independence of both cardiac translation and the insonation angle.

Other ultrasound techniques

Three-dimensional (3D) echocardiography allows 3D visualization of the heart. Good-quality real-time or live 3D imaging of the beating heart can now be obtained thanks to advancements in computer technology and the development of fully sampled matrix-array transducers. One of the major advantages of 3D echocardiography over 2D imaging is its greater accuracy for the evaluation of cardiac chamber volumes (thus avoiding conventional echocardiographic geometric modeling). Another application of 3D imaging is to acquire realistic views of cardiac valves and assess complex or equivocal congenital abnormalities (e.g., shunts), which can be particularly useful when planning a surgical correction.

Transesophageal echocardiography uses a transducer mounted at the tip of a flexible endoscope and allows imaging of the heart from the esophagus (instead of through the chest wall, as for transthoracic echocardiography). The advantage of transesophageal echocardiography is the acquisition of high-quality images, as it avoids the anatomic structures (skin, subcutaneous tissue, ribs, lungs), which may affect the quality of conventional transthoracic echocardiography. Potential indications for transesophageal echocardiography in veterinary medicine include analysis of specific cardiovascular abnormalities (thrombosis, aneurysm, cardiac tumors), cardiac monitoring during anesthesia or catheterization, and evaluation of surgical procedures such as ductus arteriosus closure.

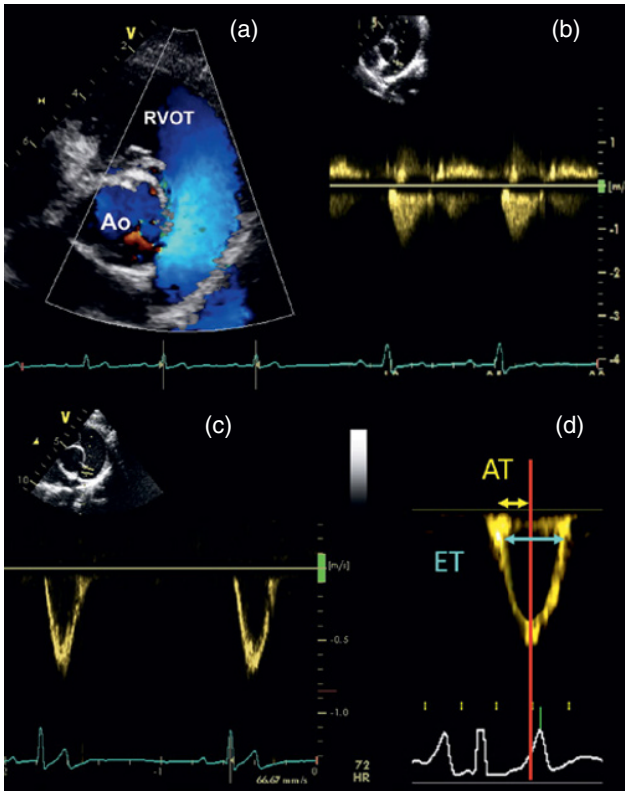

Figure 16.21 Doppler evaluation of systolic pulmonary flow in normal dogs using color flow (a), continuous-wave (b), and pulsed-wave (c,d) Doppler modes from the right parasternal transaortic short-axis view optimized for the right ventricular outflow tract (RVOT). The pulmonary flow is coded in blue (a), as it goes away from the transducer during systole. The spectral Doppler waveform (b–d) is typically negative and symmetric, with acceleration (AT) two times lower than the total ejection time (ET), as peak velocity is reached at midsystole. Using the pulsed-wave Doppler mode, the sample gate is placed in the main pulmonary artery just beyond the pulmonary valve, and the displayed flow profile is hollow as the flow is laminar. Using the continuous-wave Doppler mode, there is a filling in of the systolic pulmonary flow profile as numerous velocities are recorded all along the Doppler scan line. Some diastolic signals (corresponding to right ventricular inflows and physiologic pulmonary insufficiency) are also recorded. Ao, aorta.

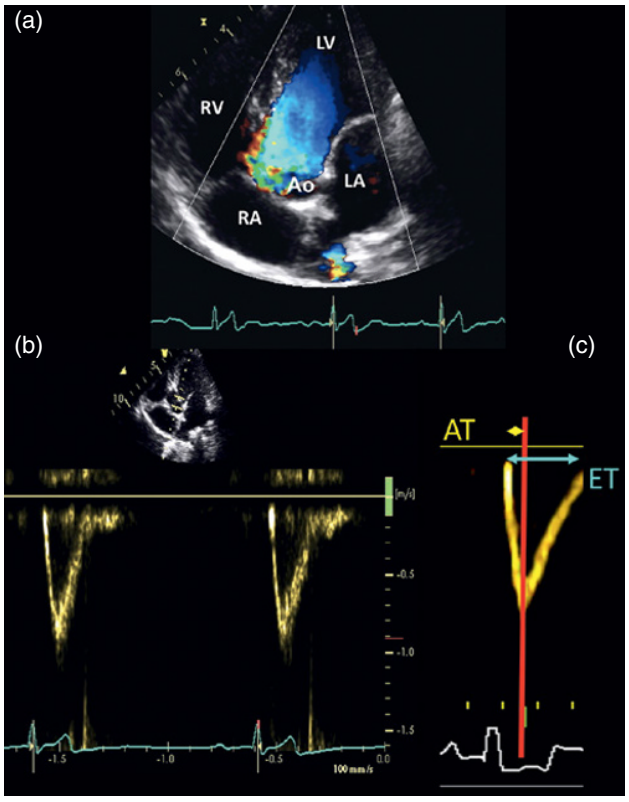

Figure 16.22 Doppler evaluation of systolic aortic flow in normal dogs using color flow (a) and pulsed-wave (b,c) Doppler modes from the left parasternal apical (or caudal) five-chamber view. The aortic flow is coded in blue (a), as it goes away from the transducer during systole. The spectral Doppler waveform (b,c) is typically negative and asymmetric, with acceleration (AT) much shorter than the half of the total ejection time (ET), as peak velocity is reached during the first third of systole. Using the pulsed-wave Doppler mode, the sample gate is placed just in the aorta beyond the aortic valve, and the flow profile is hollow as the flow is laminar. Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

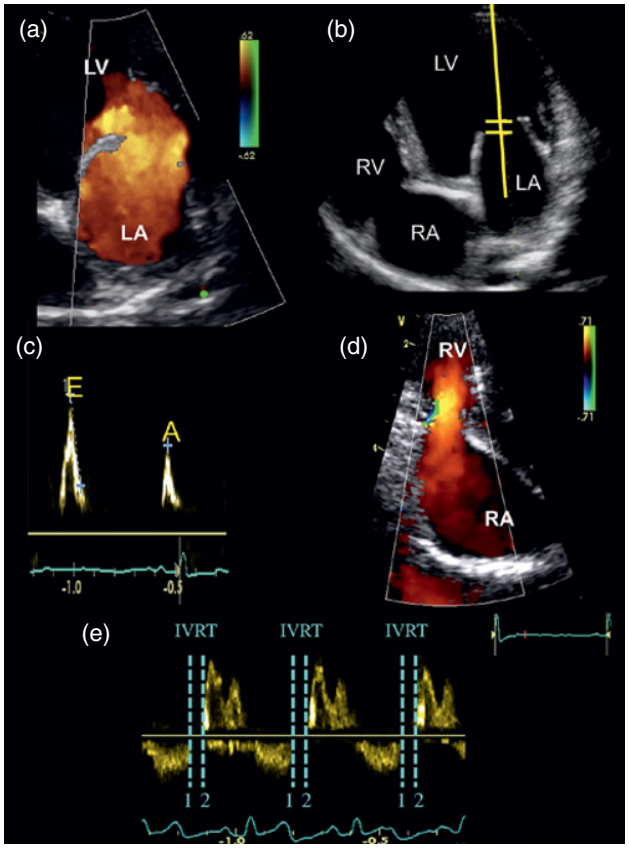

Figure 16.23 Doppler evaluation of diastolic mitral (a–c,e) and tricuspid (d) inflows in a normal dog, from the left parasternal apical and cranial four-chamber views, respectively, using color flow (a,d) and pulsed-wave (b,c,e) Doppler modes. Both flows are coded in red, as they go toward the transducer during diastole (a,d). For mitral inflow analysis using the pulsed-wave Doppler mode, the sample gate is placed at the tip of the mitral leaflets (b). The transmitral inflow pattern (c) is hollow (as the mitral inflow is laminar) and typically biphasic, including an early rapid positive filling wave (E) and a late positive filling wave (A) of lower velocity resulting from atrial contraction. The calculation of isovolumic relaxation time (IVRT) is shown in (e): IVRT represents the time between aortic valve closure (1) and mitral valve opening (2) and is an index of diastolic function. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

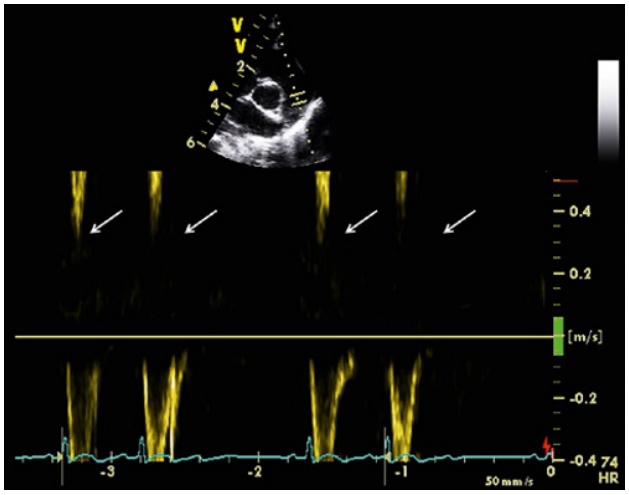

Figure 16.24 Aliasing artifact associated with the pulsed-wave Doppler mode. When blood flow velocities exceed the Nyquist limit (here 0.4 m/s for the pulmonary flow), the aliasing artifact occurs: the flow profile wraps around the image and becomes inverted (in this example positive instead of negative, arrows). The deeper the recorded blood flow, the lower the Nyquist limit.

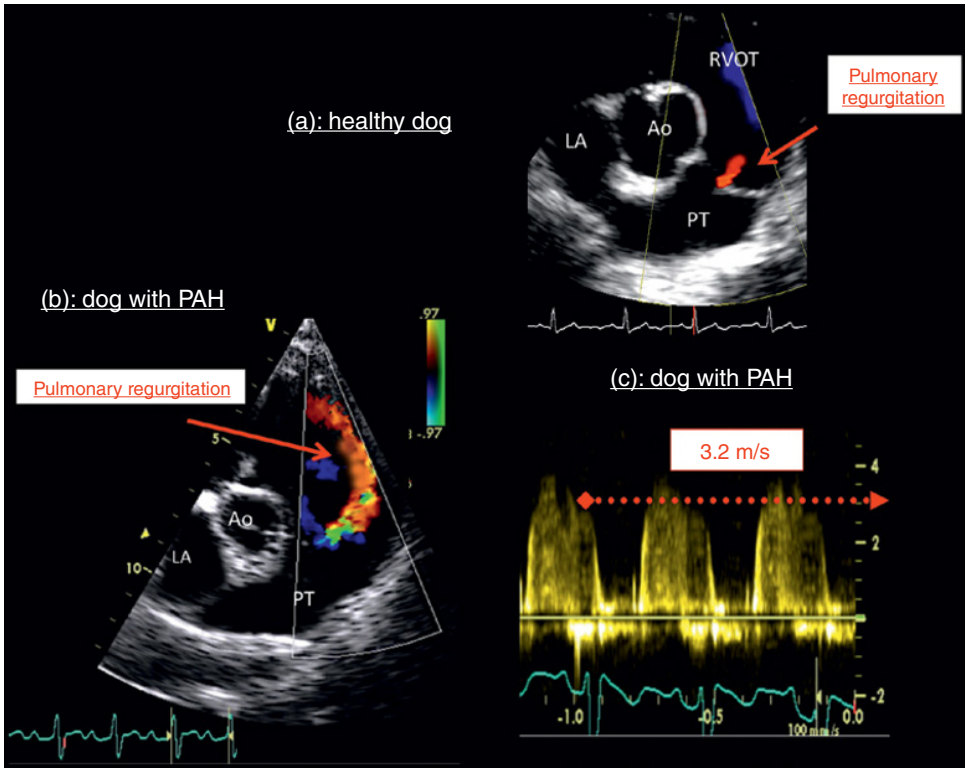

Figure 16.25 Use of pulmonary regurgitation for the diagnosis of diastolic pulmonary arterial hypertension (PAH). In the normal dog (a), color flow Doppler examination of the right ventricular outflow tract (obtained from the right parasternal transaortic short-axis view optimized for the pulmonary valve) allows the detection of a diastolic laminar mild pulmonary insufficiency. This physiologic regurgitation is encoded in red and does not extend above the most rightward level of the aortic valve. Conversely, in the dog with diastolic PAH (b,c), the color flow Doppler examination obtained from the same view shows a turbulent aliased diastolic pulmonary regurgitation going deeply into the body of the right ventricle. The maximum end-diastolic pulmonary regurgitant flow velocity measured by continuous-wave Doppler mode is high (3.2 m/s; c). According to the modified Bernoulli equation ($\Delta P = 4 \times \text{velocity}^2$), the end-diastolic pressure gradient (ΔP) across the pulmonary valve between the pulmonary trunk and the right ventricle is therefore 41 mmHg. This means that the diastolic pulmonary arterial pressure is at least 41 mmHg, which is indicative of diastolic Doppler-derived evidence of PAH (as the normal diastolic pulmonary arterial pressure is usually between 5 and 10 mmHg). Ao, aorta; LA, left atrium; PT, pulmonary trunk; RVOT, right ventricular outflow tract.

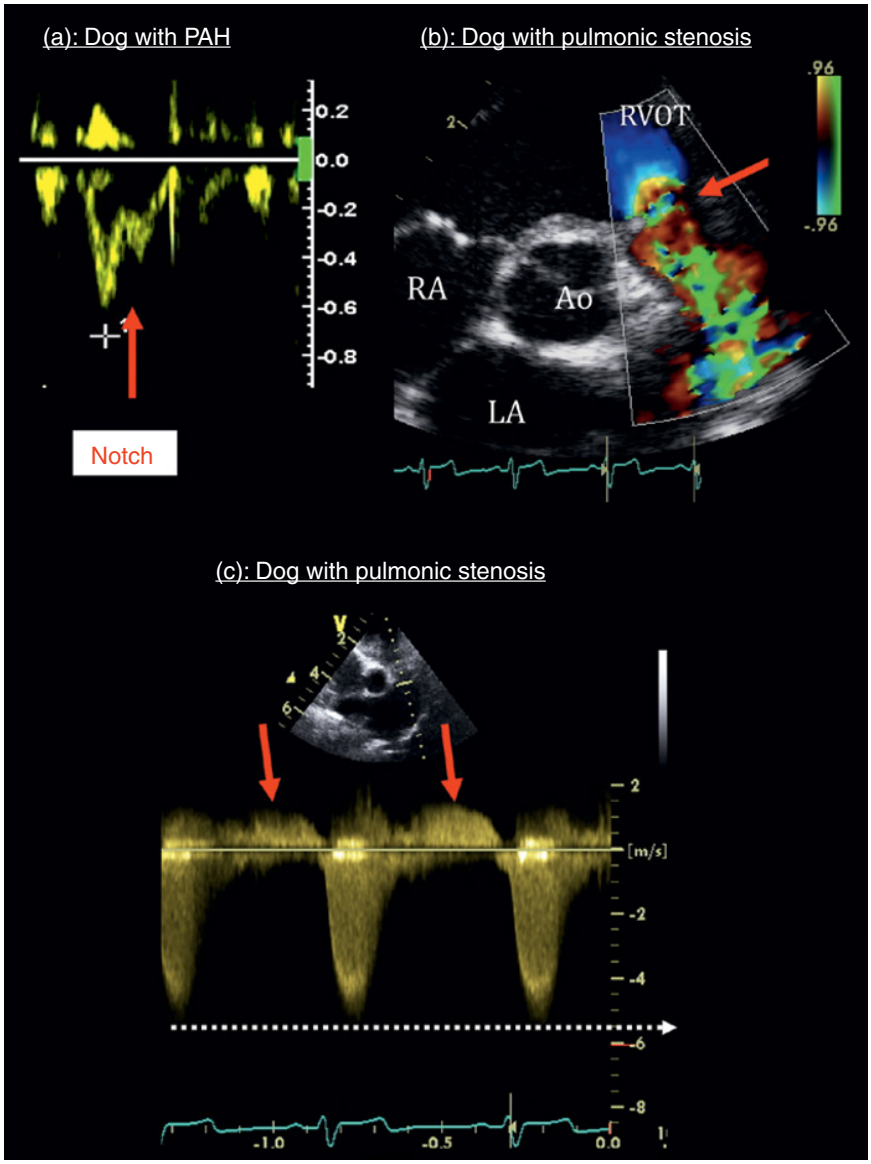

Figure 16.26 Examples of abnormal pulmonary flow patterns assessed by pulsed-wave, color flow and continuous-wave Doppler modes (a, b and c, respectively). (a) This pulsed-wave Doppler pulmonary flow velocity profile shows characteristic changes associated with pulmonary arterial hypertension, i.e., rapid acceleration time, delayed deceleration time with a midsystolic notch (*arrow*). (b,c) (dog with pulmonic stenosis) Color flow Doppler from the left cranial transaortic short axis view (b) shows blood flow acceleration proximal to the pulmonary valve and turbulences distally, with a marked narrowing of the systolic color flow map at the pulmonary valve orifice level (*arrow*), thus confirming valvular location of the pulmonic stenosis. Continuous-wave Doppler tracing of the pulmonary flow velocity confirms a severe pulmonic valve stenosis (peak diastolic flow velocity of 5.5 m/s; pressure gradient across the pulmonary valve of 121 mmHg according to the modified Bernoulli equation). Pulmonary regurgitant flow is also seen above the baseline in diastole (*arrows*). Ao, aorta; LA, left atrium; RA, right atrium; RVOT, right ventricular outflow tract.

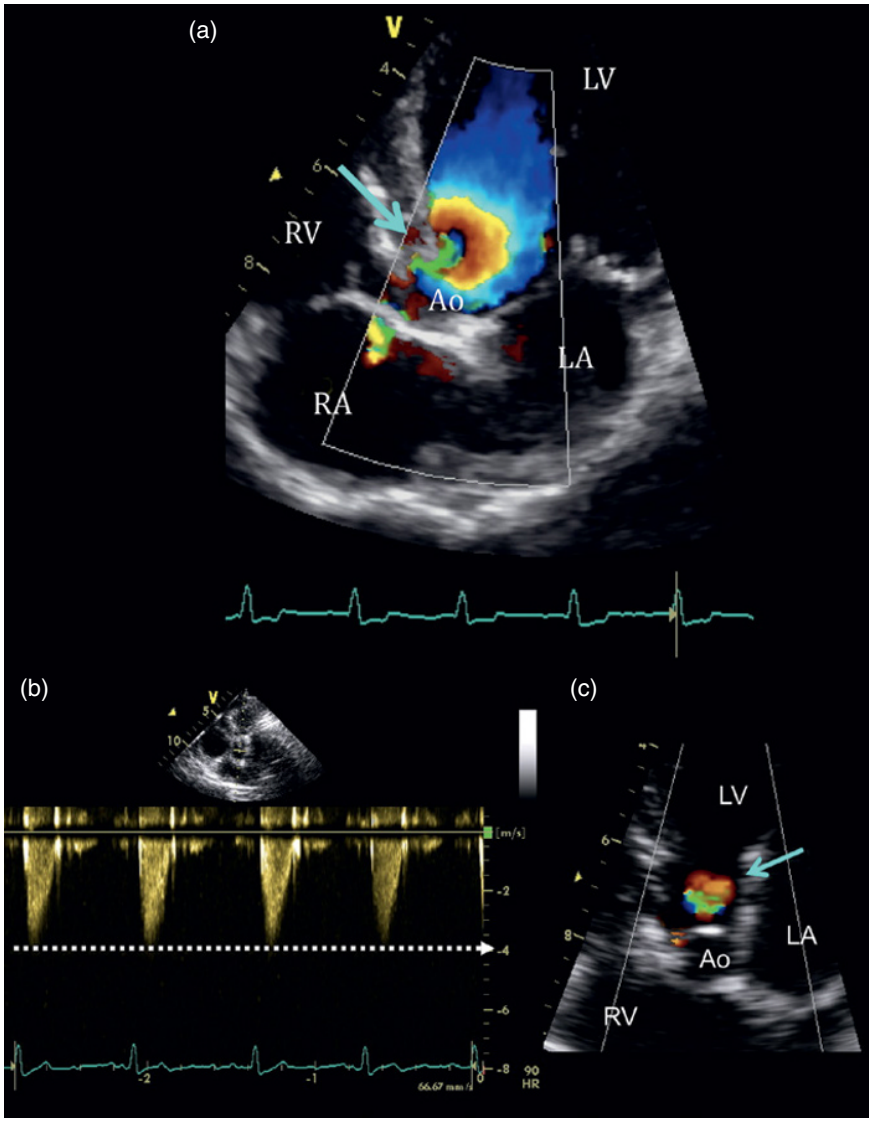

Figure 16.27 Examples of abnormal aortic flow patterns associated with subaortic stenosis assessed by color flow (a,c) and continuous-wave Doppler modes (b). (a) Color flow Doppler from the left apical five-chamber view shows blood flow acceleration proximal to the subaortic area, with a narrowing of the systolic color flow map (*arrow*), thus confirming subvalvular location of the aortic stenosis. (b) Continuous-wave Doppler peak systolic flow velocity (4 m/s) across the stenotic lesion from the same view is indicative of moderate aortic stenosis (pressure gradient across the pulmonary valve of 64 mmHg according to the modified Bernoulli equation). (c) Using the left apical five-chamber view (diastolic frame) a mild aortic insufficiency (*arrow*) is also detected just on the left ventricular side of the valvular coaptation point (beneath the aortic cusps). Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

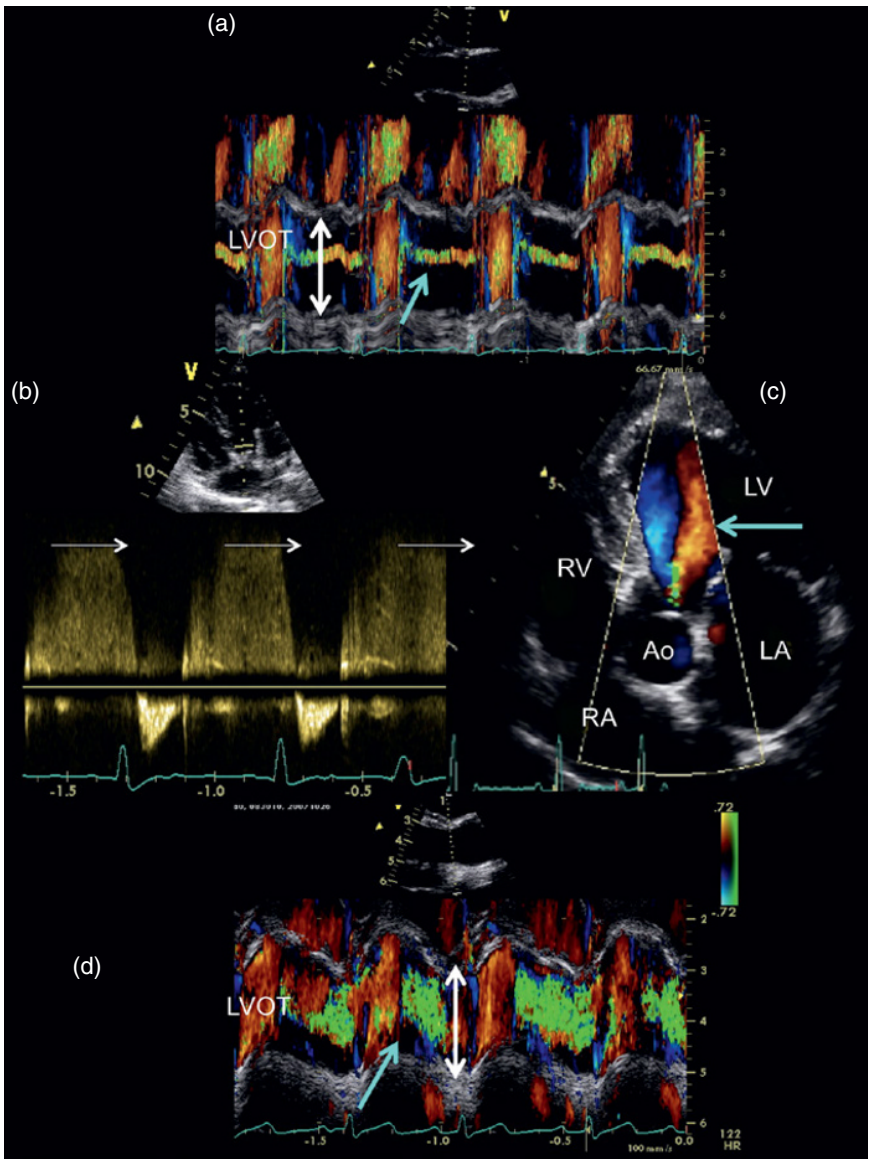

Figure 16.28 Evaluation of aortic insufficiency severity using color-coded M-mode (a,d), color flow (c) and continuous-wave Doppler modes (b). The color-coded M-mode from the right parasternal five-chamber view may be used to measure the height (or cross-sectional area) of the regurgitant aortic jet (*blue arrows*) relative to the height (cross-sectional area) of the left ventricular outflow tract (LVOT) (*double arrows*, a and d). (a) shows a mild aortic insufficiency as the jet height /LVOT height is only 8% (<25%). Conversely, the aortic insufficiency in (d) is considered as severe, as the jet height/LVOT height is high (i.e., 84%; >65%). In contrast to Figure 16.27c, a severe aortic insufficiency extending nearly to the apex (blue arrow) is also shown in (c). Continuous-wave Doppler mode confirms an aortic insufficiency signal above the baseline in (b). The aortic insufficiency velocity remains stable throughout the diastolic time (*white arrows*). This means that, despite the regurgitation, the pressure gradient across the aortic valve remains unchanged during diastole (no decrease in aortic diastolic pressure), which confirms that the regurgitation is mild. Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

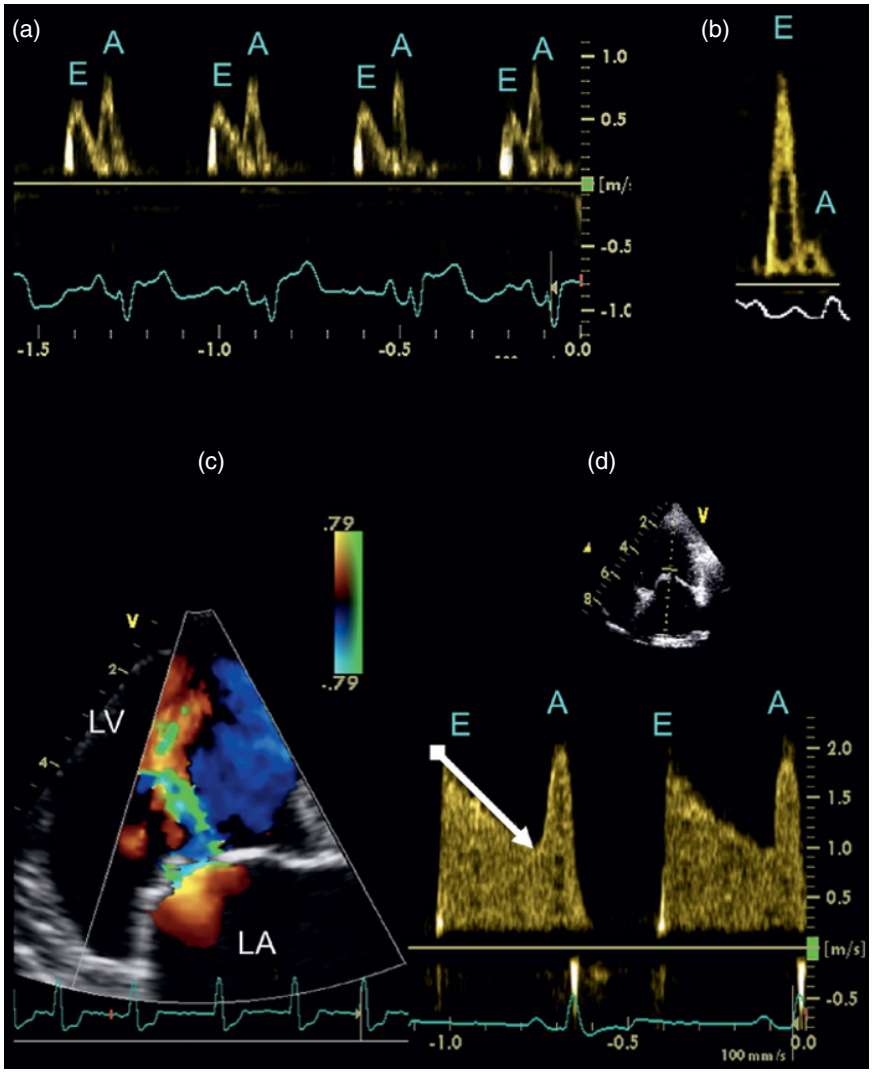

Figure 16.29 Examples of abnormal diastolic transmitral inflows obtained from left parasternal apical four-chamber views. (a) Delayed relaxation transmitral flow pattern in a cat, which is characterized by a delayed and prolonged early diastolic E wave (with an inverted E/A ratio). (b) Restrictive transmitral flow pattern, with a high early diastolic E wave (owing to high left atrial pressure) and a diminished A wave (owing to decreased left ventricular compliance) in a cat with restrictive cardiomyopathy. Doppler echocardiograms of two dogs with congenital mitral valve stenosis are presented in (c) and (d). (c) Color flow Doppler mode across the stenotic mitral valve shows a narrow aliased turbulent signal during diastole. (d) Spectral Doppler of the mitral inflow (continuous-wave Doppler mode) reveals a high peak diastolic E-wave velocity (1.9 m/s, reference range: 0.58–1.17 m/s; see Table 16.4) and a high peak diastolic A-wave velocity (2.1 m/s, reference range: 0.39–0.86 m/s; see Table 16.4). The pressure half time for the E wave, which is defined as the time needed for the peak transvalvular pressure gradient to fall to its half value, may be calculated automatically by tracing (*white arrow*) the deceleration slope of the E wave. In this case, the pressure half time is markedly prolonged (290 ms, reference range: <50 ms), thus confirming a severe mitral valve stenosis. LA, left atrium; LV, left ventricle.

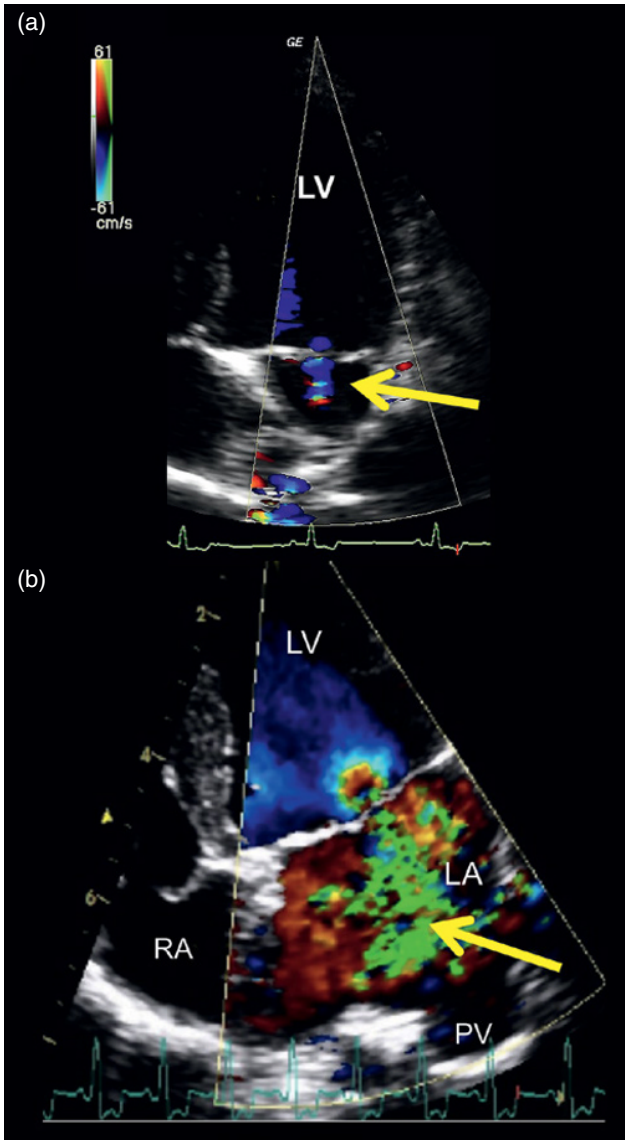

Figure 16.30 Semi-quantitative assessment of mitral insufficiency using the color flow Doppler mapping method in two dogs suffering from degenerative mitral valve disease of various grades (left parasternal apical four-chamber views). In (a), the color flow jet of mitral insufficiency (*arrow*) involves less than 20% of the left atrial chamber, which is consistent with mild valvular regurgitation. Conversely, in (b), the color flow aliased turbulent jet of mitral insufficiency (*arrow*) fills 100% of the left atrial chamber, which is consistent with severe valvular regurgitation. LA, left atrium; LV, left ventricle; RA, right atrium; PV, pulmonary vein.

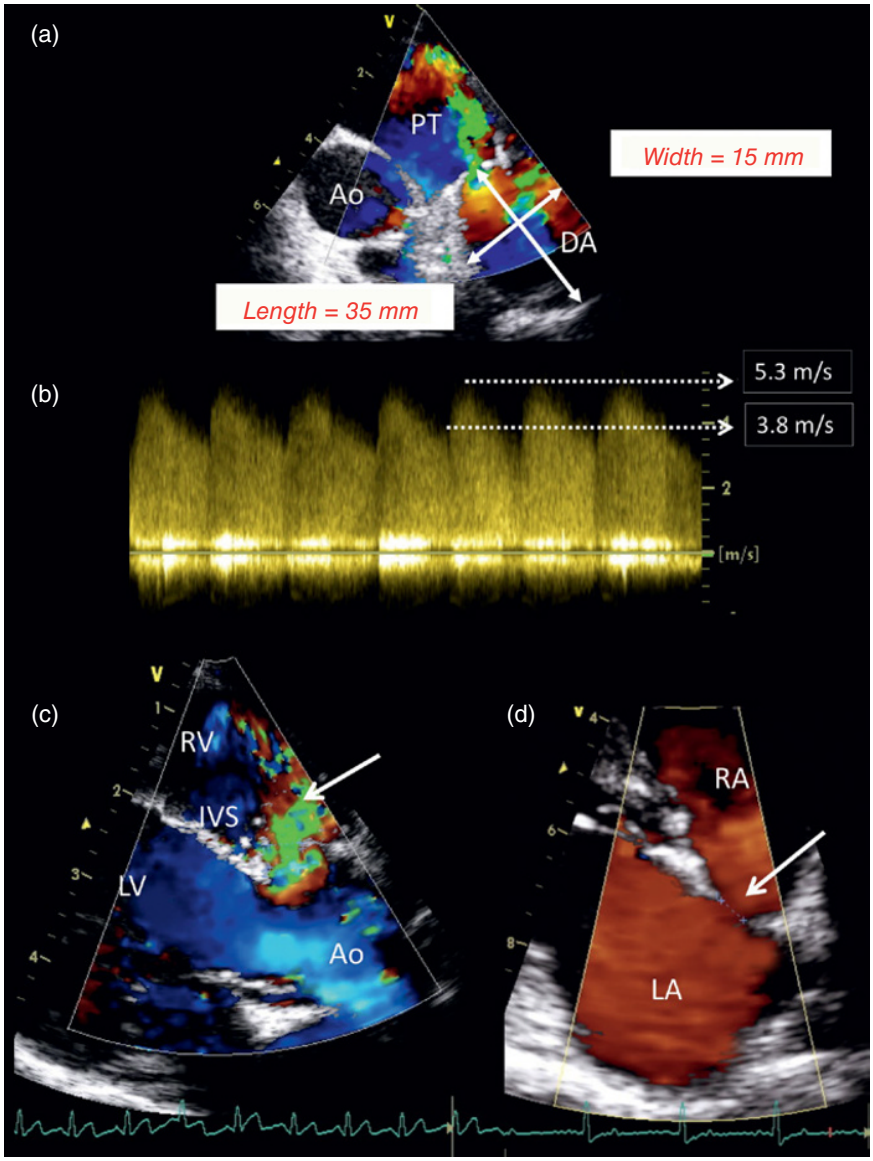

Figure 16.31 Assessment of left-to-right congenital shunts in dogs using Doppler echocardiography (a,b: patent ductus arteriosus; c: ventricular septal defect; d: atrial septal defect). (a) Image obtained from the left parasternal cranial transaortic short-axis view showing the aliased turbulent color flow jet coming from the large ductus arteriosus (DA) into the dilated pulmonary trunk (PT) during systole. Note that the DA diameter decreases abruptly at the point of insertion in the PT. (b) (same dog as in a) Continuous-wave Doppler mode confirms a continuous turbulent positive flow into the pulmonary artery of high velocity (5.3 m/s and 3.8 m/s during systole and diastole, respectively), which is consistent with a normal aortic-to-pulmonary artery pressure gradient (112 mmHg and 58 mmHg, respectively, according to the modified Bernoulli equation). (c) Color flow Doppler obtained from the right parasternal five-chamber view shows an abnormal aliased turbulent flow (*arrow*) from the left ventricle entering the right ventricle just below the septal tricuspid leaflet, through a moderate sized perimembranous ventricular septal defect. (d) Color flow Doppler obtained from the right parasternal four-chamber view shows a laminar flow (*arrow*) from the left atrium to the right atrium through a small ostium secundumtype atrial septal defect. Ao, aorta; IVS, interventricular septum; LA, left atrium; LV, left ventricle; RA, right atrium. RV, right ventricle.

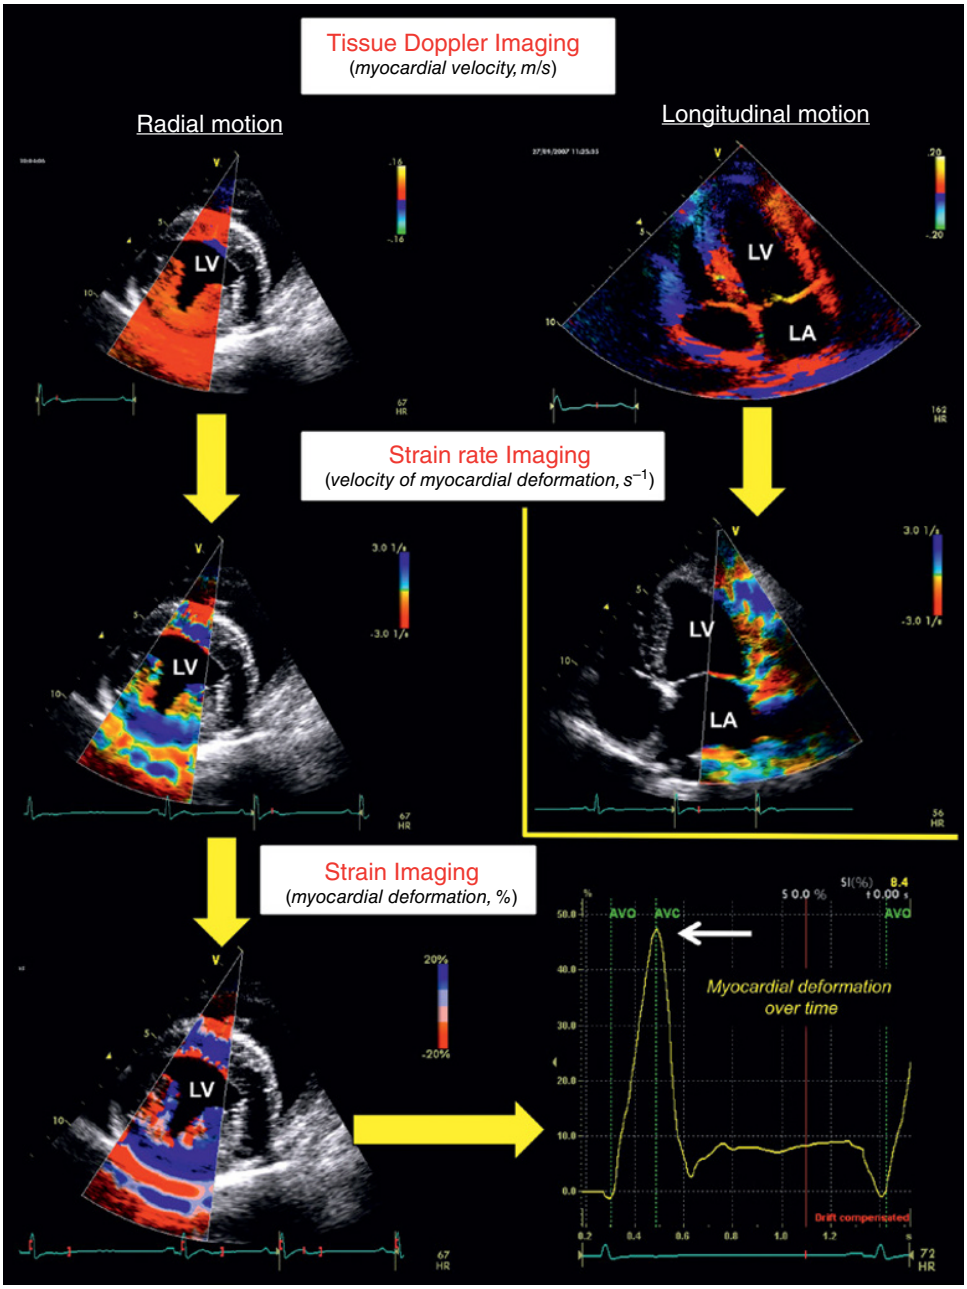

Figure 16.32 Tissue Doppler imaging (TDI) and TDI-derived techniques. Using the two-dimensional (2D) color TDI mode, myocardial velocities are superimposed in color on 2D mode images. Velocities toward the transducer are colored in red, whereas those away from the transducer are colored in blue on the right parasternal transventricular short-axis view (*left upper panel*) and the left apical four-chamber view (*right upper panel*) to analyze radial and longitudinal myocardial motions, respectively. A specific software is then used to quantify the myocardial velocities (m/s) in one or several segments. Strain rate imaging and strain imaging are two TDI-derived techniques that use the previously described velocity data to calculate deformation velocity (s^{-1}) and deformation (%) per myocardial segment length, respectively. As with 2D color TDI, the color display of strain rate and strain can be superimposed on 2D mode images using the same views (*left and right middle panels, left lower panel*). These variables can also be quantified over time by using a specific software. A normal radial strain profile of a left ventricular free wall segment in a dog is presented in the right lower panel: the radial strain (expressed in %) is positive and maximal in end-systole (*white arrow*), and then decreases during diastole, thus confirming regional systolic expansion (i.e., thickening) and diastolic compression (i.e., shortening), respectively.AVC, aortic valve closure; AVO, aortic valve opening; LA, left atrium; LV, left ventricle.

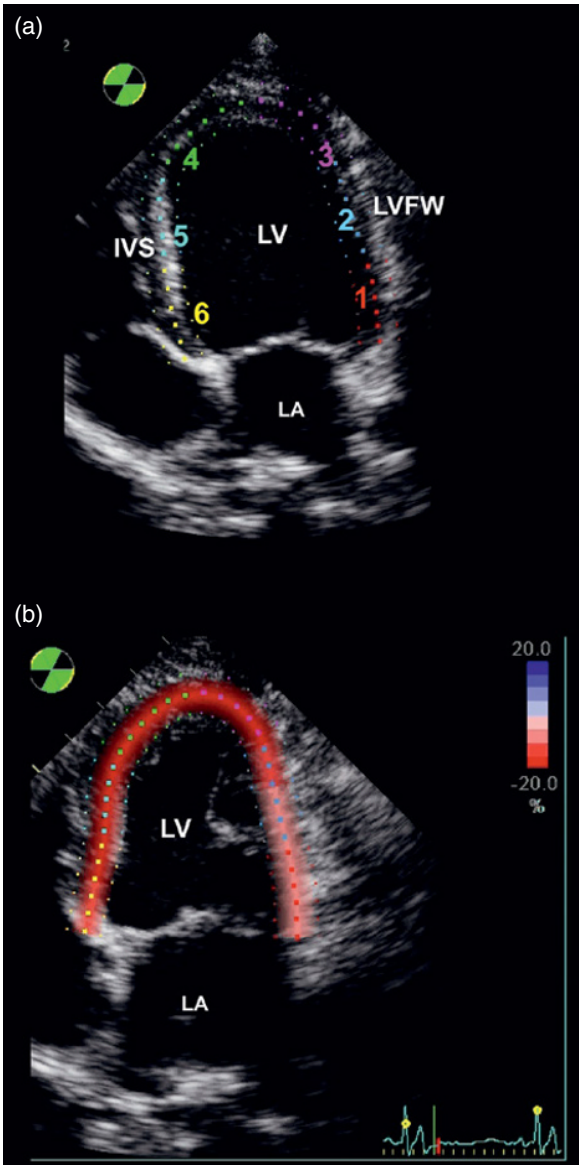

Figure 16.33 Longitudinal myocardial deformation (strain) assessed by speckle tracking echocardiography (STE). (a) The myocardial region of interest, including the interventricular septum (IVS) and the left ventricular free wall (LVFW), is automatically divided into six segments (segments #1 to #3 for the LVFW, and #4 to #6 for the IVS) using the left apical four-chamber view. (b) Example of normal two-dimensional (2D) color-coded strain obtained by STE in a healthy dog (same animal as in a). All six segments are colored in red, which means a negative strain for all six segments, thus confirming a homogeneous longitudinal shortening during systole. LA, left atrium; LV, left ventricle.

Electrocardiography

Anna R.M. Gelzer, DVM, PhD, DACVIM (Cardiology), DECVIM-CA (Cardiology)
and Marc S. Kraus, DVM, DACVIM (SAIM, Cardiology), DECVIM-CA (Cardiology)

Department of Clinical Sciences & Advanced Medicine-Philadelphia, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA, USA

Cardiac arrhythmias are defined as variations of the cardiac rhythm from normal sinus rhythm. Some cardiac arrhythmias are benign and clinically insignificant and require no specific therapy whereas others can manifest with a variety of clinical signs, such as episodic weakness or collapse (syncope), exercise intolerance or inappropriate panting/restlessness or sudden death (i.e., ventricular fibrillation). In order to diagnose the nature of an arrhythmia and determine therapeutic strategies, it is imperative to acquire an electrocardiogram (ECG).

Indications for ECG Recordings

- Document arrhythmias detected by auscultation.
- Evaluate a patient presenting for syncope (fainting) or episodic weakness.
- Heart rate and rhythm monitoring during anesthesia.
- Heart rate and rhythm monitoring in critically ill patients.
- Monitoring changes in rate and rhythm following drug administration.
- Assessing changes in ECG morphology and heart rate due to electrolyte imbalances associated with extracardiac disease or drug toxicities.
- Detection of pericardial disease.
- Identifying conduction disturbances or axis shifts associated with myocardial hypertrophy or dilation.
- Ambulatory ECG recording (Holter) for long-term monitoring of intermittent arrhythmias.

ECG Lead Terminology and Acquisition Technique

Electrocardiography is used to record electric potentials generated by the heart muscle during each cardiac cycle. These potentials are detected on the surface of the body using electrodes attached to standardized locations on the limbs and chest wall. The electrical signals are amplified by the electrocardiograph machine and displayed on special graph paper in voltage and time. The limb leads are defined as RA = right arm, LA = left arm, and LL = left leg. The output from each electrode pair (differential recording) is referred to as a *lead* and numbered with the Roman numerals I, II, and III. The limb leads form the points of what is known as Einthoven's triangle (Figure 17.1). An imaginary line connecting the two electrodes is the lead axis. Each lead looks at the heart from a different angle within the animal's frontal plane.

The Six Limb Leads

There are six limb leads which depict the cardiac depolarization in the frontal plane. Leads I, II, and III are called *bipolar* limb leads because they record the electrical activity between two limb electrodes (Table 17.1).

Using the same electrodes as leads I, II, and III, the unipolar limb leads also measure the electrical activity between two terminals, but the recording electrode is always positive and the negative terminal (called Wilson's central terminal) is made up of the sum of the electrodes attached to the right arm, left arm, and left leg. These *unipolar* limb leads view the heart from different angles (or vectors) than the bipolar leads, because the negative electrode is zeroed out, allowing the positive electrode to become the "exploring" electrode. The unipolar limb leads generate a very low voltage signal, so need to be amplified by the ECG machine (augmented). These limb leads are named after their positive electrode, located on the **L**eft arm (aV**L**), the **R**ight arm (aV**R**), and the left **F**oot (aV**F**), where the "aV" stands for augmented voltage (Figure 17.2).

Together with leads I, II, and III, augmented limb leads aVR, aVL, and aVF form the basis of the hexaxial reference system (see Figure 17.7) which is used to calculate

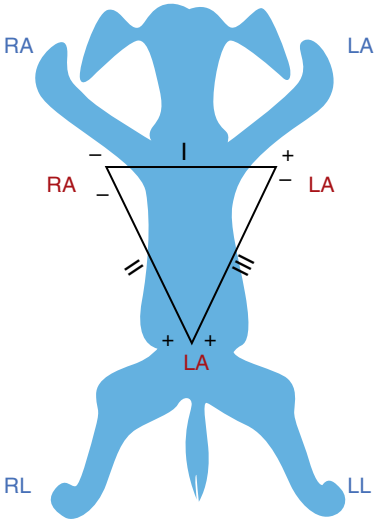

Figure 17.1 The standardized positions of the electrodes on the body are defined as RA = right arm, LA = left arm, and LL = left leg. The output from each electrode pair is referred to as a lead and numbered with the Roman numerals I, II, and III. The limb leads (I, II, III) form the Einthoven's triangle. The limb leads display the cardiac depolarization in the frontal plane.

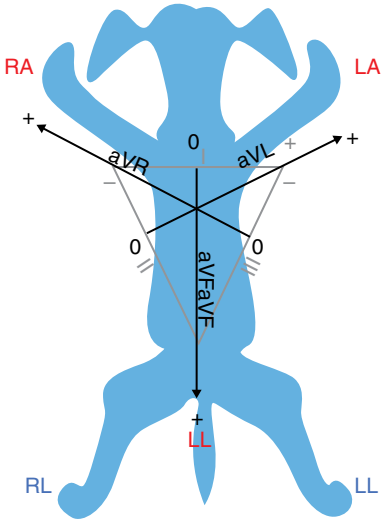

Figure 17.2 The augmented (unipolar) limb leads use the same electrodes as leads I, II, and III but the recording electrode is always positive and the negative terminal is made up of the sum of the electrodes attached to the right arm, left arm, and left leg. The augmented limb leads are named after their positive electrode, located on the **L**eft arm (aV**L**), the **R**ight arm (aVR), and the left **F**oot (aV**F**), where the "a" stands for augmented and "V" for vector.

Table 17.1 The positive and negative terminals of the six limb leads

Bipolar limb leads		Augmented unipolar limb leads	
I	R arm (–) to L arm (+)	aVR	R arm (+) to common terminal (–)
II	R arm (–) to L foot (+)	aVL	L arm (+) to common terminal (–)
III	L arm (–) to L foot (+)	aVF	L foot (+) to common terminal (–)

the heart's electrical axis (mean electrical axis) in the *frontal plane*. The positive and negative terminals of the six limb leads are listed in Table 17.1.

The Precordial or Chest Leads (V Leads)

The chest leads view the heart's electrical activity in the transverse plane. This complements the information regarding the electrical fields gained from the frontal plane (limb leads). The chest leads are termed V (*voltage*) leads. They are unipolar with the positive exploring electrode placed on the chest (precordium) coupled with Wilson's central terminal used for the negative electrode. The electrodes for the chest leads are placed directly on the chest. V1 is placed in the fifth right intercostal space just to the right of the sternum, V6 is placed in the left sixth intercostal space at the costochondral junction, while V2 to V5 are spaced equally between V1 and V6 in the sixth intercostal space on the left side. Because of their close proximity to the heart, they do not require augmentation. Left chest leads may be more sensitive than the limb leads for detection of right ventricular enlargement or allow better identification of P-waves.

Some ECG machines record one lead at a time but others can record all six or 12 simultaneous leads. The ECG signals are normally in the range of ±2 mV and require a recording bandwidth of 0.05–150 Hz. The ECG machine provides filters to reduce artifacts, such as 50 Hz cycle from inappropriate grounding (electrical interference). In cats, typically only the 150 Hz filter is used in order to include high-frequency components of the R- and S-wave. The ECG reference ground is provided through a separate electrode, either incorporated into one of the three limb leads or as a separate wire.

For ECG acquisition, the animal is positioned on its right side with the limbs perpendicular to the body and the alligator clips or patch electrodes are attached to the skin. Alcohol or a gel with a high ionic concentration is applied to the clips, acting as the transducer at the tissue–electrode interface. The size of the ECG waveform deflections depends on the distance between the heart and the electrode position. In dogs and cats, the limb leads are attached to the elbows and stifles, and color coded to identify their position. Table 17.2 lists the electrode positions.

Table 17.2 Electrode position for ECG recording in dogs and cats

ECG electrode	Position
Black	Left front leg at elbow
White	Right font leg at elbow
Red	Left back leg at stifle
Green	Right back leg at stifle

Genesis of the ECG Deflections

The ECG waveforms are generated by the spread of electrical activation through the specialized conduction system of the heart. Multiple activation wavefronts depolarize in various directions of the heart. The sum of all wavefront vectors at a point in time determines the overall magnitude and direction of the deflection in a particular surface ECG lead. The six- or 12-lead ECG provides information about the magnitude of the electrical activity of the heart and the direction of the moving depolarization wavefront in multiple orientations. A wavefront traveling towards the positive terminal of a lead results in a positive deflection of the ECG in that lead. When a wavefront travels away from the positive electrode, a negative deflection occurs.

Waveform Morphology and Intervals

The P-wave

The first electrical signal of each cardiac cycle is initiated in the sinus node. It is called the P-wave and represents the activation of the atria (Figure 17.3).

The P-wave is a small, upright wave in leads I, II, II,I and aVF, while it appears as a negative deflection in aVR and aVL. The P-wave amplitude is most prominent in lead II, because the average vector of the atrial depolarization is traveling towards the positive terminal of lead II (see Figure 17.3). Increased P-wave amplitude or duration is associated with either right or left atrial enlargement. Normal P-wave values for the dog and cat are shown in Table 17.3. Absence of P-waves is noted in instances of atrial fibrillation, atrial standstill, and sinus arrest. P-waves without corresponding QRS complexes (blocked Ps) are observed in cases of second- and third-degree atrioventricular (AV) node block. Negative P-waves may occur in conjunction with junctional or atrial premature and escape beats, indicating alternative conduction pathways or retrograde conduction across the atria.

The PR Interval

The PR interval measured from the beginning of the P-wave to the beginning of the QRS complex (see Figure 17.3) represents the time it takes for the electrical

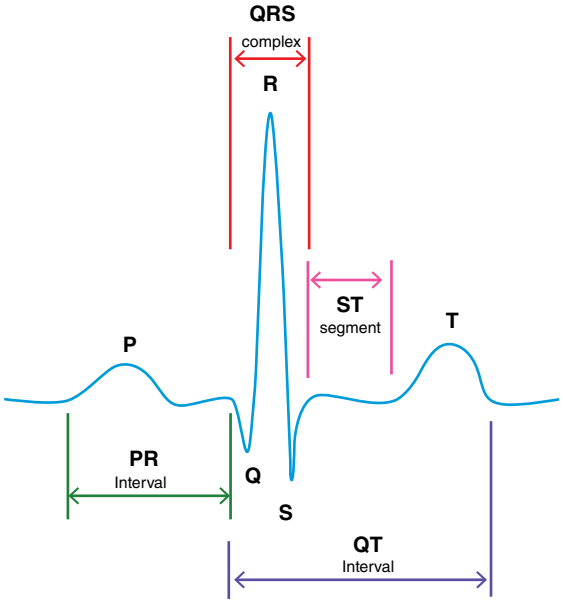

Figure 17.3 Major deflections and intervals of the ECG (lead II). See text for details.

Table 17.3 Normal ECG amplitudes and durations in the dog and cat

	Dog	Cat
Heart rate	Puppy: 70–220 bpm Adult: 70–180 bpm	120–240 bpm
Rhythm	Sinus rhythm Sinus arrhythmia	Sinus rhythm
P-wave		
Amplitude	≤0.4 mV	≤0.2 mV
Duration	≤0.04 s	≤0.04 s
PR interval	0.06–0.13 s	0.05–0.09 s
QRS		
Amplitude	≤2.5 mV, small breeds ≤3.0 mV, large breeds	≤0.9 mV
Duration	≤0.06 s	≤0.04 s
ST segment	No elevation or depression by >0.2 mV	No elevation or depression
T-wave	Positive, negative or biphasic, but ≤25% height of R-wave	Isoelectric or positive
QT interval	0.15–0.25 s (varies inversely with heart rate)	0.12–0.18 s (varies inversely with heart rate)
Mean electrical axis	+40° to +100°	0° to +160°

Source: Adapted from Tilley and Smith (2008).

impulse to conduct from the sinus node through the atria and the AV node and bundle of His. Conduction in the AV node is markedly slower, allowing time between the mechanical contraction of the atria and the ventricles. On the surface ECG, this conduction delay produces a short isoelectric segment following the P-wave, contributing to the PR interval. The normal PR interval in dogs and cats is shown in Table 17.3. Increased duration of the PR interval indicates abnormally slow conduction in the AV node, called first-degree AV block. Intrinsic AV node disease as well as certain drugs, if overdosed (beta-blockers or Ca channel blockers), may result in first degree AV block. Varying PR intervals are noted in cases of sinus arrhythmia or certain forms of second-degree AV block. Abnormally short PR intervals are rare and encountered in instances of accessory pathway-mediated arrhythmias.

The QRS Complex

When the electrical impulse emerges from the AV node, it enters the ventricles rapidly via the bundle of His, the right and left bundle branches and Purkinje network, producing the QRS complex on the surface ECG. The QRS complex thus represents ventricular depolarization. Standard nomenclature describes the first negative deflection as the Q-wave, the first positive deflection as the R-wave, and the first negative deflection following the first positive deflection as the S-wave (see Figure 17.3). Note that normal QRS complexes do not necessarily contain all three waveforms, and in dogs, a high degree of individual variability is seen. The normal sequence of ventricular depolarization results in a QRS complex of relatively short duration and with a net positive polarity in leads II, III, and aVF. The normal duration and amplitude of the QRS complex in the dog and cat are shown in Table 17.3.

A key component of ECG analysis is inspection of the QRS morphology in lead II, which can provide clues to the beat's origin, its conduction through the ventricle, and the potential presence of ventricular hypertrophy. QRS complexes generated by a beat of supraventricular origin (sinus node or supraventricular foci such as the atria or AV nodal junction) are typically narrow and positive in lead II, while those that originate from ventricular foci are wider (increased duration) and "bizarre" in their appearance compared to normal sinus beats. Conduction disturbances within the ventricles can also alter the morphology of the QRS complexes. For instance, the presence of a right or left bundle branch block slows conduction through the ventricular tissue in the respective side. This results in a QRS complex of longer duration (wide) despite the fact that the beat may have originated from a supraventricular focus or the sinus node (see Figures 17.10 and 17.12). Finally, ventricular hypertrophy can increase the amplitude and duration of the QRS complex (albeit to a lesser degree than a bundle branch block) or change the mean electrical axis (as in the case of right heart enlargement).

The T-wave

Following the QRS complex is another short, relatively isoelectric segment, the ST segment, followed by the T-wave, representing the ventricular repolarization. The ST segment connects the QRS complex and the T-wave (see Figure 17.3). However, since it is usually difficult to determine exactly where the ST segment ends and the T-wave begins, the relationship between the QT interval and T-wave should be examined together. In general, the ST segment should not be either elevated or depressed compared to baseline by more than 0.2 mV. In dogs and cats, ST segment abnormalities are occasionally detected in cases of myocardial disease (dilated cardiomyopathy), congenital heart disease (subaortic stenosis), electrolyte imbalances, acute hypoxia (anesthesia) or suspected myocardial infarction (rare).

The T-wave represents ventricular repolarization. The normal T-wave in both dogs and cats demonstrates a high degree of variability and can be positive, negative, biphasic, or of very low amplitude; however, the T-wave should be consistent from beat to beat during normal rhythm. The normal characteristics of the T-wave in dogs and cats are shown in Table 17.3. Compared to human patients, T-wave changes in the dog and cat are relatively nonspecific and poorly characterized. T-wave abnormalities can be seen in instances of electrolyte abnormalities, hypoxia, conduction abnormalities, or drug toxicity (i.e., digoxin).

The QT interval is a measure of the time between the start of the Q-wave (or R-wave if there is no Q) and the end of the T-wave and represents the entire depolarization and repolarization of the left and right ventricles. If abnormally prolonged or shortened, there is a risk of developing ventricular arrhythmias. Prolongation of the QT interval may be due to an adverse drug reaction (i.e., quinidine toxicity). Some antiarrhythmic drugs, like amiodarone or sotalol, work by creating a pharmacologic QT prolongation. A shortened QT can be associated with hypercalcemia (Box 17.1).

Evaluation of the ECG

Important features of the ECG that require analysis include heart rate, rhythm, mean electrical axis (MEA), waveform morphology, and criteria for heart enlarge-

Box 17.1 Summary of ECG waveforms

- The P-wave represents atrial depolarization
- The Q-wave is the first negative deflection representing ventricular septal depolarization
- The R-wave is the first positive deflection representing early ventricular depolarization
- The S-wave is the next negative deflection representing late ventricular depolarization
- The ST segment/T-wave represents ventricular repolarization

ment. In order to assess these characteristics, one must understand how paper speed and sensitivity settings affect ECG interpretation.

ECG Paper, Sensitivity, and Speed of Recording

ECG paper has a background pattern of small 1 mm squares and bold division lines every 5 mm in both horizontal and vertical directions, which form larger squares on the ECG paper (Figure 17.4). The ECG is typically recorded at one of two different paper speeds, either 25 mm/s or 50 mm/s. Paper speed denotes the speed at which the waveforms are being recorded. At 25 mm/s, each 1 mm square (little box, thin lined) represents 0.04 seconds and each 5 mm square (bold lined) represents 0.2 seconds, while at 50 mm/s, each 1 mm square represents 0.02 seconds and each 5 mm square represents 0.1 seconds.

ECG sensitivity refers to the amplitude of the waveforms based on electrical voltage. At standard sensitivity, an impulse of 1 millivolt (mV) will inscribe a waveform amplitude that is 10 mm tall. In cases where the ECG voltages are normally low (i.e., in cats), sensitivity can be increased (doubled) so that an impulse of 0.5 mV will create a waveform of 10 mm amplitude, thereby increasing the ability to visually inspect the individual ECG waveforms. Conversely, in animals with severe heart enlargement, sensitivity can be decreased (halved) so that waveforms do not extend past the borders of the recording paper.

Heart Rate

If the heart rhythm is regular, an "instantaneous" heart rate is easy to calculate: count the number of 1 mm squares (little boxes) between two heart beats (RR interval) and divide this number into 3000 if the paper speed is 50 mm/s (3000 is the equivalent of 1 min because 60 seconds × 50 = 3000) or into 1500 if the paper speed is 25 mm/s (Figure 17.5). This method is also useful if the animal has intermittent short runs of abnormal beats (i.e., ventricular tachycardia) and the rate of that rhythm has to be calculated.

If the heart rhythm is irregular, calculation of the average heart rate over a prescribed period of time is performed. It is useful to realize that 30 large squares (bold lined) or 150 mm represent 3 seconds at 50 mm/s or 6 seconds at 25 mm/s. Thus, heart rate is determined by

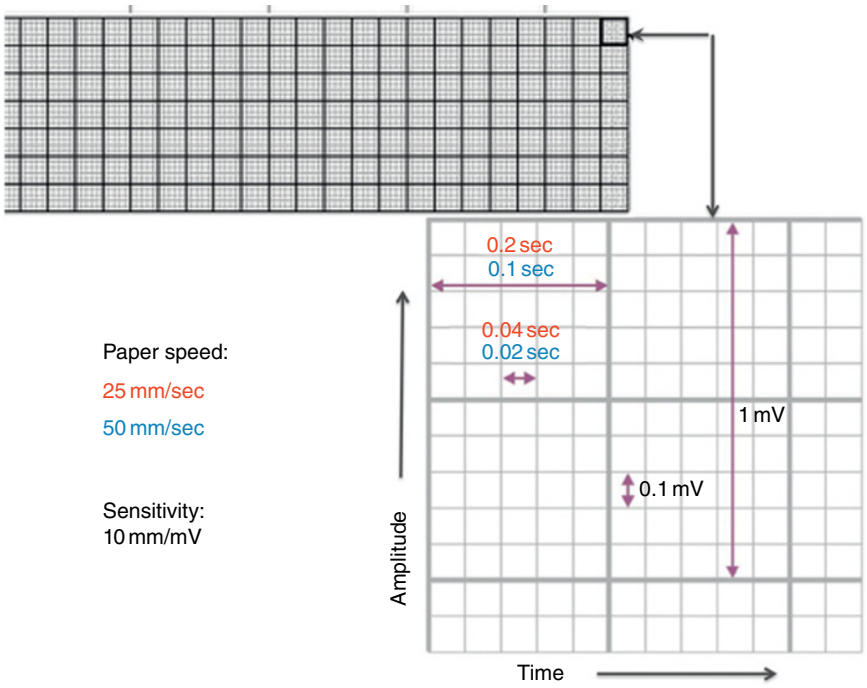

Figure 17.4 Calibration of ECG paper speed and sensitivity. See text for details.

Figure 17.5 Calculation of instantaneous heart rate between two beats is used when the rhythm is regular or if the heart rate of a short run of abnormal beats needs to be calculated. At a paper speed of 25 mm/s, the number of mm (little boxes) between two beats is divided into 1500 to calculate the heart rate per minute. At a paper speed of 50 mm/s, the number of mm between two beats is divided into 3000. See text for additional details.

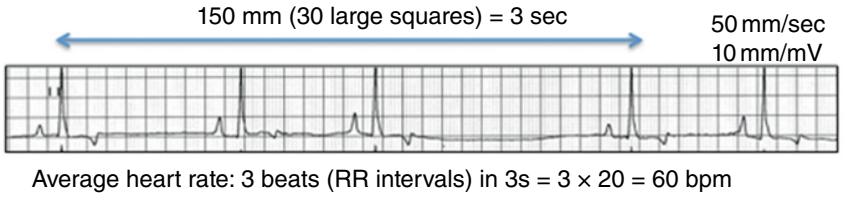

Figure 17.6 Calculation of average heart rate, used when rhythm is irregular. At a paper speed of 25 mm/s, the number of beats over a 150 mm segment of the ECG is multiplied by 10 to achieve number of heart beats per minute. At a paper speed of 50 mm/s, the number of beats over a 150 mm segment of the ECG is multiplied by 20 to achieve number of heart beats per minute.

counting the number of beats over 30 large squares and multiplying this number by 20 if the paper speed is 50 mm/s (Figure 17.6) or multiplying by 10 if the paper speed is 25 mm/s.

A commonly used shortcut takes advantage of the fact that most standard ballpoint pens are 150 mm in length. Thus, they can be placed on the ECG paper to denote a -3 or 6-second interval and the number of beats that are demarcated by the length of the pen can be quickly counted.

Rhythm

The heart rhythm describes the pattern of heart beats and sequence of the P-QRS-T-wave forms. When determining the heart rhythm, the following characteristics should be examined.

- The regularity of the heart beats: are the RR intervals regular or irregular?
- The relationship of the P-wave and QRS complexes: (a) is there a P-wave in front of every QRS complex and (b) is there a QRS complex following every P-wave?
- The origin of the heart beats: (a) sinus node or (b) ectopic (i.e., atrial, junctional, or ventricular).
- The heart rate.

In some instances, the heart rhythm changes or is composed of multiple different rhythms that each requires a separate description (Box 17.2).

Box 17.2 Rhythm analysis: important questions to ask

- Is the rate fast or slow (tachcardia vs bradycardia)?
- Is the rhythm regular or irregular? If irregular, is the rate slow, fast, or are there premature beats? A regular rhythm usually has less than 10% variation in the RR intervals.
- Are there P-waves? Are they normal (upright in lead II, i.e., is the rhythm sinus or not sinus)?
- Is there a P-wave for every QRS, is there a QRS for every P-wave? Normally there is a nearly fixed PR interval between the P-waves and the QRS complexes.
- Are the QRS complexes normal or abnormal (normal or abnormal conduction)?

Mean Electrical Axis

The mean electrical axis (MEA) describes the net direction of cardiac depolarization across the animal's frontal plane. The conventional six-lead ECG system divides the frontal plane into 12 segments, similar to the slices of a pie (Figure 17.7). By doing so, the six-lead ECG examination records the electrical activity of the heart from six different vantage points along the frontal plane in 30° increments.

The MEA normally points towards the caudal half of the animal. In the dog, the normal MEA is between +40° and +100° and in the cat, the normal MEA is

between 0° and +160°. Calculation of the MEA can be done in several ways. One way is to examine the polarity of the QRS complexes from each of the six limb leads and identify the ECG lead in which the QRS complex is isoelectric (Figure 17.8, step 1), that is, the lead in which the net polarity of the QRS complex is closest to zero. (i.e., the positive and negative deflections of the QRS waves cancel each other out). In some instances, this will be the lead in which the QRS waves are the smallest and in other instances the lead in which the amplitude of the positive R-wave is the same as the sum of the negative deflections (Q- and S-wave, i.e., net polarity of the QRS).

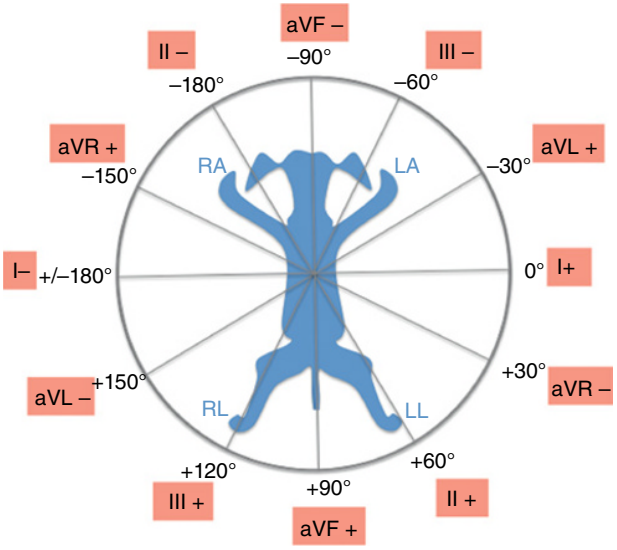

Figure 17.7 The hexaxial or six-lead ECG system divides the frontal plane into 12 segments, similar to the slices of a pie. By doing so, the six-lead ECG examination records the electrical activity of the heart from six different vantage points along the frontal plane in 30° increments.

Then identify the limb lead that is perpendicular to the isoelectric lead on the hexaxial lead system (Figure 17.8, step 2). The MEA will exist in a direction either towards the positive or negative pole of the perpendicular lead, depending on the polarity of the QRS complex in that lead (Figure 17.8, step 3). The net polarity of the QRS complex in lead II is positive in the ECG example in Figure 17.8, so the MEA points to +60° (Figure 17.8, step 4). This is considered a normal MEA for a canine.

To obtain a general direction of the MEA, a quick approach called the "pie method" may be useful (Figure 17.9). First, determine the net polarity of the QRS complex in lead I and aVF. These are the two leads which divide the heart into two perpendicular halves and create four equal pieces (quarters) of a pie.

With a normal MEA of depolarization, both lead I and aVF have a net positive polarity, and the overlapping

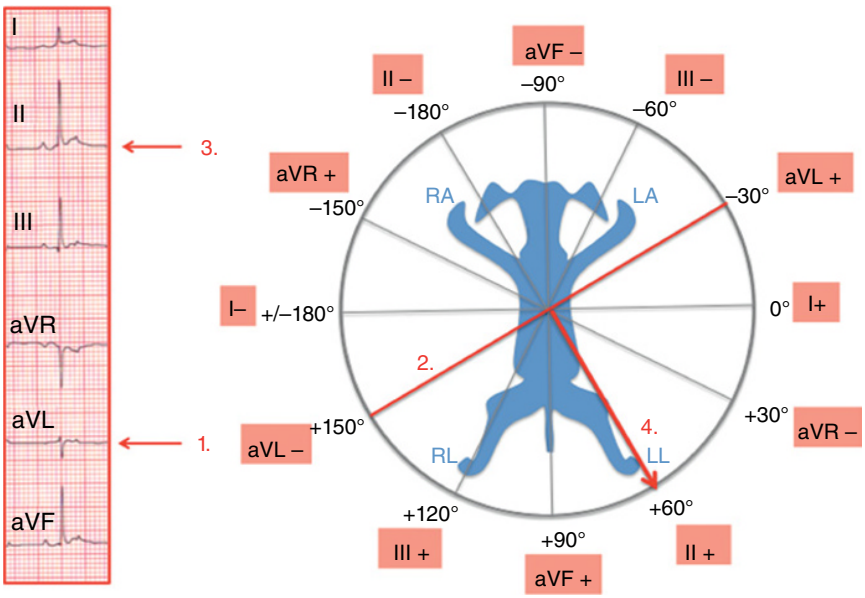

Figure 17.8 Calculation of the MEA is performed by first examining the polarity of the QRS complexes from each of the six limb leads and identifying the ECG lead in which the QRS complex is isoelectric, that is, the lead in which the net polarity of the QRS complex is closest to zero (i.e., the positive and negative deflections of the QRS waves almost cancel each other out) (step 1). Next, identify the limb lead that is perpendicular to the isoelectric lead on the hexaxial lead system (step 2). The MEA will point towards either the positive or negative pole of the perpendicular lead, depending on the polarity of the QRS complex in that lead (step 3). The net polarity of the QRS complex in lead II is positive, so the MEA points to +60° (step 4). This is considered a normal MEA for a dog.

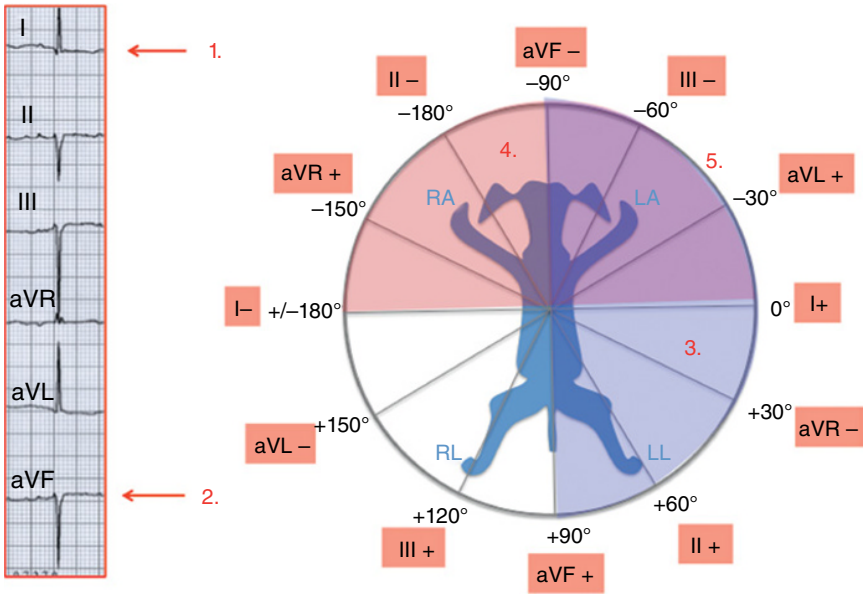

Figure 17.9 Calculation of the mean electrical axis using the "pie method." First, determine the net polarity of the QRS complex in lead I (step 1) and aVF (step 2). These two leads divide the heart into two perpendicular halves and create four equal pieces (quarters) of a pie. If the QRS in lead I is positive, the "half pie" pointing to the positive pole of lead I is shaded (step 3, blue half). If the QRS is negative in aVF, the "half pie" pointing to the negative pole of lead aVF is shaded (step 4, red half). The overlapping quarter (step 5, purple half) contains the MEA. Thus, if lead I is positive and aVF is negative, the overlapping section is 0° to –90°, indicating a left axis shift.

section thus is the pie piece (quarter) between 0° to 90°. If lead I is positive and aVF is negative, the overlapping section is 0° to –90° (see Figure 17.9) which indicates a left axis shift; if both lead I and aVF are negative, the overlapping section is 180° to –90° indicating a right axis shift.

The MEA can be within the normal range or to the right or left of the normal range. Common causes of right axis deviations include right ventricular hypertrophy (right axis shift with normal QRS duration) or right bundle branch block right axis shift with prolonged QRS duration) (Figure 17.10).

Common causes of left-axis deviations include partial left bundle branch block and left anterior fascicular block as seen in some cats with cardiomyopathies (see Figure 17.9). Note that left ventricular hypertrophy does not usually result in the left-axis shift as the normal MEA is already pointing in the direction of the left ventricular apex. Less commonly, mechanical displacement of the heart to either side of the thorax by space-occupying lesions or lung lobe atelectesis can change the MEA.

Criteria for Heart Enlargement

The criteria for heart enlargement in the dog and cat are shown in Table 17.4. In brief, atrial enlargement is manifest as P-wave of increased duration (P mitrale) or increased amplitude (P pulmonale) (Figure 17.11) or both.

Left ventricular enlargement can cause an increased R-wave amplitude and QRS duration whereas right ventricular enlargement can manifest as a right MEA shift and prominent S-waves.

Conduction Abnormalities or Bundle Branch Block

The bundle of His is specialized conduction tissue that forms the distal portion of the AV node, and divides into two main bundle branches that course left and right into the ventricular muscle. Right (RBBB) or left (LBBB) bundle branch block occurs when the impulse

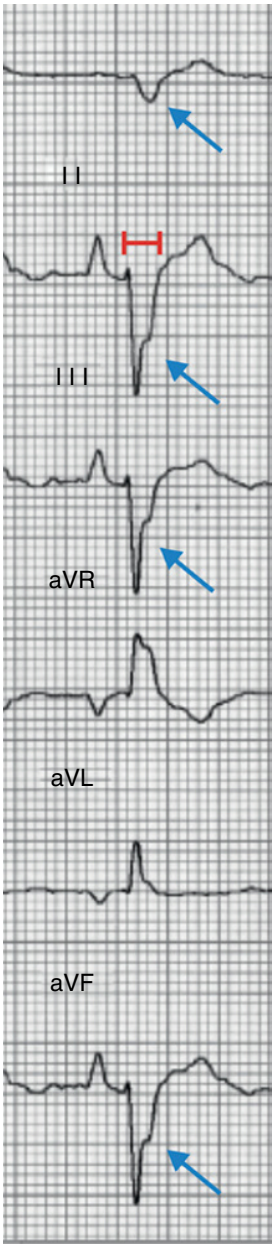

Figure 17.10 Six-lead ECG example of a right axis shift and right bundle branch block in a cat with right ventricular cardiomyopathy. The leads are I, II, III, aVL, aVR, aVF from top to bottom. The conduction disturbance is identified by the prolongation of the QRS complex (0.07 s, *red bar*) and a right axis deviation. The right axis shift is denoted by deep S-waves in leads I, II, III, and aVF (*blue arrows*) (50 mm/s; 10 mm/mV).

is blocked or slowed within either of the branches and block results in characteristic QRS waveform changes. In order to diagnose a bundle branch block, the MEA has to be determined, which requires a six-lead ECG recording. RBBB (see Figure 17.10) is characterized by a right shift of the MEA and markedly prolonged QRS duration (>0.08 s in the dog and >0.06 s in the cat), while LBBB (Figure 17.12) is characterized by a normal MEA and markedly prolonged QRS duration (>0.08 s in the dog and >0.06 s in the cat) (normal values listed in Table 17.3).

The QRS morphology with bundle branch block patterns may be confused with a ventricular rhythm. Impulse origin in most cases of bundle branch block is the sinus node, hence the rhythm is supraventricular, despite the marked change in QRS waveform morphology, and there is a P-wave associated with each QRS complex. RBBB may be a benign finding in both dogs and cats, or associated with right ventricular cardiomyopathy whereas LBBB is usually associated with significant underlying heart disease, such as dilated cardiomyopathy.

Table 17.4 ECG criteria for heart enlargement in the dog and cat

	Dog	Cat
Left atrial enlargement		
P-wave	>0.4 mV, >0.04 s	>0.04 s
	Notched	
Right atrial enlargement		
P-wave	>0.4 mV	>0.2 mV
Left ventricular enlargement		
R-wave	>2.5 mV in lead II, aVF	>0.9 mV in lead II
	>3.0 mV in large-breed dogs	
	>1.5 mV in lead I	
QRS duration*	>0.06 s	>0.04 s
Right ventricular enlargement		
S-wave	>0.35 mV in lead II	S-wave in leads I, II,
	>0.05 mV in lead I	III and aVF (>0.5 mV)
	S-wave in leads I, II III and aVF	
Electrical axis	Right shift (>+100°)	Right shift (>+160°)

Source: Adapted from Tilley and Smith 2008.
* QRS duration >0.08 s in the dog and >0.06 s in the cat can be associated with left or right bundle branch blocks. See text for more detail.

Figure 17.11 Atrial enlargement is manifest as a P-wave of increased amplitude in a poodle with degenerative AV valve disease and atrial enlargement. The blue arrow shows the tall P-wave (amplitude 0.6 mV) (50 mm/s; 10 mm/mV).

Figure 17.12 ECG example of a left bundle branch block in a rottweiler with dilated cardiomyopathy. The conduction disturbance is identified by the prolongation of the QRS complex (0.08 s; *blue bar*) but a normal MEA (50 mm/s; 10 mm/mV).

Pathophysiology of Heart Failure

Barret J. Bulmer, DVM, MS, DACVIM (Cardiology)

Tufts Veterinary Emergency Treatment & Specialties, Walpole, MA, USA

Heart failure represents a potential sequela of nearly all congenital and acquired cardiac diseases in dogs and cats. Without an appropriate understanding of the pathophysiologic alterations that produce heart failure, and the knowledge of which therapies can successfully mitigate their consequences, veterinarians will be unable to treat this life-impairing and often life-threatening condition. Therefore, the goals of this chapter are to highlight the classification schemes for heart failure, discuss normal cardiovascular physiology along with the mechanisms that contribute to the maladaptive hemodynamic and neurohormonal alterations precipitating heart failure, and outline how understanding of these mechanisms leads to targeted medical therapy.

Components of the Circulatory System

The circulatory system is composed of the heart and its associated arteries, capillaries, and veins. Appropriate function of the circulatory system further requires all of the constituents of normal circulating blood. The heart, blood vessels, and blood carry essential substances to metabolizing tissues and effectively remove unneeded by-products of metabolism. Additional functions of the circulatory system include regulation of body temperature, humoral communication, and appropriate adjustments of blood delivery depending on the underlying physiologic condition.

Determinants of Normal Cardiac Function

Mechanical function of the heart requires coordinated filling of the cardiac chambers (diastolic function) followed by an effective contraction (systolic function) to propel blood from the right and left heart to the pulmonary and systemic circulations, respectively. Impaired mechanical function may occur with disorders of the myocardium, cardiac valves, or pericardium. Effective filling and emptying, along with an appropriate increase or decrease in the rate of contraction, further rely on coordinated activity driven by pacemaker cells within the sinoatrial (SA) node and the heart's conduction system. Therefore, perturbed systolic or diastolic function produced by alterations in myocardial function, valvular integrity, pericardial confinement, volume loading, increased resistance to ejection or electrical instability may all produce cardiac dysfunction with subsequent development of heart failure (Box 18.1).

Origin of Ventricular Contraction

The electrical impulse that produces ventricular systole begins within the SA node and propagates along the specialized conduction system and cell walls to produce atrial and ventricular myocyte depolarization. Calcium influx through the L-type calcium channels within the sarcolemma along the T-tubules contributes to a larger calcium release from the sarcoplasmic reticulum (so-called calcium-induced calcium release). The rise in cytosolic calcium enhances binding to troponin-C and enables configurational changes in the actin and myosin molecules so that cross-bridge cycling (and hence myocardial contraction during systole) can occur. Diastole (myocardial relaxation) occurs as calcium influx through the L-type calcium channel and release from the sarcoplasmic reticulum terminate, and calcium is resequestered by the sarco(endo)plasmic reticulum calcium ATPase (SERCA) into the sarcoplasmic reticulum. The fall in cytosolic calcium concentration during diastole results in inhibition of the interaction of

Box 18.1 Disease conditions that may produce heart failure

Impaired cardiac filling

Pericardial disease

- Pericardial effusion with tamponade
- Constrictive pericarditis
- Uncommon forms of congenital pericardial disease (e.g., pericardial cysts)

Inflow obstructions

- Tricuspid/mitral valve stenosis
- Uncommon forms of congenital heart disease (e.g., cor triatriatum, supravalvular mitral stenosis)
- Neoplasia (e.g., obstructive heart base tumors)

Myocardial disease that has a primary component of diastolic dysfunction

- Hypertrophic cardiomyopathy
- Restrictive cardiomyopathy

Impaired cardiac ejection

Myocardial disease that has a primary component of systolic dysfunction

- Dilated cardiomyopathy (idiopathic)
- Ischemic, nutritional (e.g., taurine deficiency), toxic (e.g., adriamycin), or infectious (e.g., Chagas disease) myocardial disorders
- Arrhythmogenic right ventricular cardiomyopathy

Increased resistance to ejection

- Pulmonic/aortic valve stenosis
- Pulmonary/aortic thromboembolism or obstruction (e.g., tumors)
- Pulmonary hypertension

Volume overload

Altered blood flow resulting in volume overload

- Valvular insufficiencies (congenital dysplasia, degenerative or infective)
- Left to right shunting (e.g., patent ductus arteriosis, ventricular septal defect, atrial septal defect, arteriovenous fistulas)

Disease conditions associated with chronically elevated cardiac output

- Anemia
- Hyperthryoidism

Disorders of impulse formation or conduction

Sustained tachyarrhythmias (e.g., supraventricular tachycardia, atrial fibrillation)

Sustained bradyarrhythmias (e.g., high-grade AV block, sinus bradycardia)

Wolff–Parkinson–White syndrome

actin molecules and myosin heads that is required for contraction to occur.

Determinants of Ventricular Systolic Function

The primary determinants of ventricular systolic function are preload, afterload, and contractility. Heart rate and ventricular synchrony are additional factors that influence systolic function.

It has long been recognized that increased cardiac filling enhances systolic performance. In the normal heart, increased preload, which represents the end-diastolic distending force of the ventricular wall, produces this enhanced performance as defined by Starling's law of the heart. Surrogates for preload include the end-diastolic volume, diameter, or end-diastolic pressure. Therefore, preload is dependent on venous return, total blood volume, and distribution of the blood volume within the vascular system. The recognition that the ascending limb of the Starling curve in skeletal muscle is dictated by the extent and "optimization" of actin-myosin filament overlap does not appear to be solely responsible for enhanced systolic performance in cardiac muscle. An alternative mechanism, termed *length-dependent activation*, seems to account for augmented ventricular systolic function with diastolic stretch. The exact mechanisms behind length-dependent activation remain controversial but the basic premise is that up to a maximum length, the myofilaments become sensitized to calcium as sarcomere length increases.

The force, tension or stress experienced by the ventricular myocytes during contraction is termed the *afterload*. Afterload is the degree of interference to ventricular ejection and is determined primarily by the systemic (or pulmonary) vascular resistance with a contribution from aortic (or pulmonary arterial) impedance. Impedance is dependent on the physical properties of the vascular wall and the blood (e.g., blood density and viscosity, arterial wall diameter, and viscoelasticity) and represents the ratio of aortic pressure to flow. The Anrep effect dictates that an acute increase in afterload enhances ventricular function via stimulation of sarcolemmal stretch receptors and increased cytosolic calcium levels.

Contractility is the inherent ability of the cardiac myocytes to shorten and generate force independent of preload, afterload, or heart rate. Increased contractility represents either increased calcium movement or sensitization of the contractile proteins at a given level of cytosolic calcium. Although criticisms of this concept include the lack of noninvasive measures of isolated contractility and the impossibility of separating the molecular mechanisms of enhanced function from preload and afterload from contractility, this concept is still useful as we discuss the pathophysiology of heart failure.

The Bowditch staircase effect (also known as the Treppe effect or the positive force-frequency relationship) defines that increased heart rate not only increases cardiac output via more frequent contractions, it also enhances the force of ventricular contraction. It is hypothesized that an increased rate of depolarization and the subsequent increased sodium and calcium current across the sarcolemma produce overload of the sodium–potassium pump. The activity of the sodium–calcium exchanger is therefore augmented in the "reverse" mode, extruding sodium from the cell in exchange for increased calcium into the cell. Cross-bridge cycling is supported by the higher cytosolic calcium level.

A final determinant of ventricular systolic function is the coordinated activation (and hence contraction) of the ventricular walls, termed *ventricular synchrony*. An altered activation sequence and the lack of coordinated mechanical contraction, as witnessed with ventricular arrhythmias, right ventricular apical pacing, or in humans with markedly prolonged QRS durations, can contribute to functional and clinical deterioration. Cardiac (pacemaker) resynchronization therapy has been shown to offset some of these negative consequences in people.

The Failing Heart

Definition of Heart Failure

The 2013 American College of Cardiology Foundation and American Heart Association (ACCF/AHA) guideline for the management of heart failure defines heart failure broadly as "a complex clinical syndrome that results from structural or functional impairment of ventricular filling or ejection of blood." The biochemical mechanisms behind this complex syndrome continue to be elucidated but the macroscopic view and description of heart failure has not varied significantly from the conclusion of a panel of the National Heart, Lung and Blood Institute in 1994. They stated:

> Heart failure occurs when an abnormality of cardiac function causes the heart to fail to pump blood at a rate required by the metabolizing tissues or when the heart can do so only with an elevated filling pressure. The heart's inability to pump a sufficient amount of blood to meet the needs of the body tissues may be due to insufficient or defective cardiac filling and/or impaired contraction and emptying. Compensatory mechanisms increase blood volume and raise cardiac filling pressures, heart rate, and cardiac muscle mass to maintain the heart's pumping function and cause redistribution of blood flow. Eventually, however, despite these compensatory mechanisms, the ability of the heart to contract and relax declines progressively, and the heart failure worsens.

Although common long-standing cardiac conditions typically contribute to volume overload and development of pulmonary (left-sided) or systemic (right-sided) congestion, there are conditions (e.g., cardiac tamponade, acute pulmonary thromboembolism, acute severe valvular insufficiency) that may severely impair the ability to provide vital organs with their necessary cardiac output without fluid accumulation. Therefore, the term *heart failure* is often preferred over congestive heart failure.

Classification of Heart Failure

The American College of Veterinary Internal Medicine (ACVIM), for animals, and the ACCF/AHA, for humans, recognize a functional classification scheme, and a separate, complementary classification system that emphasizes the risk, development, and progression of heart disease. The modified New York Heart Association (NYHA) functional classification is defined as follows.

- Class I describes patients with asymptomatic heart disease (e.g., heart disease is present but there are no clinical signs even with exercise).
- Class II describes patients with heart disease that causes clinical signs only during strenuous exercise.
- Class III describes patients with heart disease that causes clinical signs with routine daily activities or mild exercise.
- Class IV describes patients with heart disease that causes severe clinical signs even at rest.

A newer veterinary system outlined in the ACVIM Consensus Statement detailing canine valvular heart disease highlights four basic stages of heart disease and failure. Because this system was devised for valvular heart disease, it is not always easily incorporated into discussion of other forms of congenital and acquired heart disease in dogs and cats, but nonetheless it is still useful for discussion of heart failure. The stages of this classification scheme are defined as follows.

- Stage A identifies patients at high risk for developing heart disease but that currently have no identifiable structural disorder of the heart (e.g., every Cavalier King Charles spaniel without a heart murmur, boxers without evidence of arrhythmia or myocardial dysfunction).
- Stage B identifies patients with structural heart disease but that have never developed clinical signs caused by heart failure. This stage is further subdivided.
  - Stage B1 refers to asymptomatic patients that have no radiographic or echocardiographic evidence of cardiac remodeling.
  - Stage B2 refers to asymptomatic patients that have hemodynamically significant cardiac disease as evidenced by radiographic or echocardiographic findings of heart enlargement.
- Stage C denotes patients with past or current clinical signs of heart failure associated with structural heart disease.
- Stage D refers to patients with end-stage disease with clinical signs that are refractory to "standard therapy."

The ABCD system is useful because it enables veterinarians to educate owners that their animal is at risk for developing heart disease even in the absence of an audible murmur, gallop or arrhythmia. This system is also useful because treatment and subsequent resolution of signs attributable to heart failure alters patient classification with the modified NYHA model whereas animals that have previously displayed heart failure always remain a Stage C or D with the newer system.

Phases of Heart Failure

Discussion of heart failure can center around three distinct phases. Phase 1 constitutes the initial cardiac injury and in most veterinary patients, this phase passes silently, without detectable clinical signs, because the disease is mild and slowly progressive (e.g., valvular disease, feline cardiomyopathies). However, some conditions (e.g., development of cardiac tamponade subsequent to bleeding of right atrial hemangiosarcoma or pulmonary thromboembolism) can produce severe life-threatening signs commensurate with the initial cardiac injury. Phase 2 is the stage wherein short-term and ultimately long-term compensatory mechanisms are activated for stabilization of cardiac output and normalization of afterload. Unfortunately, cardiac disease is often progressive and the heart's ability to hypertrophy may ultimately be overwhelmed. A heart murmur, gallop rhythm, cardiac arrhythmia, or cardiomegaly is more likely to be identified in this second phase despite the absence of significant or activity-limiting clinical signs. The hallmarks of phase 3 of heart failure are the emergence of clinical signs (e.g., exercise intolerance, lethargy, coughing, tachypnea) at rest or with minimal activity.

Phase 1 – Initial Insult

Cardiovascular disease is encountered commonly in daily veterinary practice. Patent ductus arteriosus, subaortic stenosis, and pulmonic valve stenosis are common congenital conditions in dogs while ventricular septal defect and atrioventricular valve dysplasia are more common in cats. Chronic degenerative valvular disease (CDVD) and dilated cardiomyopathy (DCM) are the most common acquired cardiac diseases in dogs while hypertrophic cardiomyopathy (HCM) is the most common acquired cardiac disease in cats. Although identification of disease at its exact onset is next to impossible, it is useful to highlight some of the available data on disease prevalence.

Congenital cardiac malformations are uncommon, with data from several veterinary schools suggesting a prevalence of 0.46–0.85%. Feline congenital heart disease is even less common with a reported prevalence of 0.2%. Although these data are several decades old, they still highlight that even at large referral centers, the prevalence of congenital heart disease is low.

However, identification of acquired cardiovascular disease is much more common and represents the majority of dogs and cats that ultimately develop heart failure. Dilated cardiomyopathy is encountered most often in large- and giant-breed dogs with a reported prevalence of 0.16–1.1%, depending on the study cited and the population investigated. In some breeds and age groups, the prevalence of DCM is much higher. For example, a study of Doberman pinschers in Europe found that only 3.3% of Dobermans 1 to <2 years of age were affected while 43.6% aged 6 to <8 years of age were affected. The prevalence of CDVD is also dependent on the breed and age of the dog, but it also varies based on the method of disease detection (e.g., auscultation, echocardiography, necropsy). While these variables cloud clear documentation of disease prevalence, there is little debate that CDVD is the most common acquired cardiac condition in dogs and represents the most common etiology for development of heart failure. Hypertrophic cardiomyopathy is the most common myocardial disease in cats although various other forms of cardiomyopathy (CM), including restrictive CM, arrhythmogenic right ventricular CM, dilated CM, and unclassified CM, may also contribute to heart failure.

Primary cardiomyopathies are a diagnosis of exclusion and true disease confirmation would require necropsy. Because of this limitation, echocardiography is most often considered the gold standard for diagnosis of CM in cats. A study in an apparently healthy, nonreferred population of 103 cats found echocardiographic alterations

consistent with CM in 16 cats (15.5%). Eleven of the 16 cats with cardiomyopathy did not have an auscultable murmur. None of the 16 cats exhibited left atrial enlargement, and hence their risk of cardiac-related complications was presumably low. But this study highlights that many asymptomatic animals have underlying heart disease and may have active maladaptive compensatory mechanisms and cardiac remodeling even in the absence of clinical signs.

Phase 2 – Compensatory Phase

With a reduction in cardiac output, the body depends on a number of short- and long-term compensatory mechanisms to maintain perfusion pressure to vital organs. The principal short-term compensatory mechanisms, activated within seconds to minutes, include activation of several neurohormonal systems and subsequent utilization of the Frank–Starling mechanism. These short-term mechanisms promote the long-term adaptive response which is myocardial remodeling/hypertrophy. Each of these mechanisms has inherent limitations and as the disease progresses, their once beneficial properties become detrimental.

Short-Term Adaptive Responses

Sympathetic Nervous System Baroreceptors in the carotid sinus and aortic arch, along with cardiopulmonary baroreceptors, cardiovascular low-threshold polymodal receptors, and peripheral chemoreceptors, are responsible for the sympathetic nervous system (SNS) outflow to the heart and peripheral circulation. Hypotension, whether related to dehydration, blood loss or cardiovascular disease, will enhance release of norepinephrine from terminal neurons to the sinoatrial and atrioventricular nodes and cardiomyocytes, and increase release of epinephrine and norepinephrine into the circulation from the adrenal gland. The catecholamines bind to cardiac beta-receptors and increase cytosolic cAMP levels via G-protein coupling to increase contractility, heart rate, the rate of ventricular relaxation, and the speed of impulse conduction through the heart. Beta-receptor stimulation also produces hyperpolarization of the pacemaker cells (possibly via increased activity of the sodium–potassium pump), reducing the membrane potential into the range of funny current (I_f) activation. Increased conductance of sodium through the funny channels further enhances the heart rate response to sympathetic activation.

The release of norepinephrine from the terminal neurons of the systemic vasculature results in vasoconstriction via activation of postsynaptic alpha-1 receptors. Occupancy of the receptor promotes breakdown of phosphatidylinositol, via phospholipase C, to inositol triphosphate (IP3) and diacylglycerol (DAG). IP3 transiently increases smooth muscle cytosolic calcium, thereby initiating the contractile cycle while DAG activates protein kinase C and is thought to induce sustained vascular contraction. The subsequent increased vascular tone promotes arterial vasoconstriction to maintain systemic blood pressure and enhanced venoconstriction to promote increased venous return. Augmented preload contributes to enhanced length-dependent activation and cardiac output via the previously described Starling's law of the heart.

Renin-Angiotensin-Aldosterone System Decreased renal perfusion pressure also stimulates the renin-angiotensin-aldosterone system (RAAS). The RAAS is complementary to the SNS wherein it provides a hemostatic mechanism for blood pressure through maintenance of sodium balance and intravascular volume. Additional stimuli for the RAAS include reduced sodium delivery to the macula densa and increased adrenergic activity.

Renin, released from the juxtaglomerular apparatus, cleaves angiotensinogen to the decapeptide angiotensin I. Angiotensin converting enzyme (ACE) cleaves the C-terminal dipeptide from angiotensin I, forming the potent vasoconstrictor angiotensin II (AT II). Similar to alpha-1 receptors, AT II promotes vascular smooth muscle contraction and maintenance of blood pressure via IP3 and DAG. ACE is also capable of cleaving the C-terminal dipeptide from the vasodilatory substance bradykinin, hence making it inactive. Therefore, ACE appears to be a regulator between vasoconstrictive/sodium retaining and vasodilatory/natriuretic mechanisms. Although all their roles have not been elucidated, four receptors for AT II have been identified and classified as AT_1, AT_2, AT_3, and AT_4 receptor subtypes. Critical activities of AT II beyond potent vasoconstriction include stimulation of aldosterone release, potentiation of presynaptic norepinephrine release, stimulation of antidiuretic hormone release, promotion of renal tubular sodium resorption, and cardiomyocyte necrosis, apoptosis, and ventricular fibrosis.

Understanding of the RAAS continues to evolve with identification of a new homolog of ACE, called ACE 2, and additional biologically active metabolites of AT II, including the angiotensin-(1-7) peptide. Additional enzymatic pathways, including chymase, cathepsin G, elastase, tonin, and tissue plasminogen activator, have been identified although their role in maintenance of blood pressure and the pathophysiologic alterations that contribute to heart failure is uncertain. In addition to the conventional circulating RAAS, all its constituents are also found in a variety of tissues, including the brain, myocardium, vasculature, kidney, and adipose tissue. The importance of tissue RAAS is likely organ, species, and disease dependent although there is growing

evidence that locally produced AT II plays a role in cardiac remodeling under certain conditions.

While AT II directly increases systemic vascular resistance to maintain blood pressure, it is also the primary stimulus for aldosterone synthesis and release from the adrenal glands. Aldosterone binds to mineralocorticoid receptors in the cytoplasm, followed by migration of the complex into the nucleus. Within the nucleus, the aldosterone–mineralocorticoid receptor complex promotes gene activation, transcription, and protein synthesis of Na+/K+ exchangers along the luminal surface of the distal tubule and collecting ducts to promote sodium and water retention in exchange for potassium excretion. Similar to the venoconstrictive effects of the sympathetic nervous system, aldosterone-mediated water retention increases preload and enhances cardiac output via the Starling mechanism. Additional rapidly acting, nongenomically mediated actions of aldosterone continue to be investigated, including cellular ion regulation, altered cellular volume, negative inotropy, and cardiac hypertrophy, fibrosis and remodeling. Increased potassium levels, corticotropin, catecholamines, endothelin-1, arginine vasopressin, and reduced hepatic clearance are additional mechanisms that contribute to increased aldosterone activity.

Additional Compensatory Mechanisms The mechanisms that maintain blood pressure and enhance preload extend beyond the SNS and RAAS. Arginine vasopressin (AVP), also called antidiuretic hormone, is released from the pituitary in response to increased plasma osmolality or hypovolemia. The SNS and RAAS also promote release of AVP. Vasoconstriction and weak inotropic actions of AVP are mediated via adherence to V_{1A} receptors. Solute free water resorption is accomplished via binding of AVP and V_{2A} receptors. Receptor activation triggers insertion of aquaporin-2 channels into the luminal surface of the epithelial cells lining the distal tubule and collecting ducts, thereby providing enhanced water retention. Endothelin-1 is another modulator of systemic arteriolar tone that acts via either ET_A receptors, to promote vasoconstriction and positive inotropic effects, or ET_B receptors, to produce endothelial-dependent vasodilation.

Long-Term Adaptive Responses

While augmentation of preload and afterload via the previously described mechanisms is able to maintain cardiac output and perfusion pressure in the short term, myocardial hypertrophy serves as the body's long-term compensatory mechanism for cardiac dysfunction. The concept of the afterload experienced by working myocytes is more readily understood in terms of wall stress as described by Laplace's law:

$$\text{Wall stress} = \frac{\text{pressure} \times \text{radius}}{2 \times \text{wall thickness}}$$

Normalization of wall stress serves as an adaptive response to reduce myocardial oxygen consumption while maintaining cardiac performance. Hence, if cardiac hypertrophy is capable of normalizing cardiac output, the previously activated short-term compensatory responses may be able to return to basal levels.

Changes in myocardial workload produce rapid and dramatic responses from the molecular mechanisms that regulate protein synthesis. The isolated heart shows increased RNA and protein synthesis within two hours of a loading stimulus while the intact heart displays similar increases within 24 hours. This tight regulation between hemodynamic function and cardiac growth has at least three signaling mechanisms: stretch-activated signals, agonists, such as AT II, catecholamines and endothelin-1, that link to protein kinase C, and growth factors, including insulin-like growth factor-1, transforming growth factor-beta, and platelet-derived growth factor, that are linked to receptor tyrosine kinases. The mechanisms behind translation of these signals to cardiac hypertrophy are complex and continue to be elucidated, but seem linked to the family of mitogen-activated protein kinases.

Increased systolic wall stress, such as systemic hypertension or severe subaortic stenosis, necessitates increased pressure generation by the left ventricle to overcome the forces opposing ejection. Laplace's law dictates that normalization of wall stress is achieved via increased left ventricular wall thickness, termed *concentric hypertrophy*, with sarcomeres replicating in parallel. The ventricular radius remains normal or may actually decline secondary to encroachment of the thickened left ventricular walls. Increased diastolic wall stress, as observed with volume overload secondary to mitral valve insufficiency, instead promotes eccentric hypertrophy. This pattern of hypertrophy is characterized by sarcomeres replicating in series, producing a larger diameter and more spherical left ventricular chamber. The wall thickness increases only modestly to try and maintain normal wall stress.

Phases of the hypertrophic response have been detailed for decades and include:

- the initial stage of developing hypertrophy where workload exceeds the output that is normal for the initial mass of the heart
- compensatory hypertrophy where work-induced growth of the myocardium normalizes wall stress
- an exhaustion phase characterized by cardiomyocyte death, myocardial fibrosis, and ventricular dilation with decreasing work output per unit of cardiac mass leading to heart failure.

Progression between these phases seems most dependent on the magnitude and type of overload wherein acute pressure overload triggers the earliest onset and fastest rate of hypertrophy. It has been postulated that while hypertrophy prevents acute cardiac insufficiency, the unbalanced "growth" at the level of the organ, tissue, cell, and intracellular organelles ultimately becomes the cause of chronic cardiac insufficiency of the hypertrophied heart.

Phase 3 – Transition to Heart Failure (Figure 18.1)

Hypertrophy may be unable to maintain cardiac output in the face of chronic and progressive cardiovascular disease and the previously beneficial short- and long-term compensatory mechanisms ultimately prove detrimental. The transition from compensated hypertrophy to the exhaustion phase is mediated by molecular mechanisms that produce:

- myocyte growth
- reexpression of fetal myocyte phenotype with a reduction in the expression of the adult phenotype
- alteration in the expression and/or function of the proteins involved in excitation-contraction coupling
- necrosis and apoptosis of cardiomyocytes
- changes within the extracellular matrix

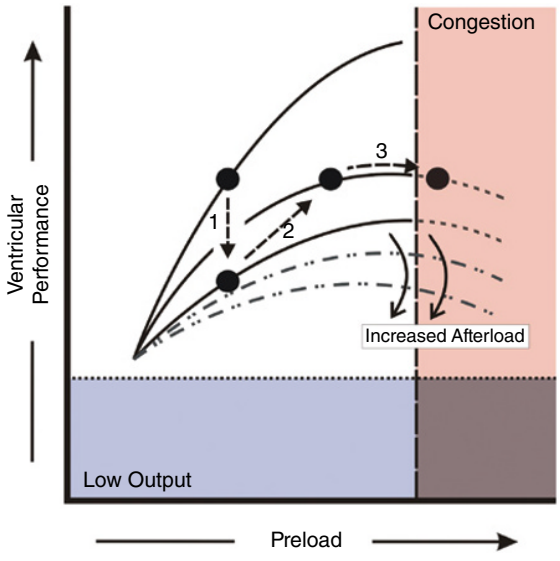

Figure 18.1 A family of Frank–Starling curves highlighting the progression to heart failure. (1) Ventricular performance declines following a cardiac insult. (2) The short-term and long-term compensatory mechanisms are activated and ultimately return ventricular performance to normal, albeit at a higher filling pressure. (3) The underlying disease progresses, myocardial remodeling becomes maladaptive and the previously beneficial compensatory mechanisms become detrimental. Further preload expansion no longer enhances ventricular performance on the flat portion of the Frank–Starling curve and instead congestion develops. Increases in afterload depress ventricular performance even further down the Frank–Starling curves.

- alterations in myocardial energetics. These alterations reduce the number of viable myocytes and/or decrease the intrinsic contractility of individual myocytes, thereby impairing cardiac performance.

The previously beneficial augmentation of preload and afterload now only serves to promote development of congestion or amplify contractility-afterload mismatch.

This cycle of disease progression continues as venous pressures continue to rise, cardiac output declines, congestion develops, and clinical signs of heart failure begin to emerge.

Myocyte Loss

A reduction in the number of viable myocytes or dysfunction of the viable myocytes may account for a component of reduced myocardial contractile function. Cardiomyocyte death appears to occur via necrosis, apoptosis, and autophagy although it is uncertain if all three are distinctive events or a continuum of overlapping processes. Exposure of norepinephrine to cultured mammalian cardiomyocytes produces a concentration-dependent decrease in viability and pathophysiologic levels of AT II also promote myocytolysis. Therefore, it seems that myocyte loss can occur via mechanisms beyond ischemia and many of these mechanisms, including catecholamines, AT II, reactive oxygen species, nitric oxide, inflammatory cytokines and mechanical strain, are increased in the failing myocardium.

Reexpression of Fetal and Neonatal Genes and Altered Contractile Proteins

Heart failure seems to alter both quantitative and qualitative protein expression, which may impair cardiac contractility. Isoforms of contractile proteins that are present during fetal and neonatal life, when protein synthesis is rapid, have been identified in some animal models of hypertrophy and myocardial failure. Pressure overload hypertrophy in rats produces a shift from the rapid myosin heavy chain (MHC) isoform (V_1) to the slow MHC isoform (V_3), enabling normal tension generation but at a lower energy cost by reaching the tension more slowly. However, in species with a predominant V_3 ventricular MHC isoform, including dogs, cats, and humans, this change seems less critical to development of heart failure. Fetal phenotypic expression of other contractile proteins, including myosin light chain, troponin-I and troponin-C, has been identified in the myocardium of humans with heart failure and may contribute to a decrease in cardiac contractile function.

Altered Excitation-Contraction Coupling

Calcium is a critical ion in regulating myocardial contraction and relaxation. Alterations in calcium conductance across the sarcolemma, release from the sarcoplasmic

reticulum, or its resequestration into the sarcoplasmic reticulum may exert profoundly negative consequences on cardiac performance. Myocytes from humans with heart failure exhibit a prolonged action potential with a blunted rise in intracellular Ca^{2+} during depolarization and a slowed rate of decline during repolarization. Slower Ca^{2+} delivery to the contractile proteins during systole and excessive cytosolic Ca^{2+} during diastole may contribute to both systolic and diastolic dysfunction. The failing myocardium also displays a negative force–frequency relationship. Rather than progressive increases in ventricular contractility with increasing heart rate, humans with heart failure have little or no increase in contractility with increased frequency of stimulation. This alteration is presumably related to impaired Ca^{2+} cycling between the sarcoplasmic reticulum and the cytosol.

Calcium conductance, release, and resequestration are critical components of normal cardiac function and numerous pumps and channels are responsible for coordinating events. Studies in failing human myocardium have found that mRNA and protein levels of SERCA, voltage-dependent Ca^{2+} channels, and the calcium release channel on the sarcoplasmic reticulum are reduced. Alterations in proteins responsible for Ca^{2+} cycling in dogs have also been identified. Therefore, altered expression or function of these proteins may negatively impact systolic and diastolic function.

Changes within the Extracellular Matrix

Ventricular remodeling is a key feature of heart failure regardless of the underlying cardiac disease or underlying phenotype (e.g., volume overload, pressure overload, primary cardiomyopathy). Changes within the ventricular geometry and function must be viewed as a summation of events occurring at the level of the cardiomyocyte, the vascular compartment, and within the extracellular matrix (ECM). Although once only viewed as scaffolding, there is now growing recognition that the ECM mediates mechanical and biological signals that contribute to the progression of heart failure.

Regulation and turnover of the ECM is a complex process dictated by mechanical stress, neurohormonal activation, inflammation, and oxidative stress. Accelerated growth of both the myocyte and ECM produced by pressure overload yield left ventricular concentric hypertrophy. Left ventricular thickening negatively impacts both of the fundamental processes that dictate diastolic function – active relaxation and passive stiffness. Shifting isoforms and phosphorylation sites of cytoskeletal proteins (e.g., titin) can impair myocyte relaxation and hamper active relaxation/early cardiac filling. Accumulation of collagen within the ECM increases ventricular stiffness, thus reducing myocardial compliance and impairing passive ventricular filling. Volume overload triggers left ventricular eccentric hypertrophy/remodeling with increased ECM turnover via an increase in the matrix metalloproteinases (MMPs)/tissue inhibitors of matrix metalloproteinases (TIMPs) ratio. The MMPs degrade collagen and other matrix components while the TIMPs either inhibit or prevent MMP activation. Isoform shifts from type I to type III collagen further contribute to a net degradation of collagen with resultant chamber dilation and progressive wall thinning.

During the compensated phase, the remodeling contributes to increased ventricular compliance with preserved systolic function. Ultimately, the progression to decompensated failure is complex and includes a combination of ECM degradation and profibrotic synthesis mediated concomitantly at different subcellular locations and within different regions of the ventricle.

Alterations in Cardiac Metabolism

The heart requires a high rate of adenosine triphosphate (ATP) hydrolysis because of its continuous mechanical work and therefore requires a constant supply of oxygen and fuel. Oxidation of fatty acids (FA) accounts for approximately 70–90% of ATP production in the fasted state while glucose utilization increases in the fed state. Because of the fundamental roles metabolism and ATP generation have in maintenance of cardiac structure and function, it is reasonable to hypothesize that alterations in cardiac metabolism have a role in the pathophysiology of heart failure. Studies in animal models and humans with advanced heart failure and systolic dysfunction have reported a decrease in the phosphocreatine/ATP ratio, ATP content, and ATP movement through creatine kinase. It is uncertain whether these alterations serve as a primary contributor to the progressive nature of heart failure or are simply an adaptation to decreased ventricular function, but significant mitochondrial changes are present in various models of cardiac hypertrophy and failure.

Decreased cardiac energy production may be secondary to impaired substrate use or altered mitochondrial function. Studies of heart failure with systolic dysfunction have identified reduced mRNA and protein expression of FA transporters with reduced cardiac FA utilization and ATP production. Studies of glucose oxidation are variable with reports of decreased, unchanged or increased glucose uptake. Varying results likely depend on the stage and type of disease, but these results may also be influenced via the channeling of pyruvate into anaplerotic pathways. Flux of pyruvate through anaplerotic pathways appears to be a hallmark of metabolic remodeling and reduces its availability for oxidation and energy production by pyruvate dehydrogenase. Nicotinamide adenine dinucleotide phosphate (NADPH) is also consumed by induction of anaplerotic pathways

which may lead to dysregulation of cellular oxidative stress, thereby contributing to the progressive nature of heart failure. Mitochondrial reactive oxygen species may produce mitochondrial damage, activation of mitogen-activated protein kinases, cardiac hypertrophy and fibrosis, again suggesting that alterations in organelles of metabolism may contribute to ventricular remodeling. The reactive oxygen species and mitochondrial damage are also strong mediators of autophagy in certain settings and may serve as an additional mechanism for remodeling and progression to heart failure.

Hemodynamics of Heart Failure and Development of Pulmonary Edema

Progressive disturbances of systolic and diastolic function may ultimately lead to development of systemic or pulmonary venous congestion as a consequence of elevated venous pressure. Increased plasma volume (via sodium and water retention) and reduced venous capacitance (via venoconstriction) no longer augment systolic function in the failing heart and instead merely precipitate clinical signs associated with congestion.

Pulmonary capillary wedge pressures exceeding 25 mmHg are likely to precipitate signs of left-sided heart failure, including cough and increased respiratory rate and effort. Pulmonary edema develops when the movement of fluid from the blood to the interstitial space, and in some instances to the alveoli, exceeds the return of fluid from the interstitial space to the blood and its drainage through the lymphatics. There is normally a continuous exchange of fluid, colloid, and solutes from the vasculature into the interstitial space so a pathologic state exists only when there is an increase in the net flux of fluid, colloid, and solutes from the vasculature into the interstitial space. The total microvascular filtration rate can change as a result of changes in filtration surface area, membrane permeability to water, hydrostatic and colloidal osmotic pressures, and membrane permeability to protein. Lymphatic flow will similarly be dictated by the hydrostatic pressure of the interstitium, the pumping pressure within the lymphatics, the systemic venous pressure, and the resistance to flow.

During stage 1 of pulmonary edema development, the interstitial volume remains normal due to the compensatory increase in lymphatic flow. In most tissues, the increase in the hydrostatic interstitial pressure with the development of interstitial edema would serve to inhibit microvascular filtration and enhance lymph flow. However, the interstitial pressure rarely reaches high enough values to use this protective mechanism because (a) the increase in the interstitial compliance allows large volume increases with small pressure increases and (b) alveolar flooding occurs at relatively low interstitial pressures (2–3 mmHg). The more protective mechanism in the lung is the decreased resistance to lymphatic flow as microvascular filtration increases. The proposed mechanism is believed to be subsequent to "tethering" of the initial lymphatics to surrounding structures which pull the lymph vessels open as the interstitial volume increases, thus increasing the radius and filtration of the lymphatics.

Stage 2 occurs when the lymphatics' capacity to remove the interstitial fluid is overwhelmed. During this stage, fluid and colloid accumulate in the interstitial areas around bronchioles, arterioles, and venules. Fluid accumulation occurs within the peribronchial and perivascular interstitial space (versus adjacent to the alveolar capillary membrane) because of its more negative pressure and more compliant properties. The enlarged lymphatics and free fluid form cuffs around the bronchioles and pulmonary blood vessels and may subsequently compress the small airways and blood vessels. Gas exchange may be relatively unaffected in the early stages of edema if there is no increase in the alveolar-capillary membrane thickness along the thin side of the interstitial space. But as capillary filtrate continues to accumulate, the less compliant interstitium around the alveolar-capillary septa also fills, the interstitial pressure rises, and alveolar flooding begins (stage 3). Arterial oxygenation decreases and in severe cases death may ensue.

Therapeutic Implications

Understanding of the pathophysiologic mechanisms of heart failure enables development of therapeutic strategies to provide symptomatic benefit and slow the natural history of disease progression. With the long-standing recognition that fluid retention and poor pump function contribute to pulmonary and systemic venous congestion and low cardiac output, the initial therapeutic strategies were to reduce preload and afterload while augmenting contractility. We continue to use these strategies today via the administration of diuretics and inodilators to combat many forms of heart failure. With further advances in the understanding of cardiac remodeling, agents capable of blocking critical neurohormonal pathways, including ACE inhibitors, beta-blockers, and aldosterone antagonists, were developed to prolong survival without imposing significant alterations in cardiac loading conditions. And with further advances in the understanding of myocyte loss, altered gene expression, dysregulation of excitation-contraction coupling, degradation of the extracellular matrix and deranged cardiac metabolism, new therapeutic agents will continue to be identified in an effort to one day halt the inevitable cycle that leads to heart failure.

Successful management of both acute and chronic heart failure typically involves alleviation of congestion, improvement in cardiac output and organ perfusion, and maintenance of normal blood pressure and cardiac rhythm. Patients with heart failure can be categorized into those with subtle symptoms such as mild exercise intolerance or respiratory signs versus patients with debilitating and life-threatening clinical signs such as severe respiratory distress, collapse, syncope, or cardiogenic shock. Congestive heart failure (CHF) specifically refers to patients with evidence of congestion in the form of pleural or abdominal effusion, pulmonary edema or, much less commonly, peripheral edema.

A variety of cardiac medications are used to restore and maintain adequate cardiac function, along with diet changes, nutritional supplements, and body cavity centesis. During therapy of both acute and chronic heart failure, patient hydration status, electrolytes, renal function, blood pressure, urine output, respiratory rate and effort, and body weight are monitored. During this time, patient quality of life can remain very high in the absence of significant amounts of congestion or adverse medication side-effects. As heart disease progresses, doses and number of cardiac drugs are increased along with increasing risk of adverse effects. In this chapter, the therapy of chronic, acute, and refractory heart failure will be presented.

Management of Chronic Heart Failure

The major goals of treatment of CHF are to alleviate and prevent mild clinical signs, reduce likelihood of recurrent episodes of acute life-threatening heart failure, and increase longevity.

Management begins with a thorough medical history and physical examination. Subtle changes in the resting respiratory rate and/or exercise capacity can be useful gauges that help clinicians formulate or modify treatment plans. In this capacity, owner education and home monitoring are essential components of successful therapy. Rarely do canine or feline patient with early CHF cough nor do they exhibit dramatic changes in activity or exercise. Thus, daily monitoring of their resting home respiratory rate is often the most effective monitoring tool to detect CHF symptoms in their early stages.

Common oral medications for treatment of chronic heart failure can be divided into the following five main groups: diuretics, vasodilators, modulators of neurohormonal systems, antiarrhythmic agents, and positive inotropes. Some medications will have effects in more than one group. In addition to these conventional therapies, nutritional supplements and dietary modification are often beneficial. In order to limit adverse reactions to medications, close monitoring of electrolytes, biochemical parameters, hydration status, and blood pressure along with serial cardiac-specific tests (i.e., chest radiographs, electrocardiograms, echocardiograms) aid the practitioner in achieving effective treatment. Each patient responds to medications differently and therapy is individualized to each cardiac patient.

Treatment of chronic heart failure depends almost entirely on medical therapy. Exceptions would include CHF due to bradycardia that is treated with artificial pacing, or CHF due to congenital heart defects such as patent ductus arteriosus that are treated using surgery or minimally invasive catheter-based techniques. Advancements in the surgical management of degenerative valve disease have been made over the past few years but due to cost and limited surgical centers that perform the surgery, surgical valve repair or replacement is not a widely available option for most pet owners. Due to the lack of controlled clinical trial data, some of the therapy for both chronic and acute heart failure is based on expert opinion.

Drugs for Treatment of Chronic Heart Failure (Table 19.1)

Diuretics

Diuretics increase production of urine through affecting the kidney's physiologic handling of water and electrolytes. Diuretics result in an increased loss of sodium (natriuresis) that is followed by water and other electrolytes. Diuretics are the first-line therapy in patients with chronic CHF, but despite their efficacy in resolving and preventing congestion, they are not typically used as monotherapy due to their activation of the renin-angiotensin-aldosterone system (RAAS). One instance when diuretics are contraindicated for the treatment of CHF is in patients with pericardial effusion and cardiac tamponade. In this group, cardiac output is markedly dependent on preload, and aggressive diuresis will worsen cardiac output, potentially leading to cardiogenic shock.

Furosemide

Furosemide is first-line therapy in the management of chronic CHF. The goal of therapy is to prescribe the lowest diuretic dose required to control the clinical symptoms of congestion and edema. Compared to treatment of pulmonary edema, relatively higher diuretic dosages are often required to help resolve body cavity effusions, such as pleural or abdominal effusion. In these instances, routine thoracocentesis or abdominocentesis can aid in minimizing the dose of furosemide needed.

There is a wide range of doses reported in the veterinary literature. In the authors' experience, furosemide doses of 1–4 mg/kg orally every 8–24 hours are utilized in treating chronic CHF in the dog. The typical starting dose of oral furosemide for a dog with first-time CHF is 2–3 mg/kg/day. Cats are particularly sensitive to the dehydrating effects of furosemide and dosages of 1–2 mg/kg every 12–48 hours are preferred, with most cats receiving a total of 1–2 mg/kg/day for first-time CHF. Lower doses spread over shorter dosage intervals may result in less diuretic resistance as high doses can lead to rebound effects and resistance due to greater stimulation of the RAAS. Pet owners who become adept at monitoring respiratory rates and effort can often make small adjustments in furosemide dosing at home to prevent recurrent CHF symptoms.

Adverse effects of diuretics include electrolyte imbalances such as hypokalemia (often mitigated with the concurrent use of angiotensin converting enzyme inhibitors (ACEI) or spironolactone), hyponatremia, azotemia, dehydration, and urinary incontinence. Renal function and serum electrolytes should be routinely monitored. The frequency of monitoring is based on furosemide dosage, concurrent medications, previous bloodwork results, and presence of concomitant conditions such as renal insufficiency. The authors recommend checking serum blood profiles within the first 10 days after starting or changing an existing dose of furosemide, after which routine rechecks every 3–6 months are performed. Doses of furosemide might also be adjusted after adding concomitant agents that can affect renal perfusion (i.e., vasodilators, positive inotropes, other diuretics, nonsteroidal antiinflammatory agents, etc.).

Spironolactone

Spironolactone is a diuretic as well as a neurohormonal blocking agent due to its inhibition of aldosterone. In chronic CHF, benefits of spironolactone involve modest diuresis and antiremodeling effects on the myocardium, kidneys, and vasculature through its blockade of aldosterone receptors. In humans and experimental animal models, spironolactone reduces pathologic tissue hypertrophy and fibrosis. In both human and veterinary patients, spironolactone improves survival times in patients with chronic CHF. Based on anecdotal experience, one author (SR) recommends considering spironolactone therapy in patients with progressive heart enlargement that have not yet experienced CHF, as well as those patients with chronic heart failure. In dogs with abdominal or pleural effusion, spironolactone is often co-administered with furosemide to help slow the recurrence of the effusion. Typical spironolactone dose in dogs is 2 mg/kg/day. Monitoring of renal function and electrolytes is recommended in a fashion similar to furosemide. The benefit of spironolactone in cats with CHF is unknown. Previous study in cats suggests that 1.7–3.3 mg/kg/day was well tolerated.

In dogs, adverse reactions include anorexia and hypersalivation that may be mitigated by administration with food or in a gelatin capsule, azotemia, and electrolyte imbalances. Reformulated and flavored preparations of spironolactone are difficult to administer due to their still unpleasant taste. Due to its potassium-sparing effects, spironolactone can also predispose to hyperkalemia. This is most common when spironolactone is used in combination with an ACEI.

Vasodilators

In the late 1980s and early 1990s, the use of vasodilators became part of the standard CHF treatment in both human and veterinary medicine. The benefits for the hemodynamic and, in the case of ACEI, neurohormonal aspects of heart failure contributed to widespread use across many different species and many types of heart disease. ACEI, nitrates, amlodipine, hydralazine, and sildenafil are the most common agents utilized in veterinary patients. The majority of clinical data in veterinary medicine involves ACEI for the treatment of chronic

Table 19.1 Commonly used drugs for the treatment of chronic heart failure

Drug	Indications	Dose	Comments/Adverse Effects
Diuretics			
Furosemide	Relief of congestion	Dog: 1–4 mg/kg q8–24h	Azotemia, dehydration
		Typical first-time CHF: 2–3 mg/kg/day	Electrolyte disturbances
		Cat: 1–2 mg/kg q12–24h Typical first-time CHF: 1–2 mg/kg/day	Monitor renal function
Spironolactone	Antialdosterone Hypokalemia Relief of congestion	Dog: 2 mg/kg/day Cat: 1-2 mg/kg/day	Weak diuretic Potassium sparing
Hydrochlorothiazide	Relief of congestion Refractory heart failure	Dog/Cat: 2 mg/kg q12h If used in addition to furosemide: starting at 0.5 mg/kg SID or 1 mg/kg q48h	Moderate diuretic Azotemia, dehydration Often used in refractory CHF combined with furosemide
Torsemide (Torasemide)	Relief of congestion	Dog/Cat: 0.1–0.6 mg/kg SID Typical CHF: 0.1–0.3 mg/kg SID Dose adjustments in 0.1 mg/kg/day increments	Potent diuretic, azotemia Electrolyte disturbances Monitor renal function
Vasodilators			
ACE-inhibitor	Anti-RAAS Hypertension	Enalapril Dog/Cat: 0.5 mg/kg q12–24h Benazepril Dog/Cat: 0.25–0.5 mg/kg q12–24h Lisinopril Dog: 0.25–0.5 mg/kg q24h Ramipril Dog: 0.25 mg/kg q24h Imidipril Dog: 0.25–0.5mg/kg q24h	Azotemia, hypotension Monitor renal function
Amlodipine	Hypertension Afterload reduction	Dog/Cat: 0.1–0.4 mg/kg q24h	Hypotension
Hydralazine	Hypertension Afterload reduction	Dog: 0.2–2.0 mg/kg q12h	Hypotension Gastrointestinal signs Tachycardia
Isosorbide dinitrate/ mononitrate sustained release	Preload reduction	Dog/Cat: 0.5–2.0 mg/kg q12h	Tolerance develops quickly
Sildenafil	Pulmonary hypertension	Dog: 1–3 mg/kg q8h	Variably effective Can be expensive
Positive inotropes			
Pimobendan	Increase contractility Arterial vasodilation	Dog/Cat: 0.25 mg/kg q12h	Contraindicated if outflow obstruction present
Digoxin	Increase contractility Supraventricular tach	Dog: 0.005–0.0075 mg/kg q12h Cat: 0.03125 mg/cat q24–48h	Long-half life Monitor serum levels Gastrointestinal signs
Beta-adrenergic blockers			
Atenolol	HCM Atrial fibrillation	Cat: 6.25–12.5 mg/cat q12–24h Dog: Atenolol 0.25–1.0 mg/kg q12h; Carvedilol 0.1 mg/kg q12h then titrated to 0.5–1.0 mg/kg q12h; Metoprolol 0.2–0.4 mg/kg q12h or 0.4–1.0 mg/kg q24h for sustained release	Bradycardia, hypotension Titrate doses in dogs with heart failure

(Continued)

Table 19.1 (Continued)

Drug	Indications	Dose	Comments/Adverse Effects
Calcium channel blockers			
Diltiazem	HCM Atrial fibrillation	Cat: 7.5 mg/cat q8h Cat: Cardizem CD 10 mg/kg q24h Cat: Dilacor 30 mg/cat q12h	Bradycardia, hypotension Gastrointestinal signs
	Atrial fibrillation	Dog: 0.5–1.5 mg/kg q8h Cardizem CD or Dilacor XR (sustained release) 3 mg/kg BID	
Verapamil	HCM	Cat: 1–5 mg/kg q12h	Potent negative inotrope Titrate over 2–3 weeks
Calcium Channel Blocker			
Aspirin	Antiplatelet	Dog: 1–5 mg/kg q24h Cat: 20–81 mg/cat q72h	Gastrointestinal signs
Clopidogrel	Antiplatelet	Cat: 18.75 mg/cat q24h Dog: 3–5 mg/kg q24h	Well tolerated
Nutritional supplements			
Taurine	Taurine deficiency	Dog: 35 mg/kg q12h	Long-term supplementation needed
L-carnitine	L-carnitine deficiency	Dog: 50 mg/kg q8h	Unknown efficacy

ACE, angiotensin converting enzyme; BID, twice a day (*bis in die*); CHF, congestive heart failure; HCM, hypertrophic cardiomyopathy; RAAS, renin-angiotensin-aldosterone system; SID, once a day (*semel in die*).

CHF and ACEI are considered the first-line choice for vasodilator therapy in dogs and cats with CHF. In humans, angiotensin receptor blockers can be used if ACEI are not tolerated (intractable cough is a common side-effect), but relatively little is known about the use of angiotensin receptor blockers in veterinary patients with chronic CHF.

ACE Inhibitors

ACE inhibitors are commonly used, including benazepril (0.25–0.5 mg/kg PO q12–24h in dogs and cats), enalapril (0.5 mg/kg PO S-BID in dogs and cats), lisinopril (0.25–0.5 mg/kg PO SID in dogs), ramipril (0.25 mg/kg PO SID in dogs), and imidipril (0.25–0.5 mg/kg PO SID in dogs). There is no obvious clinical benefit of one ACEI over the other and their differences lie in their absorption, metabolism, and excretion. Benazepril is activated in the liver to benazeprilat and, in dogs, is equally excreted by the biliary and renal routes while in cats, benazepril is primarily excreted by the biliary route. Enalapril is activated in the liver to its active metabolite, enalaprilat, and excreted by the kidneys. Lisinopril is absorbed in its active form and excreted by the kidney while ramipril may have more effect on tissue-specific RAAS and is partially excreted in the urine and feces.

The authors typically use enalapril as the first choice due to long-standing clinical experience with this agent as well as the convenient sizes of commercially available tablets in the US (2.5, 5, 10, and 20 mg). In instances of known renal dysfunction, benazepril is often the ACEI of choice due to its nonrenal excretion, especially in feline patients. Lisinopril is absorbed in its active form and does not require hepatic metabolism to be active. Lisinopril is excreted in the urine, and this drug could be chosen for patients with concurrent cardiac and hepatic disease.

In general, ACEI are well tolerated. The most common adverse events are azotemia and hypotension. In the authors' experience, initiating full dosing of an ACEI during concomitant aggressive diuretic treatment of acute CHF can occasionally lead to hypotension and severe azotemia. ACEI do not appear essential for the successful resolution of acute CHF, and the authors usually initiate ACEI therapy only once patients are stable with only mild or no remaining CHF (see Treatment of Acute Heart Failure later) and when hydration status and blood pressure are adequate. ACEI are not particularly potent arterial vasodilators and their benefits are most likely due to the long-term suppression of the RAAS. The authors recommend checking a baseline renal and electrolyte profile and within the first 10 days after starting the medication. Owners should be instructed to monitor for poor appetite, lethargy, vomiting, or changes in water consumption or urine output.

In instances where underlying renal insufficiency or volume depletion is present, the authors occasionally start enalapril at either 0.5 mg/kg q24h or 0.25 mg/kg BID for the first 3–5 days of treatment and titrating to a

higher dose over the first 7–10 days of treatment. Blood pressure, renal function, and electrolyte monitoring is performed every 3–6 months thereafter. In humans, idiosyncratic nocturnal cough is an important adverse effect, but this has not been reported in dogs, and any coughing is usually due to concurrent chronic airway disease.

Other Vasodilators

Other vasodilators used for treatment of chronic CHF include hydralazine, amlodipine, and nitrates. These agents are discussed in the section regarding treatment of refractory heart failure.

Positive Inotropes

Use of positive inotropes for the treatment of heart failure has been a subject of controversy due to a potential increase in the risk of sudden death due to arrhythmias. Conventional positive inotropes such as digoxin, dobutamine, and dopamine act by increasing cytosolic calcium that improves cardiac contractility but might also precipitate cardiac arrhythmias. The objective of positive inotropic therapy is to increase myocardial contractility and improve cardiac output and organ perfusion. Digoxin and pimobendan are the two most commonly used agents for the treatment of chronic CHF in the veterinary patient.

Digoxin

Digoxin is one of the oldest cardiac medications known and has positive inotropic and negative chronotropic (slowing conduction through the atrioventricular [AV] node) effects, as well as beneficial effects on the baroreceptors and neurohormonal axis such as the RAAS. Even though it has been used for over 200 years, its benefits for survival have not been proven. In dogs, pimobendan has largely supplanted digoxin as the positive inotrope of choice. Digoxin is associated with a high incidence of adverse reactions including gastrointestinal upset and cardiac arrhythmias. The recommended canine dose is 0.005–0.0075 mg/kg q12h. In cats, digoxin is not commonly used, in part due to the drug's long half-life. The feline dose is ¼ of a 0.125 mg tablet (0.03125 mg) every other day for smaller cats and once a day for larger cats. The dosage in patients with renal disease is reduced since digoxin is excreted by the kidneys. Dosage should be based on lean body mass and reduced in obese pets or those with significant ascites. Oral absorption of digoxin can be altered by the formulation, concurrent medications, or food. The elixir (0.05 mg/mL) is better absorbed than the tablet formulation although is not palatable to most cats. As such, slightly lower doses are often prescribed when using the elixir over tablets. Antacid agents like sucralfate will reduce the absorption of digoxin, as will diets high in fiber. Certain antibiotics like tetracyclines will alter the bacterial flora and may increase serum digoxin levels.

The primary indication for digoxin in dogs (and to a much lesser extent in cats) with heart disease is to slow AV nodal conduction and ventricular response rate in patients with atrial fibrillation. Digoxin is indicated for the treatment of atrial fibrillation, persistent atrial and sinus tachycardias, and progressive myocardial dysfunction. It may also help reduce syncope in patients with severe mitral regurgitation due to its pharmacologic effects, including its effects on baroreceptors. Contraindications for use include complex ventricular arrhythmias, renal disease, atrioventricular block, certain types of ventricular preexcitation, and sinus node dysfunction.

Due to the risk of toxicity, serum digoxin levels are typically monitored 10–14 days after initiation or any dose changes. Blood should be drawn 6–8 hours post pill to assess "trough" concentrations. Traditionally, serum digoxin levels between 0.8 and 2.0 ng/dL have been considered to be therapeutic. Based on recent data in humans, the authors commonly target a lower serum level of 0.6–1.2 ng/dL as lower levels remain beneficial but with a lower incidence of adverse reactions. In the authors' experience, gastrointestinal upset and anorexia can occur at levels as low as 1.5 ng/dL. Anecdotally, miniature schnauzers and Doberman pinschers are more sensitive to digoxin and lower starting doses are recommended for these breeds (no greater than 0.125 mg q12h as a starting dose in Dobermans regardless of their body weight). Pet owners are recommended to administer the digoxin along a consistent interval and regimen. Since certain foods and medications can alter absorption, the owner should continue the same feeding and dosing regimen once therapeutic serum levels are achieved. Changes in renal function will affect digoxin excretion, and digoxin and electrolyte levels are routinely evaluated every six months or when changes are made in concurrent medications.

Pimobendan

Pimobendan is widely used for the treatment of canine heart failure secondary to dilated cardiomyopathy (DCM) and myxomatous mitral valve disease (MMVD). Recently, studies have shown the benefits of this agent in the preclinical stage of MMVD once a moderate degree of radiographic and echocardiographic cardiac enlargement has developed.

Pimobendan is a calcium sensitizer and phosphodiesterase inhibitor and its benefits are a result of the combination of positive inotropic properties along with effects as a vasodilator. Its dual action is often indicated by the term "inodilator." Pimobendan is used as the first-line

positive inotrope and forms part of standard "quadruple therapy" for CHF in dogs along with ACEI, furosemide, and spironolactone. The recommended dose in dogs is 0.5 mg/kg/day divided into two doses given 12 hours apart. Pimobendan has also been shown to prolong time to CHF and death in asymptomatic Doberman pinschers with echocardiographic evidence of reduced systolic function and ventricular enlargement consistent with preclinical DCM. In humans, positive inotropes exacerbate cardiac arrhythmias that can lead to increased risk of sudden death, and use of pimobendan in Doberman pinschers with preclinical DCM and severe ventricular arrhythmias has not been specifically evaluated.

In general, pimobendan is well tolerated. The most common adverse reaction is anorexia and diarrhea that often resolves at lessened dosage. Pimobendan should be used with caution in disorders with a ventricular outflow tract obstruction such as congenital subvalvular aortic stenosis or hypertrophic obstructive cardiomyopathy.

Pimobendan does not have an approved use in cats with CHF, but has been occasionally used in cats with heart failure. Pimobendan is not recommended in the preclinical stages of feline cardiomyopathy or in cats with left ventricular outflow tract obstruction. Pimobendan is most often used in cats with systolic myocardial dysfunction that is associated with dilated cardiomyopathy as well as end-stage hypertrophic cardiomyopathy (HCM), restrictive cardiomyopathy (RCM), and arrhythmogenic right ventricular cardiomyopathy cases. Most reports of pimobendan use in cats utilize the same dosing protocol that is used in dogs (0.25 mg/kg BID). The overall safety and efficacy of pimobendan in cats requires further study.

Beta-Adrenergic Blockers

Beta-adrenergic blockers (BB) are part of standard care in humans with systolic dysfunction. Chronic administration of BB such as carvedilol or metoprolol results in improved contractility, myocardial protection from circulating catecholamines, and improved survival. Whether or not BB benefit veterinary patients with heart disease or failure is unknown as there are relatively limited data compared to ACEI and pimobendan. The three most common clinical situations for which BB are typically considered are rate control of atrial fibrillation wherein BB are co-administered with digoxin, in the preclinical or stable heart failure phase of DCM in dogs, and in cats with HCM or RCM, with special consideration for cats with dynamic left ventricular outflow tract obstruction.

Beta-adrenergic blockers are often used in conjunction with digoxin to treat persistent supraventricular arrhythmias such as atrial fibrillation (see Chapter 21). The BB dose can be gradually up titrated to achieve target heart rate. Overly aggressive combinations of digoxin, BB, and calcium channel blockers can produce bradycardia. Some cardiologists recommend BB during the preclinical phase of DCM in dogs. Successful institution and titration of BB is regarded as easier in the preclinical phase as opposed to starting BB after development of CHF. Sudden withdrawal of BB can result in reflex tachycardia so that dosing should continue even if CHF eventually occurs. However, the dosage may require adjustment based on clinical symptoms, blood pressure, and heart rate. Limited studies in dogs indicate that titration of BB is relatively well tolerated by patients, but the long-term effect on cardiac function and survival is unknown.

In general, BB should only be introduced in patients free of active CHF as their negative inotropic properties can acutely reduce cardiac function and exacerbate clinical signs. When used in dogs with DCM, BB are typically titrated upward over 4–8 weeks. The initial prescribed dosage of BB is as little as 1/10th of the target dose and titrated upward based on heart rate and blood pressure. The authors will often temporarily increase the dose of concurrent furosemide while introducing BB in patients with advanced disease. Gradual reduction in the dosage over several weeks is recommended if a decision is made to cease treatment with chronic BB. Systemic hypotension can be seen when BB are used concomitantly with vasodilatory drugs such as ACEI or pimobendan. BB use in the preclinical phase of MMVD is not recommended. BB are commonly used to slow heart rate in cats with HCM or RCM, especially if left ventricular outflow tract obstruction due to systolic anterior motion of the mitral valve is present (see Chapter 27). BB are usually not prescribed to cats with active CHF; rather, they are used in the preclinical or stable heart failure phases. Typically, BB are titrated to achieve in-hospital heart rate less than 160 bpm in cats. Monitoring of heart rate, systolic blood pressure, and severity of left ventricular outflow tract obstruction is recommended in cats with HCM.

The various BB are classified according to their selectivity for different beta-receptors. Additionally, there are differences involving lipophilicity, metabolism, antiarrhythmic effects, and vasodilatory properties amongst the various BB. The most common BB used in veterinary cardiology include atenolol, carvedilol, metoprolol, and sotalol.

Atenolol is a beta-1-specific antagonist dosed at 0.25–1 mg/kg BID in dogs and 6.25–12.5 mg/cat q12–24h in feline patients. Atenolol is commonly used in the treatment of HCM in cats and congenital subvalvular aortic stenosis in dogs. Carvedilol is a nonspecific BB, acting on both beta-1 and beta-2 receptors, and has adjunctive alpha-1-adrenergic blocking effects leading to vasodilation. Carvedilol is metabolized in the liver and

there are rare reports of hepatotoxicity. Initial dosage of carvedilol is 0.05–0.1 mg/kg BID and is slowly titrated upward over 4–8 weeks to a final target dose of 0.5–1.0 mg/kg BID. Metoprolol is a beta-1-specific antagonist that is metabolized by the liver. Target dose is 0.2–0.4 mg/kg BID and 0.4–1 mg/kg q24h for the sustained-release preparation. In humans, studies suggest a benefit of sustained-release formulations due to more stable blood levels. Sotalol is a nonselective BB with potassium channel-blocking antiarrhythmic properties. It is primarily used as an antiarrhythmic agent in dogs with DCM or arrhythmogenic right ventricular cardiomyopathy and is dosed at 1–3 mg/kg BID in dogs and 2 mg/kg BID in cats (see Chapter 20).

Calcium Channel Blockers

Diltiazem, amlodipine, and rarely verapamil are calcium channel blockers (CCB) used in the management of chronic heart failure. Differences in the three agents center around their propensity for cardiac effects on heart rate and myocardial contractility versus peripheral effects of smooth muscle relaxation and peripheral vasodilation. Among the most commonly used CCB, amlodipine has the greatest vasodilatory properties, followed by diltiazem and then verapamil. Conversely, verapamil is a potent negative cardiac chronotrope and negative inotrope, followed by diltiazem and then amlodipine, the latter of which has very little effect on cardiac myocardial tissue.

In dogs, the most common indication for diltiazem is for ventricular rate control in atrial fibrillation and is dosed at 0.5–1.5 mg/kg q8h (See Chapter 21) Sustained-release preparations (Cardizem® CD and Dilacor®) are dosed at 3 mg/kg BID in dogs. Diltiazem is often prescribed in cats with HCM with or without atrial fibrillation and including cats with left ventricular outflow tract obstruction. The authors use either diltiazem or atenolol in cats with severe HCM and echocardiographic evidence of diastolic dysfunction. Diltiazem is typically added to the treatment regimen once the cat is receiving furosemide, ACEI, and antithrombotic agents. In cases of active CHF, the authors often delay initiation of CCB or BB until after the patient is stable on the aforementioned cardiac drugs to try to reduce the incidence of adverse reactions, such as bradycardia or hypotension. In cats, diltiazem is dosed at 7.5 mg/cat q8h. Sustained-release diltiazem preparations are available (Cardizem CD, 10 mg/kg q24h; Dilacor XR 30 mg/cat q12 h).

Canine patients generally tolerate diltiazem while cats have a higher incidence of gastrointestinal upset, loss of appetite, and hypersalivation. The authors recommend administering diltiazem with food or encapsulating the tablet in a gelatin capsule to hide the adverse taste from the cat. Diltiazem has some negative inotropic effects that can exacerbate signs of CHF, although this is less common than with BB. Diltiazem also has mild vasodilatory properties and monitoring blood pressure and heart rate is recommended.

Verapamil is rarely used in veterinary patients although it is commonly used in humans with HCM. One author (SR) has seen benefit in feline HCM patients with severe left ventricular hypertrophy and dynamic left ventricular outflow tract obstruction. Verapamil provides heart rate control in addition to supposed effects on diastolic function. Gastrointestinal side effects are common when using verapamil and can be minimized by administering with food. In cats, verapamil has a starting dose of 1 mg/kg BID with upward titration based on clinical signs, heart rate, and blood pressure over 2–3 weeks to a maximal dose of 5 mg/kg BID, with a target heart rate between 120 and 160 bpm. Amlodipine will be discussed under the refractory treatment of congestive heart failure.

Antithrombotic Therapy

Thromboembolism is a common risk factor in human patients with chronic heart failure, especially in the presence of atrial fibrillation. In dogs, clinical systemic arterial thrombosis is uncommon while in cats, arterial thromboembolism is a devastating clinical complication of cardiomyopathy. The exact mechanism behind arterial thrombosis is complex and the most effective strategy to prevent and treat is unknown.

Chronic oral agents commonly administered to reduce the risk of thrombosis are aspirin and clopidrogrel. Less commonly, warfarin or injectable unfractionated or low molecular weight heparin are used. More recently, the use of factor Xa inhibitors like rivaroxaban and apixaban has been recommended for patients with recurrent emboli or poor tolerance to other antithrombotic agents. In one study, clopidogrel was more effective than aspirin in preventing reoccurrence of thromboembolism in cats with a previous history of thrombus. Antithrombotic agents are also empirically administered in cases with a perceived increased risk thromboembolism. These risk factors include the presence of an intracardiac thrombus, spontaneous echocardiographic contrast ("smoke"), severe left atrial dilation, protein-losing nephropathies, hypoproteinemia, pulmonary hypertension, immune-mediated hemolytic anemia or heartworm disease. For aspirin therapy, the authors utilize 20–81 mg/cat q72h in cats and 1–5 mg/kg q24h in dogs. Clopidrogrel is dosed at ¼ of a 75 mg tablet (18.75 mg) q24h in cats and 3–5 mg/kg q24h in dogs. Cats, in particular, often do not like the taste of clopidrogel, which can lead to vomiting, hypersalivation, anorexia, and difficulties in pill administration.

Antithrombotics agents can lead to adverse reactions when used with corticosteroids or nonsteroidal antiinflammatory agents and might reduce the efficacy of

some cardiac therapies such as diuretics or spironolactone. During administration, renal function is monitored and pet owners are instructed about possible gastrointestinal side-effects. Chronic monitoring of coagulation profiles is not required with aspirin and clopidrogel and thus they are more commonly used in veterinary patients than anticoagulant agents such as warfarin or heparin.

Dietary Modifications

Maintenance of caloric intake is essential in the management of chronic heart failure. Traditionally, restriction of sodium was regarded as beneficial for the management of heart disease despite concern that very low sodium diets may further activate the RAAS. Diets that are mildly (80–100 mg Na/100 kcal) or moderately (50–80 mg Na/100 kcal) restricted in sodium should be considered for patients with chronic CHF. Severely sodium-restricted diets (<50 mg Na/100 kcal) are reserved for patients with advanced heart failure, severe hypertension, or cardiogenic body cavity effusions. Monitoring of blood electrolytes, in particular sodium and potassium, is important if severely sodium-restricted diets are fed.

Chronic heart failure is a catabolic state and results in a progressive loss of body condition and muscle tone. This "cardiac cachexia" requires adequate caloric and protein intake. In patients with concurrent renal disease, protein intake needs to be balanced between these competing conditions. The catabolic state is partly a result of inflammatory mediators and some evidence suggests the benefit of fish-based omega 3 fatty acids to help slow weight loss. Supplementation with the omega 3 fatty acids is typically considered in patients with weight loss and muscle wasting as well as in patients with ventricular arrhythmias (see Chapter 26). Care should be taken to avoid the fish oils that are combined with other sources such as flax seed oil or cod liver oil due to the potential for vitamin D toxicosis. Fish oil is dosed based on the amount of beneficial omega 3 fatty acids provided. In dogs, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are dosed at 40 mg/kg and 25 mg/kg per day, respectively.

Taurine deficiency is a known cause of dilated cardiomyopathy in cats, but due to universal supplementation in commercial cat food, this form of cardiomyopathy is rarely detected. In rare cases of feline taurine deficiency, patients are supplemented with taurine at 250 mg PO BID. Taurine deficiency has also been reported in various breeds of dogs, including Newfoundlands, American cocker spaniels, and golden retrievers. In these dogs, taurine-deficient DCM is treated with 35 mg/kg taurine BID. A complete diet history and whole blood or plasma taurine assay are recommended by the authors in any dog with apparent DCM diagnosed in a breed other than the "typical" breeds (i.e., Doberman pinscher, Great Dane, boxer, mastiff, or Irish wolfhound) known for this disease. L-carnitine (50 mg/kg PO TID) and coenzyme Q10 (30–90 mg PO BID) are two additional supplements. L-carnitine is most commonly considered in American cocker spaniels that are taurine deficient. Unlike taurine deficiency, diagnosis of L-carnitine deficiency requires myocardial biopsy, which is rarely performed. In a small unpublished evaluation of Dalmatians with dilated cardiomyopathy, one of the authors (SR) found improved survival times when taurine, carnitine, and coenzyme Q10 were administered along with conventional cardiac therapy.

Therapy for Refractory Chronic Heart Failure

As previously described, conventional treatment of chronic CHF in dogs consists of "quadruple" therapy with furosemide, ACEI, pimobendan, and spironolactone. In patients with refractory CHF despite conventional therapy, additional treatments are provided in order to combat recurrent symptoms of heart failure.

Additional Diuretics

Recurrent CHF necessitates gradual increases in the doses of diuretics such as furosemide and spironolactone. A common clinical observance is the apparent reduction of diuretic efficacy as furosemide doses approach 6–12 mg/kg/day in dogs and 3–4 mg/kg/day in cats. The reasons for diuretic resistance are varied and complex. One cause is the reduction of oral bioavailability and resultant decrease in plasma concentration. This, coupled with poor organ perfusion due to low cardiac output, reduces the delivery of furosemide to the nephron. In cases of advanced CHF, and particularly in cases of recurrent abdominal or pleural effusion, the authors often consider replacing one or more oral administrations of furosemide with a daily subcutaneous injection of furosemide. Anecdotal experience indicates that restoration of diuresis can often be achieved using this strategy. As with insulin injections, owners can quickly learn to how administer SC injections at home. Injectable furosemide is light sensitive and owners are instructed to keep the drug out of direct light. Injectable furosemide is relatively alkaline and may cause reactions at the injection site that include local scabbing or plaque formation. In the authors' experience, these appear less common when using the Salix® brand of furosemide.

A common strategy in patients with refractory CHF is to layer additional diuretics onto the existing furosemide therapy. This strategy of "sequential nephron blockade" involves adding diuretics that act at sites other than the loop of Henle. Addition of hydrochlorthiazide (0.5 mg/kg SID or 1 mg/kg q48 h) or, if not already being administered, spironolactone (2 mg/kg/day) can be considered. Adverse reactions to high-dose or multiple diuretics include severe azotemia, anorexia, dehydration, and electrolyte abnormalities. This is particularly important in patients are partially anorexic or eating diets severely restricted in sodium.

Another option to improve diuresis is to replace furosemide with another diuretic such as torsemide (alternative spelling, torasemide). Torsemide, like furosemide, is a loop diuretic. In humans, torsemide is characterized by more reliable gastrointestinal absorption, a longer half-life, and adjunctive antialdosterone effects. In dogs, torsemide has a longer half-life and is well suited for both resolution and long-term control of CHF. Torsemide is markedly more potent than furosemide and the recommended dose range for treatment of CHF in dogs is 0.1–0.6 mg/kg SID. Dogs with mild CHF typically require 0.1–0.3 mg/kg SID and any increases in dose in response to reoccurrence of clinical signs are done in 0.1 mg/kg/day increments. In dogs with CHF refractory to existing doses of furosemide (typically >6 mg/kg/day), replacement of furosemide involves replacing the total daily dose of furosemide with 1/10th to 1/20th the dosage of torsemide. For example, if the existing furosemide dose was 25 mg BID, the equivalent torsemide dose would be 1/10th to 1/20th of 50 mg or 2.5–5 mg per day. There are limited reports of use of torsemide in cats. The dose range in cats is likely similar to that in dogs. Torsemide, like all diuretics, requires close monitoring of renal function, electrolytes, blood pressure, hydration status, and body weight.

Clinicians might wish to consult with a specialist to discuss individualized treatment and monitoring plans in patients with refractory CHF. In general, the need for diuretics in addition to or in place of furosemide in patients with refractory signs of CHF is considered a poor prognostic sign.

Volume depletion is caused by high dose and potent diuretics and affects renal excretion of other cardiac drugs, such as digoxin, and close monitoring of such drugs is needed.

Thus, the risk for digoxin toxicity increases with worsening hypovolemia. In late stages of CHF, free water retention by arginine vasopressin (antidiuretic hormone) can result in severe hyponatremia and hypochloremia. These electrolyte derangements can be difficult to treat. Occasionally, cautious addition of sodium chloride or potassium chloride to the diet, warm sodium chloride enemas, diuretic reduction, or cautious restriction of water intake can be performed. Hyponatremia is considered a poor prognostic sign in dogs with chronic CHF.

Additional Vasodilators

Patients with refractory CHF might benefit from vasodilator therapy in addition to standard administration of ACEI. In these instances, use of arterial vasodilators such as hydralazine or amlodipine is occasionally considered. Due to the perceived relationship between afterload (which is approximated by the aortic systolic blood pressure) and degree of mitral regurgitation, arterial vasodilators are often considered in dogs with refractory CHF due to MMVD, but their efficacy in reducing the degree of regurgitation is unknown. The limiting factor in the administration of additional vasodilators is systemic hypotension, and vasodilators are not prescribed if the baseline systemic systolic blood pressure is <100 mmHg. Amlodipine (0.–0.4 mg/kg PO BID in dogs and cats) is a calcium channel blocker with potent antihypertensive properties. A starting dosage of 0.1 mg/kg BID and uptitrating over two weeks to the higher dosage of 0.3–0.4 mg/kg BID is typically well tolerated. Prior to the widespread use of amlodipine as an antihypertensive agent in both dogs and cats, hydralazine was often used in dogs and continues to be an option in refractory cases of canine MMVD. Hydralazine (0.5–2 mg/kg PO BID) is a direct-acting vasodilator with a shorter half-life and more rapid onset of action than amlodipine. Thus, acute hypotension and reflex tachycardia are more common than with amlodipine. In emergency situations where acute arterial vasodilation is needed (i.e., acute life-threatening CHF or systemic hypertension), hydralazine is considered. Common adverse effects of hydralazine include hypotension and gastrointestinal signs.

Oral nitrate compounds such as sustained-release isosorbide dinitrate or mononitrate (0.5–2.0 mg/kg PO BID in dogs and cats) are infrequently used as a venous vasodilator. Administration is usually performed when signs of congestion persist despite diuretic usage or further increases in diuretic usage are hindered by concomitant azotemia or arterial hypotension. Due to rapid development of tolerance, oral nitrates are typically administered in two doses eight hours apart with a 16-hour drug-free interval. In humans who are intolerant of ACEI, hydralazine or amlodipine along with an oral nitrate is administered, albeit with less clinical benefit than ACEI.

Pulmonary hypertension (PHT) (see Chapter 23) is a common complication in patients with advanced heart failure, especially those with MMVD. Signs of PHT include right-sided heart failure, syncope, and persistent tachypnea in the absence of pulmonary edema.

Echocardiography can help confirm the diagnosis. Phosphodiesterase V inhibitors, such as sildenafil (1–3 mg/kg PO TID) or tadalafil (1 mg/kg PO SID) are variably effective. In the authors' experience, sildenafil seems to be more effective than tadalafil. Both drugs can be very expensive, especially in large-breed dogs. Both agents are well tolerated in dogs. Rarely, inguinal flushing and gastrointestinal upset are noted. Systemic hypotension is rare. Monitoring of the clinical symptoms as well as pulmonary and systemic pressures is recommended.

Positive Inotropes

In cases of refractory heart failure due to DCM or MMVD, off-label dosages of pimobendan are often utilized. The authors will increase frequency of dosing from 0.25 mg/kg BID to TID followed by a slow titration to 0.5 mg/kg TID as needed. Additional pimobendan can also be effective in cases of biventricular heart failure as well as in patients with PHT. Cats with DCM or other forms of systolic dysfunction also appear to tolerate doses of pimobendan greater than 0.25 mg/kg BID. On rare occasions, three days of dobutamine infusion in the hospital at 2.5–10 µg/kg/min can be considered as there might be some residual positive inotropic benefit for some time after the hospitalization. Oral digoxin can be added to the existing treatment regimen, especially if tachyarrhythmias such as atrial fibrillation are present. Care should be taken to monitor serum digoxin levels to avoid toxicity.

Cough Suppression

Many canine patients with chronic heart failure develop a cough secondary to bronchial compression as a result of bronchomalacia and severe atrial dilation. In the absence of CHF, a variable amount of cough suppression is achieved with hydrocodone (0.22–0.44 mg/kg PO B-QID) or butorphanol (0.55 mg/kg PO B-QID). Bronchodilators, such as aminophylline or theophylline, are typically ineffective.

Therapy of Acute Life-Threatening Heart Failure

Therapy for acute-life threatening heart failure is based on many of the same principles that guide therapy for chronic heart failure, namely diuresis to alleviate congestion, vasodilators to reduce preload and afterload, and positive inotropes to improve myocardial contractility (Table 19.2). In acute heart failure, hemodynamic abnormalities such as congestion and low cardiac output predominate and therapy is targeted towards resolution of congestion, such as pulmonary edema, pleural effusion, or ascites, and improvement of forward cardiac output and tissue perfusion. In general, more attention is given to stabilization of hemodynamics versus interruption of neurohormonal systems, such as the RAAS or sympathetic nervous systems that are so critical to treatment of chronic heart failure.

Diuretics

Diuretics are a mainstay of treatment of acute CHF. Treatment induces potent and rapid diuresis. Parameters commonly monitored during diuresis include respiratory rate and effort, body weight, urine production, electrolytes, renal function, and blood pressure. Furosemide is the most commonly used diuretic for the treatment of acute CHF. When given by IV, IM, or SC routes, diuresis begins within 5–10 minutes and reaches a peak at 30–60 minutes with duration of action between two and three hours. A typical initial dose is 2–4 mg/kg IV/IM/SC in dogs and 1–2 mg/kg IV/IM/SC in cats. Because of its relatively short duration of action, repeated bolus injections of furosemide are needed if respiratory rate and other clinical signs are not improved within 2–4 hours after initial dose. During administration, patients should produce large quantities of dilute urine, and failure to induce diuresis should alert clinicians to the possibility of underlying renal dysfunction, poor forward cardiac output, and/or reduced renal perfusion. In patients with left-sided CHF such as pulmonary edema, the simplest way to monitor response to diuretics is to monitor respiratory rate and effort. Most patients with severe pulmonary edema will exhibit respiratory rates at presentation >45 breaths/min with increased abdominal effort and orthopnea. As diuretics resolve pulmonary edema, the respiratory rate and effort should begin to decrease, signaling an ability to reduce frequency of diuretic injections to q6–8h. Continued improvement in respiratory rate and effort over the subsequent 12–24 hours leads to replacement of parenteral furosemide with oral furosemide.

Diuretic therapy for treatment of acute CHF should be personalized for individual patients depending on the severity of clinical signs, current or previous therapy with oral diuretics, co-administration of other heart failure medications, hydration status, renal function, and blood pressure. In general, patients with extreme respiratory distress or those already receiving oral diuretics will require higher initial starting doses and more frequent repeated boluses, while those with preexisting renal dysfunction, dehydration, or low blood pressure will require more conservative dosing. Renal and electrolyte bloodwork as well as blood pressure measurement are typically performed as soon as practicable after

Table 19.2 Commonly used drugs for the treatment of acute heart failure

Drug	Indications	Dose	Comments/Adverse Effects
Diuretics			
Furosemide	Relief of congestion	Dog: 2–4 mg/kg IV/IM/SC q2–4h; 0.66 mg/kg IV bolus followed by 0.66 mg/kg/h CRI Cat: 1–2 mg/kg IV/IM/SC q2–4h	Azotemia, dehydration Electrolyte disturbances Monitor renal function Repeated doses based on respiratory rate and other signs
Vasodilators			
ACE inhibitor	Anti-RAAS Hypertension	Enalapril Dog/Cat: 0.5 mg/kg q12–24h Benazepril Dog/Cat: 0.25–0.5 mg/kg q12–24h Lisinopril Dog: 0.25–0.5 mg/kg q24h Ramipril Dog: 0.25 mg/kg q24h Imidipril Dog: 0.25–0.5 mg/kg q24h	Azotemia, hypotension Monitor renal function Initiation might be delayed until acute congestion resolved
Sodium nitroprusside	Hypertension Afterload reduction Preload reduction	Dog: 1–10 µg/kg/min CRI	Hypotension, monitor blood pressure Light sensitive Typically only used for 12–48 h
Nitroglycerin	Afterload reduction Preload reduction	Dog: 1–10 µg/kg/min CRI	Hypotension, monitor blood pressure Typically only used for 12–48 h
Hydralazine	Hypertension Afterload reduction	Dog: 0.2–2.0 mg/kg q12h	Hypotension Gastrointestinal signs
Sildenafil	Pulmonary hypertension	Dog: 1–3 mg/kg q8h	Variably effective Expensive
Positive inotropes			
Dopamine	Poor contractility	Dog: 1–10 µg/kg/min CRI	Tachycardia, arrhythmias Used only for 12–48 h
Dobutamine	Poor contractility	Dog: 2.5–10 µg/kg/min CRI	Tachycardia, arrhythmias (less than dopamine) Used only for 12–48 h
Pimobendan	Poor contractility Afterload reduction	Dog: 0.25 mg/kg q12h 0.15 mg/kg IV once	Contraindicated if outflow obstruction present
Digoxin	Poor contractility Supraventricular tach	Dog: 0.005–0.0075 mg/kg q12h Cat: 0.03125 mg/cat q24–48h	Long half-life Monitor serum levels Gastrointestinal signs Typically only used if atrial fibrillation is present

ACE, angiotensin converting enzyme; CRI, constant rate infusion; IM, intramuscular; IV, intravenous; RAAS, renin-angiotensin-aldosterone system; SC, subcutaneous.

initial presentation, and can help guide the initial or subsequent dosing strategy. In the majority of instances, mild azotemia, electrolyte abnormalities, increased total protein, loss of body weight, and other signs of volume depletion will be detected after the first 18–24 hours of diuretic therapy. In many cases, mild increases in BUN or creatinine and mild clinical dehydration are noted and do not necessitate complete cessation of the diuretic therapy. The possibility of severe azotemia, electrolyte imbalances, or acute kidney injury, particularly if preexisting renal dysfunction is present, is the main limiting factor regarding the dose and frequency of diuretic administration. In cases where diuretic therapy results in these signs, temporary cessation of diuretic administration along with replacement fluids administered either SC or IV might be needed.

In treating acute CHF, clinicians continuously weigh hydration status and renal function against the degree of

respiratory compromise and prescribed dose of diuretics. There is no "one size fits all" formula for diuretic administration and clinicians should constantly reassess their therapy during the first 18–24 hours. The authors discourage the routine use of IV fluid administration at the same time diuretics are being administered. Rather, they recommend offering water *ad libitum* during treatment of acute CHF to allow patients to semi-self-regulate their hydration status. Given the potency of the loop diuretics, patients will be unable to consume enough water to replace the fluids being lost. In cases of dire CHF or instances where patients obsessively drink repeated quantities of water when offered, water restriction might be needed.

While diuretics are generally considered a highly effective means of relieving congestion, inadequate response to diuretics or the inability to administer sufficient doses due to renal disease necessitates additional strategies to improve renal perfusion and decrease intravascular pressure though positive inotropes and vasodilators.

Positive Inotropes

Acute heart failure is accompanied by decreased cardiac output. Decreased tissue perfusion, particularly to the kidneys, activates sodium- and water-retaining mechanisms, such as the RAAS and SNS, leading to signs of congestion. Poor perfusion of the proximal convoluted tubule can decrease response to furosemide as active secretion of furosemide into the nephron's intraluminal space is required for its diuretic effect. Positive inotropes increase myocardial contractility and cardiac output and are particularly indicated in instances of low-output (forward) heart failure wherein signs of cardiac shock, such as weakness, pallor, hypotension, and hypothermia, are evident. Positive inotropes are often used in dogs with DCM, and less commonly in dogs with MMVD. Because most forms of feline cardiomyopathy are diastolic in nature, positive inotropes are rarely used in cats with heart failure. Positive inotropes act via increased binding of calcium ions to the myocardial actin-myosin-troponin complex, either by increasing intracellular calcium concentration or by increasing the sensitivity of the actin-myosin-troponin complex to calcium binding.

Commonly administered positive inotropes include sympathomimetic agents such as dopamine or dobutamine, calcium sensitizers such as pimobendan, and intracellular calcium agents such as digoxin. Dopamine is a precursor of norepinephrine while dobutamine is a synthetic catecholamine, and both agents bind to myocyte beta-adrenergic receptors in order to increase myocardial contractility and heart rate. At high doses, both agents also act on peripheral alpha-1 receptors to cause unwanted arterial vasoconstriction. In dogs, dopamine (1–10 µg/kg/min) or dobutamine (2.5–10 µg/kg/min) are administered via constant rate infusion (CRI) and titrated upwards to effect. Both agents are diluted in small volumes of 5% dextrose to limit the total volume of fluids administered to dogs with acute CHF. During administration, blood pressure, mentation, muscle tone, urine output, and other indices of improved tissue perfusion such as body temperature or blood lactate guide dose titration. For both dopamine and dobutamine, the rate-limiting factor during administration is tachycardia, tachyarrhythmias, or excessive vasoconstriction. Efficacy likely is best within the first 48 hours of administration, after which the effects wane as beta-receptors are saturated or downregulated.

Pimobendan is a calcium sensitizer and phosphodieterase inhibitor. Its positive inotropic action is due to its ability to increase the binding of calcium ions to the actin-myosin-troponin complex without a substantial increase in intracellular calcium concentration. This mechanism provides improved cardiac contractility without substantial concomitant increases in myocardial oxygen or energy demands. Pimobendan (0.25 mg/kg PO BID or 0.15 mg/kg IV once in dogs followed by start of oral dosing 12 hours after injection) can used in place of either dopamine or dobutamine when constant rate infusion is not practical. Pimobendan is well tolerated in dogs with acute CHF and oral dosing continues into the chronic phase of CHF once the acute episode of CHF is resolved.

Digoxin is a digitalis glycoside with modest positive inotropic effect as well as ability to reduce or slow conduction through the AV node. Its use in acute heart failure is limited by its variable oral bioavailability, long half-life, and narrow therapeutic window. Use of digoxin for acute heart failure has been largely replaced by pimobendan except in instances of atrial fibrillation or supraventricular tachycardia wherein oral digoxin (0.005–0.0075 mg/kg PO BID) is used to help slow the ventricular heart rate. The long-half life of digoxin precludes rapid achievement of therapeutic serum levels, and digoxin therapy is usually combined with other antiarrhythmic agents such as diltiazem (see Chapter 21). Toxicity includes arrhythmias and gastrointestinal signs such as vomiting, anorexia, and diarrhea. The authors discourage the use of IV digoxin administration due to a high incidence of toxicity.

Vasodilators

Venous and arterial vasodilators reduce preload and afterload, respectively. In cases of acute CHF, venous vasodilation is often used in conjunction with diuretics to help rapidly relieve congestion. Arterial vasodilation reduces peripheral vascular resistance/afterload and encourages improved cardiac output.

Nitroprusside is a potent mixed vasodilator capable of both venous and arterial vasodilation. It acts by releasing nitric oxide, which induces vascular smooth muscle relaxation. Nitroprusside is metabolized very rapidly and is administered via CRI (1–10 µg/kg/min in dogs). Its rate-limiting factor is systemic arterial hypotension, and blood pressure monitoring is highly recommended during use. Typically, the dosage is adjusted to achieve a systolic arterial blood pressure no lower than 90 mmHg. The short half-life of nitroprusside allows clinicians to effectively make changes in infusion rates in response to blood pressure. Nitroprusside, while highly effective, is only occasionally used due to its need for CRI and sensitivity to light that requires the administration set to be covered in light-protective wrapping. Similar to dopamine or dobutamine, nitroprusside infusions are given short term, typically not longer than 48 hours. At very high doses or for extended periods of administration, accumulation of nitroprusside metabolites such as cyanogen can result in toxicity. Nitroprusside is rarely used in cats. At the time of writing, supply shortages of nitroprusside have severely curtailed its use and alternative nitric oxide donors such as IV nitroglycerin (1–10 µg/kg/min) have been used.

ACE Inhibitors

ACE inhibitors form a cornerstone of therapy of chronic CHF. Their utility in acute life-threatening CHF is less evident. Compared to hydralazine or nitroprusside, the arterial dilating effects of ACEI are modest. ACEI's ability to decrease AT II and aldosterone production appears more beneficial over longer periods of time as opposed to rapidly acting short-term effects in acute CHF. The rate-limiting factors affecting ACEI use include azotemia and systemic arterial hypotension. The authors occasionally delay initiation of ACEI until acute CHF is stabilized with diuretics, positive inotropes, and other vasodilators, and are especially cautious in patients already suffering from systemic hypotension or in those that required very high doses of diuretics to alleviate congestion and are significantly dehydrated. In these cases, ACEI administration might be delayed until the patient's hydration status and renal bloodwork are reevaluated. They are then prescribed as part of the chronic CHF therapy with close monitoring of renal bloodwork and systemic blood pressure.

Additional Therapies for Acute CHF

Oxygen supplementation is provided in cases of respiratory compromise and hypoxemia. Inspired O_2 concentration is typically increased to 40% through the use of oxygen cages or, in the case of large dogs, nasal insufflation. Manual removal of pleural, pericardial, or abdominal fluid should be performed if these effusions are a cause of respiratory compromise. In patients that are extremely anxious, mild sedation with morphine (0.1–1.0 mg/kg SC/IM in dogs), acepromazine (0.1–0.2 mg/kg SC/IM in dogs) or butorphanol (0.1–0.3 mg/kg IM/IV in dogs or cats) can be considered. Care must be taken to avoid oversedation as further compromise of respiratory function can result. Bronchodilators such as aminophylline or theophylline or cough suppressants such as hydrocodone are rarely needed in cases of acute CHF.

Ventricular Arrhythmias

Amara H. Estrada, DVM, DACVIM (Cardiology)[1] and Romain Pariaut, DVM, DACVIM (Cardiology), DECVIM-CA (Cardiology)[2]

[1] *Department of Small Animal Clinical Sciences, University of Florida, Gainesville, FL, USA*
[2] *Department of Clinical Sciences, College of Veterinary Medicine, Cornell University, Ithaca, NY, USA*

Etiology/Pathophysiology

Ventricular arrhythmias (VA) such as single ventricular premature depolarizations (contractions) (VPCs) can be seen in normal animals in *low* numbers (less than 50 per 24-hour period on a Holter monitor). They are very commonly seen in association with noncardiac disease, possibly due to myocardial ischemia, electrolyte abnormalities or other factors surrounding the underlying disease. For example, VPCs can be seen following vehicular trauma (traumatic myocarditis), surgery, gastric dilation and volvulus, splenic disease, immune-mediated hemolytic anemia and/or polycythemia, hypoxia, the use of anesthetic agents (especially thiobarbiturates), pancreatitis, prostatitis, and neurologic disease. Thus, ventricular arrhythmias are relatively common to any number of different systemic diseases. They may also be associated with primary underlying myocardial diseases such as dilated cardiomyopathy in Doberman pinschers and arrhythmogenic right ventricular cardiomyopathy in boxers. They can also be idiopathic in origin, meaning that no underlying systemic or cardiac disorder can be identified.

The most important clinical considerations with VPCs are whether there is an underlying systemic or cardiac cause of the VPCs and whether there is the need to treat the VA. Decisions to treat VA should be based on hemodynamic consequences and the risk of degeneration of the VA into an unstable rhythm such as ventricular fibrillation. Single VPCs do not cause clinical signs as they are transient and hemodynamically not significant. What is more important is attempting to identify malignant characteristics of VPCs or patient groups that might be more susceptible to the development of an unstable rhythm that can lead to sudden death. However, our ability to predict the likelihood of sudden death associated with VPCs is poor. It appears that in dogs and cats with VPCs and no underlying heart disease, the number of VPCs is not predictive of the risk of sudden death, which in this setting is typically low. When there is underlying myocardial disease, the presence of VPCs may indicate an increased risk of sudden death or simply be a marker for the severity of the disease (for example, Doberman pinschers with dilated cardiomyopathy or cats with hypertrophic cardiomyopathy). The presence of VPCs in boxers with familial ventricular arrhythmias may indicate an increased risk of sudden death.

Signalment

Certain breeds with specific underlying cardiac diseases are predisposed to malignant VA. Doberman pinschers with dilated cardiomyopathy, boxers with arrhythmogenic right ventricular cardiomyopathy, dogs with severe subaortic stenosis, young German shepherds with inherited ventricular arrhythmias, dogs and cats with myocarditis and cats with hypertrophic cardiomyopathy represent situations where a VA may signal increased risk for clinical signs or sudden death. Other than the specific patient groups and underlying type of cardiac diseases mentioned above, there is no other specific age, breed or sex predilection

History and Clinical Signs

Dogs with VA secondary to systemic disease often do not need the VA to be treated as the arrhythmia tends to be self-limiting if the underlying disease is addressed. For example, a patient with VPCs and gastric dilation-volvulus does not necessarily require antiarrhythmic therapy for the VPCs, and instead needs relief of the dilation and volvulus. This will in turn lead to resolution of the

arrhythmias, usually within 72 hours. Dogs with single VPCs and underlying myocardial disease may or may not need to be treated. More often, the presence of VPCs in a patient with underlying heart disease indicates the need to further investigate the arrhythmia (e.g., with 24-hour ambulatory ECG [Holter] analysis) to determine if more serious arrhythmias are occurring at other times (Figure 20.1).

An example would be a Doberman pinscher with dilated cardiomyopathy, who is already receiving therapy but is found to have a newly discovered ventricular arrhythmia. Immediate introduction of antiarrhythmic therapy in this case may or may not be appropriate and further evaluation with Holter monitoring would be recommended. Patients with VPCs do not show clinical signs associated with only single premature beats. Even with ventricular tachycardia, if the rate of the ventricular is below 200–220 bpm, no clinical signs may be present. The rate at which a ventricular tachycardia will cause clinical signs will depend on many underlying factors such as rate, underlying myocardial function, species, and/or breed. Typically, however, when the rate of the ventricular tachycardia is rapid (greater than 250 bpm), signs of poor cardiac output will be present and syncope may occur. Clinical signs will also be influenced by the degree of underlying heart disease. Thus, the patient with systolic dysfunction and ventricular arrhythmias may exhibit clinical signs at a slower ventricular rate than a patient without underlying myocardial disease and ventricular tachycardia. Patients with more serious ventricular arrhythmias (ventricular tachycardia, ventricular fibrillation) and compromised/diminished myocardial function may have a history of exercise intolerance, shortness of breath, syncope or near syncope.

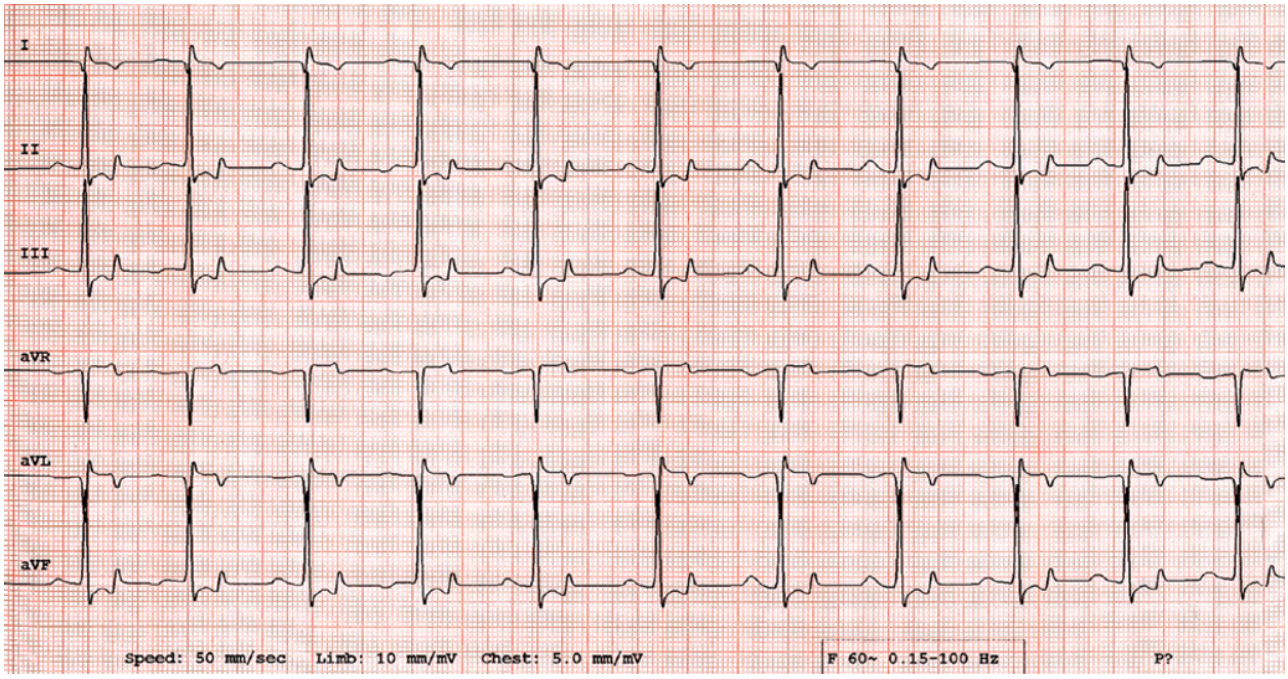
Diagnosis

Two basic ECG characteristics of VPCs are that they are premature in their timing (earlier than the sinus beat) and they are wide and bizarre in morphology compared to the sinus beat (Figures 20.2 and 20.3). They appear wide and bizarre because VPCs originate below the bundle of His and therefore cannot take advantage of the specialized conduction system. They therefore must depolarize the ventricles muscle cell to muscle cell. This is relatively slow and produces a wide and bizarre complex. QRS complexes can be positive or negative in lead II, depending on the site of origin of the VPC, and they have no relationship to the P-waves. Because depolarization occurs in an abnormal fashion, repolarization is also abnormal and there is typically a large and bizarre T-wave which is opposite in polarity to the VPC.

Ventricular premature depolarizations can occur in patterns such as ventricular bigeminy (every other beat is a VPC) and ventricular trigeminy (every third beat is a VPC). This type of pattern, however, does not correlate with severity or potential malignancy of a ventricular rhythm. More important characteristics of potentially dangerous ventricular arrhythmias include the rate of firing of a VPC and the morphology of a ventricular rhythm. If a VPC fires rapidly and occurs close to the peak of the preceding T-wave (so-called R-on-T phenomenon), depolarization during this time may predispose to ventricular fibrillation (Figure 20.4).

Ventricular rhythms can be monomorphic (one morphology) or polymorphic (several different morphologies), with the polymorphism generally considered to imply multiple origins or pathways for the arrhythmia, thus increasing the potential for degeneration into a malignant arrhythmia (Figure 20.5).

A ventricular couplet is two consecutive VPCs, a ventricular triplet is three consecutive VPCs, and ventricular tachycardia is >3 consecutive VPCs occurring at a rate of >170–180 bpm. Ventricular tachycardia is considered sustained if it lasts >30 seconds and nonsustained if it lasts <30 seconds. A ventricular rhythm that is less than approximately 140–170 bpm is not truly a tachycardia and is therefore best termed an accelerated idioventricular rhythm (sometimes referred to as slow ventricular tachycardia) (Figure 20.6).



Accelerated idioventricular rhythms are seen commonly in hospitalized patients in association with noncardiac diseases as mentioned in the beginning of the chapter. These are often benign, the rate is too slow to cause clinical signs and they often do not require therapy.

Therapy

Prior to discussing specific therapeutic interventions, it is important to review the main objectives of treating a ventricular arrhythmia: (1) to improve hemodynamics in order to alleviate clinical signs and (2) to prevent sudden death.

When making the decision to treat or not, it is important to attempt to determine whether the arrhythmia is causing hemodynamic compromise. A healthy heart can tolerate many types of VA whereas a diseased heart cannot. Therefore, the presence or absence of underlying cardiac disease is an important factor in this decision. Evaluation of the peripheral pulse quality, mucous membrane color, attitude of the patient, and arterial blood pressure can be helpful in determining whether hemodynamics are being affected. Sustained ventricular tachycardia at a high rate is more likely to cause hemodynamic compromise than an idioventricular rhythm or a ventricular tachycardia firing at slower rates.

(b)

Figure 20.1 ECG and Holter tracings from a boxer dog acquired during a screening clinic for arrhythmogenic right ventricular cardiomyopathy. (a) Six-lead ECG showing a normal sinus rhythm present with a heart rate of approximately 136 bpm. (Paper speed 50 mm/s, sensitivity 10 mm/mV.) (b) A full screen shot from a 24-hour Holter worn by the same dog. There is ventricular bigeminy present throughout the ECG on this screen (VAs in red). (Paper speed 50 mm/s, sensitivity 10 mm/mV.)

Figure 20.2 Lead II ECG from a dog with single monomorphic ventricular premature contractions (*arrows*). (Paper speed 50 mm/s, sensitivity 5 mm/mV.)

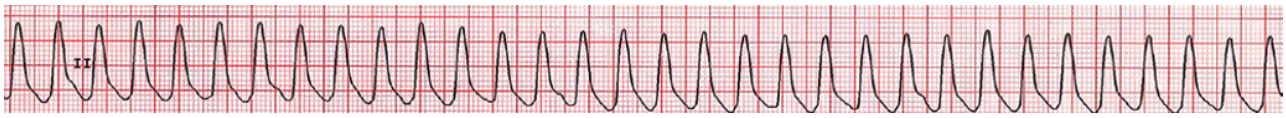

Figure 20.3 Lead II ECG from a cat with a monomorphic ventricular tachycardia at a rate of approximately 375 bpm. (Paper speed 50 mm/s, sensitivity 10 mm/mV.)

Figure 20.4 ECG strip from a dog in ventricular fibrillation. Ventricular fibrillation on the left portion of the tracing isT terminated with an external biphasic defibrillation shock, which restores a spontaneous rhythm. Note that the morphology of the two beats after defibrillation is altered (aberrant conduction) as a result of myocardial stunning from the electrical shock.

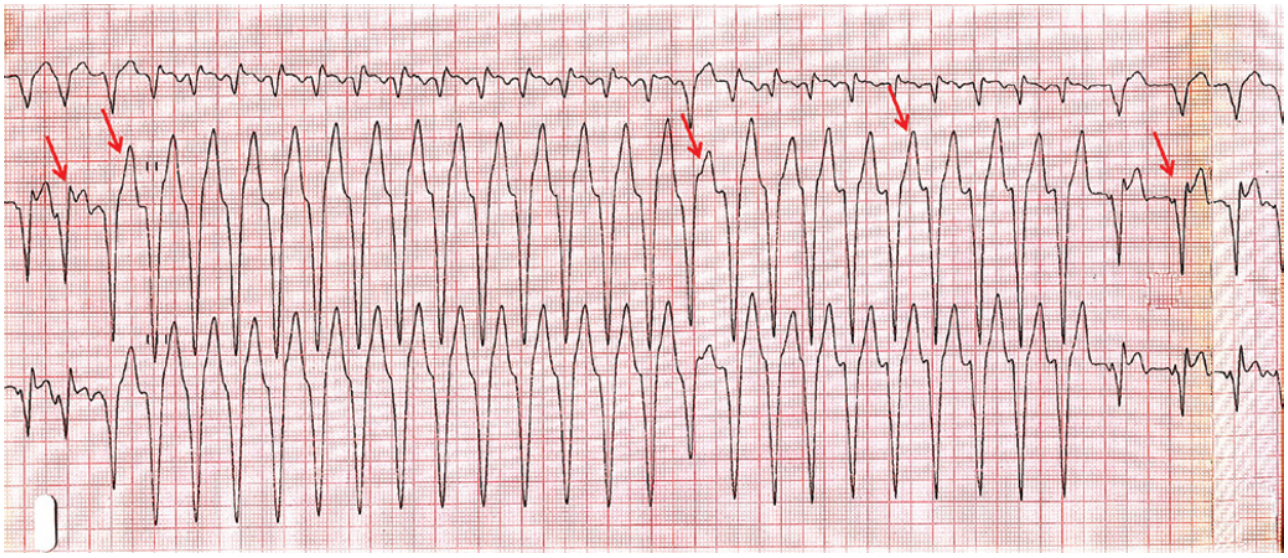

Figure 20.5 Three-lead ECG from a Doberman pinscher with polymorphic ventricular tachycardia. Note the abrupt changes in morphology of the ventricular complexes throughout the ECG (*arrows*). (Paper speed 50 mm/s, sensitivity 10 mm/mV.)

The second important consideration for decisions regarding the initiation of antiarrhythmic or other therapeutic intervention for a ventricular arrhythmia is whether the arrhythmia is likely to degenerate into ventricular fibrillation, which will cause sudden death. Again, the presence or absence of underlying cardiac disease is important since a healthy heart can tolerate more than a diseased heart. It is believed that the faster the

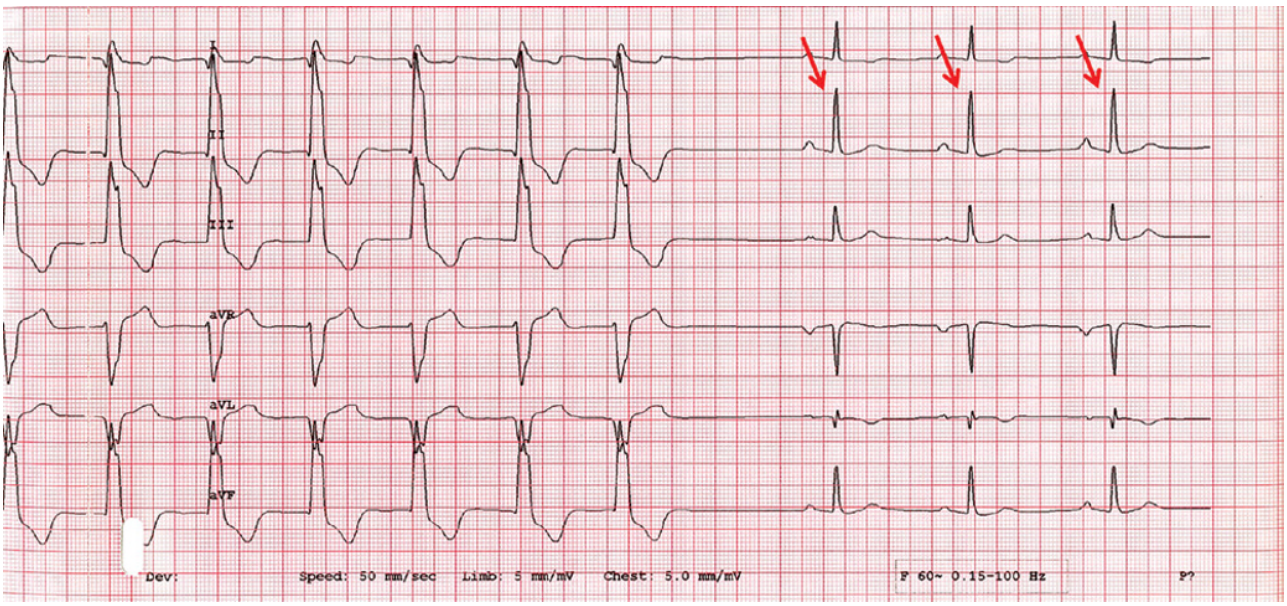

Figure 20.6 Six-lead ECG from a dog with an accelerated idioventricular rhythm. Note that the initial seven beats are wide and bizarre in morphology as typical for ventricular ectopy, but the rate is slow (approximately 125 bpm). When the idioventricular rhythm breaks spontaneously, normal sinus beats are then seen (*arrows*) at a rate of approximately 90 bpm. (Paper speed 50 mm/s, sensitivity 5 mm/mV.)

ventricular tachycardia, the more likely a beat will fall within the vulnerable period and induce ventricular fibrillation (R-on-T phenomenon). Polymorphic ventricular tachycardia is also thought to be more dangerous than monomorphic ventricular tachycardia. As mentioned above, certain patient groups appear to have an increased risk of sudden death associated with ventricular tachycardia.

Acute Therapy of Ventricular Tachycardia

Initial therapy for dogs or cats with ventricular tachycardia that is thought to be malignant and directly related to the current clinical signs is an IV bolus of lidocaine (see Table 20.1 for doses).

Lidocaine should be used with caution in cats, as they are very sensitive to its CNS effects. In both cats and dogs, it is important to determine plasma or serum potassium concentration as lidocaine will be less effective when hypokalemia is present. Thus, if lidocaine fails to convert a ventricular rhythm, assessment of a patient's electrolyte values, specifically potassium, is required. Additionally, hyperkalemia can also be a cause of supraventricular rhythms which can mimic the appearance of ventricular tachycardia in a cat.

Fortunately, most ventricular arrhythmias are responsive to therapy with lidocaine. However, some severe ventricular arrhythmias may not terminate following lidocaine injection, and in this situation, IV procainamide would be the next antiarrhythmic to administer.

Table 20.1 Typical medication doses

Drug name	Dosage
Amiodarone	Oral: 10–20 mg/kg PO q24h for 7–10 days then reduce to 3–15 mg/kg PO q24–48 h thereafter (D)
Atenolol	Oral: 0.2–1 mg/kg q12–24h (D), 6.25–12.5 mg q12–24h (C)
Esmolol	IV bolus: 0.2–0.5 mg/kg over 1 min, repeat q5min (D, C)
Lidocaine	IV bolus: 2 mg/kg over 30 s; maximum three boluses (D) 0.25–0.5 mg/kg (C) CRI 25–80 µg/kg/min (D)
Mexiletine	Oral: 4–8 mg/kg PO q8h (D)
Procainamide	IV bolus: 5–15 mg/kg over 1 min (D) 1–2 mg/kg (C) CRI 20–50 µg/kg/min (D)
Sotalol	Oral: 1–3 mg/kg q12h (D, C)

C, cat; D, dog; IV, intravenous; CRI, constant rate infusion; PO, by mouth (*per os*).

Intravenous procainamide may result in hypotension and should therefore be administered slowly. With refractory ventricular arrhythmias, magnesium sulfate supplementation can also be considered. Magnesium has primary antiarrhythmic properties similar to Class III agents, so supplementation works well in combination with lidocaine or other Class I agents. Early administration may

prevent worsening of ventricular arrhythmias and low magnesium concentrations may result in hypokalemia that is nonresponsive despite adequate supplementation. Other alternatives, such as synchronized cardioversion, esmolol or precordial thump, can be attempted if the above therapies fail to improve hemodynamic stability.

Precordial thump for control of ventricular arrhythmias was previously recommended as an initial maneuver in the treatment of ventricular tachycardia (VT) or ventricular fibrillation, but is now only considered for patients with witnessed, monitored and unstable VT resulting in cardiac arrest/asystole. A precordial thump is a very carefully aimed blow with the fist to the chest with the intent to interrupt a life-threatening rhythm. The thump is thought to produce an electrical depolarization of 2–5 joules, but is only effective if used near the onset of ventricular fibrillation. The precordial thump for VT remains controversial as precordial blows can trigger ventricular fibrillation (i.e., commotio cordis). It should only be used for asystole or ventricular fibrillation when a defibrillator is unavailable for use.

Chronic Therapy of Ventricular Tachycardia

All chronic antiarrhythmic agents have the potential to act as proarrhythmics, so their use should be monitored. This is ideally done by obtaining a 24-hour Holter recording before and 8–15 days after initiation of antiarrhythmics. If worsening arrhythmias develop, then a proarrhythmic effect should be considered as an underlying etiology. In addition, all antiarrhythmic agents have significant toxicity profiles. In both dogs and cats, the authors' first choice for chronic ventricular arrhythmia therapy is sotalol. Although not a pure beta-blocker, sotalol has significant beta-blocking effects, and should therefore be used with caution and slowly uptitrated in dogs with significant ventricular systolic dysfunction, such as those with dilated cardiomyopathy. In addition, it should not be combined with other beta-blockers. It is the first choice for boxers with arrhythmogenic right ventricular cardiomyopathy.

Amiodarone is a drug that appears to be very effective for refractory arrhythmias but it has been reported to have significant and severe side-effects. The low end of the dosage range should be used first and uptitrated only if necessary. There are many side-effects to the chronic use of amiodarone. It may cause a hepatopathy, so liver enzymes should be evaluated before starting and periodically while receiving amiodarone and any time anorexia develops. It may also cause neutropenia of unknown clinical significance and neurologic signs, and/or ataxia, especially at higher doses and with prolonged use. Amiodarone can be combined with a beta-blocker. Additionally, it does not appear to have significant negative inotropic effects and is thus safe to use in patients with ventricular dysfunction. The authors have not used this drug in cats.

Mexiletine is another useful antiarrhythmic agent, but has become increasingly more difficult to find for veterinary patients and has several times come off the market. It is often used in combination with atenolol or sotalol for refractory arrhythmias or as an initial antiarrhythmic agent for dogs with systolic dysfunction. The authors have not used mexiletine as an antiarrhythmic in cats.

Although antiarrhythmics are usually successful at controlling clinical signs in animals with ventricular arrhythmias, their ability to decrease the risk for sudden death is uncertain. Recently, the use of implantable cardioverter defibrillators (ICD) has been investigated in dogs. These devices, which have similarities with pacemakers, are extensively used in people to terminate life-threatening episodes of ventricular tachycardia or fibrillation with high-energy electrical shocks. Accurate detection of arrhythmias amenable to electrical therapy is, however, still challenging in dogs. Advances in ICD technology and programmability may help to expand their use in veterinary medicine.

Supraventricular Arrhythmias

Romain Pariaut, DVM, DACVIM (Cardiology), DECVIM-CA (Cardiology)[1] *and Amara H. Estrada, DVM, DACVIM (Cardiology)*[2]

[1] *Department of Clinical Sciences, Cornell University, Ithaca, NY, USA*
[2] *Department of Small Animal Clinical Sciences, University of Florida, Gainesville, FL, USA*

Arrhythmias are classified as supraventricular or ventricular based upon the location of the cardiac tissues responsible for their occurrence. Supraventricular anatomic structures include the sinus and atrioventricular (AV) nodes, the His bundle, the atrial myocardium, the ostia of the coronary sinus, pulmonary veins and venae cavae (Figure 21.1).

Arrhythmias can be further divided into bradyarrhythmias (heart rate <60 bpm in dogs; <100 bpm in cats) or tachyarrhythmias (heart rate typically >180–200 bpm in dogs; >220–240 bpm in cats). Major bradyarrhythmias include sinus bradycardia, sick sinus syndrome (sinus node dysfunction), atrial standstill and atrioventricular (AV) blocks. Among tachyarrhythmias, atrial fibrillation (AF) is by far the most common. Other forms of supraventricular tachycardia (SVT) are less commonly encountered in clinical practice (Table 21.1).

Sinus Bradycardia

Etiology/Pathophysiology

Sinus bradycardia (or exaggerated sinus arrhythmia) is rarely a primary disorder and is usually benign in small animal patients. It results from an underlying disease responsible for excessive vagal tone, particularly gastrointestinal, respiratory, neurologic, and ocular diseases. Drugs (digoxin, opioids, calcium channel blockers, beta-blockers), hypothermia, and hypothyroidism are other extrinsic causes of sinus bradycardia. Though rare, sinus bradycardia, when diagnosed in an animal with impaired consciousness, should raise the suspicion of elevated intracranial pressure leading to brainstem compression. The clinical picture of this physiologic response, known as the Cushing's reflex, combines bradycardia, systemic hypertension and an abnormal respiratory pattern, characterized by periods of apnea.

Signalment

There is no breed or age predisposition. These animals are usually free of any underlying cardiac disease.

History and Clinical Signs

Most dogs and cats do not display clinical signs that can solely be attributed to sinus bradycardia. However, extreme cases of sinus bradycardia may cause lethargy and collapse.

Diagnosis

On the surface ECG, P-waves are accompanied by QRS complexes and the QRS complexes are in direct association with the preceding P-wave, such that the PR interval is relatively constant. The P-waves are typically positive in leads II, III, and aVF. When markedly elevated vagal tone is the cause for the bradycardia in dogs, a wandering pacemaker, which corresponds to a variation in the amplitude of the P-wave usually in relation to the respiratory cycle, may be present. The QRS complexes are usually narrow (duration <60 ms in dogs; 40 ms in cats) (Figure 21.2).

Therapy

Treatment is usually not necessary. However, vagally induced bradyarrhythmias respond to the administration of parasympatholytic medications. An increase in heart rate following the intravenous administration of atropine or glycopyrrolate confirms the contribution of excessive vagal tone to the bradycardia. Transient AV block frequently occurs following parenteral administration of atropine, most likely because of an initial blockade

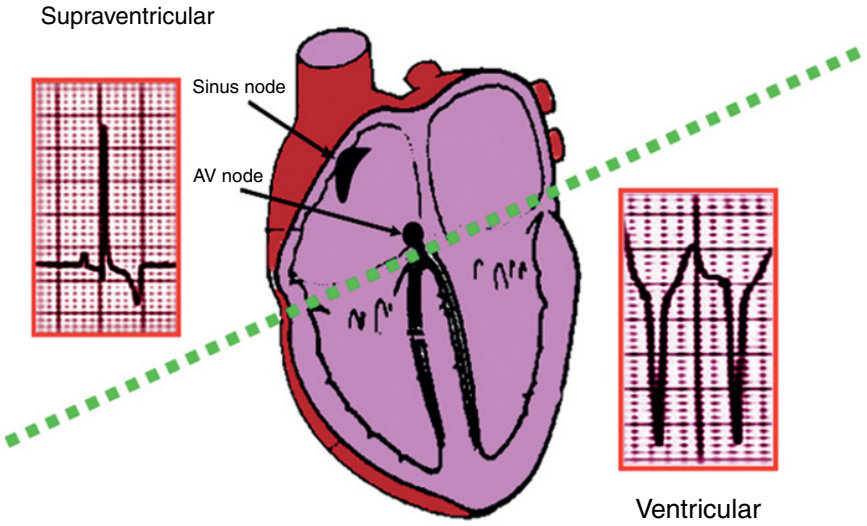

Figure 21.1 Supraventricular structures include the sinus node, the atrial myocardium, the atrioventricular node (AV node), the His bundle and the ostia of the veins entering the atria. Supraventricular rhythms are characterized by a narrow QRS complex, while ventricular rhythms are characterized by a wide and "bizarre" QRS complex.

Table 21.1 Differential diagnosis of supraventricular arrhythmias

	Rate (beats/min)	P-waves (II,III,aVF)	QRS complexes	P:QRS relationship	Regularity
Sinus bradycardia	<60 (D) <100 (C)	Positive Wandering pacemaker	Narrow	P before QRS 1:1	Regular, or regularly irregular (sinus arrhythmia)
Sick sinus syndrome	Variable pauses >3 s	Positive Negative Occasionally absent	Narrow Wide (VEB)	P before QRS	Irregular
Atrial standstill	20–60 (D)	Absent	Wide(VEB)	None	Regular
First-degree AV block	WNL	Positive Wandering pacemaker	Narrow	P before QRS 1:1	Regular, or regularly irregular (sinus arrhythmia
Second-degree AV block	WNL pauses	Positive	Narrow Wide(BBB)	P before QRS Isolated P	Irregular
Third-degree AV block	20–60 (D) 80–140 (C)	Positive	Narrow (JEB) Wide (VEB)	None	Regular
Atrial fibrillation	100–120 Lone AF 150–180 No CHF >180 CHF	Absent Fibrillation waves	Narrow Rarely wide(BBB)	None	Irregular
Focal atrial tachycardia	210–230	Positive Negative	Narrow Rarely wide(BBB)	P before QRS	Regular or irregular
Atrial flutter	180–350	Absent Flutter waves	Narrow Rarely wide(BBB)	None	regular or irregular
Junctional tachycardia	120–200	Negative	Narrow Rarely wide(BBB)	P during or after QRS	Regular
AV reciprocating tachycardia	190–300	Negative	Narrow Rarely wide(BBB)	P after QRS	Regular

AF, atrial fibrillation; AV, atrioventricular; BBB, bundle branch block; C, cat; CHF, congestive heart failure; D, dog; JEB, junctional escape beat; VEB, ventricular escape beat.

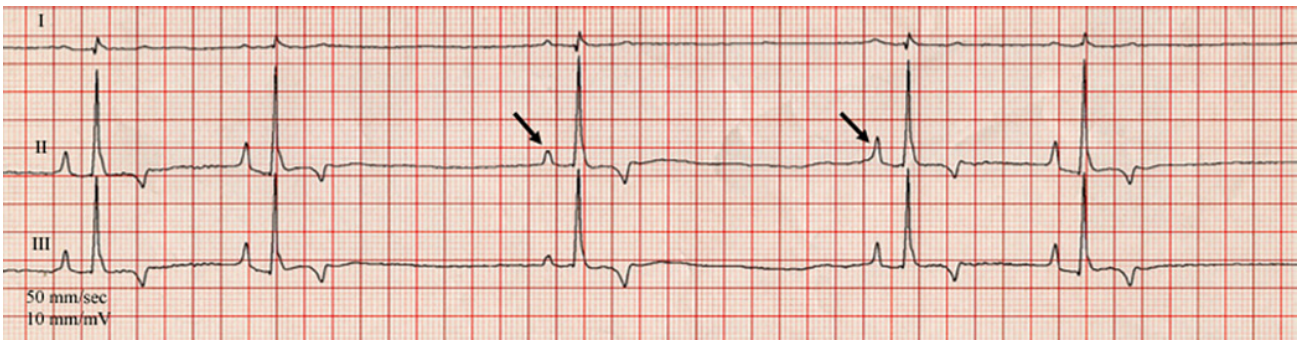

Figure 21.2 ECG of a healthy dog illustrating respiratory sinus arrhythmia with a wandering pacemaker (*arrows*).

of presynaptic muscarinic receptors that normally inhibit acetylcholine release. Once postsynaptic muscarinic blockade is established, this transient bradycardia resolves. The bradycardia subsides sooner after intravenous administration, due to a more intense chronotropic response than seen with subcutaneous and intramuscular injections. Side-effects associated with repeated injections of parasympatholytic agents, such as mydriasis, dry mouth, constipation, urinary retention, and on occasion neurologic signs, limit their chronic use.

Prognosis

In most cases, resolution of the extrinsic cause will be accompanied by a return to normal heart rate.

Sick Sinus Syndrome (Sinus Node Dysfunction)

Etiology/Pathophysiology

Sick sinus syndrome is a disease of the tissues of the conduction system characterized by periods of normal sinus rhythm or sinus bradycardia, interspersed with long periods of sinus arrest and a failure of the AV and ventricular pacemakers to initiate an escape rhythm. Lack of cardiac output resulting from a pause of approximately 6–8 seconds can lead to syncope. Histopathologic examination of the sinus node reveals degenerative changes characterized by the extensive replacement of nodal cells by fibrous and fibro-fatty tissue.

Epidemiology

Sick sinus syndrome is the indication for 15–25% of permanent pacemaker implantation in dogs. It has not been reported in cats.

Signalment

It affects older dogs with a higher prevalence in miniature schnauzers. It is also reported in pugs, cocker spaniels, dachshunds, West Highland white terriers, and other small terrier breeds. Females are at higher risk of developing sick sinus syndrome than male dogs.

History and Clinical Signs

Initially, dogs show signs of confusion, stumbling or episodic weakness, during which they become recumbent with no alteration of consciousness. These signs then progress to syncope, sometimes triggered by exercise or excitement. However, in the early stages of the disease, signs may be absent or limited to a decrease in activity level.

Diagnosis

Physical Examination

Physical examination frequently reveals periods of bradycardia, asystole or short runs of tachycardia followed by long pauses (Figure 21.3).

The presence of an apical systolic left-sided murmur on auscultation is common as these dogs are also predisposed to degenerative mitral valve disease.

Electrocardiography

Sinus arrest and sinus block cannot be differentiated, and are identified as a prolonged pause without a P-wave on the ECG. A variant of the disease, sometimes called bradycardia-tachycardia syndrome, is characterized by periods of paroxysmal SVT followed by a period of asystole, caused by the temporary failure of the sinus rhythm to resume when the tachycardia abruptly terminates.

A partial or adequate increase in heart rate in response to atropine is common in these dogs and does not rule out the presence of sick sinus syndrome, particularly when there are ECG findings compatible with the syndrome in the face of syncopal episodes. However, the use of opioids and other sedatives frequently results in a worsening of the periods of asystole. It is not uncommon that dogs which were asymptomatic while awake become hemodynamically unstable after sedation or while under anesthesia.

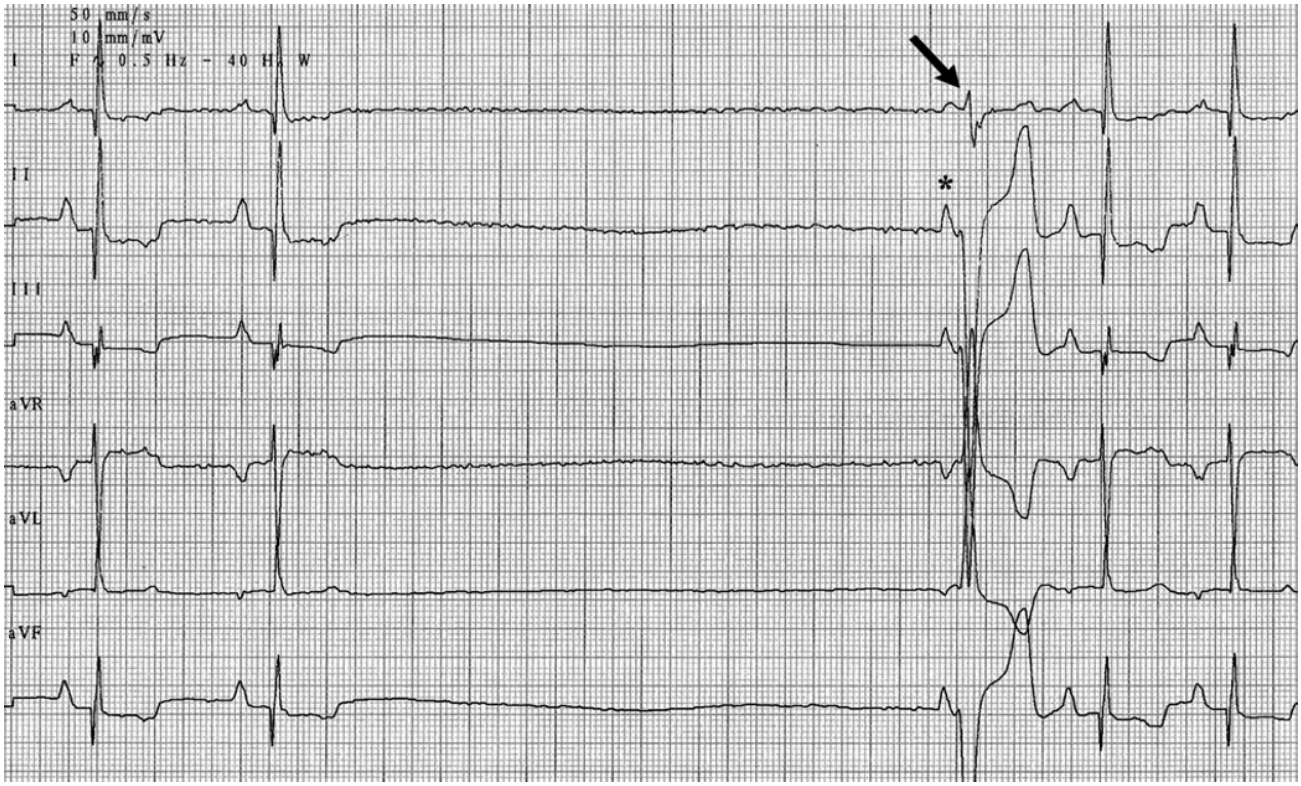

Figure 21.3 Six-lead ECG of a dog with sick sinus syndrome. After the first two sinus complexes, there is an unexpected 2.3-second pause that is terminated by a ventricular escape beat (*arrow*). Note that the propagation to the ventricles of a P-wave (*) is prevented by the occurrence of the escape beat.

Therapy

Medical Therapy

Two drugs are occasionally successful at temporarily increasing heart rate and alleviating clinical signs in dogs with sick sinus syndrome. Terbutaline is a selective beta-2-agonist commonly used as a bronchodilator. Aminophylline or theophylline is a phosphodiesterase inhibitor and bronchodilator with mild chronotropic effects. See Table 21.2 for drug dosages.

Pacemaker Therapy

Long-term management of sick sinus syndrome requires permanent pacemaker implantation. The goal of pacemaker therapy is to stimulate a heartbeat when necessary in order to maintain the heart rate within a predetermined range that optimizes cardiac output. The basic function of a pacemaker is to deliver an electric current to the heart that triggers contraction. Modern pacemakers also sense the intrinsic cardiac electrical activity, only delivering an impulse if the native conduction system fails to depolarize (Figure 21.4).

For optimal cardiac performance, the pacing system should mimic normal physiology as closely as possible. Therefore, atrial pacing when AV nodal function is unaffected by disease may be preferred in order to maintain synchrony between atrial and ventricular activity. However, the simplest and most commonly used type of pacing in veterinary patients involves a single lead placed in the right ventricle via the jugular vein.

Prognosis

Sudden death is rare in dogs with sick sinus syndrome. However, long-term quality of life is typically diminished with medical therapy alone. Conversely, permanent transvenous pacemaker implantation alleviates clinical signs in the majority of dogs with sick sinus syndrome.

Persistent Atrial Standstill

Etiology/Pathophysiology

Persistent atrial standstill, or "silent atrium," corresponds to the absence of atrial tissue depolarization and contraction, despite normal sinus nodal activity. Histologically, extensive fibrosis extends throughout the atria. It may occur secondary to the progression of

Table 21.2 Drug dosages and indications

Drug name	Dosage	Indications
Atropine	SC, IM, IV: 0.02–0.04 mg/kg (D, C)	Sinus bradycardia Sick sinus syndrome, First- and second-degree AV block
Glycopyrrolate	SC, IM, IV: 0.005–0.01 mg/kg (D, C)	Sinus bradycardia Sick sinus syndrome, First- and second-degree AV block
Terbutaline	Oral: 0.2 mg/kg q8–12h (D) 0.625 mg q8–12h (C) IV: 0.01 mg/kg IV (D, C)	Sinus bradycardia Sick sinus syndrome
Isoproterenol	CRI: 0.04–0.09 µg/kg/min, to effect (D,C)	Second- and third-degree AV block
Aminophylline/ Theophylline	Oral: 10 mg/kg q12h (extended release) (D, C) IV: 10 mg/kg (D)	Sick sinus syndrome
Digoxin	Oral: 0.005 mg/kg q12h (D)	AF (rate control)
Diltiazem	IV bolus: 0.1–0.4 mg/kg over 5 min (D, C) CRI: 0.05–0.15 mg/kg/h (D, C) Oral: 1–2 mg/kg q8h (D, C) 3 mg/kg q12h (extended release) (D) 15–30 mg q12–24h (extended release) (C)	SVT (rate control or conversion) AF (rate control)
Atenolol	Oral: 0.2–1 mg/kg q12-24h (D) 6.25–12.5 mg q12–24h (C)	SVT (rate control or conversion) AF (rate control)
Esmolol	IV bolus: 0.2–0.5 mg/kg over 1 min, repeat q5min (D, C)	SVT conversion
Procainamide	IV bolus: 5–15 mg/kg over 1 min (D) 1–2 mg/kg (C) CRI: 20–50 µg/kg/min (D)	SVT conversion
Lidocaine	IV bolus: 2 mg/kg over 30 s. Maximum 3 boluses (D) 0.25–0.5 mg/kg (C)	SVT conversion Vagally mediated AF conversion
Sotalol	Oral: 1–3 mg/kg q12h (D, C)	SVT conversion SR maintenance

primary cardiac disease, myocarditis, or as a manifestation of a neuromuscular disorder. However, the etiology often remains unknown.

Hyperkalemia is described as a cause for transient atrial standstill. Other possibilities include quinidine or digoxin toxicity, myocardial infarction, hypoxia, and hypothermia.

In the presence of persistent atrial standstill, the combination of chronic bradycardia, lack of atrial contribution to ventricular filling and decreased atrial natriuretic peptide production results in low cardiac output, increased circulating blood volume, and ultimately heart failure.

Epidemiology

It is a rare arrhythmia in dogs, and there are only a few documented cases in cats.

Signalment

Atrial standstill has been identified in various dog breeds, with a possible higher prevalence in English springer spaniels. It usually affects young adults, but can be diagnosed as early as 4–6 months of age. Most cats diagnosed with atrial standstill have echocardiographic changes consistent with hypertrophic cardiomyopathy.

History and Clinical Signs

Most animals show signs of low cardiac output, including profound lethargy and syncope, in addition to evidence of left- or right-sided congestive heart failure. In rare cases of muscular dystrophies, progressive skeletal muscle wasting may occur.

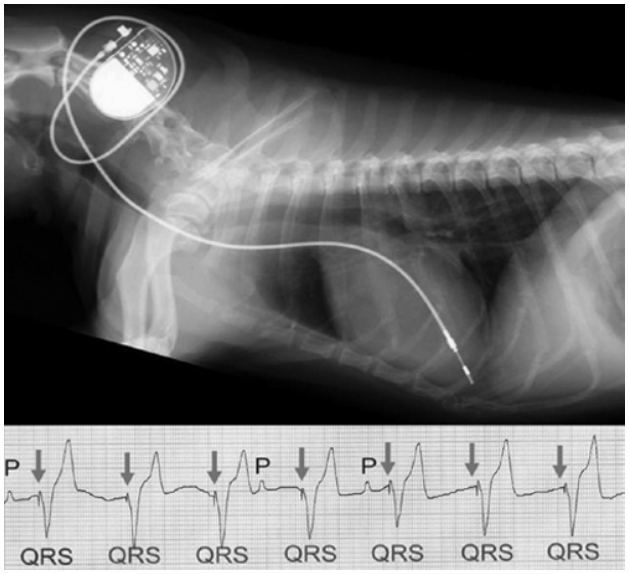

Figure 21.4 Permanent transvenous pacemaker in a dog with third-degree atrioventricular block. The upper panel is a lateral radiographic view of the thorax showing a transvenous lead implanted in the right ventricular apex and connected to a pacemaker generator secured subcutaneously in the region of the neck. The ECG tracing in the lower panel shows regular right ventricular pacing (*arrows*) and occasional P-waves that are dissociated from the ventricular complexes. Note that the QRS complexes are wide and "bizarre" and preceded by a pacing spike.

Diagnosis

Electrocardiography

The ECG of persistent atrial standstill is characterized by a lack of P-waves with a regular ventricular or AV nodal escape rhythm, at a rate of 20–60 bpm in dogs. In cases of transient atrial standstill from hyperkalemia, a narrowing of the T-wave and an increase in its amplitude occur when plasma potassium concentration increases above 5.5–6 mmol/L. As potassium concentration continues to rise, it leads to bradycardia associated with reduced P-wave amplitude and a widening of the QRS complexes. The P-waves then disappear, mimicking the ECG of persistent atrial standstill (Figure 21.5). Another term used to describe this rhythm disturbance associated with hyperkalemia is sinoventricular rhythm.

Echocardiography

On echocardiogram, mild to severe atrial dilation is present with no evidence of atrial contraction. Some degree of ventricular dilation is usually visible.

Therapy

Treatment relies on permanent transvenous ventricular pacemaker implantation.

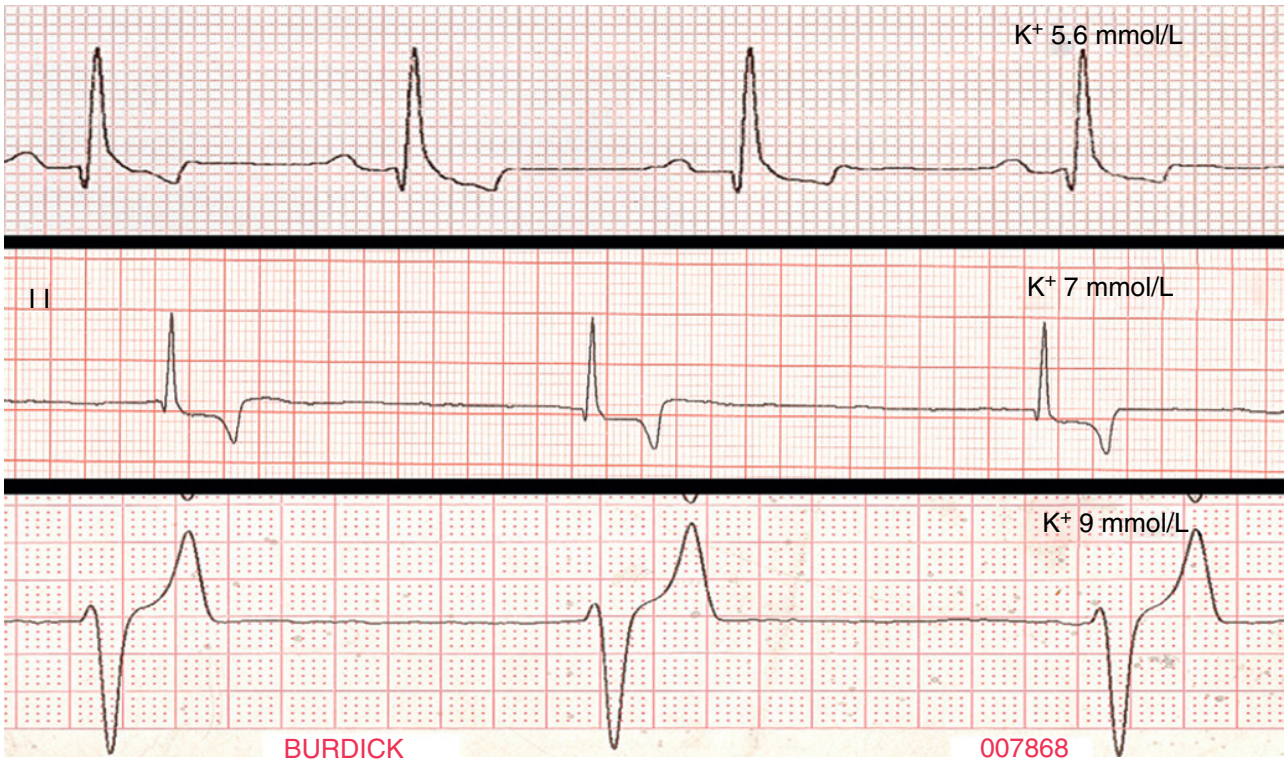

Figure 21.5 ECG strips of a dog with hyperkalemia. As serum potassium increases (top to bottom panel), heart rate decreases, QRS complexes widen, T-waves become tall and peaked, and P-wave amplitude decreases.

Prognosis

Myocardial damage usually progresses, extending to the ventricles. Most animals succumb within 12–18 months after initial diagnosis, despite pacemaker implantation.

Atrioventricular Block

Etiology/Pathophysiology

Causes of AV block include excessive vagal tone, AV node fibrosis, inflammation or infiltration, and potentially drug toxicity (calcium channel blockers, beta-blockers, or digoxin). Age-related fibrodegenerative changes in the AV node is the most common cause of AV block in dogs.

Epidemiology

Atrioventricular block represents between 60% and 80% of the indications for permanent pacemaker implantation in dogs. The prevalence of clinically significant AV block is much lower in cats than dogs. When AV block does occur in cats, it is typically associated with cardiomyopathy. Fortunately, feline escape rhythms are typically faster than canine (80–120 bpm) and pacing therapy is usually not required.

Signalment

Atrioventricular block is more common in geriatric pets. Most dogs are above 10 years of age at the time of diagnosis. Labradors, cocker spaniels, West Highland white terriers, beagles, German shepherds, springer spaniels, Cavalier King Charles spaniels, and dachshunds are overrepresented. Cats with high-degree second-degree and complete AV block are typically older than 10 years of age. There is no evidence of breed or sex predisposition in this species.

History and Clinical Signs

The hemodynamic effect of AV block depends on the rate of ventricular contraction. However, one-third of cats, and occasionally dogs, with advanced AV block may show no apparent signs, and bradycardia is detected on physical examination. More commonly, animals show signs of anorexia, lethargy, exercise intolerance, disorientation, episodic weakness, and syncopal episodes. Some animals develop right-sided congestive heart failure and, less commonly, left-sided congestive heart failure if the bradycardia is left untreated.

Syncopal episodes are rarely witnessed in cats with AV block and dyspnea is a more frequent chief complaint by owners of cats presented with AV block, whether congestive heart failure is present or not.

Diagnosis

Electrocardiography

There are three types of AV block. With first-degree AV block, all the atrial impulses are conducted to the ventricles, but the PR interval is prolonged on the ECG (PR >130 ms in dogs, >90 ms in cats). Second-degree AV block is diagnosed when some P-waves are not followed by a QRS complex on the surface ECG. Second-degree AV block is said to be high grade when the number of atrial impulses that fail to be conducted (P-waves not followed by a QRS complex) to the ventricles are more than the number of impulses that are conducted (P-waves followed by a QRS complex). Third-degree or complete AV block is characterized by an absence of conducted P-waves to the ventricles. The ECG displays independent atrial and ventricular activities (Figure 21.6).

Cardiac output is dramatically reduced. In response, the atrial rate, which is under adrenergic tone, is elevated. Electrical activation of the ventricles is dependent on an escape rhythm beyond the site of block. In dogs, the QRS complexes are generally wide and bizarre at rates around 20–60 bpm. In cats, the escape rhythm is usually seen as narrow QRS complexes, indicating their origin in the area of the His bundle, and it occurs at a rate of 80–140 bpm.

Finally, the ventricular rate is regular, unless ventricular premature beats originating from ischemic areas of myocardium are present.

Echocardiography

An echocardiogram is indicated to identify concomitant structural cardiac disease, which is frequent in cats with complete AV block. It is also essential to identify cardiac neoplasia that can infiltrate and disrupt the AV nodal tissue, to assess systolic function in the presence of myocarditis, and to determine the degree of volume overload secondary to chronic bradycardia.

Other Methods

Serum cardiac troponin I can be used to assess the degree of myocardial damage and raise a suspicion of myocarditis. Although a mild elevation of plasma cardiac troponin I level is common in dogs with complete AV block, marked increases suggest myocarditis as the cause for the AV block.

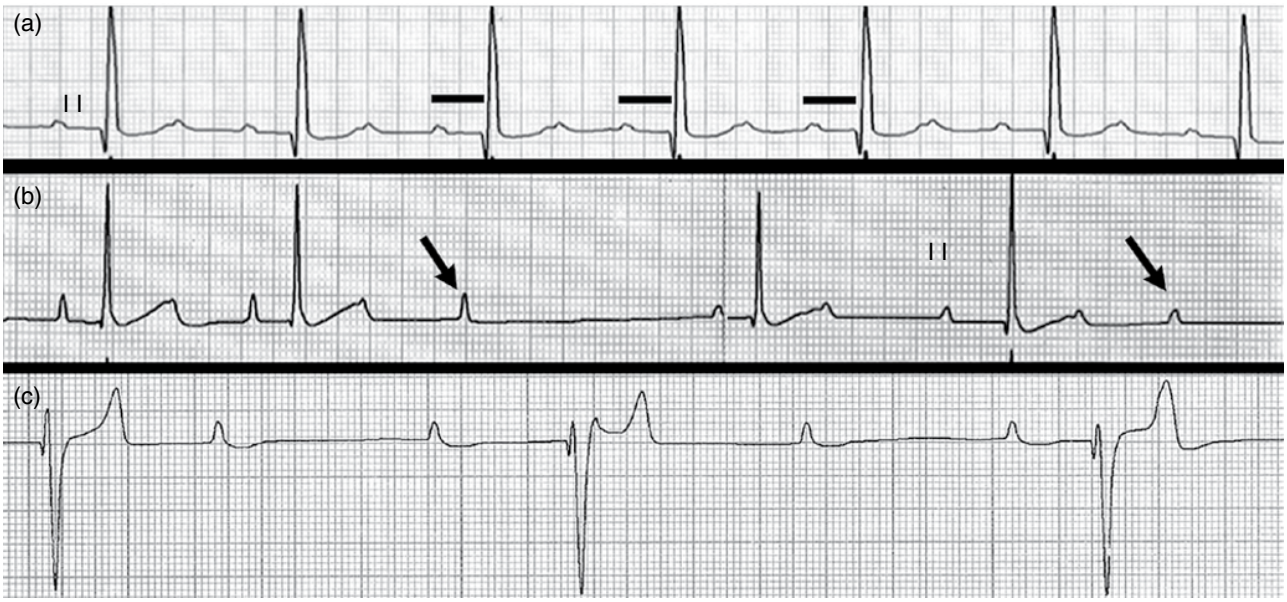

Figure 21.6 ECG strips of dogs with atrioventricular block. (a) First-degree atrioventricular block: there is a prolongation of the PR interval (180 ms, recording speed at 50 mm/s) and all the P-waves are associated with a QRS complex. (b) Second-degree atrioventricular block: the third and sixth P-waves (*arrows*) are not followed by a QRS complex, indicating an intermittent failure of the impulse to propagate to the ventricles. (c) Third-degree atrioventricular block: there is complete dissociation between the P-waves and the QRS complexes. The ventricles are activated by an escape rhythm at a rate of 37 bpm (recording speed at 50 mm/s).

Therapy

Medical Therapy

Sympathomimetic chronotropes increase heart rate by beta-adrenergic stimulation. Agents with beta-2 effects cause systemic vasodilation, whereas drugs with associated alpha stimulation cause vasoconstriction. Dopamine (5–10 µg/kg/min IV) and dobutamine (2–10 µg/kg/min IV) may contribute to an increase in heart rate and systolic function. They are usually administered as a continuous rate infusion and the dose is increased to effect. They are particularly indicated in the management of beta-blocker overdose. Isoproterenol, a pure beta-agonist, improves conduction in the AV node and the His–Purkinje system, which may result in the partial or complete resolution of AV block. It may also increase the rate of a ventricular escape rhythm in complete AV block, but usually with limited success. It is administered as a continuous rate infusion and its dose adjusted to effect. However, it causes a significant decrease in diastolic blood pressure via beta-2 stimulation. Finally, respiratory and metabolic acidosis decrease its effectiveness.

Pacemaker Therapy

Permanent ventricular pacemaker implantation is the treatment of choice for dogs and cats with clinical AV block.

Prognosis

In dogs, following permanent pacemaker implantation, estimated survival at one year is approximately 85%. Most dogs will usually die of noncardiac-related causes, unless concurrent progressive degenerative valvular disease or cardiomyopathy is present.

Pacemaker implantation may not be required in the vast majority of cats with complete AV block. Indeed, these animals have a median survival greater than one year without pacemaker therapy. Finally, the presence of underlying structural heart disease or congestive heart failure at the time of diagnosis may not significantly alter their prognosis.

Atrial Fibrillation

Etiology/Pathophysiology

Atrial fibrillation is characterized by uncoordinated atrial activation from multiple simultaneous electrical wavelets resulting in inadequate mechanical contraction and an irregular ventricular response rate. Atrial dilation is a risk factor for developing AF. However, it commonly occurs in large-breed dogs with only mild to moderate atrial dilation, and it is rarely present in small-breed dogs with degenerative mitral valve disease despite extreme atrial dilation. It is also rarely diagnosed in cats. Fibrosis, inflammation, and autonomic imbalances are other important contributors to the initiation of AF.

Epidemiology

In dogs, AF is one of the most common types of tachyarrhythmias that require treatment. Most dogs with AF

have underlying primary cardiac disease, in the form of dilated cardiomyopathy or degenerative mitral valve disease. Less commonly, "lone atrial fibrillation" occurs in giant-breed dogs with structurally normal hearts. Atrial fibrillation is rarely identified in cats but most cats with AF have underlying structural cardiac disease with atrial enlargement. Many of these cats also show signs of congestive heart failure.

Signalment

The vast majority of dogs with AF are giant- and large-breed dogs. In the giant-breed group, Irish wolfhounds, mastiffs, Newfoundlands, rottweilers, and Great Danes are overrepresented, with a male predisposition. Cats with AF are usually older males.

History and Clinical Signs

Most dogs with "lone" atrial fibrillation are asymptomatic. Conversely, some dogs with compensated cardiac disease and AF show signs of lethargy, exercise intolerance, and rarely anorexia, cough or syncope. When AF occurs in the presence of congestive heart failure, generalized weakness, dyspnea, cough, and abdominal distension from ascites are usually present. Cats frequently show signs of an underlying cardiac disease, including dyspnea and arterial thromboembolism. However, AF can also be an incidental finding on auscultation in this species.

Diagnosis

Physical Examination

On physical examination, AF is identified as a sustained and irregularly irregular rhythm accompanied with pulse deficits. A murmur may be ausculted, as severe underlying cardiac disease is common in dogs with AF.

Electrocardiography

On the surface ECG, AF is an irregular tachyarrhythmia, with usually narrow QRS complexes and no P-waves that can be replaced by an undulation of the baseline, or F-waves. It is also permanent, indicating that sinus rhythm never spontaneously resumes following initiation of AF. The average heart rate is typically above 180–200 bpm (Figure 21.7).

The rate is much lower with "lone" AF, usually approaching 100–120 bpm at rest. Although atrial fibrillation is a SVT, concurrent lesions of the ventricular conduction system (bundle branch block) may result in widening of the QRS complexes that may resemble those of ventricular tachycardia.

Ambulatory 24-Hour Holter Recording

Determination of the average ventricular rate during AF is critical information in deciding upon a treatment strategy. Unfortunately, brief ECG recordings obtained in an unfamiliar environment do not adequately reflect the daily variations of heart rate. Heart rate is therefore better assessed from a 24-hour Holter recording. For reference, the average heart rate of healthy dogs varies between 85 and 100 bpm. Conversely, it is approximately 120 bpm in dogs with "lone" AF, 155 bpm in dogs with underlying cardiac and 200 bpm in dogs with congestive heart failure.

Therapy

Treatment Strategy

A rate-control strategy is usually applied to the treatment of AF. This approach aims at slowing ventricular rate in response to the rapid supraventricular impulses which are bombarding the AV node. Control of the number of impulses, which are able to conduct through the AV node, will help in alleviation of clinical signs and prevention of further deterioration of ventricular function. However, it does not terminate the arrhythmia.

Rate-control is based on using drugs to decrease the ability of the AV node to conduct impulses. The need for pharmacologic control of the heart rate is determined from the heart rate distribution obtained from a baseline 24-hour Holter recording. The effect of rate-control drugs is then assessed on a follow-up Holter two weeks after treatment initiation. What constitutes adequate rate control has not been precisely defined and may depend on the animal's underlying myocardial function. Usually, an average heart rate of no greater than 120–140 bpm is considered adequate to observe clinical improvement. If the average heart rate is considered too high, drug dosages are increased by small increments with close monitoring of the animal's clinical status, as response to antiarrhythmics varies between patients. In contrast, medical therapy is usually not needed in dogs with "lone" AF. "Lone" AF can be successfully terminated via DC electrical cardioversion. However, there does not appear to be any benefit in converting the rhythm when adequate/appropriate rate-control therapy is effective.

Medical Therapy

Calcium Channel Blockers

Diltiazem is widely used for the management of AF. A graded dose of diltiazem results in a decrease in ventricular response rate, because of slower action potential propagation in the AV node. Oral formulations include an extended-release form. When evaluated for long-term management of AF, a dose of 3–5 mg/kg q12h PO of the extended-release formulation usually achieves satisfactory rate-control. Better rate-control, especially during periods associated with high adrenergic tone, can be obtained by adding digoxin to the treatment regimen. Calcium channel blockers decrease ventricular

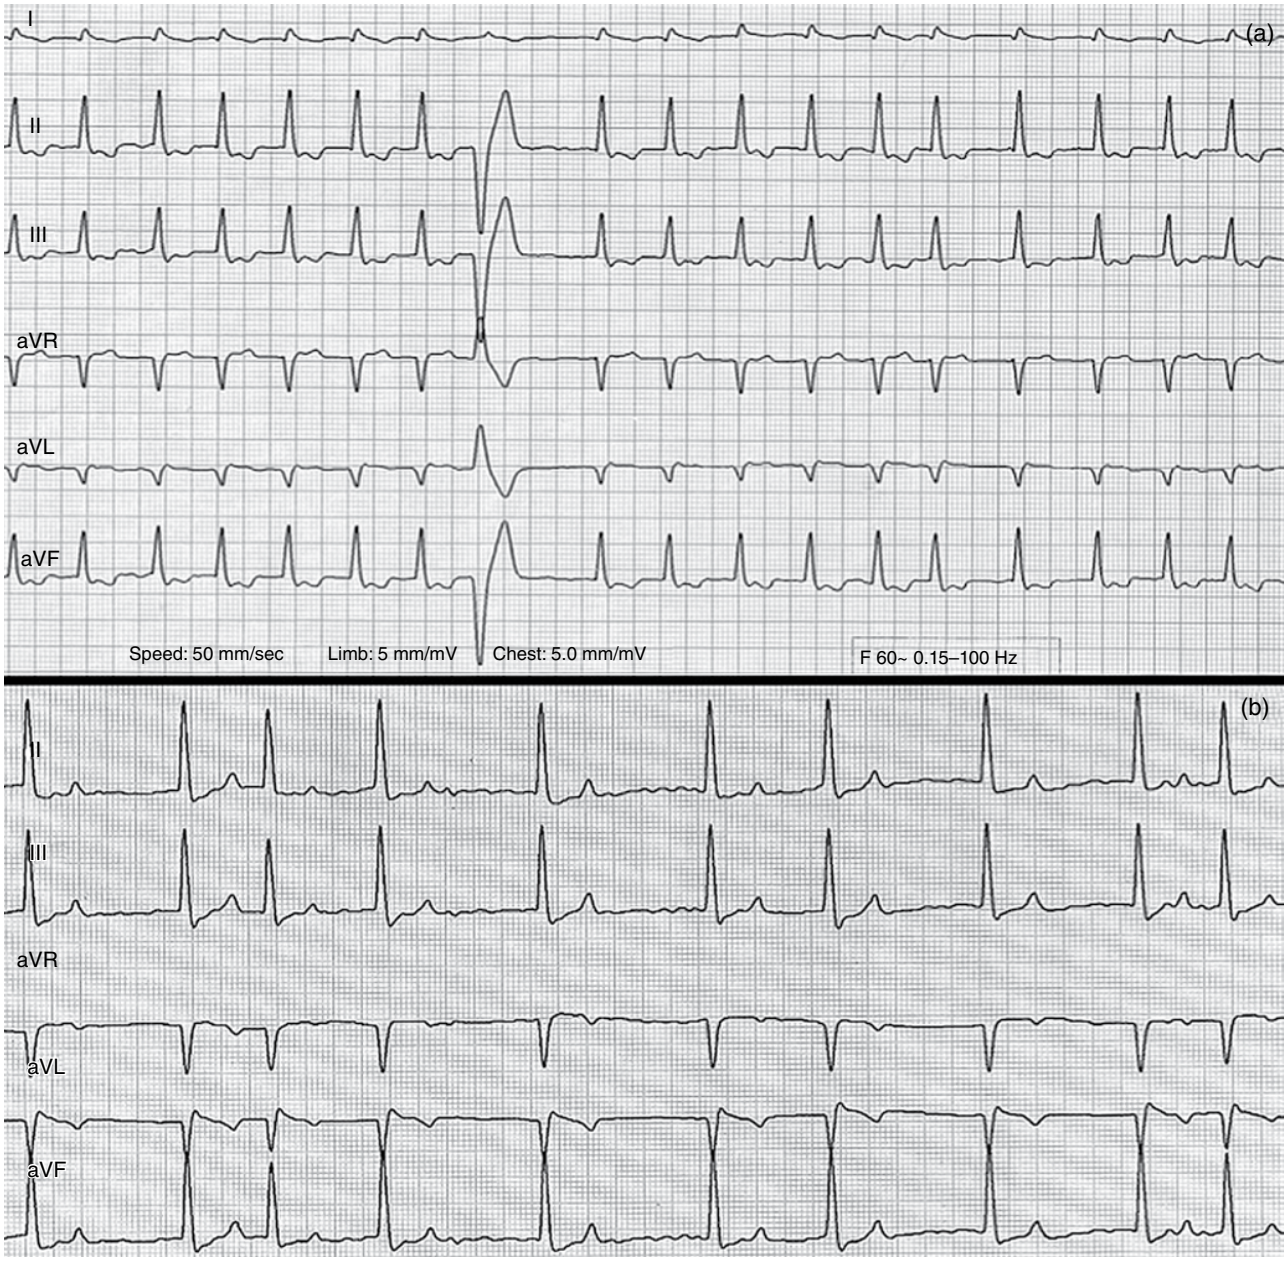

Figure 21.7 Six-lead ECG of a dog with atrial fibrillation (speed: 50 mm/s). (a) Atrial fibrillation appears as an irregular and narrow QRS complex tachycardia at a rate of 220 beats. Note that the eighty complex has a wide and "bizarre" morphology, suggesting it is a ventricular premature contraction (VPC). (b) Following administration of rate-control medications, atrial fibrillation is still present but the heart rate has decreased to 140 bpm.

contractility and may cause hypotension when used in animals with severely depressed cardiac function.

Beta-Blockers

The range of indications and side-effects for beta-blockers is very similar to that of calcium channel blockers. Beta-1-selective agents, such as atenolol, are preferred to nonselective agents that can cause bronchospasm.

Prognosis

Long-term prognosis is good for dogs with "lone" AF. However, in some breeds, in particular Irish wolfhounds, it may be considered an early sign of dilated cardiomyopathy. In AF dogs with heart disease, median survival has been reported to be 32 months. However, it was only five months when congestive heart failure was present. In cats, treatment targeted at AF is rarely required as their

ventricular response rate usually approaches the heart rate recorded in cats with sinus rhythm and heart failure.

Other Forms of Supraventricular Tachyarrhythmia

Etiology/Pathophysiology

Initiation of tachyarrhythmias requires a suitable substrate and precipitating factors. Interstitial fibrosis, inflammation, ischemia or atrial chamber dilation, combined with adrenergic stimulation and electrolyte abnormalities promote the risk for tachyarrhythmia. It is therefore expected that SVTs are commonly diagnosed in pets with heart failure.

Supraventricular tachyarrhythmias encompass focal atrial tachycardia, atrial flutter, focal junctional tachycardia, and atrioventricular reciprocating tachycardia. Focal atrial tachycardia is caused by the rapid and repeated activation of a small area of diseased atrial myocytes. Atrial flutter results from an electrical impulse circling rapidly and continuously around a large area of myocardium. Focal junctional tachycardia is caused by the rapid discharge of cells in the area of the AV node. Finally, atrioventricular reciprocating tachycardias result from the presence of an accessory pathway, which is a small strand of muscle tissue bridging the atria and ventricles through the cardiac skeleton and forming an alternative route of atrioventricular or ventriculoatrial electrical conduction besides the atrioventricular node. When conduction is also possible from atrium to ventricle, preexcitation may be identified during periods of sinus rhythm as short PR intervals and a widening of the initial portion of the QRS complexes (Figure 21.8). This finding confirms the existence of an accessory pathway. During episodes of atrioventricular reciprocating tachycardia, the impulse typically descends along the atrioventricular node to the ventricles and returns to the atrium using the accessory pathway.

Sustained tachyarrhythmias can lead to the development of heart failure, a phenomenon known as tachycardiomyopathy. It is likely that a sustained rate above

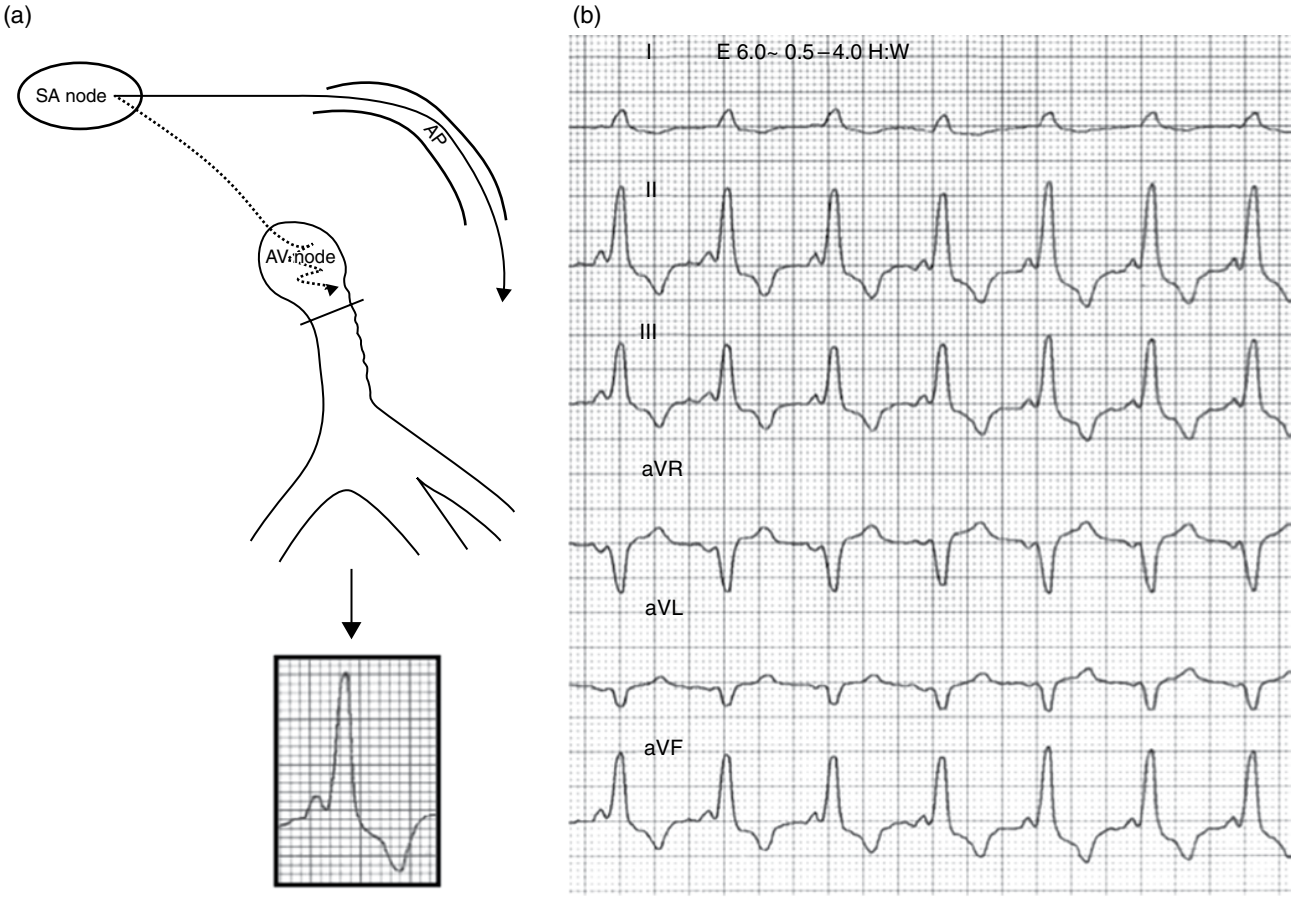

Figure 21.8 Ventricular preexcitation. (a) When a dog has an accessory pathway (AP), the sinus impulse may conduct simultaneously through the atrioventricular node and the abnormal muscle bundle. Ventricular activation is initiated without delay from the accessory pathway, resulting in a short PR interval and widening of the QRS complex. (b) Six-lead ECG of a dog with ventricular preexcitation.

250 bpm can induce severe myocardial dysfunction within 3–4 weeks in dogs.

Epidemiology

Supraventricular tachycardias other than AF are rare in both dogs and cats.

Signalment

Large- and giant-breed dogs, in addition to brachycephalic breeds, are more commonly diagnosed with SVTs. Tachyarrhythmias associated with an accessory pathway have more frequently been reported in Labradors.

History and Clinical Signs

Signs of SVTs include weight loss, lethargy, exercise intolerance, excessive panting, and dyspnea. However, it is not uncommon for dogs to be perceived as being nonclinical. Owners of dogs with SVTs may report "seeing" their pet's heart pounding in the chest during episodes of tachycardia. Weakness and transient loss of consciousness are less common with SVT. Additionally, SVTs may only be recognized at the time of physical examination in dogs with signs of congestive heart failure.

Diagnosis

Physical Examination

Cardiac auscultation is a useful diagnostic tool to calculate heart rate, detect occasional ectopic beats, and distinguish between paroxysmal and sustained arrhythmias. While paroxysmal SVTs are usually regular, SVTs may also be irregular. Some dogs experiencing episodes of paroxysmal SVT will be in sinus rhythm at the time of presentation. Femoral pulses may be weaker during bouts of tachycardia.

Electrocardiography

It is critical to differentiate supraventricular from ventricular tachycardia. However, treatment can be initiated without identifying the exact mechanism of an SVT.

The first step in the diagnosis of tachyarrhythmias is recognizing that an uninterrupted and irregular (a variation >100 ms between RR intervals) tachycardia is typically AF. Once AF is ruled out, SVTs must be differentiated from ventricular tachycardia by looking at the morphology of the QRS complexes. Ventricular tachycardias have wide QRS complexes (>0.06 s in dogs; >0.04 s in cats) followed by a large T-wave directed opposite to the QRS complex, whereas the main characteristic of SVTs is narrow QRS complexes, indicating that electrical impulses, once they reach the ventricles, propagate within specialized muscular bundles of the His–Purkinje conduction system, similar to normal sinus beats. However, on occasion, SVTs can display wide QRS complexes if a bundle branch block is present. In these challenging cases, the identification of P-waves associated with QRS complexes confirms the origin of the arrhythmia above the His bundle. P-waves can occur before, during or after the QRS complexes. They can be positive or negative. Oftentimes, P-waves are buried within the T-waves. Although rarely effective, vagal maneuvers can be done to slow AV conduction, revealing hidden P-waves associated to QRS complexes.

It is important to consider that ventricular tachycardias are much more frequent than SVTs. Following careful examination of the ECG, if uncertainty persists about the origin of a wide QRS complex tachycardia, it should be first treated as if it were ventricular tachycardia.

Ambulatory 24-Hour Holter Recording

The information collected from Holter recordings includes the number of episodes and their duration, the modes of arrhythmia onset and termination, and information about the overall heart rate, especially when the animal is in a familiar environment. Evaluation of heart rate distribution over 24 hours in the light of an activity log completed by the owner during the period of recording is a source of valuable information on the circadian pattern of the arrhythmia and on the contribution of adrenergic tone to the initiation and rate of the arrhythmia.

Echocardiography

An echocardiogram is useful to assess for the presence of structural cardiac disease and tachycardia-induced cardiomyopathy.

Therapy

Decision to Treat

Treatment is justified when SVTs cause clinical signs, which are directly related to their rate and duration, as well as ventricular performance. In the absence of obvious clinical signs, treatment should be considered if tachycardia-induced cardiomyopathy is suspected. When SVTs are intermittent, relating the clinical signs to the arrhythmia may be challenging. In that situation, long-term recording of the cardiac rhythm via ambulatory 24-hour Holter recording, or preferably with a wearable or an implantable loop event recorder, is indicated.

A rate-control or rhythm-control strategy, which consists of restoring sinus rhythm, can be applied to the treatment of SVTs. Drug selection is based on the type of arrhythmia, the risk of adverse reactions, and the degree of cardiac dysfunction. Other factors to take into account include decreased oral medication absorption, drug

metabolism and elimination in the presence of ascites, as well as decreased hepatic and renal blood flow that accompany heart failure. Moreover, drug selection may depend on the level of certainty regarding the nature of the arrhythmia. Indeed, it may be challenging to determine the origin of wide-complex tachycardias, which are characteristic of ventricular tachyarrhythmias but on occasion correspond to SVTs with aberrant intraventricular conduction. For example, drugs used for rate-control management of SVTs, in particular calcium channel blockers, may cause hemodynamic collapse if given in the presence of rapid ventricular tachycardia and would persist at a fast rate despite treatment. Besides the drugs used for chronic management, paroxysmal SVTs may require emergency intervention when they cause hemodynamic instability.

Acute Management

Antiarrhythmic drug administration should always be preceded by attempts to identify and eliminate potential triggers for the arrhythmia. This includes correcting electrolyte disturbances, hypoxemia, hypovolemia, and acidosis.

Common drugs used for the management of SVTs include calcium channel blockers (diltiazem), beta-blockers (esmolol), sodium channel blockers (procainamide, lidocaine), and drugs that combine several antiarrhythmic properties (sotalol).

Diltiazem

On occasion, diltiazem terminates SVTs if the arrhythmia mechanism is dependent on the AV node. Diltiazem can be administered as intravenous boluses and constant rate infusion for acute management of tachyarrhythmias.

Esmolol

Esmolol is a short-acting intravenous beta-1-selective blocker that is rapidly metabolized by blood esterases. It is used for rate-control and termination of AV node-dependent SVTs. However, it may be less effective than intravenous diltiazem.

Procainamide

Procainamide has been used for the management of SVTs. It is also indicated for acute management of broad-complex tachycardias, when discrimination between SVT and ventricular tachycardia is difficult, as it is also very effective in terminating ventricular arrhythmias. Unfortunately, it is no longer available in an oral formulation and the IV formulation has limited availability outside the United States.

Lidocaine

While lidocaine is extensively used as first-line therapy for acute termination of ventricular tachycardia, its use for treatment of SVT has only been reported recently. It has been shown to terminate episodes of SVTs in the presence or absence of an accessory pathway. Lidocaine has also been used successfully to terminate recent onset of paroxysmal atrial fibrillation initiated by elevated vagal tone in large-breed dogs with normal cardiac function. One to two boluses of lidocaine restored sinus rhythm within 30–90 seconds, while causing mild self-limited hypotension following the intravenous bolus.

Sotalol

Although availability of the IV formulation of sotalol is limited, the oral formulation can be used for acute management of SVTs, as most of them are not immediately life-threatening. Sotalol has potassium channel and mild beta-blocking properties, which make it a good option to terminate and prevent/decrease the recurrence of focal atrial tachycardias, atrial flutter, and AV reciprocating tachycardia. Conversion of those arrhythmias back to sinus rhythm usually occurs 2–4 hours after oral administration of the drug.

Long-Term Management

Termination of the arrhythmia and maintenance of sinus rhythm is the preferred approach for the long-term management of SVTs (rhythm-control strategy). It is more likely to succeed when limited structural cardiac changes are present. However, rate-control strategies used for the management of atrial fibrillation can also safely be applied to the control of most sustained SVTs.

Among various antiarrhythmic medications, sotalol has proven to be the most effective rhythm-control drug. Conversion to sinus rhythm usually occurs just a few hours after oral administration, but it can take up to a few days to observe a response. Sotalol is also effective at preventing arrhythmia recurrence. The negative inotropic effect of sotalol is modest compared to other beta-blockers. Nonetheless, dogs with myocardial failure should be closely monitored while receiving sotalol. Atrioventricular reciprocating tachycardia usually responds well to sotalol, which alters the electrophysiologic properties of all the cardiac structures necessary for the maintenance of this arrhythmia, including the accessory pathway, the atrial myocardium, the AV node, and the ventricular myocardium. In dogs that fail to respond to monotherapy, sotalol can be combined with mexiletine (5–7 mg/kg q8h) with better results.

Nonpharmacologic Treatment of Supraventricular Arrhythmias

Synchronized DC cardioversion and radiofrequency catheter ablation have been successfully used to treat supraventricular arrhythmias. In particular, dogs with AV reciprocating tachycardia show the best results with

radiofrequency ablation. The technique consists in identifying the location of the accessory pathway, usually around the tricuspid valve annulus, and delivering radiofrequency energy to permanently damage the tissue and block electrical conduction along the abnormal muscle bundle. However, the necessary equipment is available in only a few specialized veterinary centers.

Prognosis

Adequate rhythm or rate-control prevents complications, such as tachycardia-induced cardiomyopathy. When the arrhythmia terminates following the administration of antiarrhythmic medications, it is critical to monitor with frequent 24-hour Holter recordings for any signs of arrhythmia recurrence.

Systemic Hypertension

Rebecca L. Stepien, DVM, MS, DACVIM (Cardiology)

Department of Medical Sciences, University of Wisconsin School of Veterinary Medicine, Madison, WI, USA

Etiology/Pathophysiology

Systemic hypertension (HT) describes a situation of sustained elevation of blood pressure (BP). Systemic hypertension is a clinical condition and should be considered a clinical complication of certain diseases rather than a disease in itself. In veterinary medicine, systolic blood pressure (SBP) is the value most often used to assess BP status in the conscious clinical patient, and systemic hypertension is typically diagnosed when reliable measures of SBP deliver values ≥160 mmHg. Clinically detectable damage caused by HT may be noted in the eyes, central nervous system, heart, and kidneys. Injury related to HT in these organ systems is often collectively termed "target organ damage" (TOD). Target organ damage may be clinically obvious, especially in the ocular or nervous systems. In other cases, TOD may be subtle and result in accelerated progression of deterioration of damaged organs (e.g., accelerated deterioration of renal function) rather than overt clinical signs.

In veterinary patients, systemic hypertension has typically been identified as one of three types: situational (so-called "white coat") hypertension, systemic hypertension secondary to systemic disease, and idiopathic systemic hypertension. Once situational hypertension has been ruled out, systemic hypertension secondary to systemic disease is more common than idiopathic hypertension. The designation of HT as "idiopathic" in a given patient is dependent on a thorough search for common diseases associated with HT.

Pathophysiology of Systemic Hypertension

The pathophysiologic mechanism(s) of any individual's elevated BP is likely related to the cause of the HT, but the specific pathways leading to sustained elevations in BP are poorly understood for most diseases. Blood pressure in health is modulated by interaction of diverse physiologic systems affecting the heart, kidney, brain, and vasculature. These systems rely on neural modulation (via the sympathetic nervous system [SNS]), hormonal modulation (e.g., renin-angiotensin-aldosterone system [RAAS], natriuretic peptides), vascular resistance modulation by circulating or local vasoactive mediators (e.g., endothelin, thromboxane, prostaglandins, etc.) and any structural changes (e.g., arteriosclerosis) that may be present. Abnormalities in any of these contributing factors or the interaction among these factors may alter arterial BP.

In health, increased BP typically leads to natriuresis in the normal kidney and lowering of systemic BP. No matter what the mechanism by which the initial elevation in BP occurs (e.g., catecholamine excess or alterations in RAAS activity), if "normalization" of elevated BP via natriuresis does not occur or is inadequate, abnormality in renal sodium handling is implied, and this may be the final common pathway for many etiologies of HT.

The fact that multiple and complicated pathophysiologic pathways are involved in modulation of BP and development of HT has three clinical repercussions. First, HT due to different diseases is likely to respond to different medications, based on the pathophysiologic pathway of the development of HT in an individual patient. Second, lack of complete understanding of these pathways limits our ability to apply specific physiologic blocks to lower BP, and nonspecific vasodilation becomes the treatment of choice for many cases of HT. Last, because any decrease in BP below the individual's current set point (normal or abnormal) is likely to stimulate reactive, BP-increasing responses from modulating systems like the SNS and RAAS, simultaneous blockade of these systems may be required when direct vasodilators are used in order to optimize response.

Pathophysiology of Target Organ Damage

Arterial blood flow is maintained at relatively constant levels in the brain, kidneys, and eyes through a process of vascular autoregulation, wherein small resistance vessels constrict when BP is elevated and dilate when BP is decreased to maintain flow. Hypertensive damage in these organs occurs when these autoregulatory mechanisms fail. Elevated BP without adequate resistance vessel constriction causes overdistension of vessels, which leads to damage to endothelial tight junctions and allows protein and plasma leakage into interstitial tissue in affected tissue beds (i.e., tissue edema). If excessive vascular resistance vessel constriction occurs, ischemia of local tissues may result in focal hemorrhage and necrosis. Permanent structural changes such as arteriosclerosis may develop, decreasing vascular distensibility. Any combination of these mechanisms may result in clinical signs of TOD (Table 22.1).

Epidemiology

The most common diseases associated with HT in dogs include acute or chronic renal disease, especially protein-losing renal disease, hyperadrenocorticism, adrenal tumors, including pheochromocytomas and aldosterone-secreting tumors, and diabetes mellitus. The most common diseases associated with feline HT include chronic renal disease, feline hyperthyroidism, hyperaldosteronism, and diabetes mellitus. In both species, the suspected association (medical or age group related) between subclinical renal dysfunction and both diabetes mellitus and hyperthyroidism may partially account for the occurrence of HT in affected animals. Ten to 15% of hyperthyroid cats that are normotensive at the time of diagnosis may become hypertensive after successful therapy for hyperthyroidism, indicating other mechanisms of HT at work in these patients. The prevalence of idiopathic and situational HT remains unclear for both species.

Signalment

Systemic hypertension is associated with many diseases that are more common in older animals, but aging itself is not a cause of HT. In the case of secondary HT, the signalment of affected animals reflects groups at risk for the underlying disease. In cats, because two common

Table 22.1 Evidence of target organ damage. Clinical signs of target organ damage and additional recommended testing

Organ system affected	Associated clinical findings	Recommended diagnostic testing
Eyes	Acute blindness due to retinal detachment or severe hyphema Retinal hemorrhage Retinal vascular narrowing or tortuosity Focal retinal transudates Focal retinal ischemic degeneration Partial or complete retinal detachment Papilledema	Fundoscopic examination Coagulation/platelet assessment if hyphema or retinal hemorrhage
Brain	Seizures (focal facial or grand mal) "Stroke-like" intracranial neurologic deficits Decreased mentation/obtundation Photophobia Nystagmus	Complete neurologic examination Additional imaging (e.g., MRI)
Kidneys	Proteinuria Microalbuminuria Progressive decrease in renal function	Serum BUN and creatinine Complete urinalysis Urine culture Quantitation of proteinuria or albuminuria Advanced renal testing (e.g., GFR)
Heart	Left ventricular concentric hypertrophy Arrhythmia Gallop rhythm Systolic heart murmur Increased sensitivity to fluid loading (unexpected acute heart failure after fluid administration) Epistaxis	Auscultation Thoracic radiographs Echocardiography Doppler echocardiography may be required to rule out other causes of LV hypertrophy (e.g., subaortic stenosis) Assessment for coagulation/platelet abnormalities if epistaxis

Note: recommended testing list is not exhaustive, additional testing may be indicated in individual patients.
BUN, blood urea nitrogen; GFR, glomerular filtration rate; LV, left ventricle; MRI, magnetic resonance imaging.

diseases associated with HT are diseases of older cats (chronic kidney disease [CKD] and hyperthyroidism), the age distribution of hypertensive cats tends to include a greater proportion of older than younger patients.

History and Clinical Signs

Patients with HT are typically identified by BP measurements taken when a suspicious underlying disease or condition (e.g., proteinuria, hyperadrenocorticism) is diagnosed or suspected. Blood pressure should also be monitored in any patient receiving drugs that can cause vasoconstriction, such as phenylpropanolamine, a common medication for urinary incontinence that is responsible for BP elevations in some dogs. Additional HT patients are recognized when evidence of TOD (e.g., ocular hemorrhage, neurologic signs, gallop heart sound) is identified. In these patients, further evaluation (see Table 22.1) after diagnosis of HT may reveal the underlying cause. The clinical history of hypertensive patients may be consistent with the underlying disease (e.g., polyuria/polydypsia with renal disease), reflect TOD (e.g., acute blindness due to retinal detachment or obtundation due to increased intracranial pressure) or reveal use of hypertensive medications (e.g., phenylpropanolamine). Because of the high variability of clinical signs, and because changes in mentation and behavior due to HT may be subtle or attributed to aging changes, a high level of suspicion for HT should be maintained regarding possible reasons for and signs of HT in clinical patients.

Diagnosis

Patient Selection and Set-Up

Blood pressure should be measured in dogs and cats with diseases known to be associated with HT, and in those animals showing evidence of TOD. In both species, diagnosis or suspicion of renal disease (acute or chronic, proteinuric or nonproteinuric), adrenal neoplasias (e.g., pheochromcytoma or aldosterone-secreting tumors) and diabetes mellitus should lead to BP assessment. In cats, evaluation of hyperthyroidism should include BP assessment and BP should be reevaluated after successful therapy for hyperthyroidism. Similarly, suspicion of or diagnosis of hyperadenocorticism in dogs should include evaluation of blood pressure.

Animals with evidence of TOD (see Table 22.1) should have BP measured at the earliest opportunity regardless of underlying disease, so that intervention may ease or prevent further damage. If an animal with TOD is diagnosed as HT, antihypertensive therapy should begin immediately.

Nonspecific screening of patients for HT is not recommended. The prevalence of HT in healthy-appearing animals without causative disease is low, so many positive diagnoses of HT in this patient group will be false positives due to situational hypertension. Normal animals may be tentatively diagnosed with HT when elevated BP is a result of agitation or anxiety during BP evaluation. These animals may be identified as anxious during measurement, and repeat measurements later in the day or the following day after a period of acclimation may render more accurate results. Animals without causative disease or evidence of TOD may be accepted as normotensive if a confirmatory BP measurement after an initial HT measurement is within normal range. In most cases, animals with known causative disease or TOD and initially elevated BP are confirmed as "true" HT if confirmatory measurement is performed.

Commonly available methods to assess BP in dogs and cats include direct measurement (via arterial puncture or arterial cannulation) or indirect (noninvasive) methods, including Doppler sphygmomanometry and oscillometry. Although high-definition oscillometry (HDO) is now available, results may not be comparable to other methods and repeatable measurements may be difficult to obtain in awake cats. "Standard" oscillometry (widely available in stand-alone monitors or anesthesia monitors) or Doppler sphygmomanometry is currently recommended for clinical use.

Prior to BP measurement, the patient should be allowed to relax with minimal restraint for 5–10 minutes in a quiet area. The owner may help calm the animal during the measurement if appropriate. Systolic BP is typically used for clinical decision making and heart rate should be recorded in all patients. Notation of heart rate and any rhythm abnormalities may assist with full evaluation of the patient; tachycardia during BP measurement may signal increased patient anxiety, or provide additional information regarding underlying disease status (e.g., sinus tachycardia or arrhythmias in thyrotoxic cats). A gradually decreasing heart rate during measurement repetitions may occur in a patient that is slowly relaxing, and additional measurements at the lower heart rate may provide more accurate results than the initial measurements at a higher heart rate.

Methods of Measurement

Direct Blood Pressure Measurement

Direct arterial BP measurement is performed by inserting a needle or catheter attached to a pressure transducer into a peripheral artery in a clinical patient to obtain a pressure trace. Arterial cannulation using the dorsal

pedal artery is most frequently used for anesthesia and postanesthesia monitoring, but is typically impractical for clinical use on conscious patients for diagnostic purposes. Direct femoral puncture may be used for acute measurement of BP in conscious animals with local anesthesia, but is time-consuming and cumbersome in clinical practice.

Doppler Sphygmomanometry

Doppler sphygmomanometry (DS) is the most common method of measuring BP in cats and is also used commonly in dogs. A piezoelectric crystal attached to an audio amplifier is applied to the skin overlying a peripheral artery and an occlusion cuff inflated with a pressure bulb is positioned proximally on the same limb. The BP cuff is premeasured and sized such that the width of the cuff is approximately 40% of the circumference of the limb at the level of cuff placement.

In dogs and cats, the forelimb is the most common measurement site with the animal in lateral recumbency or sitting and the limb held at the level of the right atrium. The cuff is placed at mid-antebrachium and attached to the sphygmomanometer. The probe (with coupling gel) is held or taped in place over an artery distal to the cuff (usually the palmar arterial arch) and the position is adjusted until a clear pulsatile audio signal can be detected. The cuff is inflated to approximately 20–40 mmHg past the point at which the sound of blood flow is occluded and then slowly deflated. The pressure at which the sound signal reappears is recorded as the systolic BP. As the cuff is further deflated, the audio signal will become muffled – this pressure may be recorded as diastolic BP but is less reliable than the systolic BP by this method. Three to five repeated measurements taken approximately 30 seconds to one minute apart can be averaged to render a representative SBP.

Oscillometry (OSC)

Oscillometric BP devices deliver systolic, diastolic, and mean BP values as well as heart rate. These systems are most reliable in cats when a tailhead cuff is used in unrestrained sternal recumbency, but forelimb (radial level), hindlimb (metatarsal level or proximal to hock in recumbent animal) or tailhead (in standing or recumbent animals) cuffs may be used in dogs.

The cuff width is chosen similarly to the DS technique. The cuff is positioned with the bladder of the cuff (usually identified on the cuff by a small arrow) centered squarely over the artery and secured. The OSC machine is set to read BP at approximately one-minute intervals. The arithmetic mean of 3–5 SBP replicates is used as a representative value, with any obvious erroneous or outlying values discarded. OSC equipment may be unable to read BP accurately at high heart rates (>180 bpm) or if an arrhythmia is present, and a Doppler or invasive measurement system should be used in these patients. Doppler and OSC devices may not deliver the exact same results in a given patient, nor will different measurements sites in the same patient deliver the exact same results for SBP. Therefore, the same technique and the same cuff site should be used consistently in a given patient when monitoring BP over time.

Therapy

Acute or chronic HT may result in life-altering or life-limiting TOD and may affect the quality and therefore length of life in an affected patient. The goals of HT therapy are to stop or limit the extent of TOD in affected animals and to improve the quality of life in all patients. This may be accomplished by use of medications that decrease SBP and concurrent therapy of underlying causative disease. In all cases, control or resolution of the underlying condition is an important part of HT management.

Medical Therapy

The goal of therapy of HT is reduction of SBP to <160 mmHg, and ideally to 120–140 mmHg. Optimal therapy of HT usually involves use of a direct vasodilating agent (e.g., amlodipine or hydralazine) along with an agent to prevent reactive stimulation of the RAAS (usually an angiotensin-converting enzyme inhibitor [ACEI] or more recently, angiotensin receptor blockers [ARBs], e.g., telmisartan).

In *cats*, amlodipine (0.625–1.25 mg per cat PO q24h) is often successful as a single agent to control HT, with minimal side-effects in most patients. In *dogs*, ACEIs (enalapril or benazepril 0.25–0.5 mg/kg PO q12–24h) are useful in decreasing proteinuria commonly associated with HT and are typically considered a first-line agent to treat HT of any etiology. Angiotensin-converting enzyme inhibitors alone may not bring BP into the desired range in dogs and amlodipine (0.2–0.4 mg/kg PO q24h) or hydralazine (0.5–2.0 mg/kg PO q12h) may be added. The once-daily dosing regimen of amlodipine makes use of this drug more appealing than twice-daily dosing with hydralazine in most patients. Telmisartan has recently been approved for therapy of HT due to CRD in cats and expected decreases in SBP are similar to those expected with amlodipine therapy. Spironolactone (1–2 mg/kg PO q12h) has theoretical benefits in limiting RAAS activation in chronic HT, but studies supporting improved quality of life or survival outcomes with this medication are lacking at this time. Beta-blocking medications like

atenolol do not appear to provide reliable BP control, but may be useful to limit tachycardia in thyrotoxic cats. Alpha-blocking (e.g., prazosin) or mixed adrenergic-blocking medications (e.g., labetolol) have not been systematically evaluated in clinical veterinary patients.

In patients with evidence of acute TOD (e.g., intracranial neurologic signs or acute blindness due to retinal detachment), medications with quick onset of action should be used, with a goal of reducing the SBP by ~25% in the first few hours. The most commonly used rapid-onset medication for this purpose is hydralazine, which may have onset of action within 1–2 hours. Acutely, furosemide 1–2 mg/kg IV can be administered to nonazotemic patients, but this medication is not suitable for long-term therapy of HT. If continuous intravenous infusion is possible, sodium nitroprusside (typically diluted in 0.9% saline) can be administered beginning at a rate of 1–2 µg/kg/min with upward titration as needed to attain the goal of 25% reduction of SBP in the first few hours. Alternatively, fenoldopam, a selective dopamine-1 receptor agonist, can be delivered as a constant rate infusion (CRI) at an initial dose of 0.1 µg/kg/min, with doses titrated upward by 0.1 µg/kg/min at 15-minute intervals until the 25% reduction in SBP is reached, with a maximal infusion rate of 1.6 µg/kg/min. Constant BP monitoring is required when using sodium nitroprusside or fenoldopam due to the rapid onset of action and potent BP-lowering effects of these medications.

Some diseases (hyperadrenocorticism in dogs, hyperthyroidism in cats) may contribute to systemic hypertension through mechanisms that may be at least partially reversible with therapy for the underlying disease. In dogs with hyperadrenocorticism, successful medical or surgical therapy may be associated with decreased but not always normalized BP. Similarly, hyperthyroid cats that are hypertensive prior to therapy for hyperthyroidism may have normal BP after successful therapy for hyperthyroidism or maintain elevated BP. Additionally, cats successfully treated for hyperthyroidism may develop HT post treatment. In order to manage these complicated canine and feline HT cases, close monitoring of BP is recommended both before and after therapy of the underlying disease.

While no specific treatment protocols have been published, a reasonable approach to these patients follows the general approach to management of HT with some modification of follow-up decision making. Patients with these diseases and BP ≥180 mmHg may be considered to be at increased risk for TOD and despite plans to modify the underlying disease state, should be treated for their HT as other therapies commence. Once underlying disease therapy starts, the BP should be monitored periodically throughout the course of treatment until the underlying disease is alleviated or resolved. Blood pressure should be assessed again at this point, and consideration given to discontinuing the antihypertensive medication on a trial basis in normotensive patients (this should only be attempted in patients with no co-morbid risks factors and no evidence of TOD). In patients with pretreatment BP <180 mmHg, therapy of the underlying disease can commence without concurrent therapy of HT as long as no evidence of TOD is present, with post-treatment monitoring of BP recommended. Rechecking BP post therapy for feline hyperthyroidism should be performed regardless of pretreatment BP, since late-developing HT (i.e., 3–6 months post normalization of thyroid status) has been documented in these patients.

Monitoring

Use of higher doses of amlodipine or hydralazine or use of "normal" doses in debilitated animals may result in hypotension, which may be discernible as weakness, lethargy or mental dullness and prerenal azotemia. In most cases, discontinuing the medication for 1–2 doses and then decreasing the subsequent dosage administered will result in clinical improvement, but cautious fluid administration may be required to resolve azotemia. Amlodipine may cause gingival hyperplasia in some animals; discontinuation of this medication and substitution of hydralazine or telmisartan is recommended in affected animals. Use of ACEI in dehydrated animals may result in prerenal azotemia and occasionally hyperkalemia. Again, temporary discontinuation of ACEI and reinstitution when hydration is normalized should improve renal function.

Once target blood pressure has been achieved with therapy, routine monitoring at least every three months is recommended. Body weight and condition may change over time, requiring adjustment of BP medication dosing. In dogs, dosage increases may be necessary over time to maintain BP in the target range. In patients in whom improvement of SBP into target range is difficult, partial reduction of SBP should still be sought. The risk of TOD increases with increasing SBP, so even some degree of improvement may be beneficial.

Prognosis

Prognosis for improvement in HT and decreased incidence and degree of TOD is good in patients treated promptly and monitored closely. Animals with retinal detachment may regain some amount of vision but may not attain complete normality. Decreased proteinuria may be noted in

animals receiving ACEIs or ARBs. In many patients, improvement may be subtle, but noted by the patient's owner as improvements in wakefulness, interest in eating and interaction, and increased activity. Improvement in general quality of life is reported in many patients.

Proof of improved survival in treated veterinary HT patients is lacking, but because untreated TOD contributes to decreased quality of life, untreated HT may lead to euthanasia.

Pulmonary Hypertension

Heidi B. Kellihan, DVM, DACVIM (Cardiology)

Department of Medical Sciences, University of Wisconsin, Madison, WI, USA

Etiology/Pathophysiology

Pulmonary hypertension (PH) is an elevation in systolic pulmonary arterial pressure greater than 30 mmHgI. Typically, PH is a complication of other primary diseases and occasionally occurs as an idiopathic process. Pulmonary arterial pressure is influenced by pulmonary blood flow, pulmonary vascular resistance, and pulmonary venous pressure. Ultimately, PH can be considered an umbrella term encompassing pulmonary arterial hypertension (precapillary PH) and pulmonary venous hypertension (postcapillary PH) (Figure 23.1).

Normally, the pulmonary vasculature is composed of thin-walled, low-pressure, high-capacitance, and low-resistance vessels. The pulmonary vasculature receives the complete cardiac output from the right heart with every contraction. Pulmonary hypertension results when there is an imbalance in pulmonary vascular mediators favoring vasoconstriction and muscularization of pulmonary arteries.

The three main components involved in PH development are the endothelin pathway, the prostacyclin pathway, and the nitric oxide pathway. In the presence of PH, the endothelin pathway contributes to the release of the potent vasoconstrictor, endothelin-1 from endothelial cells, resulting in pulmonary artery vasoconstriction, smooth muscle cell proliferation, and increased collagen synthesis. Prostacyclins, released by the pulmonary artery endothelium, normally mediates vasodilation, yet with PH, the vasodilatory effects are negated and the result is pulmonary artery vasoconstriction, cellular proliferation, and thrombosis. In the normal setting, nitric oxide release from vascular endothelium leads to an increase in vasodilatory cGMP. In the presence of PH, the nitric oxide pathway is deranged and results in vasoconstriction, smooth muscle cell proliferation and hypertrophy, platelet aggregation, and adhesion.

In addition to alterations in pulmonary vascular mediators contributing to PH, hypoxia also directly affects pulmonary vascular tone. Hypoxia (globally or locally) results in pulmonary artery vasoconstriction, which is in contrast to the systemic vasculature which vasodilates in response to hypoxia. Pulmonary artery vasoconstriction, in response to hypoxia, is a compensatory mechanism to divert blood away from hypoxic lung. Unfortunately, in the setting of PH, hypoxia from respiratory disease and left-sided congestive heart failure will worsen preexisting PH severity.

The vascular changes that result from the imbalance of these pathways promote muscularization of normally nonmuscular peripheral pulmonary arteries, medial hypertrophy, loss of peripheral pulmonary arteries, intimal proliferation, and vascular thrombosis. Ultimately, these vascular changes result in an increase in pulmonary vascular resistance leading to right ventricular hypertrophy that can result in congestive heart failure and death.

Epidemiology

Since PH usually occurs secondary to another disease process, the presence of PH in the population is potentially extensive. In reports of PH in dogs, the majority of cases result from left-sided heart disease (53%), pulmonary disease (28%), pulmonary thromboembolism (4%), heartworm disease (4%), congenital heart disease (i.e., left-to-right shunts) (3%), and miscellaneous causes (7%).

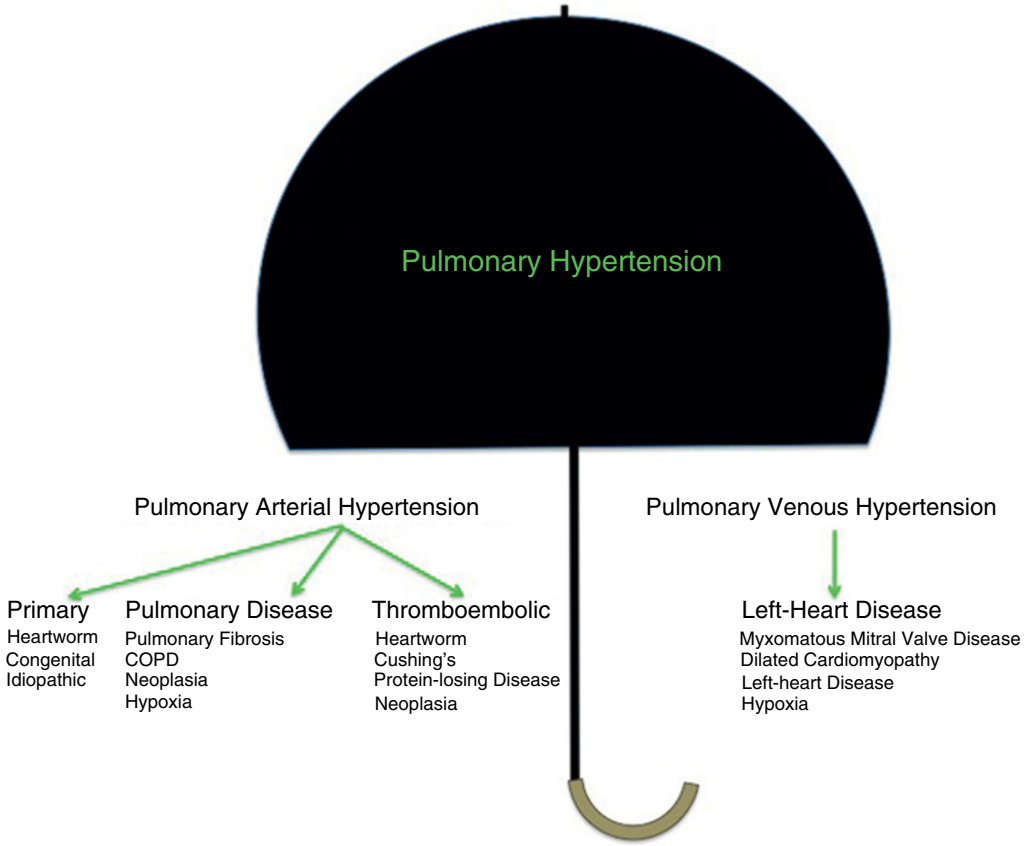

Figure 23.1 Pulmonary hypertension classification (see text for details). COPD, chronic obstructive pulmonary disease.

Signalment

The typical signalment of the patient with PH is a middle-aged to older small-breed dog, which reflects the population of dogs that are predisposed to myxomatous mitral valve disease and chronic pulmonary disease. The exceptions to this typical signalment include the young heartworm-infected dog and the dog with congenital heart disease that results in a reverse patent ductus arteriosus, reverse ventricular septal defect or reverse atrial septal defect.

History and Clinical Signs

The clinical history of the dog with symptomatic PH typically includes a combination of cough, dyspnea, lethargy, exercise intolerance, reported heart murmurs, ascites, and syncope. Because PH is often a consequence of underlying cardiac and pulmonary disease, it may be difficult to determine if the etiology of the clinical sign is a direct result of the PH or the underlying disease process.

Physical Examination

Dogs with PH often have abnormal physical examination findings that could be directly associated with increased pulmonary artery pressure or may be present secondary to the underlying disease process that resulted in the PH. These findings may include mitral and/or tricuspid insufficiency, heart murmurs, split or prominent second heart sounds, pulmonary crackles, cyanosis, and ascites. In most cases, detection of these abnormal physical examination findings in combination with typical clinical signs leads the clinician to suspect a diagnosis of PH.

Diagnosis

The goals of diagnosing PH include defining the underlying etiology of the PH, determining the severity of PH, assessing for evidence of right heart impairment, and to obtain information that may aid in patient prognostication.

Right Heart Catheterization

Right heart catheterization is the gold standard in diagnosing PH. Unfortunately, in veterinary medicine right heart catheterization is usually prohibitive due to the need for sedation and the unacceptable level of invasiveness required. Right heart catheterization provides true measurements of pulmonary artery pressure, right ventricular pressure, right atrial pressure, and pulmonary capillary wedge pressure. In addition, cardiac output measurements can be obtained to calculate pulmonary vascular resistance. Pulmonary vascular resistance (PVR) can be calculated by the following equation and expressed as dynes*sec*cm^{-5}.

$$PVR = \left[\left(mPAP - PCWP\right) \times 80\right]/CO$$

where mPAP indicates mean pulmonary artery pressure, PCWP is pulmonary capillary wedge pressure, and CO is cardiac output. Measuring and calculating mPAP, PCWP, and PVR help to determine the etiology of the PH. Based on these measurements, PH can be further classified as pulmonary arterial or venous hypertension. Pulmonary arterial hypertension can be diagnosed if the mPAP is increased, the PVR is elevated, and the PCWP is normal. Pulmonary venous hypertension can be diagnosed if the mPAP is increased, the PVR is normal, and the PCWP is elevated.

Thoracic Radiography

Pulmonary hypertension cannot be diagnosed by thoracic radiographs but there are specific changes associated with PH that, when present, would support the diagnosis of PH. Right heart enlargement, pulmonary artery enlargement, and pulmonary artery tortuosity are abnormalities that may suggest the presence of PH (Figure 23.2).

On the other hand, thoracic radiographs may only show changes that represent the underlying disease process that results in PH development (i.e., left-sided heart disease, left-sided congestive heart failure, primary pulmonary disease, patent ductus arteriosus). Noncardiogenic pulmonary edema can form as a direct result of PH and is typically in a patchy, diffuse alveolar lung pattern.

Electrocardiogram

The electrocardiogram is of limited use in contributing to PH diagnosis. If there are findings of a right axis deviation or evidence of right heart enlargement, this would help support the diagnosis of PH (Figure 23.3).

Echocardiogram

Echocardiography is the standard, noninvasive method for quantifying and diagnosing PH in veterinary medicine. Tricuspid regurgitation enables the clinician to estimate the systolic pulmonary artery pressure (Figure 23.4) and pulmonic insufficiency provides estimation of the mean and diastolic pulmonary artery pressures (Figure 23.5).

Based on tricuspid regurgitation, PH can be classified as mild (≥2.8 to <3.5 m/s, ≥31 to <50 mmHg), moderate (3.5–4.3 m/s, 50–75 mmHg) or severe (>4.3 m/s, >75 mmHg). Multiple two-dimensional, M-mode, and Doppler echocardiographic findings support the diagnosis of PH when tricuspid regurgitation is or is not present, and they include interventricular septal flattening (Figure 23.6), right ventricular hypertrophy, right ventricular dilation, decreased tricuspid annular plane systolic excursion, main pulmonary artery enlargement, abnormal pulmonary artery flow profiles, and decreased relative area change (a.k.a. distensibility index) of the right pulmonary artery.

White arrows show the borders of the tricuspid regurgitation jet. RA, right atrium; RV, right ventricle. (b) Spectral Doppler of the tricuspid regurgitation jet. * indicates the peak velocity (4.8 m/s, 92 mmHg).

Therapy

The goals of treatment for patients with PH are to treat the underlying disease, improve clinical signs (i.e., exercise intolerance, cough, syncope, congestive heart failure), lower pulmonary artery pressure, improve right ventricular function, prolong survival, and improve quality of life. Since PH is a sequela of an underlying disease in many patients, treating the underlying problem is often the first step. Targeting the primary disease (i.e., medications for

LV, left ventricular lumen; RV, right ventricular lumen.

congestive heart failure, anticoagulants for pulmonary thromboembolism, oxygen for respiratory disease) in conjunction with directly lowering PA pressures is often necessary.

There are multiple treatment options that target the different pathways involved in PH. Unfortunately, in veterinary medicine many are extremely cost prohibitive (i.e., endothelin antagonists cost ~$50 000/year) or require frequent and impractical administration of medication (i.e., prostacyclins require a continuous rate infusion or 6–12 times daily dosing).

Sildenafil

Sildenafil (Viagra® and Revatio®) is a selective phosphodiesterase-5 inhibitor that specifically targets receptors in the pulmonary vasculature and results in pulmonary artery vasodilation. In dogs with PH, sildenafil is administered at a dose of 1–2 mg/kg orally q8h. Sildenafil has been shown to lower the estimated pulmonary artery pressures in dogs and to improve clinical signs, survival times and quality of life. For the most part, sildenafil has minimal side-effects (i.e., gastrointestinal upset) in most cases of PH, with the exception of left-sided heart disease. Sildenafil can lower the pulmonary artery pressure to a dangerous level in dogs with elevated pulmonary venous pressure, resulting in flooding of the pulmonary capillaries and subsequent congestive heart failure. In dogs with left-sided heart disease, sildenafil is indicated only if the patient is syncopal or in right-sided congestive heart failure and pimobendan should be considered a viable alternative treatment option in these cases as a pulmonary artery vasodilator.

Prognosis

The prognosis for patients with PH is variable and dependent on the underlying disease process. With the advent of sildenafil, the prognosis for PH in dogs has improved. Now that there is a viable treatment option, clinicians are more readily recognizing PH as a clinical syndrome in patients with clinical signs, physical examinations findings, and diagnostic testing results consistent with PH.

Congenital Heart Disease

Brian A. Scansen DVM, MS, DACVIM (Cardiology)

Department of Clinical Sciences, Colorado State University, Fort Collins, CO, USA

Congenital heart disease (CHD) accounts for a small subset of dogs and cats presenting for veterinary care, estimated to account for less than 10% of cardiac disease in these species. However, the spectrum of CHD is broad and complex – making the diagnosis, treatment, and prognosis for these animals more challenging. Successful diagnosis and treatment of CHD provides great potential impact on patient survival – e.g., correctly diagnosing and closing a patent ductus arteriosus (PDA) can give an animal an additional decade or more of life. Since some forms of CHD are curable, it is imperative that animals with CHD not be missed during pediatric general examination.

Etiology

Causes of CHD

The precise etiology of CHD in nearly all veterinary species is not known. In humans, both genetic and environmental factors (drug use, toxin exposure, or infectious diseases during pregnancy) have been implicated in the genesis of CHD. In some breeds of dog there is a clear familial component, though the genetics have not been fully elucidated for any defect. Examples of diseases with a well-recognized inheritable component include patent ductus arteriosus (PDA) in the poodle, atrial septal defect (ASD) in the standard poodle and Doberman pinscher, subaortic stenosis (SAS) in the Newfoundland, pulmonary valve stenosis (PS) in the beagle, tetralogy of Fallot and related defects in the keeshond, ventricular septal defect (VSD) in the beagle and English springer spaniel, and tricuspid valve dysplasia (TVD) in the Labrador retriever.

The following paragraphs define some of the more common congenital heart malformations seen in animals as well as briefly describing the pathophysiology of such lesions. Figure 24.1 provides gross postmortem examples of several of these defects.

Left-to-Right Shunting Lesions

A shunt is defined as an abnormal mixing of blood in the heart or great vessels. The consequences of mixing between the left and right heart (shunting) vary depending on their magnitude and direction. In a left-to-right shunt (meaning from the systemic circulation to the pulmonary circulation) the signs are principally of volume overload to the lungs and the left heart because the normal amount of blood flowing to the lungs is augmented by the amount added from the shunt before returning to the left heart. Conversely, right-to-left shunts (where blood is diverted from the venous system to the systemic arterial system) result in poor oxygenation and cyanosis.

Patent Ductus Arteriosus

The ductus arteriosus is a normal structure in the fetus derived from the left sixth aortic arch and allows for the diversion of blood away from the lungs *in utero* when the lungs are not expanded by air. Within the first 12–24 hours after birth, the ductus begins to constrict in response to increased oxygen tension and is closed within the first week of life. If the ductus remains open, the fall in pulmonary vascular resistance allows flow from the aorta to the pulmonary artery. Persistent patency of the ductus arteriosus is the most common CHD of the dog and appears to be the second most common defect of the cat. Definitive therapy is an option for animals with PDA (via either interventional closure or surgical ligation) and long-term survival is excellent after closure if heart failure or frequent arrhythmias have not yet developed.

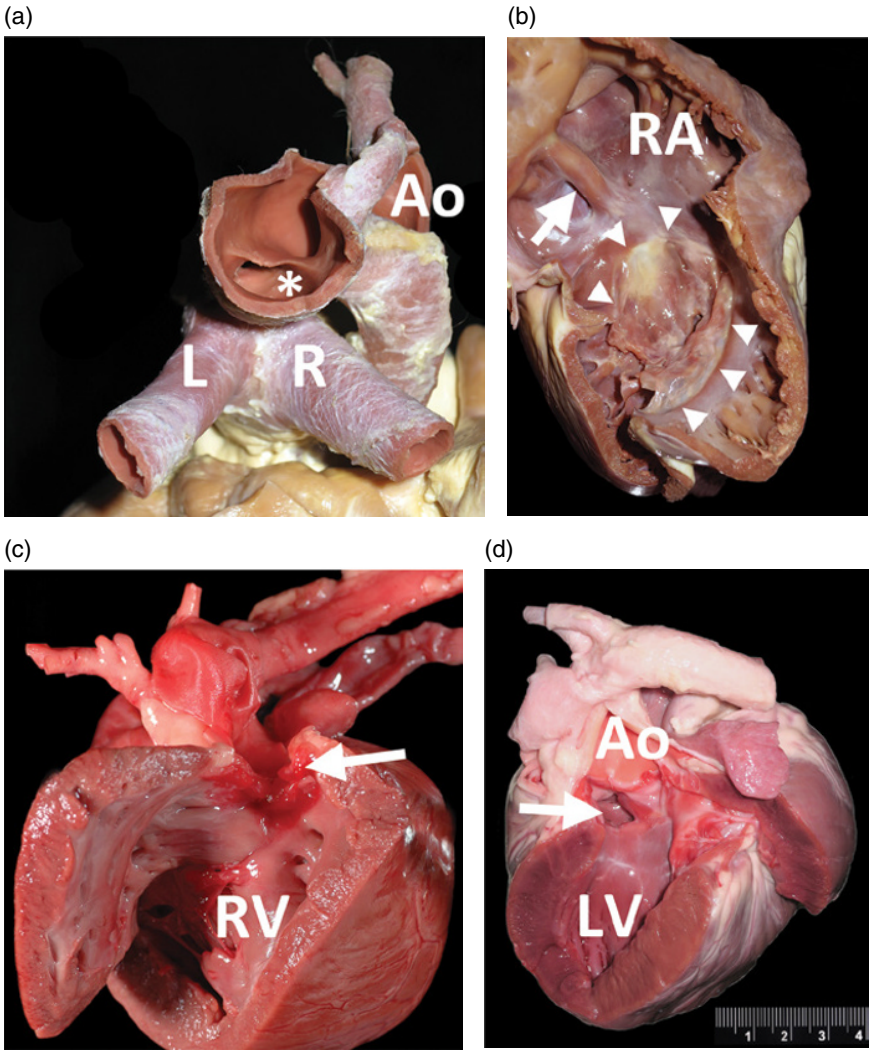

Figure 24.1 Gross postmortem specimens of common congenital heart defects. (a) A dog with patent ductus arteriosus; the image is taken from a caudal perspective with the descending aorta (Ao) coming toward the viewer. The origin of the ductus (*asterisk*) within the aorta can be seen traversing ventral toward the pulmonary artery, which is seen below as the left (L) and right (R) branches. (b) A dog with tricuspid valve dysplasia showing severe right atrial (RA) enlargement, a sheet-like tricuspid valve with fused, thick leaflets (*arrowheads*), and the ostium of a patent foramen ovale (*arrow*). (c) A dog with pulmonary valve stenosis showing moderate right ventricular (RV) hypertrophy and thickened pulmonary valve leaflets (*arrow*). (d) A dog with a large ventricular septal defect (*arrow*), seen in the membranous septum at the junction of the left ventricle (LV) and aorta (Ao).

Ventricular Septal Defects

Ventricular septal defects are the most common form of CHD in cats, and are also seen in ~9% of dogs with CHD. The pathophysiology of VSD is such that small defects (restrictive) may be well tolerated and not result in overt signs of cardiac dysfunction. Larger defects, however, result in the shunting of large volumes of blood from the left ventricle to the pulmonary circulation. The result of this increased pulmonary flow is damage to the lung vasculature and volume overload as the blood returns to the left heart. VSDs can occur in several different areas along the interventricular septum and numerous classification schemes have been developed to characterize the location of the defect. Exact confirmation of the size of the defect and secondary cardiac changes (e.g., aortic insufficiency or left ventricular enlargement) carry prognostic information for the clients. Additionally, some defects may be in a location amenable to catheter-based closure.

Atrial Septal Defects

As with a VSD, an atrial septal defect is a hole in the intracardiac septum separating the left and right heart. ASD is a rare defect in small animals, accounting for 2–6% of cases. In addition, it is often seen in association with other defects.

The degree of shunting depends on the size of the defect and the relative resistance of the pulmonary versus the systemic circulation. Typically, flow is driven from the left atrium across the ASD to the right, thereby increasing blood flow through the lungs. In contrast to left-to-right shunts such as PDA and VSD that result in left heart enlargement, atrial-level shunts cause right heart enlargement as the increased pulmonary venous return is shunted to the right atrium. With profound shunting, pulmonary hypertension and shunt reversal (Eisenmenger's physiology) may occur. Flow across the atrial septum may also develop if right atrial pressure becomes elevated, even in the presence of a normally formed atrial septum. This develops because the atrial septum is composed of two membranes that are closed during the first week of life as left atrial pressure exceeds right atrial pressure. If the animal has right-sided heart disease that elevates right atrial pressure (pulmonary stenosis, tricuspid dysplasia, tetralogy of Fallot), then the membranes may remain separate and allow flow across the atrial septum from right to left, referred to as a patent foramen ovale (PFO).

In the setting of a large ASD or concurrent defects, presenting signs will be an asymptomatic heart murmur, pulmonary overcirculation, or weakness, lethargy, or cyanosis associated with pulmonary hypertension and shunt reversal.

Atrioventricular Septal Defects

Defects of the atrioventricular septum (AVSD) may be considered separate from ASD or VSD. The atrioventricular septum is composed of centrally located tissue derived from the endocardial cushions. With an AVSD, defects may occur in the interatrial septum above the atrioventricular valves (a primum defect) or the interventricular septum just below the atrioventricular valves (inlet VSD), and may cause concurrent malformations of the atrioventricular valves. These defects were formerly referred to as endocardial cushion defects or defects in the atrioventricular canal. Signs vary depending on the relative size of each defect, but both congestive heart failure and cyanosis are common. AVSDs are relatively uncommon in dogs, but are seen in roughly 10% of cats with CHD.

The diagnosis is made by demonstration of the atrioventricular valves in the same imaging plane and variably sized defects in the ventral interatrial septum, inlet interventricular septum, and septal leaflets of the atrioventricular valves. There are also partial forms of AVSD recognized, depending on the presence/absence of atrial and ventricular septal defects as well as the degree of development of distinct mitral and tricuspid annuli.

Stenotic Valve Lesions

Subaortic Stenosis

Aortic stenosis occurs almost exclusively in the dog and is very rare in the cat. In almost all cases, obstruction is the result of subaortic tissue that narrows the left ventricular outflow tract. The tissue may be a discrete fibrous ridge or a tunnel-like narrowing. Rarely, valvar aortic stenosis is seen with fusion and/or thickening of the valve leaflets. In order to maintain forward stroke volume, such that the same volume of blood is pumped out of the left ventricle with each heartbeat, the blood must accelerate through the narrowing at a higher velocity. This requires that a greater left ventricular pressure be generated. The elevated left ventricular pressure leads to increased left ventricular wall stress and the development of concentric left ventricular hypertrophy.

The natural history of SAS includes a near normal lifespan for patients with mild disease; those with moderate to severe disease may experience exercise intolerance, syncope, left-sided congestive heart failure, or sudden cardiac death. All patients with SAS are believed to be at higher risk for development of bacterial endocarditis due to damage of aortic valve integrity from the turbulent, high-velocity jet. As such, antibiotic prophylaxis is advised for surgical or dental procedures, or in cases of potential bacteremia (e.g., skin laceration).

Screening young dogs for SAS bears some mention. First, SAS may progress as the dog grows because the subvalvar ridge does not change in size while the heart and stroke volume increase with the patient's development. Therefore, the final assessment of severity can only be made when the patient is full grown or nearly so. Second, screening breeding dogs for mild disease is a very real clinical problem as some breeds (boxer, greyhound, etc.) have aortic flow velocities that, with excitement, may be considered mild stenosis. This creates a gray zone between normal and mildly affected that can make breeding recommendations challenging.

Pulmonary Valve Stenosis

Pulmonary valve stenosis (PS) is principally a disease of the valve leaflets and/or annulus, rather than the subvalvar region as in SAS. PS comes in varying forms – fusion of the valve leaflets resulting in a narrowed orifice and doming valves, valvular thickening and dysplasia resulting in thick immobile valves that do not open normally, and annular hypoplasia where the valve annulus is abnormally small. The same hemodynamic derangements described above for SAS apply to the right ventricle in patients with PS. Right ventricular concentric hypertrophy is common and at times can be so severe as to create a dynamic and muscular subvalvar obstruction. In these instances, the right ventricle (RV) hypertrophies to such

an extent that it obstructs blood flow from getting out of the right heart during contraction.

The natural history of PS is more benign than for SAS, although patients may similarly suffer exercise intolerance, syncope, sudden cardiac death, and right-sided congestive heart failure if the disease is severe. Dogs with PS do not appear to be at an increased risk for endocarditis. Elevated right atrial pressure in the presence of a PFO may allow shunting of blood across the atrial septum from right to left and the development of cyanosis and secondary erythrocytosis. PFO is seen in ~30% of dogs with PS as the atrial septum does not close normally at birth due to elevated right atrial pressure. If flow from the right atrium to left atrium is substantial across a PFO, the animal may have significant mixing of poorly oxygenated blood from the right atrium to the left and clinical cyanosis.

Mitral and Tricuspid Valve Stenosis

Mitral valve dysplasia (MVD) and TVD may result in stenosis of these valves. Atrioventricular valve stenosis is rare in small animals, but both mitral stenosis and tricuspid stenosis are occasionally encountered in dogs and cats. These lesions lead to progressive atrial enlargement, atrial arrhythmias, and congestive heart failure if left untreated.

Regurgitant Valve Lesions

Mitral and Tricuspid Valve Dysplasia

Congenital malformations of the atrioventricular valves are considered rare in dogs, but account for a greater proportion of congenital heart disease in cats. Mitral valve dysplasia or TVD is a developmental abnormality of valve formation, resulting in abnormal leaflet shape, attachment, and/or function. Animals with MVD or TVD have pathology that typically results in regurgitation of the affected valve; however, a combination of stenosis and regurgitation may be encountered. Chronic mitral valve regurgitation leads to left ventricular and left atrial volume overload and dilation in the setting of MVD, which may lead to left-sided congestive heart failure. Similar progression may be seen in the right heart for TVD. Postmortem findings of dysplastic atrioventricular valves display fused and malformed leaflets with shortened chordae tendineae. Direct attachment from the papillary muscle to the valve is common.

Aortic and Pulmonary Valve Dysplasia

Congenital defects of the semilunar valves typically result in stenosis, as described above. In both SAS and PS, regurgitation, or insufficiency, of the affected valve is commonly observed by color Doppler imaging. Pulmonary valve insufficiency can even be seen in the majority of otherwise apparently healthy dogs when screened by Doppler echocardiography. However, aortic or pulmonary insufficiency is typically well tolerated and seldom of clinical significance. Rarely, cases of aortic or pulmonary valve dysplasia resulting in a predominantly regurgitant valve with severe insufficiency are detected, which may progress to cardiac decompensation.

Malformations of the Great Vessels

Vascular Ring Anomalies

Several malformations of the arterial system have been described in animals; the most common clinical presentation is a pediatric animal with dysphagia. The basic pathophysiology of these malformations is an embryologic defect resulting from abnormal persistence or regression of fetal vascular structures (aortic arches), ultimately leading to an abnormal spatial arrangement of the major intrathoracic arteries relative to the trachea and esophagus. Clinical signs are the direct result of extraluminal compression of the esophagus (resulting in megaesophagus, regurgitation, or aspiration pneumonia) and/or trachea (resulting in inspiratory stridor, coughing, or dyspnea). Persistence of the right aortic arch is the most common vascular ring observed in small animals. Therapy is directed at surgical decompression and transection of the offending structure, though esophageal dysfunction may persist if not corrected at a young age.

Cyanotic Heart Disease

Tetralogy of Fallot

Cyanotic heart disease is not common in small animals, but tetralogy of Fallot (ToF) is recognized in 2–6% of cases of CHD. ToF is the most common cyanotic CHD of humans and the four components of the tetralogy are right ventricular outflow tract obstruction, right ventricular hypertrophy, VSD, and dextroposition of the aorta. The underlying pathophysiology of this defect is believed to result from incomplete rotation and faulty partitioning of the developmental outflow tracts (comprising the distal portions of the left and right ventricles and the proximal portion of the great vessels). In simple terms, the aorta receives more of the embryologic tissue and aortic development occurs at the expense of the pulmonary trunk. Therefore, the ventricular septum cannot close because the aorta is enlarged and deviated to the right. The result of right ventricular outflow obstruction with a VSD is that deoxygenated blood is diverted to the systemic circulation, causing cyanosis, weakness, and collapse. Long-standing sequelae include erythrocytosis and blood hyperviscosity due to increased erythropoiesis.

Epidemiology

The prevalence of CHD in the dog and cat is difficult to quantify due to a lack of routine perinatal care, occurrence of conditions that are not apparent on routine physical examination, and hospital biases in published reports. The work of Detweiler and Patterson in the Philadelphia area suggested a CHD prevalence rate of 0.56% among 5000 dogs surveyed in the mid-twentieth century, while Buchanan found a rate of 0.67% for all dogs presented to the University of Pennsylvania between 1987 and 1989.

While the true prevalence of CHD in dogs and cats is unknown, there are data available evaluating the relative incidence of specific malformations in each species. The author compiled data from several studies in an attempt to summarize the relative prevalence of CHD in small animals. Ten applicable studies of CHD prevalence in dogs were found in the veterinary literature, comprising a sum of 4694 defects. When totaled, PDA (26%), SAS (24%), and PS (22%) were the most common and of nearly equal incidence. As such, these three diseases should be highest on a practitioner's differential list when listening to a puppy with a loud heart murmur; other congenital malformations of the heart are less common.

There are fewer data available about CHD prevalence in the cat. When evaluating several studies of CHD prevalence in cats, five studies covering 435 defects can be found. Ventricular septal defect appears to be the most common defect in the cat, comprising over 18% of cases. PDA is not generally considered a common disease in the cat, compared to the dog, but was noted in over 11% of defects. Dysplasia of the atrioventricular valves (mitral or tricuspid) each accounted for an additional 10% of defects. Feline CHD, therefore, should be considered distinct from and with a different incidence of common defects than canine CHD. Semilunar valve disease (PS and SAS) is exceedingly rare in cats.

Signalment

Age

Most animals with CHD present at a young age. However, adult animals with undiagnosed CHD may present later in life and often as a result of complications (heart failure, syncope, or cyanosis) from their cardiovascular disorder if it was not detected at an earlier age.

Sex

Both sexes are commonly afflicted with CHD, though sex predilections for some specific conditions have been identified. PDA has been reported to occur more commonly in female dogs, with a 3:1 female predominance. Pulmonary valve stenosis has not been recognized as having gender predominance except in the English bulldog, where males are more commonly afflicted than females. A male predominance for TVD has also been reported in the veterinary literature. In the cat, a male predominance has been suggested for atrioventricular valve malformation, aortic stenosis, and tricuspid valve dysplasia.

Breed

Numerous breed predilections have been reported for animals with CHD, particularly dogs. Table 24.1 shows a listing of common defects and the breeds known or suspected to have an increased prevalence of each defect. This table should not be considered authoritative or exhaustive, as spontaneous defects can occur in any breed at any time. Additionally, the incidence of CHD will likely change as breed populations continue to evolve. In the cat, few breed predilections are recognized other than endocardial fibroelastosis, which is reported to have a higher prevalence in Burmese and Siamese breeds.

History and Clinical Signs

Animals with complex defects or severe CHD may present within the first days to weeks of life due to failure to thrive, dyspnea, cyanosis, or syncope. It is likely that most puppies and kittens with severe cardiac malformations die early in life and prior to veterinary examination. The common history for dogs and cats with CHD is that of an asymptomatic pet with an appointment for a wellness exam, deworming, and vaccination. Auscultation during the physical examination of these patients is often the first and earliest clue that CHD may be present – as such, careful and thorough examination of all young animals is advised.

Diagnosis

Auscultation

Screening for congenital cardiac disease typically begins with a thorough physical examination performed at the first general health examination. Auscultation is imperative for screening of CHD as the most common forms of CHD typically present with a systolic (SAS, PS, VSD, TVD) or continuous (PDA) murmur. Auscultation in puppies and kittens should be performed in a quiet room with appropriate restraint and sufficient time devoted to a thorough examination.

Table 24.1 Breed predilection of common congenital heart defects in the dog

PDA	SAS/AS	PS	VSD	ASD	MVD	TVD	ToF	Vasc Ring
Australian shepherd	Bouvier de Flandres	Airedale terrier	Beagle	Boxer	Bull terrier	Boxer	English bulldog	Cocker spaniel
Bichon frise	Boxer	American Staffordshire terrier	Brittany spaniel	Doberman pinscher	German shepherd	German shepherd	Keeshond	German shepherd
Cavalier King Charles spaniel	Bull terrier	Beagle	Chow chow	Standard poodle	Golden retriever	Golden retriever	Wire-haired fox terrier	Great Dane
Chihuahua	Dogue de Bordeaux	Boxer	English bulldog		Great Dane	Great Dane		Irish setter
Cocker spaniel	English bulldog	Boykin spaniel	English springer spaniel		Mastiff	Labrador retriever		
Collie	German shepherd	Bull mastiff	French bulldog		Newfoundland	Old English sheepdog		
English springer spaniel	Golden retriever	Cavalier King Charles spaniel	German shepherd		Rottweiler	Weimeraner		
German shepherd	Great Dane	Chihuahua	Keeshond					
Keeshond	Newfoundland	Cocker spaniel	Newfoundland

AS, valvar aortic stenosis; ASD, atrial septal defect; MVD, mitral valve dysplasia; PDA, patent ductus arteriosus; PS, pulmonary valve stenosis; SAS, subaortic stenosis; ToF, tetralogy of Fallot; TVD, tricuspid valve dysplasia; Vasc Ring, vascular ring anomaly; VSD, ventricular septal defect.

For dogs, all valve areas should be evaluated, including the mitral valve area on the left thoracic wall where the apical impulse is felt most strongly, the semilunar valve area (aortic and pulmonary valves) at the left heart base (the ventral 2nd–4th intercostal spaces), the area of the great vessels just dorsal to the left heart base, and the tricuspid valve area on the right thoracic wall. In the cat, localization of individual valve areas is more problematic and auscultation is usually directed along the left and right sternal border, moving from caudal to cranial on either side.

Murmur location and intensity are useful in differentiating between types of CHD as well as for distinguishing a physiologic or innocent murmur from that caused by CHD. Left and right apical systolic murmurs are commonly due to atrioventricular valve regurgitation and, in a young animal, if an apical systolic murmur is heard, defects of MVD and TVD should be considered most strongly. The murmur of a typical membranous VSD is harsh and systolic at the right sternal boarder. Left basilar systolic murmurs can be more problematic as they can indicate either an innocent murmur or CHD such as SAS, PS, or ASD. High-intensity murmurs (grade IV–VI or louder) usually indicate the presence of significant CHD regardless of location and are an indication for more advanced diagnostics. However, less intense murmurs (grade III–VI or less) may originate either from CHD or an innocent cause.

Evaluating left basilar systolic murmurs with a rubric of the 6 Ss (Table 24.2) can be useful to try and guide the need for additional diagnostic testing. In general, a soft left basilar systolic murmur heard in a young puppy or kitten that decreases in intensity over the first months of life and/or disappears by 6 months of age is likely to be innocent. If the murmur is loud or harsh, continuous or diastolic in duration, or associated with concurrent cardiac signs (arrhythmia, cough, syncope), then CHD should be considered more likely and further testing should be advised.

Other aspects of a cardiac physical examination include evaluation of the mucous membranes, jugular veins, and pulse quality. Mucous membranes should be evaluated for evidence of cyanosis, which may be indicative of a right-to-left intracardiac shunt. Very poor peripheral perfusion can be suggested by pale mucous membranes and/or a prolonged capillary refill time even in the absence of an obvious heart murmur. Hypokinetic femoral pulses are commonly detected in moderate to severe SAS, while a hyperkinetic pulse quality is suggestive of a wide pulse pressure from PDA or severe aortic insufficiency. Jugular pulsation with or without distension can suggest tricuspid regurgitation or elevated right-sided pressures due to tricuspid valve dysplasia, PS, or pulmonary hypertension from severe left-to-right shunting defects.

Additional Diagnostic Tests

While the physical examination is an important aspect of screening for the presence of CHD, it is difficult to make a definitive diagnosis from signalment and physical examination alone. Ancillary diagnostic tests, like thoracic radiography and electrocardiography (ECG), may be useful in narrowing the differential diagnostic list and determining disease severity, but can also add cost to the initial evaluation without providing definitive diagnostic information. In current veterinary practice, echocardiography with Doppler is considered the gold standard diagnostic test for confirmation of CHD.

Table 24.2 An auscultation rubric, the six Ss, for evaluation of a left basilar systolic murmur in a young animal to help determine the likelihood that the murmur is physiologic or innocent versus pathologic

Descriptor	An innocent or physiologic murmur is more likely	Significant congenital heart disease is more likely
Sensitive	The murmur is absent or much softer at rest; it changes with position or phase of respiration	The murmur is present at rest or with activity; it can be heard at all times
Short	The murmur is of short duration, predominantly early systolic	The murmur remains loud throughout nearly all of systole
Single	There are no other associated abnormal heart sounds or physical exam abnormalities; no clicks, gallops, or arrhythmias are heard	Additional auscultatory abnormalities are present and/or there are other physical exam abnormalities
Small	The murmur is localized to the left base or one single location, it does not radiate	The murmur radiates from the point of maximal intensity
Soft	The murmur is soft or quiet; generally grade I or II out of VI	The murmur is loud, generally grade III–VI or louder
Systolic	The murmur duration is limited to systole	The murmur is continuous or a diastolic component can also be appreciated

Electrocardiography

Electrocardiography may be beneficial in detecting cardiac changes related to CHD, though is most useful for characterizing dysrhythmias heard on auscultation. CHDs that cause ventricular enlargement, such as PS and SAS, may provide a substrate for ventricular arrhythmias secondary to myocardial ischemia. However, ECG is a more specific rather than sensitive test as animals with CHD may have a normal ECG. Figure 24.2 shows examples of rhythm disturbances that may be seen in the setting of CHD. Again, it should be noted that such findings are supportive of a diagnosis, but not definitive.

Thoracic Radiography

Similar to ECG, thoracic radiographs provide useful supplementary information in the evaluation of a patient with suspected CHD. However, thoracic radiography is most useful when the veterinarian suspects an animal's heart disease has decompensated and resulted in pulmonary edema or pleural effusion. If signs of respiratory compromise or cough are apparent on examination, thoracic radiographs are strongly advised. In the asymptomatic animal with a murmur, however, they are less specific than echocardiography in confirming a diagnosis. Figure 24.3 provides examples of radiographic evidence of decompensated heart failure secondary to CHD.

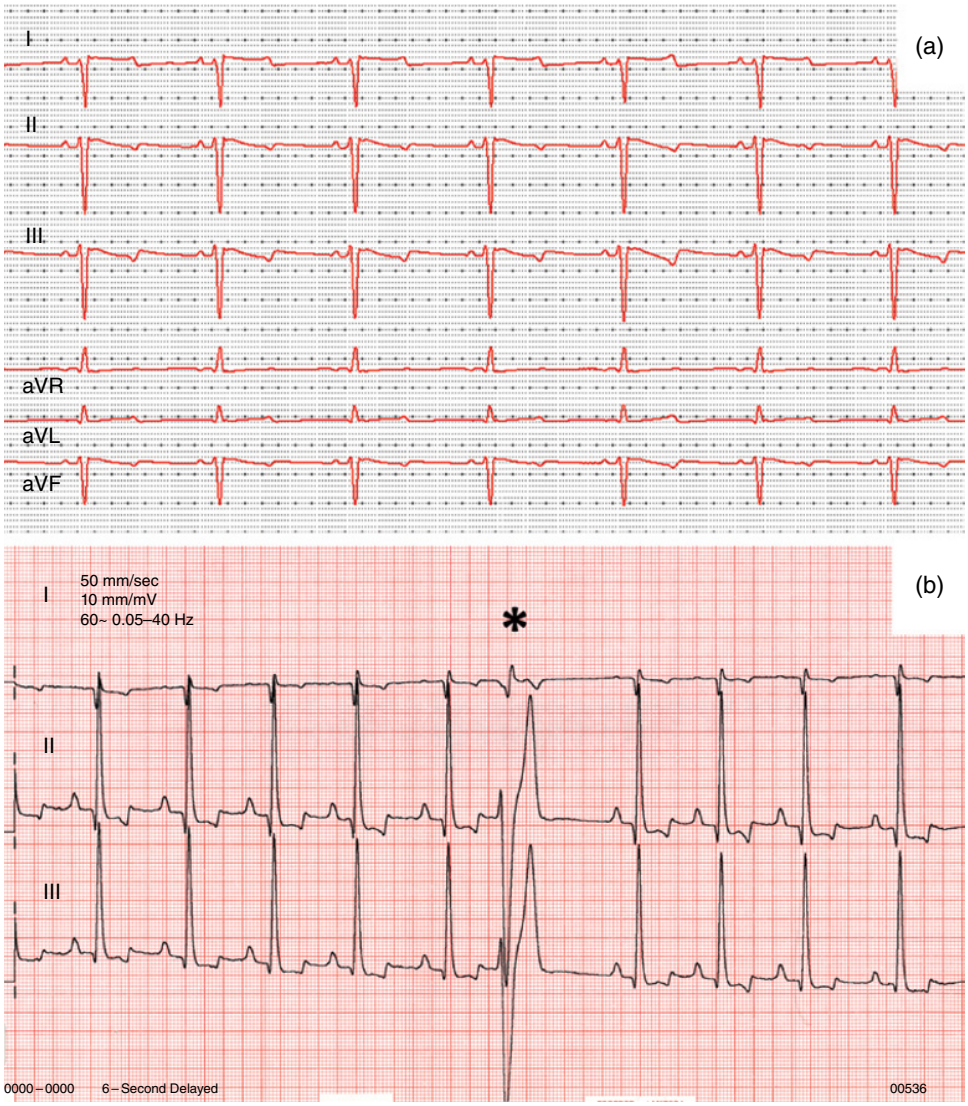

Figure 24.2 Example ECG traces from two dogs with congenital heart disease, recorded at 50 mm/s paper speed, calibration of 1 cm/mV. (a) Six-lead ECG from a 1.5-year-old miniature pinscher with pulmonary valve stenosis. A regular rhythm with right axis deviation, characterized by prominent S-waves in leads I, II, and III, is seen. (b) A three-lead ECG trace from a 1-year-old golden retriever with subaortic stenosis. An underlying sinus arrhythmia is seen with one premature ventricular complex (*asterisk*). The R-wave amplitude is tall, consistent with left ventricular hypertrophy, and the ST segment is mildly depressed, consistent with subendocardial ischemia – both findings common in dogs with subaortic stenosis.

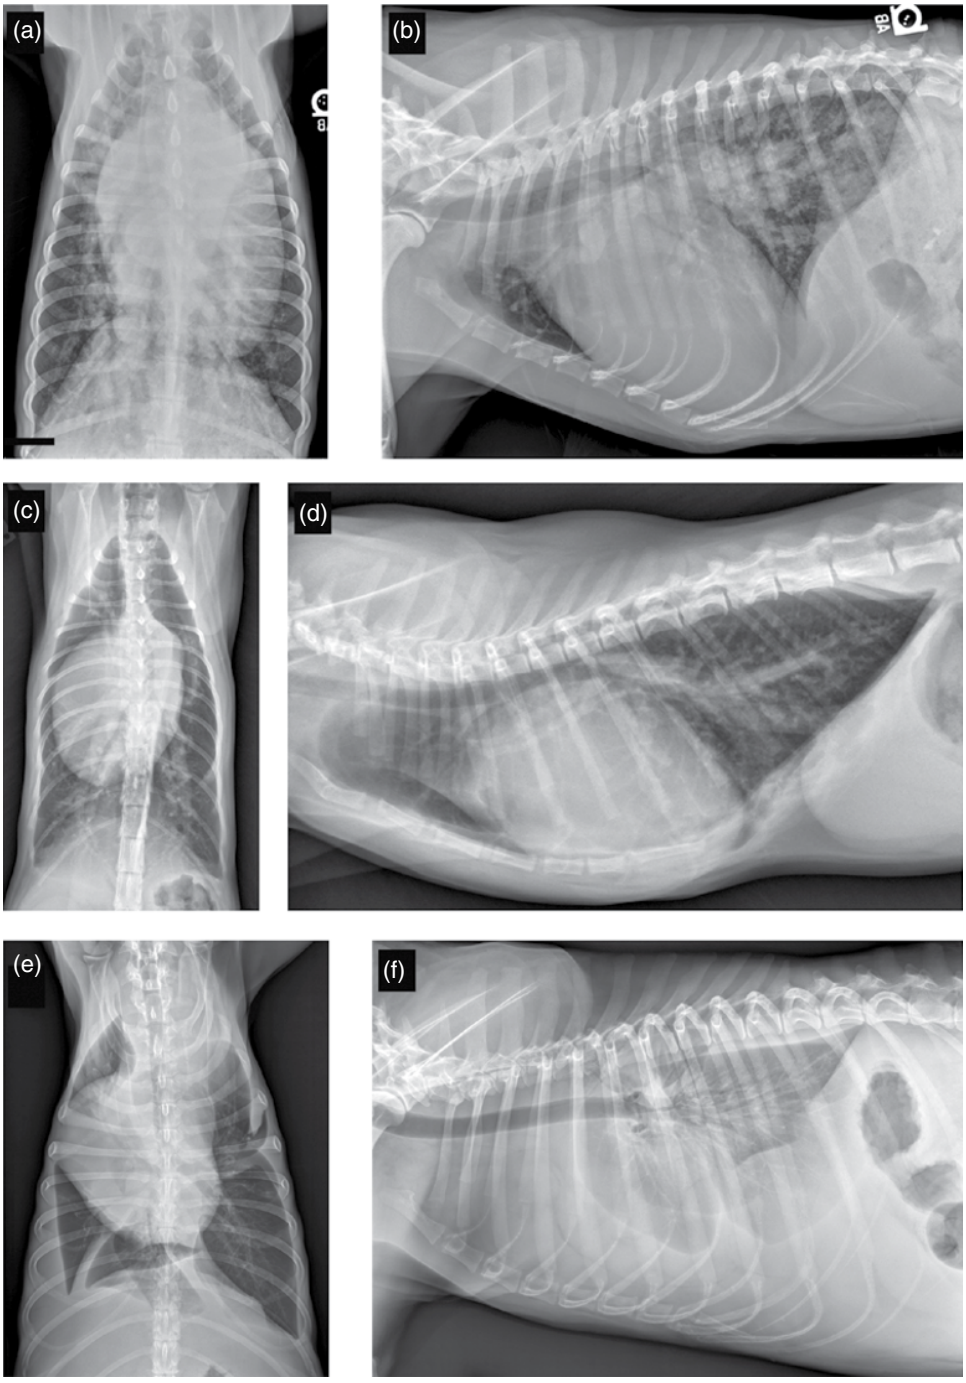

Figure 24.3 Compilation of thoracic radiographs from two dogs and a cat with congenital heart disease and decompensated heart failure. (a,b) A 1.5-year-old mixed-breed dog with a PDA. Severe left heart enlargement, dilation of the aortic arch, pulmonary venous distension and tortuosity, and perihilar interstitial densities are apparent. (c,d) A 5-month-old Angora cat with a large atrial septal defect. Severe cardiac enlargement, pulmonary overcirculation, and mild pulmonary interstitial infiltrates are apparent. (e,f) A 3-year-old German shepherd dog with tricuspid valve dysplasia and right-sided congestive heart failure. Right atrial and ventricular enlargement is evident in the dorsoventral view (e). In the lateral view (f), the thoracic structures, including the cardiac silhouette, are obscured by severe pleural effusion.

Cardiac Biomarkers: Troponin and NT-proBNP

In recent years, the use of cardiac biomarkers to screen animals for the presence of acquired cardiovascular disease has gained in popularity. The biomarkers receiving the most attention in veterinary cardiology include cardiac troponin I (cTnI) and the amino terminus of the prohormone B-type natriuretic peptide (NT-proBNP). There have been no comprehensive studies looking at the utility

of these tests in animals with CHD, though evidence in human cardiology suggests that these markers are often elevated in children with severe CHD. At this time, no guidance can be given for or against the utility of cardiac biomarkers in screening animals for CHD.

Echocardiography

History, physical examination, thoracic radiography, and ECG are all useful diagnostic tests for determining the presence of CHD, but are less capable of making a definitive diagnosis, assessing disease severity, or ruling out the presence of multiple or complex congenital lesions. In veterinary medicine, echocardiography with Doppler is the noninvasive gold standard for definitive diagnosis of CHD. All animals with a high suspicion of CHD should ideally have a detailed echocardiogram performed by a veterinarian trained in the diagnosis of CHD. Echocardiography allows for the detection of specific types of CHD, the presence of concomitant defects, and assessment of disease severity, risk for complications, direction of cardiac shunting, estimate of intracardiac pressures, and likelihood of congestive heart failure. Echocardiography is also necessary in assessing the need for therapy as well as for planning interventional or surgical options. Figure 24.4 provides representative two-dimensional images of common CHD seen in the dog and cat by echocardiography.

Angiography

Nonselective or selective angiography with fluoroscopic visualization of cardiac structures was historically the definitive test for CHD prior to the advent of echocardiography. For some defects, angiography is still utilized, particularly for lesions of the great vessels that are not easily appreciated by ultrasound. Figure 24.5 shows a nonselective, digitally subtracted angiogram of a right-to-left shunting PDA in a cat, while Figure 24.6 shows a right ventriculogram from a dog with PS. In practice, angiography is used most commonly at the time of interventional therapy to confirm the diagnosis, visualize the defect to be addressed, and guide intervention with balloon or device, as discussed in the interventional therapy section.

Cross-Sectional Imaging

Cardiac computed tomography and magnetic resonance imaging allow three-dimensional reconstructions of the heart and great vessels. Such imaging modalities are commonly employed in human medicine to evaluate children with CHD and case reports of their use in veterinary medicine are present in the literature. Figure 24.7 shows a three-dimensional reconstruction of a computed tomographic angiogram in a dog with PS. The benefit of cross-sectional imaging is likely greatest in instances of complex CHD where the cardiac anatomy can be viewed from multiple perspectives *in situ*.

Therapy

Medical Therapy

Asymptomatic Disease

Treatment of asymptomatic CHD depends on the specific underlying disease and its severity, so definitive diagnosis is essential. In general, diseases of moderate to severe outflow tract obstruction causing concentric hypertrophy (e.g., SAS and PS) are treated by the author with beta-blockers such as atenolol. Atenolol is typically uptitrated in dose over 4–8 weeks, starting at 0.2–0.5 mg/kg (0.1–0.2 mg/lb) q12h PO and increasing to a target dose of 1–1.5 mg/kg (0.4–0.7 mg/lb) q12h PO. The rationale for such therapy is that beta-blockers help to reduce the force of myocardial contraction, thereby reducing myocardial oxygen demand and protecting the diseased/hypertrophied myocardium. The antiarrhythmic properties of atenolol are also believed to be of benefit as these patients are at risk for life-threatening arrhythmias. Atenolol is often chosen given its low cost, appropriate size tablets, and ease of administration.

Therapy for asymptomatic diseases of volume overload such as moderate to severe mitral or tricuspid regurgitation and left-to-right shunting defects like PDA, prior to development of CHF, is controversial. However, the addition of angiotensin converting enzyme (ACE) inhibitors such as enalapril at 0.5 mg/kg (0.2 mg/lb) q12h PO is common if there is severe ventricular dilation, impaired cardiac output, and atrial enlargement suggesting high risk for development of CHF.

Symptomatic Disease

Medical therapy of symptomatic CHD depends on the type of lesion and developing clinical signs. Diseases of outflow tract obstruction (SAS, PS) commonly cause exercise intolerance and syncope related to reduced cardiac output, inappropriate baroreceptor activation, and/or ventricular arrhythmias. Life-threatening or symptomatic ventricular arrhythmias are treated with antiarrhythmic agents. Sotalol at a dose of 1–2 mg/kg (0.4–0.9 mg/lb) q12h PO is typically the first-line antiarrhythmic of choice so long as ventricular function is not severely depressed. Syncope that occurs without ventricular arrhythmias (presumed to be reflex-mediated syncope whereby the cardiac hypertrophy stimulates an exaggerated baroreceptor response) is typically treated with beta-blockade. Modification of exercise level with avoidance of high-level intense or burst activity will also commonly reduce this clinical sign.

Diseases of left-sided volume overload will commonly cause symptoms of cough in the dog prior to the onset of CHF due to severe left atrial enlargement and resultant left bronchial compression. Bronchial compression in the absence of CHF may be treated with

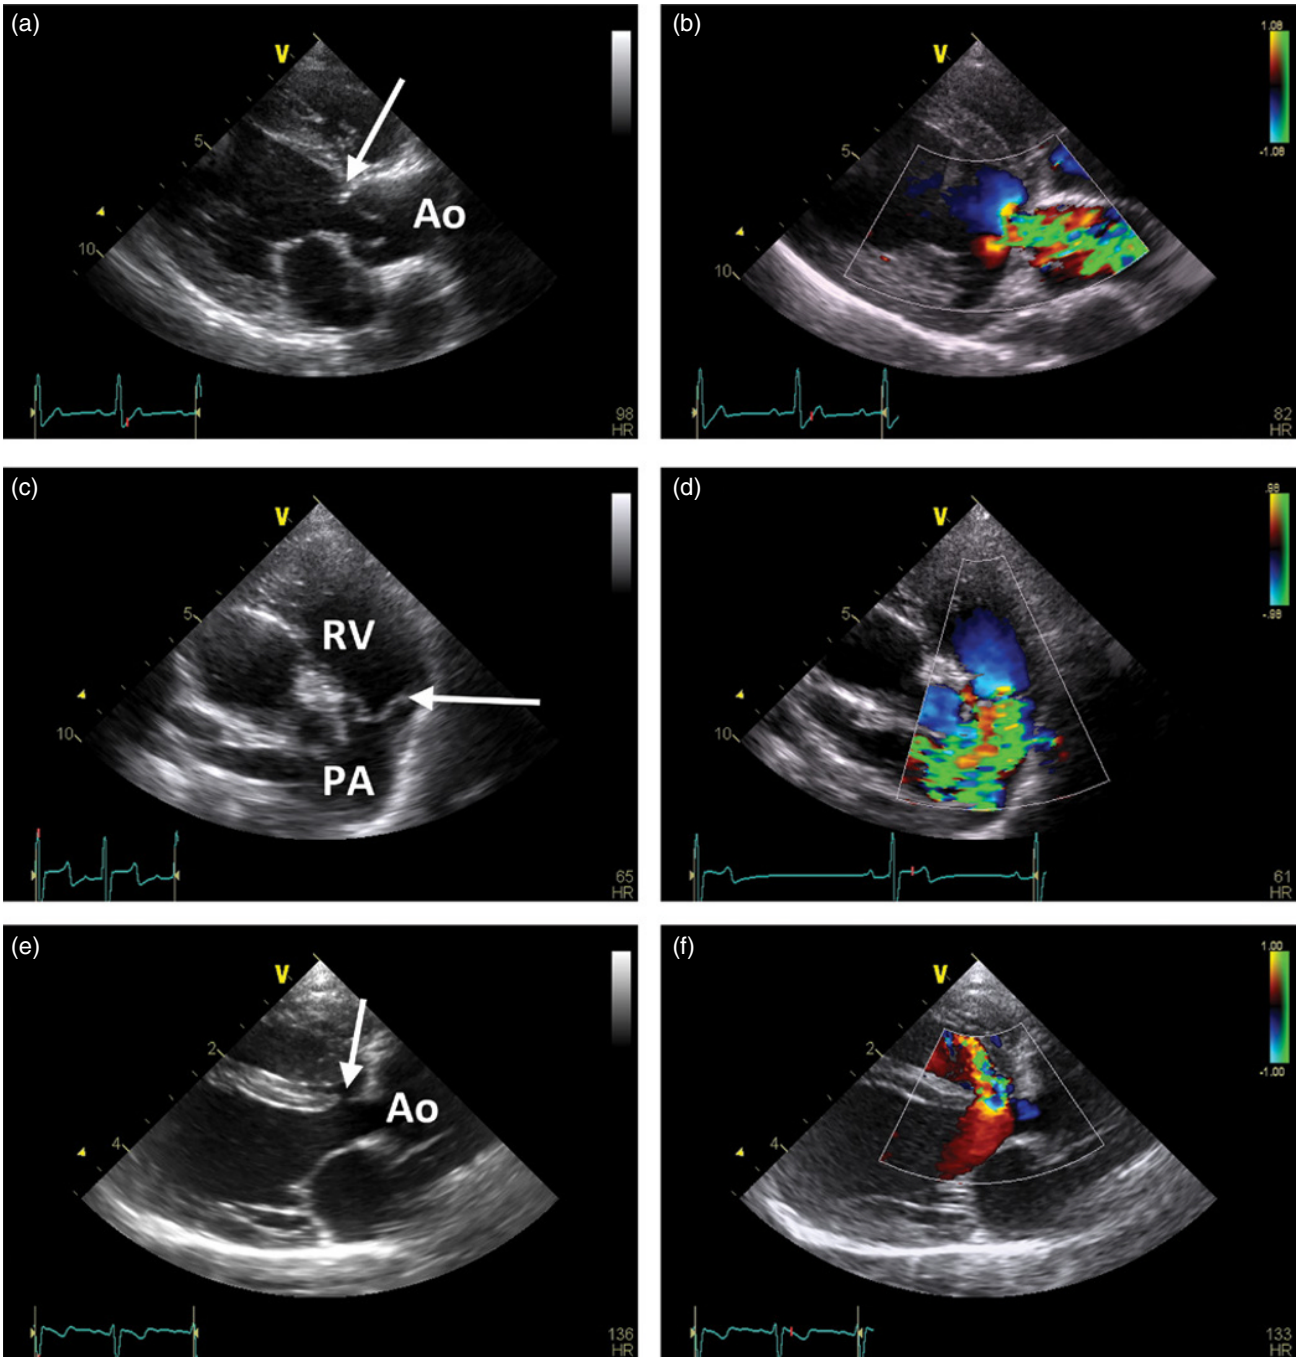

Figure 24.4 Representative two-dimensional echocardiographic images of common congenital heart defects in two dogs and a cat. (a,b) Long-axis images from a 6-month-old Newfoundland with subaortic stenosis. The ascending aorta (Ao) is dilated and there is a ring of hyperechoic tissue (*arrow*) immediately below the aortic valve. Turbulent flow is seen originating at this location in (b). (c,d) Short-axis images of pulmonary valve stenosis in a 9-month-old mixed-breed dog. The right ventricle (RV) is hypertrophied, the pulmonary trunk (PA) is dilated, and the pulmonary valve leaflets are thickened and fused together at their tips (*arrow*). Turbulence begins at the level of the stenosed valve in (d). (e,f) Long-axis images of a membranous ventricular septal defect (VSD) in a cat. Immediately below the aorta (Ao) there is a drop-out in the ventricular septum consistent with a VSD (*arrow*). Color Doppler shows the direction of the turbulent flow across the VSD from left to right in (f).

ACE inhibitors and low-dose furosemide (1 mg/kg [0.5 mg/lb] q12h PO) to decrease preload and left atrial pressure, thereby reducing bronchial compression and minimizing symptoms.

Pulmonary hypertension can develop in CHD secondary to left-to-right shunting lesions such as PDA, VSD, and ASD or secondary to chronic, severe elevations in left atrial pressure. Pulmonary hypertension therapy is

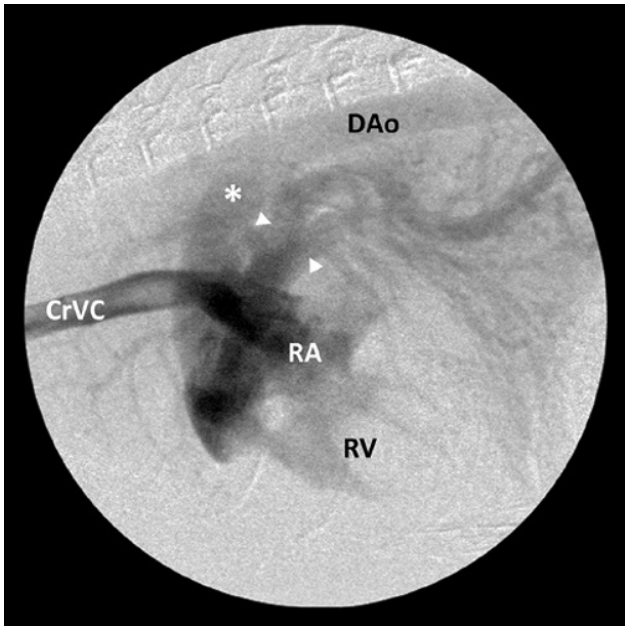

Figure 24.5 Lateral nonselective digitally subtracted angiogram of a right-to-left shunting PDA in a 1-year-old cat. The injection was made into a cephalic vein and contrast can be seen in the cranial vena cava (CrVC), right atrium (RA), right ventricle (RV), and pulmonary arteries (*arrowheads*). Contrast can be seen to communicate from the pulmonary artery through the ductus (*asterisk*) and into the descending aorta (DAo).

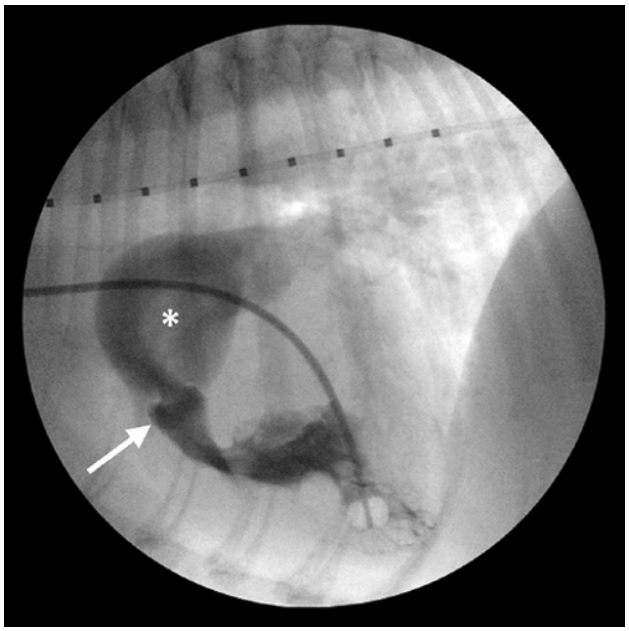

Figure 24.6 Selective right ventriculogram from a 6-month-old English bulldog with pulmonary valve stenosis. An angiographic catheter is present in the right ventricle and contrast is injected, highlighting thickened and doming pulmonary valve leaflets (*arrow*), muscular hypertrophy and narrowing of the right ventricular outflow tract below the valve, and a dilated pulmonary trunk (*asterisk*). A calibration catheter is present in the esophagus.

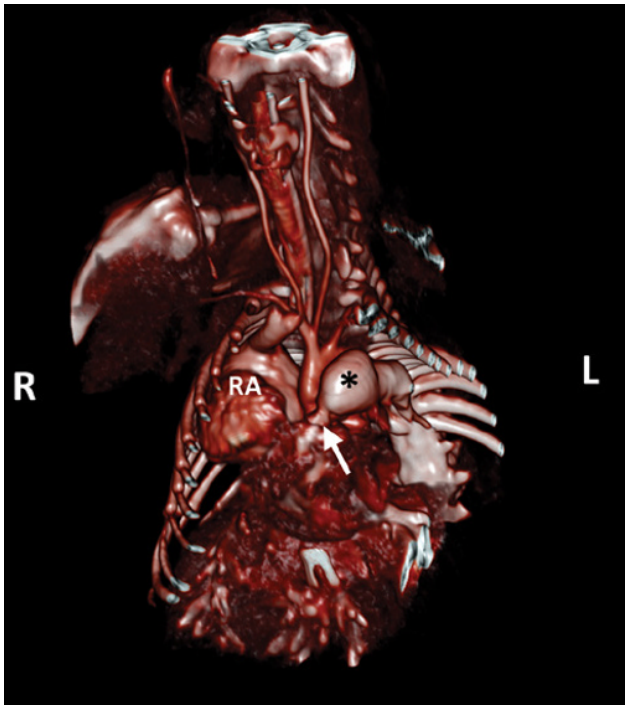

Figure 24.7 Three-dimensional reconstruction of a computed tomographic angiogram in a 2-year-old English bulldog with pulmonary valve stenosis. The thorax is viewed from a ventral perspective and the narrowed pulmonary valve annulus can be seen (*arrow*) with poststenotic dilation of the pulmonary trunk (*asterisk*) and a severely dilated right atrium (RA).

instituted with the development of secondary symptoms such as severe exercise intolerance, syncope, right-sided CHF, and shunt reversal causing right-to-left shunting, hypoxemia, and erythrocytosis. Therapy is aimed at pulmonary vasodilation, most commonly with phosphodiesterase-V inhibitors like sildenafil (usual dose 2 mg/kg [1 mg/lb] q8–12h PO).

Defects leading to pulmonary hypertension and shunt reversal (so-called Eisenmenger's physiology) lead to cyanosis and secondary erythrocytosis (packed cell volume >55%) and are treated with periodic phlebotomy or chemotherapeutic agents causing reduction in RBC production, such as hydroxyurea. The aim of phlebotomy or hydroxyurea therapy for cyanotic heart disease is a packed cell volume of approximately 55–60% as this level of erythrocytosis balances increased oxygen-carrying capacity without hyperviscosity.

Severe congenital cardiac disease due to either pressure or volume overload will commonly lead to development of left- or right-sided CHF. Left-sided CHF presents with coughing, tachypnea, and respiratory distress secondary to pulmonary edema, whereas right-sided CHF presents with signs of jugular distension, hepatomegaly, ascites, and/or pleural effusion. CHF, regardless of cause, is treated with diuretics and ACE inhibitors.

In the author's experience, right-sided CHF will commonly need higher doses of oral furosemide or an alternative diuretic such as torsemide due to the potential for intestinal edema causing decreased gastrointestinal absorption. ACE inhibitors should always be used in the treatment of chronic CHF to decrease RAAS activation associated with advanced heart failure and diuretic administration.

Pimobendan has become standard of care in the treatment of CHF secondary to acquired cardiac diseases, such as dilated cardiomyopathy and chronic degenerative valve disease. While no definitive data are available on the use of pimobendan in congenital cardiac disease, most cardiologists advocate its use with CHF due to diseases of volume overload such as PDA or mitral valve dysplasia. The administration of pimobendan as a treatment for CHF secondary to diseases of pressure overload like SAS and PS is becoming more commonplace. However, extralabel use of pimobendan should be done cautiously in the setting of outflow tract obstruction due to potential for increase in pressure gradient, wall stress, and myocardial oxygen consumption. Consultation with a veterinary cardiologist is advised prior to pimobendan use in cases of SAS and PS with CHF.

Surgical and Interventional Therapy

Congenital heart disease can be palliated medically, as noted above, but also may be treated by minimally invasive (interventional) or traditional surgical techniques whenever possible. An accurate diagnosis of CHD is critical to appropriately guide therapy as some animals can go on to live a normal life if treated early.

The decision to operate or pursue transcatheter therapy relates to the expertise of the veterinarian performing the procedure, anatomy of the defect, and client preference. Prospective comparison studies are lacking in veterinary medicine, though retrospective data on PDA closure suggest comparable to improved outcomes from a transcatheter approach compared to surgery. Novel devices, such as the Amplatz™ canine ductal occluder, have greatly improved the ease with which PDA occlusion can be performed from a transarterial approach (Figure 24.8). Gordon *et al*. showed complete PDA occlusion in 40 of 41 dogs treated by a transarterial canine-specific device with no perioperative mortality compared to a reported perioperative mortality of 2–8% in the surgical literature during open PDA ligation [1].

The CHD conditions which currently have a well-established surgical or interventional treatment option include PDA, persistent right aortic arch (PRAA), and PS. Dogs with VSD or ASD have been successfully treated by both surgical and interventional techniques and, though costly, open surgical repair and newer transcatheter devices for closure of these defects may be considered for the motivated client. Cyanotic ToF dogs can be palliated by surgical construction of a systemic-to-pulmonary anastamosis, typically a modified Blalock–Taussig shunt, which improves pulmonary blood flow and lessens central cyanosis. Open-heart repair of ToF has also been described in the dog. Atrioventricular valve dysplasia is seldom treated by surgical or interventional techniques but if a stenotic component is present, balloon valvuloplasty of the tricuspid or mitral valve may be considered. Open surgical repair of a dysplastic valve may also be considered for the motivated client.

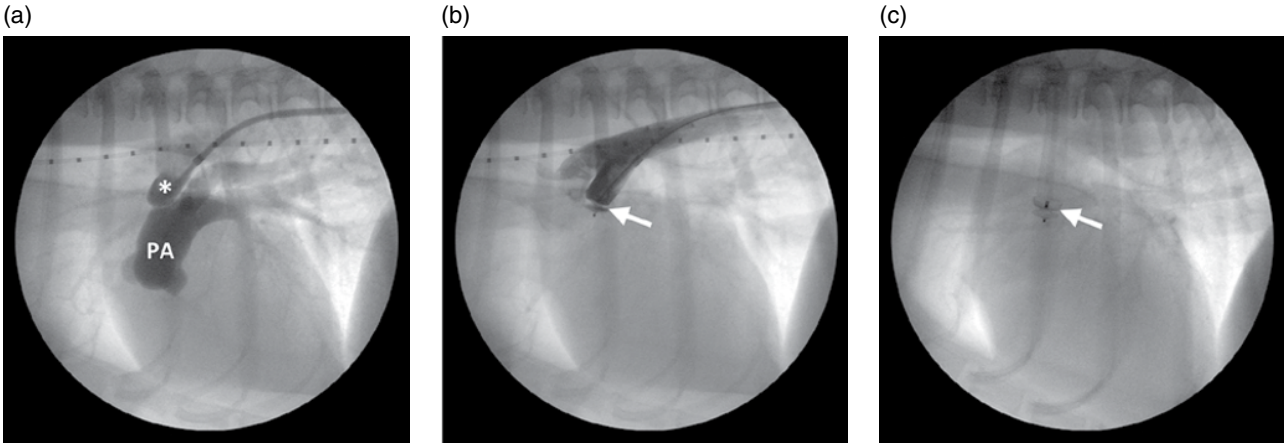

Figure 24.8 Fluoroscopic images obtained during transcatheter occlusion of PDA in a 2-year-old mixed-breed dog. (a) A sheath has been advanced from the femoral artery to the thoracic aorta and injected contrast agent defines the ductus (*asterisk*) and the pulmonary trunk (PA). (b) The Amplatz™ canine ductal occluder (*arrow*) has been advanced through the same sheath and deployed across the ductus, with contrast showing complete ductal occlusion. (c) The wire attached to the Amplatz™ canine ductal occluder has been removed as well as the sheath, and the device (*arrow*) is left permanently in place.

Prognosis

The prognosis for the animal with CHD is heavily dependent on the underlying condition and the severity of the defect. Mild stenosis of the semilunar valves (PS, SAS) rarely causes morbidity or altered survival. Conversely, dogs with severe SAS have been reported to have median survival of only 1.5–4 years. For left-to-right shunting lesions, prognosis is highly dependent on the volume of shunt flow. Small shunts (e.g., restrictive VSDs) are often well tolerated and can be associated with a normal lifespan. Large PDAs, however, are known to result in mortality of 60% or more within a year of diagnosis if they are not closed by surgery or intervention.

For most CHD, there is a paucity of literature on prognosis and survival. Experienced cardiologists have seen animals with severe disease live a near-normal lifespan, while other animals with moderate disease die from the defect prematurely. At the present time, predicting the precise prognosis for an individual animal with CHD is very difficult. Serial evaluations to detect asymptomatic cardiac dysfunction or dysrhythmias, as well as the development of clinical signs (cough, lethargy, collapse, etc.), are currently the methods used to monitor these animals.

Canine Degenerative Myxomatous Mitral Valve Disease

Etiology and Pathophysiology

Canine chronic myxomatous mitral valve disease (MMVD) is the result of a progressive myxomatous degeneration of mitral valve leaflets and chordae tendinae. Pathologic changes include excessive deposition of mucopolysaccharide, fragmentation of elastin, and disorganization and disruption of collagen.

The exact etiology of the disease has not been established. Because the disease has a high prevalence in some breeds, such as Cavalier King Charles spaniel (CKCS), a genetic predisposition has been hypothesized. Swenson and co-workers provided the first evidence of a genetic predisposition in 1996. These authors reported that CKCS dogs with a more severe disease status produced more offspring with murmurs and with murmurs of higher intensity than dogs with a low-intensity status. They concluded that MMVD is inherited as a polygenic trait. The same etiology has been reported for other breeds. It has also been reported that the threshold for the expression of the disease is lower in males than in females. This would explain why males present with the disease at a younger age.

Recently, using a genome-wide association study, two specific loci associated with development of MMVD in CKCS have been identified. It is likely that other factors might contribute to the development of the disease, including the anatomy of the mitral valve, obesity, and exercise. Recently, serotonin has been hypothesized as playing a role in the pathogenesis of MMVD. However, despite similarities in the myxomatous pathology of serotoninergic and degenerative mitral valves, a direct cause–effect relationship between serotonin and the pathogenesis of MMVD has not been established.

Activation of valvular interstitial cells (VICs) is likely to play an important role in the pathogenesis of the disease. VICs represent the most common cell type in the cardiac valves and are responsible for extracellular matrix synthesis, valvular repair, and remodeling. VICs are commonly present in a quiescent state but can be activated by endothelial damage or valvular stress. Activated VICs are able to synthesize collagen, fibronectin, elastin, and growth factors and are responsible for extracellular matrix remodeling through production of matrix metalloproteinases and their inhibitors (tissue inhibitors of metalloproteinases [TIMPs]). Eventually, this process leads to decreases in collagen content and deposition of proteoglycan, typical of the myxomatous degenerative process. In summary, it can be hypothesized that in dogs with a genetic predisposition for the disease, mechanic stimuli can activate VICs with valvular remodeling and myxomatous degeneration. This hypothesis would support the theory that myxomatous degeneration is the end-result of a continuous process of damage and repair as a result of mitral valve stress.

The myxomatous degeneration of the valve leaflets eventually leads to prolapse and valvular insufficiency. Accordingly, mitral valve prolapse usually precedes mitral valve insufficiency. Mild mitral valve insufficiency is generally well tolerated by dogs and is not associated with any compensatory response because it is not associated with decreased cardiac output. However, if the disease progresses and regurgitation through the mitral valve into the left atrial becomes more severe, cardiac output decreases and activation of compensatory mechanisms occurs. These mechanisms include activation of the renin-angiotensin-aldosterone system (RAAS) and sympathetic nervous system, and increased release of endothelin, vasopressin, and natriuretic hormones. Due to the chronic nature of the disease, these mechanisms are not necessarily activated in the early stages of MMVD. This consideration has important therapeutic

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

implications. In particular, when the RAAS becomes activated in dogs with natural occurring MMVD has been the source of much controversy. Some studies suggest that the RAAS might be activated relatively early in the history of the disease, whereas other studies suggest otherwise. Further complicating the picture is the observation that in dogs, alternative pathways for angiotensin II production, such as the chymase pathway, may be particularly active. Moreover, it is possible that release of natriuretic hormones from the dilated left atrium and ventricle might balance RAAS and sympathetic activation.

Moderate to severe mitral valve regurgitation leads to left ventricular volume overload, left atrial and left ventricular enlargement. Mitral valve insufficiency due to MMVD represents a unique hemodynamic condition with increased preload and decreased afterload. This is because a significant volume of left ventricular preload is ejected into the left atrium at the beginning of systole. Because the left atrium is a low-pressure chamber, there is no increase in cardiac work. This is likely the reason why many dogs with severe mitral valve regurgitation can tolerate this situation for a long time without presenting clinical signs.

Left ventricular eccentric hypertrophy, decreased afterload, and increased sympathetic activation produce hyperkinetic left ventricular function. Therefore, the recognition of normal values for fractional shortening or ejection fraction during an echocardiographic exam in dogs with left ventricular enlargement suggests the presence of a systolic dysfunction. Systolic dysfunction has been recognized to play an important role in disease progression and it is independent of clinical status. It has been hypothesized that systolic dysfunction in dogs with MMVD is the consequence of inadequate hypertrophy. Wall stress imposed by pure volume overload might not be a very potent stimulus for cardiac hypertrophy, and experimental canine models of MMVD systolic dysfunction were associated with inadequate left ventricular hypertrophy. Systolic dysfunction is more apparent in large-breed dogs affected by MMVD.

Left atrial function also plays an important role in the pathophysiology of the disease. Slowly progressing mitral valve regurgitation is associated with a progressive dilation of the left atrium. If left atrial compliance is maintained, filling pressure is also maintained close to normal limits. Accordingly, patients with severe mitral regurgitation do not develop pulmonary edema. However, chronic dilation of the left atrium is associated with left atrial hypertrophy and remodeling that, with time, decreases compliance and leads to development of pulmonary edema. In dogs with rupture of a major chorda tendinea, there is an acute worsening of mitral regurgitation. In this condition, the left atrium has no time to enlarge and there is a sudden increase of left atrial pressure with development of acute pulmonary edema.

Epidemiology

Myxomatous mitral valve disease is the most common heart disease in dogs and the most frequent cause of congestive heart failure in this species. MMVD in dogs represents 75% of all cardiovascular disease in this species. The prevalence of the disease varies with age and whether the study is based on necropsy, echocardiographic or clinical findings. The prevalence of MMVD has also been correlated with breed. In some breeds, such as the CKCS, the prevalence of the disease in animals older than 10 years is greater than 90%. Males are also reported to develop the disease at a younger age than females. Although the disease is more commonly diagnosed in small-breed dogs, it can occur in large-breed dogs.

History and Clinical Signs

Myxomatous mitral valve disease is a chronic disease in which the clinical presentation is variable. Some patients remain asymptomatic for all their lives, whereas others develop life-threating pulmonary edema and chronic congestive heart failure (CHF). Most dogs with mild to moderate MMVD are generally free of clinical signs.

The presence of clinical signs is generally related to the severity of the disease. Dogs with pulmonary edema have tachypnea and dyspnea. It has been reported that the normal respiratory rate at rest for dogs should be less than 30 breaths per minute. Accordingly, an increased respiratory rate at rest might represent the first clinical sign of worsening of the disease. Dogs with pulmonary edema are often anxious and have difficulties sleeping. They often cannot lie in lateral recumbency and prefer a sternal position (orthopnea). Weight loss is common in dogs with advanced stages of MMVD and CHF. Patients that develop right-sided heart failure have abdominal distension due to ascites. Syncope is occasionally reported in dogs with MMVD. Arrhythmias, pulmonary hypertension, vasovagal syncope, and coughing can cause syncope in these patients.

Cough represents the most common complaint for dogs affected by MMVD, especially in small breeds. It should be stressed that cough is a general clinical sign of respiratory disease and its presence in a dog with a murmur is not an indicator for starting treatment for CHF. Old small-breed dogs are commonly affected by tracheobronchial disease and by MMVD. In these patients, the cough is often the result of their primary respiratory disease and not heart disease. A recent study has shown that cough was not associated with the presence of active

CHF in 206 dogs with MMVD at different stages. In this study, cough was associated with left atrial enlargement and the presence of an abnormal radiographic airway pattern. Left atrial enlargement compressing the mainstem bronchus is believed to induce cough in patients with primary bronchomalacia.

Diagnosis

The American College of Veterinary Internal Medicine Specialty of Cardiology consensus panel has published guidelines for the diagnosis and treatment of canine chronic valvular heart disease. The guidelines propose a modification of a staging system for MMVD that is currently used to classify human patients with heart failure (Table 25.1). This classification introduces the concept of patients at risk for developing MMVD but that currently do not have heart disease (stage A). The reason for introducing this stage is to encourage veterinarians to develop appropriate screening programs and inform owners regarding the risk of an animal developing the disease.

Diagnosis of MMVD is generally suspected following a careful auscultation. In early stages of MMVD a midsystolic click may represent the only auscultatory finding. The click is often intermittent and can be better appreciated at higher heart rates. It is believed the midsystolic click is caused by vibration of the prolapsing mitral valve leaflets and by the tensing of redundant chordae tendineae. In dogs with mild MMVD and mild mitral regurgitation, a low-intensity, early systolic murmur localized on the left apex can be heard. The murmur can be intermittent and intensity can vary with heart rate and phase of respiration. When moderate to severe mitral regurgitation is present, the murmur becomes holosystolic or pansystolic, more intense, and harsher. In more severe cases, the murmur radiates to the base of the left thorax and to the right side of the thorax. It should be emphasized that the intensity of the murmur does not always correlate with the severity of MMVD; that is, loud murmurs do not automatically indicate severe disease.

The auscultatory findings can be influenced by several factors such as observer experience, obesity, panting, presence of arrhythmias, and breeds. In a study on preclinical MMVD dogs, 26% of dogs with a confirmed echocardiographic diagnosis of MMVD did not have a murmur and large-breed dogs with MMVD have less intense murmurs compared with small-breed dogs. Thus, diagnosis of MMVD should not rely only on auscultatory findings. Indeed, the ACVIM consensus recommends that although the presence of midsystolic click or left apical murmur in a typical breed is strongly suggestive of MMVD, echocardiographic confirmation of the diagnosis is required. Echocardiography can evaluate the morphology of the valve leaflets and quantify the degree of cardiac enlargement. The echocardiographic characteristics of MMVD include prolapse or thickening of one or both mitral valve leaflets (Figure 25.1).

Mitral valve prolapse is defined as an abnormal systolic displacement or bowing of the mitral valve leaflets from the left ventricle toward the left atrium. In dogs, some studies suggest that the right parasternal four-chamber, long-axis view is the gold standard used to identify the presence of mitral valve prolapse. Because

Table 25.1 Classification system for dogs affected by myxomatous mitral valve disease (MMVD)

Stage	Definition
A	Dogs at risk for developing MMVD that have no identifiable cardiac structural disorder (i.e., Cavalier King Charles spaniel, dachshunds)
B1	Dogs with MMVD that have never developed clinical signs and have no radiographic or echocardiographic evidence of cardiac remodeling
B2	Dogs with MMVD that have never developed clinical signs but have radiographic or echocardiographic evidence of cardiac remodeling (i.e., lef-sided heart enlargement)
C	Dogs with MMVD and past or current clinical signs of heart failure associated with structural heart remodeling. Dogs presenting in heart failure for the first time may show severe clinical signs requiring hospitalization
D	Dogs with end-stage MMVD and heart failure that is refractory to standard therapy (i.e., furosemide, angiotensin converting enzyme inhibitors, pimobendan +/- spironolactone)

Source: Adapted from Atkins *et al.* (2009).

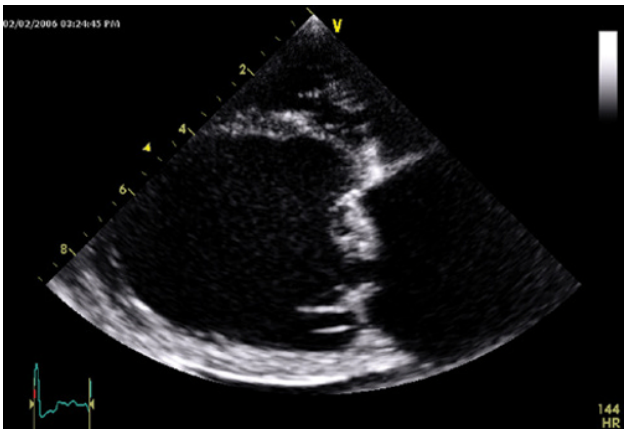

Figure 25.1 Echocardiographic right parasternal long axis view of the left atrium, mitral valve, and left ventricle. The mitral valve leaflets appear thickened and prolapse in the left atrium.

echocardiographic diagnosis of mitral valve prolapse is dependent on the morphology of the valve, and because the normal mitral valve and mitral valve annulus present a wide range of normality, we recommend that the diagnosis of mitral valve prolapse should be confirmed in at least two echocardiographic views. Indeed, we have recently reported that in dogs, mitral valve morphology is saddle shaped, similar to what has been reported in people. Therefore, using the right parasternal long-axis view may lead to an overestimation of the mitral valve prolapse.

The ACVIM consensus statement recommends thoracic radiography for all dogs with MMVD to assess the hemodynamic significance of the murmur through evaluation of heart size and pulmonary vasculature and to obtain a baseline when the patient is asymptomatic. Careful evaluation of thoracic radiographs may help in diagnosing concomitant primary respiratory diseases that may be the cause for clinical signs, such as cough or dyspnea. Thoracic radiographs, together with physical examination, are also essential for monitoring dogs with MMVD. A change in radiographic cardiac dimensions observed between two different time points has been suggested as a powerful predictor of outcome in dogs with MMVD.

Prognosis

Myxomatous mitral valve disease is characterized by a long preclinical period and many affectws dogs die for reasons other than CHF. A study including a population of 558 dogs affected by MMVD at different stages has shown that more than 70% dogs were alive at the end of the follow-up period of 6.6 years (Figure 25.2).

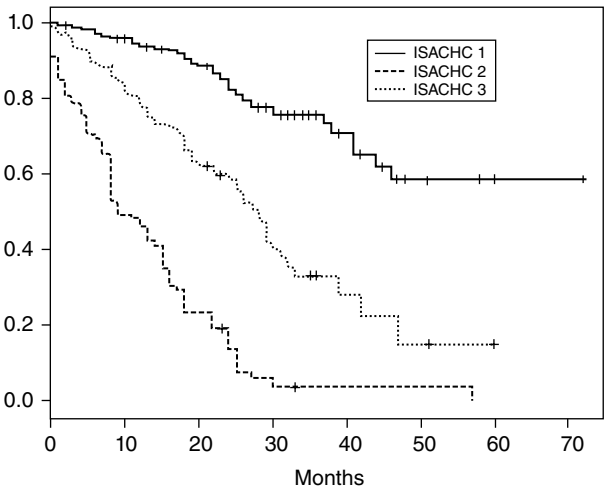

Figure 25.2 Survival curves for dogs with different stages of heart failure according to the International Small Animal Cardiac Health Council. Class 1 ISACHC are dogs with preclinical MMVD, class 2 ISACHC are dogs with moderate congestive heart failure, and class 3 ISACHC are dogs with severe heart failure (showing clinical signs at rest and requiring close monitoring). *Source:* Borgarelli *et al.* (2008). Reproduced with permission of John Wiley.

In another study of 256 dogs affected with preclinical MMVD, the overall mortality was 27%, with cardiac death accounting for 11% during the 833-day observation period. The same study showed that 30/83 dogs that were available for reexamination progressed to a more advanced stage of MMVD. Reported risk factors associated with progression of the disease or death included age, gender, intensity of heart murmur, degree of valve prolapse, severity of valve lesions, the degree of mitral valve regurgitation, degree of left atrial enlargement, severity of eccentric hypertrophy, rupture of chordae tendinae, and increased concentration of natriuretic peptides. Left atrial enlargement, assessed by echocardiography, seems to represent one of the most reliable independent predictors of death. The risk of death from cardiac disease for dogs with a left atrium/aortic root ratio exceeding 1.7 was 2.1 times that of dogs with smaller atria.

Another study reported that plasma N-terminal pro-brain natriuretic peptide (NT-proBNP) concentration and indexed left ventricular end-diastolic diameter were independent risk factors for development of first-onset CHF. The presence of pulmonary hypertension due to MMVD was recently reported to be associated with higher risk of death.

Therapy

The Asymptomatic Dog (Stage B: ACVIM Consensus)

Treatment of dogs with asymptomatic MMVD has been a subject of controversy over the past years. This stage includes dogs with the disease who have never developed CHF. This group represents the majority of dogs diagnosed with MMVD. The ACVIM consensus suggests that asymptomatic dogs could be further subdivided into those with no radiographic or echocardiographic evidence of cardiac enlargement (stage B1) and those with evidence of cardiac remodeling suggested by the presence of left atrial and ventricular enlargement (stage B2). This subclassification emphasizes the fact that asymptomatic dogs are a heterogeneous group, including patients with very mild disease as well as those with more advanced disease that are more likely to develop clinical signs of CHF.

The ACVIM consensus group unanimously recommended not treating dogs with MMVD in stage B1 of the disease. In contrast, no consensus was reached for dogs in stage B2. Two multicenter double-blinded studies evaluating the efficacy of enalapril on delaying the onset of CHF in stage 1B dogs with MMVD have shown no

significant effect of angiotensin converting enzyme inhibitor (ACEI) therapy on the primary outcome variable, which was time from inclusion in the study to the onset of signs of CHF. Based on these results and the observation that only a relatively small percentage of dogs with asymptomatic disease progress to CHF or die as a consequence of the disease, the author does not support treatment with an ACEI.

A recent multicenter clinical trial reported that pimobendan delays onset of congestive heart failure in a subpopulation of dogs with stage B2. It should be highlighted that enrolled dogs had significant cardiomegaly identified by specific echocardiographic criteria. It is possible, although not proven, that dogs in advanced stage B2 may benefit from other medical treatments such as spironolactone. This emphasizes the importance of developing biomarkers able to identify patients at higher risk for developing CHF. A study conducted on 72 asymptomatic dogs with MMVD showed that NT-proBNP at a cut-off of 466 pmol/L had 80% sensitivity and 76% specificity in predicting 12-month progression to cardiac death or CHF. Although these data appear very promising, further studies are needed to confirm the value of NT-proBNP in distinguishing those patients that will progress to CHF. Accordingly, assessment of stage B dogs should include evaluation of multiple parameters including clinical, radiographic, and echocardiographic findings.

The Symptomatic Dog (Stage C: ACVIM Consensus)

According to the ACVIM consensus, stage C includes animals with MMVD and current or previous clinical signs of CHF. Management of these patients is based on administration of a combination of several medications, including diuretics, ACEIs, and pimobendan. Although no study has proven the efficacy of furosemide in dogs with MMVD, there is a general consensus that diuretics are essential for patients with CHF. The majority of dogs enrolled in the multicenter studies evaluating the efficacy of the ACEI and pimobendan in symptomatic dogs with MMVD were on concomitant treatment with furosemide. The diagnosis of CHF should be reevaluated if diuretics do not improve clinical signs in dogs with suspected CHF. The dosage of furosemide should be adjusted in order to keep the patients free from clinical signs. Although the suggested mean dosage for these patients is 2 mg/kg PO q12h, it could range from 0.5 mg/kg PO q12h to 4–6 mg/kg PO q8h.

In human patients with CHF, teaching patients to adjust their furosemide dosage on the basis of monitoring their weight and their clinical signs significantly reduces the number of hospitalizations and may be associated with prolonged survival. A similar approach with dogs in CHF is desirable but difficult. The use of an ACEI together with furosemide in stage C dogs is based on evidence provided by several multicenter double-blind studies which provide evidence that an ACEI added to therapy including furosemide improved the quality of life and survival time.

Two recent studies have shown that pimobendan improved survival and quality of life in stage C dogs compared to standard treatment with an ACEI and furosemide. The first study was conducted as a blinded, randomized, positive-controlled, multicenter study and included 76 dogs. The study had a mandatory 56-day treatment period that was followed by an optional long-term treatment phase. In this study, pimobendan significantly improved a clinical measure of disease severity and survival. The results of this study led to a larger study in 260 dogs with stage C MMVD. This was a prospective multicenter randomized single-blinded study and the primary endpoint was a composite of cardiac death, euthanasia for heart failure, or treatment failure. Dogs were randomized to therapy with either ACEI or pimobendan. Pimobendan was associated with significant improvement in the endpoint variables and this benefit persisted after adjusting for all baseline variables. All dogs enrolled in this study were on concomitant furosemide treatment. It should be stressed that none of these studies answer the question of whether triple therapy involving furosemide, ACEI, and pimobendan would be superior to double therapy with pimobendan plus furosemide. The ACVIM consensus recommended that chronic management of stage C dogs includes a combination of ACEI, pimobendan, and furosemide.

Spironolactone has been recently approved in Europe for treatment of dogs with MMVD. In one study, spironolactone when added to furosemide and ACEI +/− digoxin decreased risk of cardiac-related death or euthanasia for cardiac reasons by 69% in dogs with moderate to severe MMVD. The dosage of spironolactone used in the clinical trial was 2 mg/kg q24h. One criticism of this study is that a relatively low number of cases reached the endpoint compared to other studies evaluating stage C dogs. One possible mechanism of action for spironolactone would be related to its antifibrotic effects. Geriatric dogs affected by MMVD have intramyocardial arterial changes associated with areas of replacement fibrosis. The exact role of vascular or myocardial fibrosis in the pathogenesis of MMVD is still to be clarified. Positive effects of aldosterone blockers such as spironolactone could also be related to the mechanism of aldosterone escape. Aldosterone concentrations can be elevated in dogs with MMVD despite receiving an ACEI. This phenomenon is dependent on the dose of concomitant furosemide and has been attributed to incomplete inhibition of ACE activity.

Digoxin is commonly used to treat dogs with concomitant atrial fibrillation in order to control the heart rate. There are no controlled studies in veterinary medicine evaluating digoxin, but it is believed that its administration could improve clinical signs of heart failure in dogs.

In the author's experience, most dogs can be managed using a combination of furosemide, ACEI, pimobendan, and spironolactone. Treatment should be individualized for each patient and the goal is to keep the animal free of clinical signs of CHF for as long as possible.

The Dog with Refractory Heart Failure (Stage D: ACVIM Consensus)

Stage D includes dogs refractory to treatments for stage C. Many of these dogs also have right-sided heart failure, which leads to congestion of the gastrointestinal tract that can decrease absorption of oral medications. Providing furosemide by subcutaneous injection may help to restabilize the patient. Chronic use of furosemide can also lead to furosemide resistance and it is likely that many stage D patients develop this condition. In these dogs the use of an alternative loop diuretic, such as torsemide, may represent a valid alternative. Adding a diuretic with a different mechanism of action such as a thiazide represents another alternative. The goal in these cases is to induce "sequential nephron blockade" and improve diuresis. Patients on high doses or combinations of diuretics should have their electrolytes and renal function monitored closely.

Amlodipine at the dosage of 0.05–0.1 mg/kg q12h is listed in the ACVIM consensus statement as a possible treatment for dogs with stage D CHF in order to obtain a more effective reduction in afterload and improve cardiac output. Arteriolar vasodilation associated with the use of this drug can lead to severe hypotension. It is, therefore, recommended to uptitrate the dosage of amlodipine and monitor the blood pressure in order to avoid hypotension. In the author's experience, intravenous vasodilators, such as sodium nitroprusside, can also help resolve an acute episode of pulmonary edema.

Valvular Infectious Endocarditis

Etiology and Pathophysiology

Valvular infectious endocarditis (IE) is a severe acquired valvular disease of dogs and cats that is frequently caused by bacterial infections. The most common pathogens associated with IE in the dog and the cat are *Staphylococcus* and *Streptoccoccus* sp. Recently, *Bartonella* sp. has been associated with IE, and has been considered responsible for up to 28% of IE in the dog. Less commonly, IE has been associated with fungi and *Rickettsia* spp. IE starts with damage of the endothelium that triggers the coagulation process. IE requires bacteremia. The most common sources of bacteremia are discospondylitis, prostatis, pneumonia, urinary tract infection, pyoderma, and intravenous catheters. Circulating bacteria can bind to the coagulum and induce inflammation that leads to expression of integrins that further facilitate bacterial adhesion to the damaged tissue. Some bacteria, such as *Staphylococcus* sp., might increase their ability to bind to the coagulum through increased expression of microbial surface adhesive molecules. Vegetative lesions containing bacteria provide a protective barrier and obstacle to antibiotic penetration. Moreover, bacteria can produce enzymes that lead to further tissue damage.

The only cardiovascular disease associated with an increased risk of IE is subaortic stenosis. Historically, periodontal diseases have been thought to increase the risk of bacterial endocarditis, but an association has never been demonstrated.

Epidemiology

Infectious endocarditis is a rare condition in dogs and cats. According to published data, prevalence of the disease varies from 0.005% to 0.09% in the dog. The prevalence in cats has not been reported but IE is less frequently noted in this species. A recent retrospective study has suggested that IE is becoming more common. This might be attributed to the increased recognition of the disease due to the availability of echocardiography. Large-breed dogs are more commonly affected. A review of published data shows that the mitral valve is most commonly affected (60%) followed by the aortic valve (29%). Both the aortic and mitral valves are affected in 5% of the dogs, whereas the pulmonic and tricuspid valves are rarely affected in dogs (4%).

History and Clinical Signs

Clinical signs in patients with IE are various and nonspecific. Many patients show clinical signs related to the underlying systemic disease that produced the bacteremia. Analysis of published case series including 183 dogs with IE showed that the most common clinical sign is lameness (67%), followed by anorexia (55%), lethargy (55%), acute onset of respiratory distress (52%), and syncope/weakness (15%). Fever is reported in 48% of cases. Presence of a murmur is reported in only 55% of cases with a definitive diagnosis of IE. The reason for the relatively low prevalence of murmurs may be similar to what has been previously described for murmurs in patients with MMVD. Moreover, when only the aortic valve is affected, the murmur can be diastolic and difficult to recognize. The recognition of a new systolic

or diastolic murmur in a patient with a predisposing condition should be considered suspicious for IE. Patients with aortic IE and severe aortic insufficiency may present bounding femoral pulses. Thirty-seven percent of dogs with IE present with clinical signs of CHF at the time of the diagnosis.

Diagnosis

Diagnosis of IE is challenging. Antemortem diagnosis involves blood cultures, preferably performed before antibiotic treatment is started. Three to four blood samples should be collected aseptically from different venous sites at least one hour apart and submitted for aerobic and anaerobic culture. Blood samples should also be collected and cultured for *Bartonella* spp. Recently, polymerase chain reaction (PCR) has been proposed as an alternative method for the diagnosis of *Bartonella* infection. A complete blood count (CBC) and serum biochemistry profile should be performed in all patients with suspected IE in order to assess multiorgan involvement. Leukocytosis, thrombocytopenia, anemia, hypoalbuminemia, increased liver enzymes, and azotemia are the most commonly reported laboratory findings in dogs with IE.

Echocardiography allows the identification of vegetative valvular lesions and assessment of the severity of the valvular insufficiency and is complementary to blood cultures in establishing the diagnosis of IE in the dog and cat. Typical lesions are represented by an hyperchoic, mobile, irregular-shaped mass adherent to the valve (Figure 25.3).

Valvular insufficiency is a common finding. Patients with chronic valvular IE and severe valvular regurgitation may present with left ventricular eccentric hypertrophy. Although the presence of typical valvular lesions strongly supports the diagnosis of IE, small lesions on the mitral valve can be difficult to differentiate from lesions due to myxomatous degeneration.

The diagnostic criteria for IE in dogs and cats is modified from the human "Duke criteria". Major criteria for diagnosis are a positive echocardiogram, new valvular insufficiency, and a positive blood culture (≥2 positive cultures or ≥3 positive cultures with common skin contaminants). Minor diagnostic criteria are fever, medium to large dog (>15 kg), subaortic stenosis, thromboembolic disease, immune-mediated disease, positive blood cultures not meeting major criteria, and *Bartonella* serology ≥1:1024. A definitive diagnosis of IE involves the presence of two major criteria or one major and two minor criteria. The presence of one major and one minor criteria or three minor criteria is suspicious for IE.

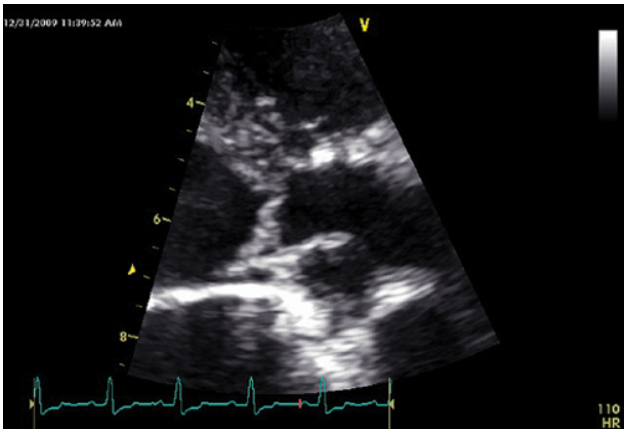

Figure 25.3 Echocardiographic long axis image of the aortic valve. A hyperchoic, mobile, irregular-shaped mass is present adherent to the valve leaflet.

Treatment

Long-term bactericidal antibiotics are the main therapy for patients affected by IE. Broad-spectrum combinations of antibiotics such as enrofloxacin and ampicillin should be administered empirically if blood culture is not available or pending. Treatment of *Bartonella* spp. involves doxycycline, fluoroquinolones, or azithromycin. In dogs requiring hospitalization, intravenous aminoglycosides such as amikacin have been recommended. Ideally, antibiotic therapy is guided by results of culture and sensitivity testing. Oral antibiotics are often continued for 6–8 weeks. Serial echocardiograms or blood cultures are used to monitor response to therapy. Patients with heart failure secondary to IE should be treated with standard CHF treatment.

Prognosis

Generally, patients with IE have a relatively poor prognosis. Outcome is related to the degree of valvular regurgitation and nature of the underlying predisposing cause. Dogs with aortic IE fare worse than dogs with mitral IE (three days versus 476 days median survival time).

Canine Myocardial Disease

M. Lynne O'Sullivan, DVM, DVSc, DACVIM (Cardiology)

Department of Companion Animals, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Canine myocardial diseases are those that affect the heart muscle, as opposed to valvular, endocardial, or pericardial diseases. Cardiomyopathies are the most common myocardial diseases in dogs, and are a "heterogenous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction" according to the American Heart Association. They may be classified clinically according to structural and functional phenotype: dilated, hypertrophic, restrictive, and arrhythmogenic right ventricular. Dilated cardiomyopathy (DCM) is by far the most common cardiomyopathy in dogs. Arrhythmogenic right ventricular cardiomyopathy (ARVC) is seen most commonly in the boxer, and hypertrophic cardiomyopathy (HCM) is reported in dogs but is rare. Restrictive cardiomyopathy is not recognized in dogs. Other forms of canine myocardial disease include myocarditis (infectious, inflammatory, toxic, traumatic), infiltrative disease (neoplastic, storage diseases), ischemic disease, myocardial disease secondary to systemic hypertension, and muscular dystrophies affecting the heart. The focus of this chapter is the cardiomyopathies.

Dilated Cardiomyopathy

Etiology/Pathophysiology

Dilated cardiomyopathy is a primary myocardial disease characterized by dilation and systolic dysfunction of the left or both ventricles, in the absence of valvular, pericardial, congenital, coronary artery, or hypertensive heart disease. The DCM phenotype may be the result of various myocardial insults, which are often not identified, rendering many cases idiopathic. In dogs, those "insults" are in many cases genetic mutations leading to altered cardiac protein structure and function, particularly in the pure breeds predisposed to DCM. In humans, 30–50% of cases of DCM are familial or inherited, and mutations involving over 50 cardiac genes have been described to date. Mutations in two genes (PDK4 and titin) have been associated with DCM in Doberman pinschers in North America, but do not account for all cases. The PDK4 mutation was not significantly associated with DCM in a group of European Dobermans in which DCM was linked to a different chromosome (candidate genes yet unidentified). This highlights the complex nature of the role that genetics play in this disease and that multiple genetic factors are involved, even within one breed. Juvenile DCM in the Portuguese water dog has been linked to chromosome 8 and candidate gene identification is ongoing.

Additional well-recognized etiologies in dogs include nutritional deficiencies (taurine, carnitine) and tachycardia induced (secondary to sustained tachyarrhythmia). Infectious and toxic causes of myocarditis, characterized by myocardial inflammation and necrosis, can produce a DCM-like phenotype (ventricular dilation, systolic dysfunction, arrhythmias) in the chronic phase, and may be worth considering as the underlying "insult" in certain clinical presentations or geographic areas. Examples include bacterial (e.g. *Borrelia burgdorferi*, *Bartonella*), viral (e.g., parvovirus, West Nile virus), protozoal (e.g., *Trypanosoma cruzi* [Chagas disease], *Toxoplasma gondii*), fungal (e.g., *Aspergillus*, *Blastomyces*, *Coccidioides*), and toxic (e.g., anthracyclines) agents. The above-mentioned nonfamilial, nonidiopathic causes make up a very small percentage of the total DCM caseload, as idiopathic or familial cases are most common.

On a whole-heart level, the primary abnormality is a reduction in contractility. This results in a reduction in stroke volume (the volume ejected) and an increase in end-systolic volume (the volume remaining in the heart after ejection), in turn resulting in progressive increases in end-diastolic volume. A reduction in

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

blood pressure and tissue perfusion activates a number of neuroendocrine and cytokine systems intended to maintain stroke volume and blood pressure, primarily through sodium and water retention and vasoconstriction. Stretch receptors and remodeling pathways are triggered, leading to lengthening of individual myocytes (eccentric hypertrophy) and chamber dilation, maladaptive extracellular matrix remodeling, and cell death. Consequences of these alterations in cardiac structure and function eventually include congestive heart failure (CHF) and arrhythmias (see Chapter 18).

Epidemiology

The prevalence of DCM among canine referral populations has been reported to be 0.3–1% (equivalent to 1–3 cases per 300 patients examined). Underreporting of sudden death (SD) cases might result in underestimation of any figure, thus the true prevalence in the general dog population is unknown. Any prevalence data will be heavily influenced by the distribution of breeds and ages (prevalence increases with age) of the population under study. The prevalence is high in certain breeds based on retrospective studies and prospective screening studies. One European study of Irish wolfhounds (IW) found a prevalence of 24%. In the Great Dane, prevalence has ranged from 12% to 36% in different geographic areas. Prevalence in Dobermans has ranged from 45% to 60% in various studies. Some studies report overrepresentation of males, while in Dobermans there are gender differences in how the disease manifests and at what age, with females having a higher incidence of ventricular arrhythmias as the sole abnormality and males manifesting echocardiographic abnormalities and CHF at an earlier age.

The mode of inheritance is known for specific breed groups. In the Doberman and the Newfoundland, DCM is inherited as an autosomal dominant trait with incomplete penetrance. Both X-linked and autosomal dominant patterns of inheritance have been suggested in the Great Dane, whereas inheritance is autosomal recessive with sex-specific alleles in the IW. The juvenile form described in the Portuguese water dog is autosomal recessive.

The natural history of the disease is such that dogs experience a preclinical or occult phase during which echocardiographic or electrocardiographic evidence of the disease is present (see Diagnosis) but clinical signs are absent (ACVIM stage B). The length of this phase is variable and likely extends over months to years, depending on the breed. In the Doberman, previous retrospective work suggested a median preclinical phase of just over a year whereas new prospective clinical trial data suggest a median of two years with the use of pimobendan. The preclinical phase can be quite prolonged in the IW, averaging 48 months in one trial.

The overt phase follows, characterized by the onset of clinical signs including syncope, SD, or those typical of CHF (ACVIM stage C). In the Doberman, 25–30% experience SD before CHF. Survival time following the onset of CHF or syncope is again breed and etiology dependent, with Dobermans and Great Danes experiencing the shortest survival times among breeds (see Prognosis).

Risk factors for the development of DCM apart from breed may include taurine deficiency (in cocker spaniels, Labrador and golden retrievers, or nontraditional DCM breeds), sustained tachyarrhythmias, myocarditis, or chemotherapy (anthracyclines).

Signalment

Dilated cardiomyopathy occurs predominantly in middle-aged to older, medium- to large-breed dogs. The most commonly reported breeds in North America and Europe include the Doberman pinscher, IW, Great Dane, Newfoundland, boxer, Labrador and golden retrievers, cocker spaniel, Scottish deerhound, Afghan hound, St Bernard, German shepherd, Old English sheepdog, Airedale terrier, standard poodle, Rottweiler, and mastiff. Small-breed dogs are uncommonly affected but sporadic cases can be found.

Age at diagnosis is typically between 4 and 8 years, depending on breed. Much younger and much older dogs may certainly be affected, regardless of breed. Specific juvenile forms of DCM are described in the Portuguese water dog, Doberman, and toy Manchester terrier, resulting in rapidly progressive CHF or SD at weeks to months of age. Sporadic cases in very young dogs of other breeds may occur, and should prompt consideration of viral myocarditis or primary tachyarrhythmia as an underlying cause.

Many studies report a gender bias in males. While this is not corroborated in all studies of individual breeds, it is the case for the majority of studies involving multiple breeds. Male Dobermans and IWs may be affected at an earlier age than females.

History and Clinical Signs

History may be unremarkable and preclinical cases identified by an incidental abnormality on physical exam (such as a heart murmur, gallop, or arrhythmia) or by prospective screening in high-risk breeds. Some of these dogs in the preclinical stage may have surprisingly profound cardiac dysfunction in the absence of clinical signs. More often, dogs are presented because of clinical signs of a fairly acute nature. Respiratory signs are the most common, including coughing and/or increased respiratory rate or effort due to pulmonary edema from left-sided CHF. With severe pulmonary edema, expectoration

of pink-tinged fluid may be noted. Pleural effusion from right-sided CHF can also produce increased respiratory rate and effort. Other signs include exercise intolerance, weakness, syncope, abdominal distension due to ascites, weight loss, and reduced appetite or anorexia (see Chapter 15). Sometimes SD is the first clinical sign noted. The typical clinical signs exhibited may vary by breed. For example, Dobermans tend to have a higher incidence of syncope and SD and their pulmonary edema and resultant respiratory signs are often quite severe, whereas IWs and Newfoundlands frequently present with evidence of right-sided CHF (ascites and pleural effusion).

The most common abnormalities detected on physical examination are a soft systolic murmur over the mitral or tricuspid area (often grade 1–3/6) and weak peripheral pulses. However, various studies have reported murmurs in as few as 33% and as many as 76%, so the absence of a murmur does not rule DCM out, and physical examination may be normal in the early preclinical phase. Additional findings may include a diastolic gallop (low-frequency third heart sound), an arrhythmia (ventricular premature contractions and atrial fibrillation most common), pulse deficits (if an arrhythmia is present), and jugular venous distension or pulsation. For dogs in CHF, additional findings may include pale or cyanotic mucous membranes, increased lung sounds or pulmonary crackles, tachycardia, tachypnea, dyspnea, hypothermia, and hepatomegaly (hepatic congestion) or a fluid wave (ascites) on abdominal palpation.

Diagnosis

The diagnosis of DCM involves a minimum of an echocardiogram and electrocardiogram (ECG). Holter recording (24-hour ambulatory ECG) is the most appropriate form of ECG in breeds where ventricular arrhythmias are common or an early finding such as Dobermans, for longer term heart rate (HR) assessment in atrial fibrillation, or if a cause for syncope is sought. In cases where echocardiography is not immediately available, thoracic radiographs may be useful for detecting cardiomegaly, and plasma N-terminal pro-B-type natriuretic peptide (NT-proBNP) level can be useful in Dobermans for assessing likelihood of preclinical disease. For dogs with suspected CHF, thoracic radiographs and serum biochemistry should be performed. The role for blood-based tests including biomarkers, taurine levels, and genetic tests is also discussed below. Screening should be performed yearly in high-risk breeds.

Electrocardiography

While arrhythmias are frequently reported on ECG (89% of cases in one large retrospective study), they can be very intermittent. Ventricular arrhythmias (VA) (ventricular premature contractions [VPCs] or ventricular tachycardia [VT]) and atrial fibrillation (AF) are most common, but are not specific for DCM on their own (Figures 26.1 and 26.2).

There are differences between breeds in arrhythmia manifestation. VA are very common in Dobermans, boxers, and Great Danes, so their presence should always raise suspicion of DCM in these breeds. In one study in Dobermans, one or more VPCs on a 5-min ECG was almost 97% specific for detecting a level of VA on Holter recording that would be suggestive of DCM. However, the presence of VPCs on a 5-min ECG alone is fairly insensitive for detecting DCM. Studies report 44–64% of affected Dobermans and 54% of affected Great Danes

Figure 26.1 Lead II ECG, 12.5 mm/s, 5 mm/mV. VPCs in a Doberman pinscher with DCM. A short run of VT is seen at the beginning of the ECG followed by intermittent single monomorphic VPCs.

Figure 26.2 Lead II ECG, 25 mm/s, 5 mm/mV. Atrial fibrillation in a Golden retriever with DCM. Note the irregular rhythm, absence of P-waves, and presence of baseline undulations or fibrillation waves.

had at least one VPC on a 5-min ECG and during echo exam, respectively, emphasizing that many affected dogs will have a normal in-hospital ECG.

Atrial fibrillation (AF) is more common in IWs and Newfoundlands and is often an early finding in IWs (found in 75% of occult DCM cases, >90% of overt DCM cases). In other breeds it tends to be associated with more advanced or overt disease. Importantly, giant-breed dogs can also have "lone" AF unassociated with gross cardiac pathology, in which case the HR is often normal. However, in the IW, it is hypothesized that AF may be a precursor to DCM in many cases.

Additional ECG findings can include tall and wide QRS complexes (lead II R-wave >3.0 mV, QRS duration >0.06 ms) associated with left ventricular (LV) enlargement, notched R-waves associated with microscopic ischemia, wide P-waves (lead II P duration >0.04 ms) associated with left atrial enlargement, and sinus tachycardia (particularly in CHF cases). Note that these ECG findings are neither sensitive nor specific for DCM.

Holter Recording

Given that arrhythmias apart from AF are typically intermittent and in-house ECGs are relatively insensitive, Holter recordings can be very useful for diagnosing and quantifying arrhythmias, for seeking cause of collapse by coupling clinical signs with rhythm analysis, and for assessing therapeutic response to antiarrhythmics. In Dobermans, the presence of >300 VPCs/24h, or two subsequent recordings within a year with 50–300 VPCs/24h, may be suggestive of DCM. Coupling a Holter recording with a NT-proBNP level can increase sensitivity for initial screening (see Circulating Biomarkers). Whether these Holter criteria are appropriate for breeds other than Dobermans is not known, but in one study, 70% of affected Great Danes had a similar degree of arrhythmia. Holter monitoring is also useful for monitoring HR in cases of AF as it yields a more accurate assessment of rate control. Care should be taken to utilize Holter analyses that have been manually edited and verified by qualified personnel as purely automated analyses are notoriously inaccurate.

Thoracic Radiography

Thoracic radiographs are relatively insensitive to detect the mild cardiac enlargement typical of occult cases. In instances of more severe disease, they can reveal varying degrees of cardiomegaly (left-sided or generalized). Thoracic radiographs are always indicated if CHF is suspected. In addition to LV enlargement, findings in CHF include left atrial and possibly right-sided enlargement, pulmonary venous distension and varying degrees of pulmonary edema (interstitial changes in mild to moderate cases and alveolar opacities with air bronchograms in severe cases). The distribution of pulmonary edema is often greatest in the caudodorsal lung fields, but can be diffuse in severe cases (Figure 26.3).

In Doberman pinschers, the degree of radiographic cardiomegaly is often surprisingly modest, even in the

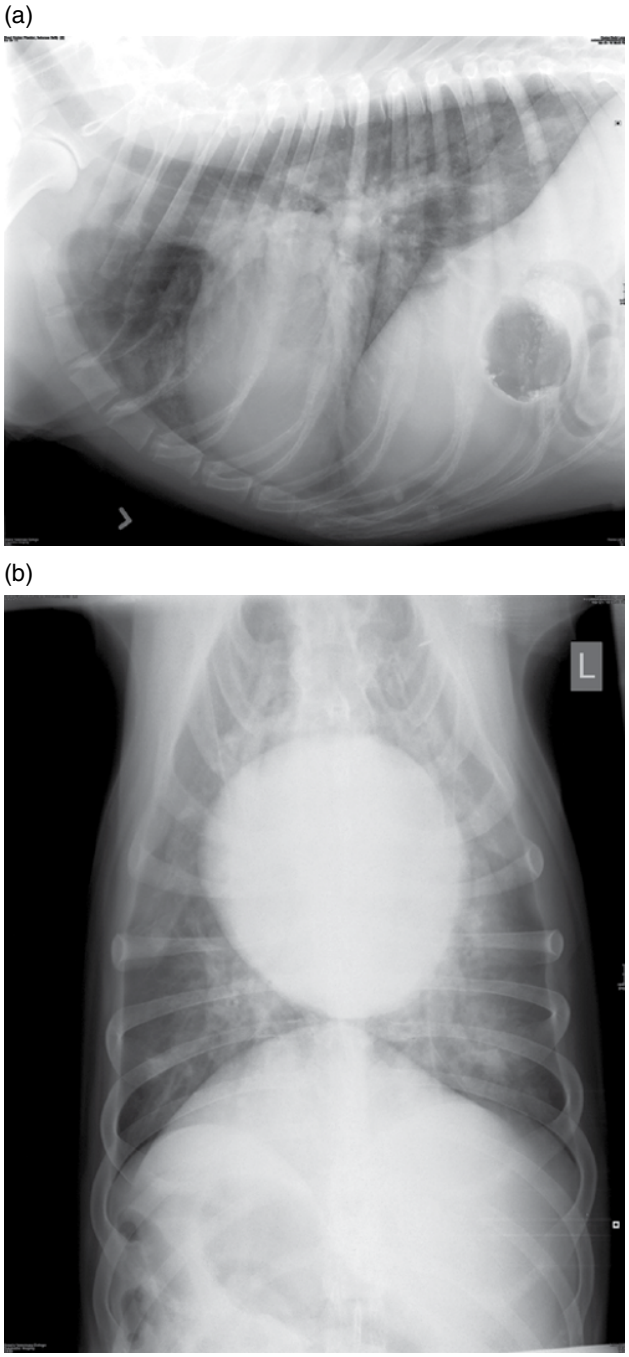

Figure 26.3 Lateral (a) and VD (b) thoracic radiographs in a Doberman with DCM and CHF. Note the cardiomegaly (including left atrium), pulmonary venous distension, and diffuse interstitial pulmonary infiltrates (worse caudodorsally but also present cranioventrally).

face of severe dilation on echocardiography. This phenomenon might be due to the Doberman's relatively deep chest conformation and the relative lack of right heart involvement compared to other breeds. Breeds with frequent right-sided involvement such as IWs and Newfoundlands often also have pleural effusion, as do dogs that develop AF.

Echocardiography

Echocardiography is necessary for identification and quantification of the characteristic structural abnormalities, including LV chamber dilation and systolic dysfunction, and equally important for ruling out other cardiac causes apart from DCM for these findings (e.g., valvular disease, congenital shunt) (Figure 26.4).

Increased LV end-systolic dimension (LVESD) and/or volume (LVESV) is noted, along with increased LV end-diastolic dimension (LVEDD) and/or volume (LVEDV). Linear dimensions (diameters) are generated from an M-mode of the LV in a short- or long-axis view immediately below the mitral valve, and volumes are preferentially generated by tracing the LV endocardium in a right parasternal long-axis or left apical four-chamber view and using automated software for Simpson's method of discs. These parameters are often indexed to body weight (BW) or body surface area (BSA) to normalize for differences in body size and conformation. In Dobermans, volume indices have been shown to be more sensitive in detection of LV dilation than diameters. Normal parameters and breed-specific criteria suggesting the diagnosis of DCM from various studies are presented in Table 26.1. The reader is referred to the Further Reading list for more detailed information on the methods and views used.

Left ventricle wall motion is globally and symmetrically reduced in most cases, but some dogs may have increased septal motion compared to the free wall owing

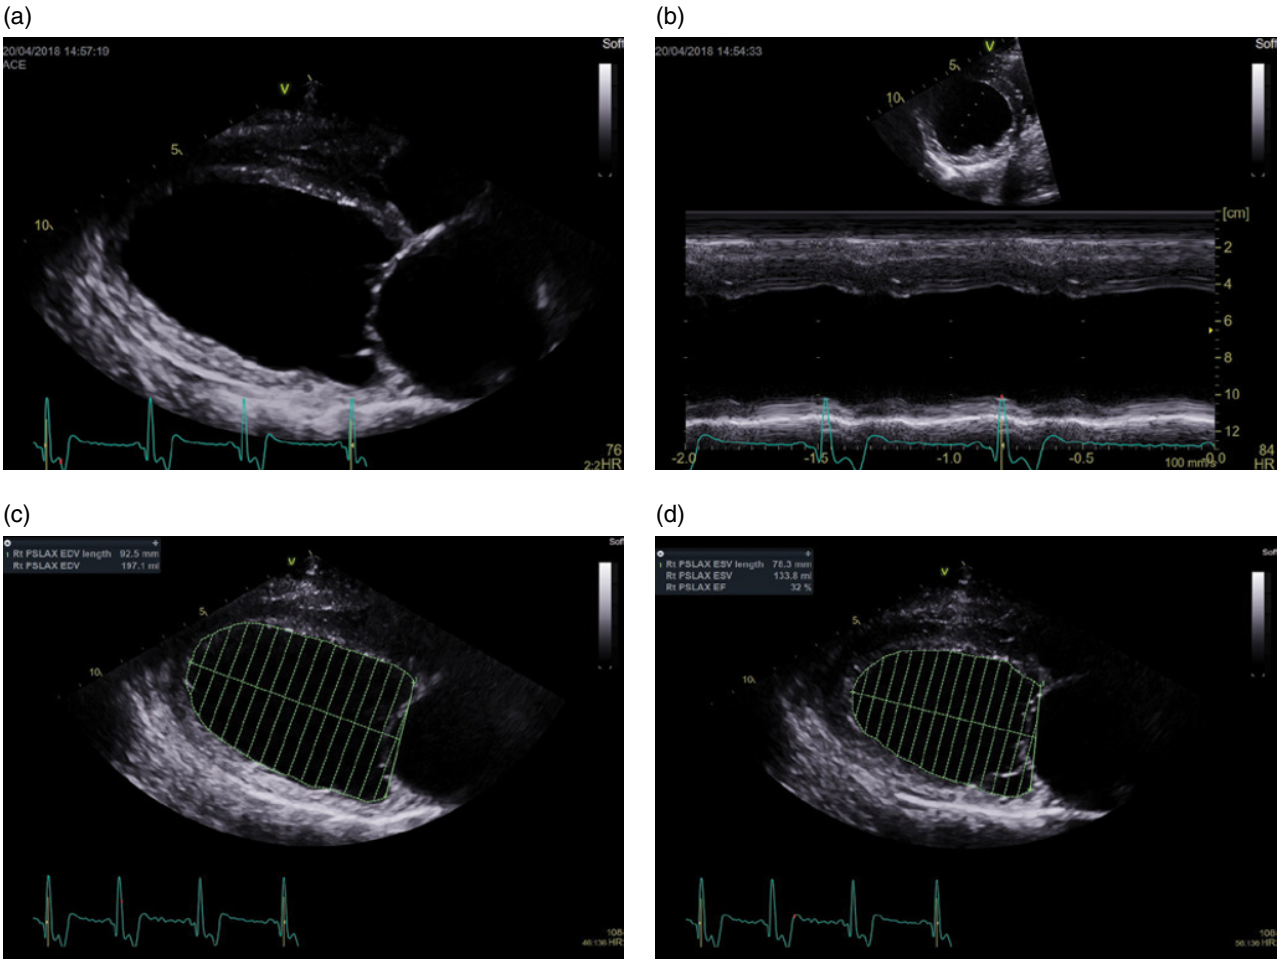

Figure 26.4 Two-dimensional echocardiographic images (right parasternal long-axis view) and M-mode (right parasternal short-axis view) from a Doberman with DCM. The left heart is in the far field and right heart in the near field. (a) Note the dilated LV in this systolic frame. (b) M-mode shows reduced systolic septal and LV free wall motion. (c,d) LV volume measurement in diastole and systole by Simpson's method of discs.

Table 26.1 Echocardiographic parameters in normal dogs and breed-specific criteria suggestive of diagnosis of DCM

Parameter	Normal value
Normal parameters	
LVEDD index = LVEDD ÷ $BW^{0.294}$[a]	1.27–1.85 (95% PI)
LVESD index = LVESD ÷ $BW^{0.315}$[a]	0.71–1.26 (95% PI)
LVESV index (LVESV ÷ BSA)	<30 mL/m^2 (note this value is likely overly conservative)
Parameter	**Abnormal value**
Breed-specific criteria for diagnosis of DCM	
Dobermans[b]	
LVEDD	>48 mm (M) or >46 mm (F)
	Or >0.1749 × BW + 40.3 mm
LVESD	>36 mm (M or F)
	Or > 0.1402 × BW + 35.0 mm
LVEDV index (LVEDV ÷ BSA)	>95 mL/m^2
LVESV index (LVESV ÷ BSA)	>55 mL/m^2
Irish wolfhounds[c]	
LVEDD	>61.2 mm
LVESD	>41 mm
LVESV index (LVESV ÷ BSA)	>41 mL/m^2
Great Danes[d]	
LVEDD	>56.1 mm (M) or >54.0 mm (F)
LVESD	>42.7 mm (M) or >41.7 mm (F)
LVESV index (LVESV ÷ BSA)	>44 mL/m^2

BSA, body surface area; BW, body weight in kg; DCM, dilated cardiomyopathy; F, female; LVEDD, left ventricular end-diastolic dimension; LVEDV, left ventricular end-diastolic volume; LVESD, left ventricular end-systolic dimension; LVESV, left ventricular end-systolic volume; M, male; PI, prediction interval.

to mitral regurgitation. Indices of ejection such as fractional shortening (FS) and ejection fraction (EF) are reduced (EF <40%). FS, while easy to calculate and often reported, is not a reliable measure of systolic function. As a result, there is not a definitive cut-off below which is diagnostic of DCM and little emphasis should be placed on this number alone. Having said that, in DCM dogs with CHF, FS is often <15%.

Additional two-dimensional findings can include left atrial dilation with more advanced disease, reduced mitral valve excursion, increased mitral valve E-point to septal separation, decreased LV sphericity index, and right ventricular and atrial dilation with biventricular disease.

Doppler findings can include secondary mitral regurgitation due to annulus dilation and papillary muscle dysfunction, evidence of diastolic dysfunction (abnormal transmitral flow patterns including impaired relaxation, pseudonormal, and restrictive), reduced aortic velocities, and reduced myocardial tissue velocities.

Circulating Biomarkers

Cardiac biomarkers include hormones released by cardiac myocytes in response to stretch and other stimuli

(NT-proBNP), or substances released from myocardial tissue in response to injury (cardiac troponin-I [cTnI]). Note that biomarker testing is never intended to be used in isolation and should not replace gold standard testing (e.g., echocardiography, thoracic radiography for CHF); rather, it may be a tool to complement, and in some instances justify, other indicated diagnostics. Diagnoses and therapeutic recommendations cannot be made on biomarker results alone.

The utility of NT-proBNP in identifying likelihood of occult disease has been examined in the Doberman. NT-proBNP >550 pmol/L had a sensitivity of 78.6% and specificity of 90.4% for detecting echocardiographic abnormalities in one study. It is more sensitive in the detection of structural disease than arrhythmic disease. Another study in Dobermans suggests that the combined use of Holter monitoring and NT-proBNP >457 pmol/L (either being abnormal) yields increased sensitivity (94.5%) and specificity (87.8%). A cTnI >0.22 ng/mL (Immulite®, Troponin I, Diagnostics Products Corporation, Los Angeles) yielded 79.5% sensitivity and 84.4% specificity for detection of DCM in another study. Dobermans with NT-proBNP or cTnI greater than these values should be evaluated with echocardiography.

For the differentiation of CHF from primary respiratory disease in dogs presenting with respiratory signs, plasma NT-proBNP >2447 pmol/L (using second-generation assay) was 81.1% sensitive and 73.1% specific in a study including 8% DCM cases in a variety of breeds. This may have utility when physical exam and thoracic radiography are ambiguous and echocardiography is not available, but otherwise may not provide added value.

Plasma Taurine

Whole-blood or plasma taurine should be measured (using heparinized samples) in cocker spaniels, retrievers, Dalmatians, any atypical DCM breed, or any case with a history of lamb-based diet, vegetarian diet, low-protein diet, grain-free diet (currently being investigated), or any unbalanced home-made diet. Whole-blood concentration <150 nmol/mL or plasma concentration <40 nmol/mL indicates significant taurine deficiency. Note that taurine deficiency is not necessarily related to amounts of taurine consumed, but may be due to abnormal absorption or excretion of taurine or its precursor amino acids (methionine and cysteine), abnormal taurine synthesis, or reduced protein digestibility limiting availability of precursors.

Genetic Tests

Tests are available for two genetic markers associated with DCM in Dobermans in North America (PDK4 and titin mutations) through the Veterinary Genetics laboratory at North Carolina State University (https://cvm.ncsu.edu/nc-state-vet-hospital/small-animal/genetics/). Note that these two mutations do not account for all DCM cases in Dobermans, a negative test does not assure a dog will not develop DCM, nor does a positive test assure the dog will develop clinical disease. With this in mind, genetic testing cannot replace standard clinical screening. Appropriate sample types include EDTA whole-blood or buccal swabs. Results may be:

- negative – individual does not carry that particular mutation (but there may be other mutations so not guaranteed to never develop DCM)
- positive heterozygote – individual carries one copy of the mutated gene and may or may not develop clinical disease
- positive homozygote – individual carries two copies of the mutated gene and may or may not develop clinical disease but if so, may be more severe.

The greatest utility of genetic testing is determining suitability for breeding. It is recommended that homozygous dogs not be bred, and heterozygous dogs should be bred only to negative dogs and only so long as they do not express the phenotype.

Therapy

Preclinical DCM (ACVIM Stage B)

Goals of therapy in preclinical cases include slowing systolic dysfunction, preventing ventricular remodeling and disease progression, and delaying CHF or SD. Two drugs for which there is evidence of these benefits are pimobendan and angiotensin converting enzyme inhibitors (ACEI). See Table 26.2 for all drug doses.

Pimobendan, a calcium sensitizer with positive inotropic and vasodilatory effects, delayed the progression of preclinical disease in Dobermans in a multicenter, placebo-controlled, double-blinded clinical trial. The PROTECT trial enrolled 76 Dobermans with preclinical DCM. The pimobendan group had a significantly longer time to the composite endpoint of onset of CHF or SD compared with the placebo group (63% increase in time to endpoint, nine months longer). Additionally, the pimobendan group had significantly longer overall survival time compared with the placebo group. There was no increase in VA noted on one-month recheck Holter monitoring and no increase in SD in the pimobendan group. It is important to note that all dogs in this study had presence of echocardiographic systolic dysfunction, so these results are not necessarily applicable to Dobermans presenting with VA alone. Pimobendan was also shown to prolong the time to CHF or SD in IWs with preclinical DCM, AF, or both. The similarity in pathology and pathophysiology among different breeds would suggest potential benefit in breeds other than Dobermans and IWs, but specific studies are required.

Table 26.2 Doses of commonly used cardiac medications in dogs (see text for indications)

Drug	Dose
ACEI	
Benazepril	0.25–0.5 mg/kg q12–24h PO
Enalapril	0.25–0.5 mg/kg q12h PO
Positive inotrope	
Pimobendan	0.25–0.3 mg/kg q12h PO
Dobutamine	5–15 µg/kg/min IV CRI
Dopamine	1–5 µg/kg/min IV CRI
Diuretic	
Furosemide	2–5 mg/kg q8–12h PO or IV
	0.5–1 mg/kg/h IV CRI
Spironolactone	2 mg/kg q24h PO
Hydrochlorothiazide	0.5–2 mg/kg q12h PO
Antiarrhythmic	
Sotalol	1–3 mg/kg q12h PO
Mexiletine	5–8 mg/kg q8h PO
Diltiazem	0.5–3 mg/kg q8h PO (for immediate release formulation)
	0.05–0.1 mg/kg IV slow bolus
	followed by 1–5 µg/kg/min IV CRI
Digoxin	0.003–0.005 mg/kg q12h PO (to max 0.25 mg/dog q12hr)
Lidocaine	2 mg/kg IV bolus (max. 4 boluses)
	followed by 30–70 µg/kg/min IV CRI
Beta-blocker	
Atenolol	0.25–1.0 mg/kg q12h PO
Carvedilol	0.1–0.5 mg/kg q12h PO
Vasodilator	
Sodium nitroprusside	1–5 µg/kg/min IV CRI
Supplements	
Taurine	500–1000 mg q12h PO (<25 kg)
	1000–2000 mg q12h PO (>25 kg)
L-Carnitine	50–100 mg/kg q8h PO
Omega-3 fatty acids	78 mg eicosapentaenoic acid and 497 mg docosahexaenoic acid per dog per day

ACEI, angiotensin converting enzyme inhibitor; CRI, constant rate infusion; IV, intravenous; PO, by mouth (*per os*).

The role of the renin-angiotensin-aldosterone system (RAAS) in maladaptive cardiac remodeling and progression of systolic dysfunction is well known. In addition to their mixed vasodilatory and natriuretic properties, ACEI exert benefit by antimyocardial remodeling effects. A retrospective study in Dobermans found that time to CHF or SD was significantly prolonged with benazepril treatment, with a 55–64% reduction of risk of those outcomes compared to no treatment. While the strength of evidence is not as strong as that for pimobendan, the author advocates the use of ACEI in preclinical DCM based on the collective evidence in the human and veterinary literature, unless there is a specific contraindication to this class of drug. Evaluation of renal function one week after initiation and periodically thereafter is recommended.

While there is good evidence in the human literature that beta-blocker therapy reverses LV remodeling, improves LV systolic function and patient symptoms, and prolongs life in chronic heart failure, clinical data are lacking on the use and efficacy of beta-blockers in canine DCM. Concerns with beta-blocker use typically include hypotension or CHF due to bradycardia and negative inotropy when first administering; therefore, they must be used with caution and uptitrated slowly.

Taurine supplementation should be initiated in any case suspected or documented to be due to taurine deficiency. L-carnitine can be simultaneously added or initiated after three months if there is inadequate response with taurine alone.

The patient with clinically significant VA is worthy of separate consideration. In humans, the risk of SD increases with declining systolic function or a history of syncope, yet there is no clear evidence that any antiarrhythmic (AA) drug is effective in preventing SD. In Dobermans, increasing LVEDV, presence of VT, and VPCs yielding instantaneous HR ≥260 bpm are associated with increased risk of SD. There are no studies addressing the efficacy of AA therapy in canine DCM. AA therapy may be considered in any DCM patient with frequent VPCs (>1 per minute) or VA with higher complexity or rate (couplets, triplets, or VT with instantaneous HR >180 bpm). Typical choices for AA therapy include sotalol, a AA with both beta-blockade and K+ channel blockade properties (initiating low doses and titrating upwards is often advised due to the beta-blockade), mexiletine, a Na^+ channel blocker, or a combination of the two.

Monitoring the preclinical patient should include physical examination, echocardiography, and ECG or ideally Holter recording every 4–6 months. If AA therapy is initiated, it is best to monitor therapeutic efficacy with Holter monitoring within 1–2 weeks of initiating therapy. Due to a high degree of daily variability, an in-house ECG is an inadequate alternative.

Overt DCM (ACVIM Stage C, CHF): Outpatient Therapy

Therapeutic goals in the CHF patient include resolution of clinical signs and improvement in quality of life

in addition to delay in disease progression and prolongation of survival. Strategies include intravascular volume reduction to resolve pulmonary edema or decrease cavitary effusions, improvement in hemodynamic performance through decreased systemic vascular resistance and improved contractility, neurohumoral modulation, arrhythmia management, and nutritional management.

The mainstay of treatment of edema and effusions remains diuretics, with furosemide the most commonly used agent. It may be administered orally or intravenously depending on the severity of CHF and whether the patient is being treated as an inpatient or outpatient. Following edema resolution, the dose may be lowered to the effective dose that maintains the patient free of respiratory signs and edema. Given its relatively short duration of action, dosing more than twice daily may be more effective. Substantive pleural effusion or ascites should be relieved with thoraco- and abdominocentesis, respectively.

Angiotensin converting enzyme inhibitor is indicated for RAAS blockade and vasodilatory effects, particularly in the setting of furosemide use which heightens RAAS stimulation. The results of veterinary clinical trials using enalapril and benazepril report improved quality of life, and although the improvements in survival did not reach statistical significance for DCM dogs, there is clear evidence of mortality reduction in human patients and ACEI use is considered standard therapy in dogs with DCM and CHF.

Three placebo-controlled trials have found significantly longer time to treatment failure or longer survival time in DCM dogs treated with pimobendan in addition to diuretics and ACEI, so pimobendan is considered part of standard therapy for CHF due to DCM.

The aldosterone antagonist spironolactone significantly reduces morbidity and mortality in humans with CHF and LV systolic dysfunction. While similar evidence is lacking in dogs with DCM, a study in Dobermans with CHF suggested a reduced risk of AF with spironolactone therapy. Spironolactone is often used in the patient that is still symptomatic despite use of triple therapy with furosemide, ACEI, and pimobendan, whereas some, including the author, advocate using it initially as part of standard therapy. Spironolactone is licensed for use in dogs with CHF in Europe.

Management of the overt DCM patient with VA includes optimal management of congestion and hemodynamics to reduce sympathetic nervous system stimulation and improve perfusion. Specific AA therapy may also be indicated. Patients with VA may be managed as outlined above for the preclinical stage. DCM patients with AF and in-hospital HR >150 bpm are candidates for rate control with AA therapy. While cardioversion to sinus rhythm may be physiologically ideal, rate control is much more feasible. Evidence suggests that the combination of diltiazem with digoxin is more efficacious for rate control than either drug alone. A target mean HR <125 bpm on Holter recording is ideal, and given higher HR in hospital, target mean HR on in-hospital ECG should be <140–150 bpm. Alternative therapy choices include a beta-blocker or sotalol, though beta-blockers should not be initiated in the setting of acute or poorly managed heart failure.

Cardiac cachexia is identified commonly in DCM CHF patients and nutritional support is an important part of therapy. Due to anorexia, increased energy requirements, and production of inflammatory cytokines, lean muscle mass is lost in the chronic heart failure patient. Management involves providing adequate calories and protein, and there is evidence that supplementation with omega-3 fatty acids is beneficial. While diets restricted in sodium are commonly advocated, the effects on quality of life or survival have not been assessed in dogs.

Overt DCM – Severe Life-Threatening CHF

Parenteral means of decreasing intravascular volume, increasing contractility, decreasing vascular resistance, and treating arrhythmias may be necessary in cases of severe CHF. Administration of oxygen by nasal prongs, cannula or cage is indicated in the case of hypoxia. Administration of intravenous (IV) furosemide by bolus or constant rate infusion (CRI) is the single most important and effective strategy to initiate promptly. Multiple boluses may be administered 30–60 minutes apart until the respiratory rate drops 50% from initial presentation or effort improves. If there is inadequate response after three doses, CRI should be initiated. Alternatively, one bolus followed immediately by CRI is preferred if the patient has preexisting azotemia or is particularly severe. Careful monitoring of volume status, renal function, and electrolytes is required. Thoracocentesis is indicated if substantive pleural effusion is contributing to dyspnea.

If rapid AF is present, initiation of IV diltiazem is indicated to reduce HR below 140–150 bpm. In cases of VA in the setting of CHF, treatment may be warranted if VT is present, signs of weakness or collapse are present, or the patient is a breed with a high incidence of SD such as Dobermans and boxers. IV lidocaine is typically the first treatment of choice.

In the absence of arrhythmias, IV furosemide may be enough to stabilize some patients whereas others will require the addition of a parenteral positive inotrope +/– vasodilator. Dobutamine CRI is the IV positive inotrope of choice for treatment of severe edema and hypotension. Side-effects include nausea/vomiting and exacerbation of VA, in which case the dose should be decreased. It is important to note that if AF is present, IV diltiazem

should be initiated for rate control before dobutamine to avoid life-threatening tachycardia. Dobutamine is typically administered for <72 hours due to the development of receptor refractoriness. If dobutamine is not available or feasible, then oral pimobendan should be started as soon as possible.

Sodium nitroprusside is a potent mixed vasodilator that may be added as a CRI for the treatment of severe life-threatening edema. Blood pressure must be monitored very frequently, preferably invasively and continuously. Side-effects include hypotension (which can be quickly resolved by stopping or decreasing the dose due to its very short duration of action), and rarely cyanide toxicity with high dose and prolonged use (>72 hours). With the initiation of all of these infusions, careful attention must be paid to the volumes of fluids being administered, and solutions should be concentrated as much as possible to reduce the total volume being administered.

Following stabilization, weaning of IV medications and transition to the oral medications discussed above (as for outpatient) is carried out.

For the refractory CHF patient (those with advanced CHF that continue to have clinical signs despite standard therapy – ACVIM stage D), management strategies include confirming owner compliance with current medications, identifying complicating concurrent conditions (poorly controlled or new arrhythmias, systemic diseases such as hyperadrenocorticism, neoplasia, infectious or inflammatory conditions), and changing medication strategies. The latter can include an increase in the frequency or change in route of furosemide administration (IV bolus or CRI for short periods), addition of diuretics such as spironolactone or hydrochlorothiazide (the latter should be accompanied by a reduction in furosemide dose), stricter sodium restriction, increase in inodilator and/or ACEI dose, or short-term parenteral positive inotrope (dobutamine) or vasodilator (nitroprusside) administration as described above.

Follow-up/Monitoring of Overt DCM

The focus of follow-up is respiratory status (respiratory rate and effort, degree of pulmonary edema or pleural effusion on thoracic radiography), renal status and electrolyte balance (renal chemistry and electrolytes), body condition and hydration (body weight, body condition score [BCS]), HR and rhythm (auscultation, ECG or Holter), and perfusion (body temperature, blood pressure, renal chemistry, electrolytes). These assessments may be made as frequently as weekly at the initiation of therapy to every 1–2 months once patients are stable. While ACEI and pimobendan doses are often optimized at the onset, diuretic doses are adjusted to balance pulmonary and renal/hydration needs. Following initiation of or change in dose of AAs, recheck ECG or ideally Holter is advised within 1–2 weeks to assess VA control or rate control in the case of AF, and medications adjusted accordingly. One cannot expect to eliminate VA but rather a reduction of the frequency, complexity, and HR is a reasonable goal (preferably reduction of >80%). In the case of AF, HR targets must be individualized to what appears to be optimal for the patient based on the assessments above, but a general guideline is a target mean HR <125 bpm on Holter or <140–150 bpm in hospital.

Prognosis

Dogs with preclinical disease may go several years without clinical signs, so the diagnosis does not imply immediate risk of morbidity or mortality. Data on the length of this phase are lacking for most breeds except the Doberman and IW. Based on the PROTECT trial, the median time to CHF or SD following diagnosis of occult disease in Dobermans was 718 days in the pimobendan-treated group and 441 in the placebo group. IW may have a very prolonged preclinical phase, with an average of 48 months in a recent clinical trial.

Unless a reversible underlying cause is identified (e.g., taurine deficiency, primary tachyarrhythmia), the prognosis for DCM is often poor once overt clinical disease (CHF) develops, with most survival times being in months. The median survival time in a large retrospective study with mostly overt dogs was 19 weeks, with one-year and two-year survival rates of 28% and 14%, respectively. Fifty percent of dogs were euthanized for their heart disease in this study, while 40% died from their heart disease, and 3% died for other reasons, emphasizing the almost inevitably terminal nature of this disease. In the Doberman, one-year survival rates of 10% or less have been reported, and treatment with triple therapy (ACEI, furosemide, pimobendan) yielded a median survival time of 130 days. IW may have a better prognosis once in CHF, with median survival time of five months in those dying of their disease but 14 months in those still alive at the time of writing of one study.

Factors associated with shorter time to CHF or SD in the PROTECT trial included an increase in LVESD index, increased baseline HR, and ≥4 VPCs on a 3-min ECG. Factors associated with negative prognosis in overt DCM have included increased LVESV index, decreased EF, presence of pulmonary edema on radiographs, presence of ascites, presence of VPCs on ECG, increased serum creatinine, decreased plasma protein, Great Dane breed, and restrictive transmitral flow pattern on Doppler echocardiography. Factors associated with increased risk of SD in Dobermans include larger LVEDV, presence of VT, VPCs with instanteous HR ≥260 bpm, and higher cTnI.

Arrhythmogenic Right Ventricular Cardiomyopathy

Etiology/Pathophysiology

Arrhythmogenic right ventricular cardiomyopathy is a progressive myocardial disorder characterized by partial to complete replacement of the right ventricular (RV) myocardium with fatty or fibro-fatty tissue, presence of ventricular arrhythmias, and risk of SD. The distribution of pathologic changes is greater in the subepicardium, and the left ventricle is not spared despite being a predominantly RV disorder. In humans, a majority of cases are familial or inherited and genetic mutations in at least 20 genes encoding mostly proteins of the desmosome (region of intercalated discs between myocardial cells involved in mechanical and electrical coupling) have been implicated. A few nondesmosomal genes, including the cardiac ryanodine receptor (RyR2, calcium release channel of the sarcoplasmic reticulum), have also been involved.

Arrhythmogenic right ventricular cardiomyopathy is likewise a familial (inherited) disorder in the boxer. The disease, once referred to as "boxer cardiomyopathy," has been reclassified as ARVC due to its similarities with the human disease. To date, none of the mutations described in people have been found in the boxer. Rather, an 8-base pair deletion in the striatin gene has been linked to ARVC in some American boxers, though its causal role has been challenged. Striatin is an intercalated disc protein that co-localizes with three of the desmosomal proteins implicated in ARVC in people. There is also some suggestion that the RyR2 is involved as affected boxers have a deficiency of calstabin2, a RyR2 protein.

Arrhythmogenic right ventricular cardiomyopathy in dogs manifests as ventricular tachyarrhythmias predominantly of RV origin (left bundle branch block [LBBB] configuration) and patients are at risk of SD from ventricular fibrillation (Figure 26.5).

Supraventricular tachyarrhythmias may also occasionally be noted. In boxers, the hearts are most often structurally normal on gross examination, unlike in humans where RV dilation, systolic dysfunction, and aneurysms are common. A small percent of boxers experience systolic dysfunction and heart failure, whereas this may be more common in English bulldogs, another affected breed.

Epidemiology

The true prevalence of ARVC in the boxer is unknown, but anecdotally it would appear to be quite common. The prevalence in other breeds is very low.

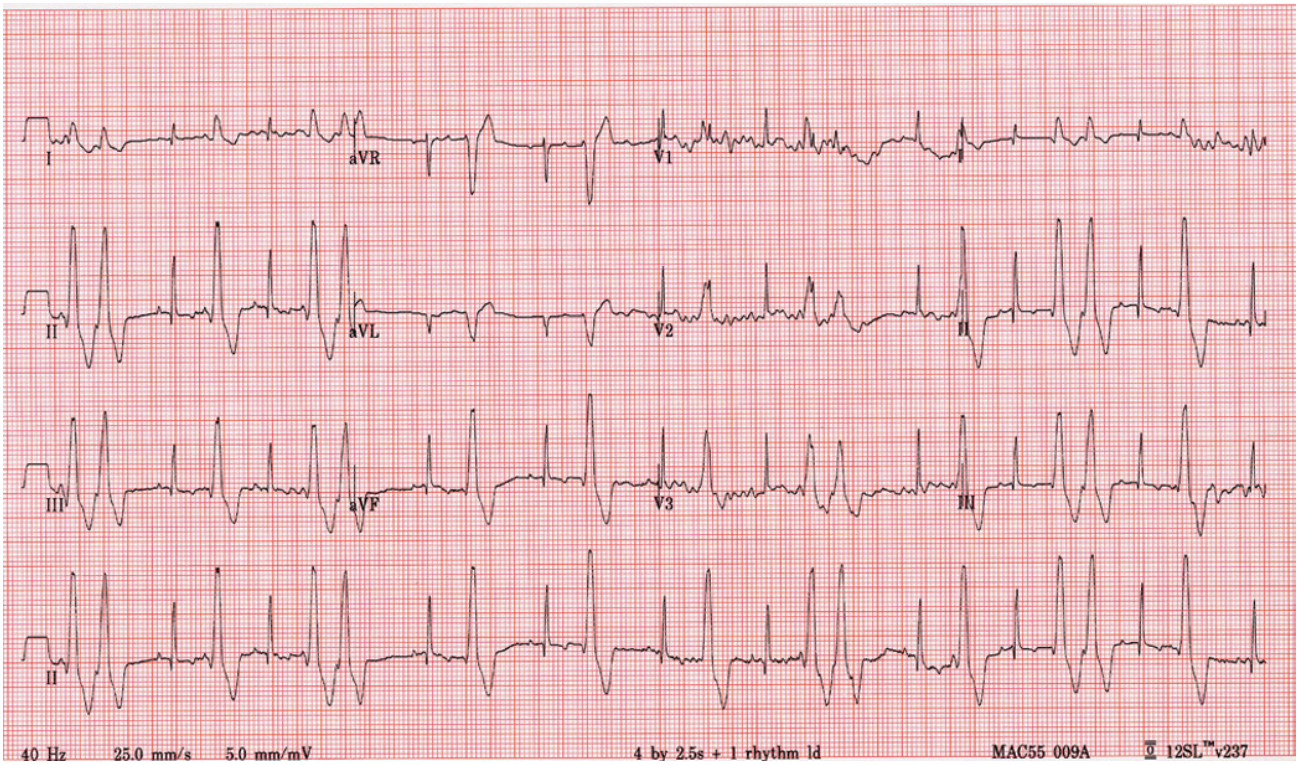

Figure 26.5 Nine-lead ECG, 25 mm/s, 5 mm/mV. Right ventricular VPCs (left bundle branch block configuration) in a boxer with ARVC. There are periods of ventricular bigeminy (alternating VPCs and sinus beats) and several VPC couplets.

The mode of inheritance in the boxer is autosomal dominant with incomplete and age-related penetrance and variable expression. Dogs homozygous for the striatin mutation exhibit a more severe form of disease and there may be association with myocardial failure.

The natural history of the disease in the boxer can be quite variable. Frequently, dogs may present with incidental VA and remain asymptomatic for years. The percentage of boxers that develop syncope has varied from 33% to 68% in different studies. The percentage that experienced SD in one prospective longitudinal study was 31%. Less than 10% of boxers develop myocardial failure and CHF. In contrast, in a case series of 31 English bulldogs with ARVC, 52% had CHF (38% left-sided, 33% right-sided, and 19% biventricular failure).

Risk factors for the development of ARVC apart from breed are unknown. Risk of SD in boxers appears to be higher with a previous history of syncope, more frequent VPCs, more complex VA (couplets, triplets, runs of VT), and more runs of VT. In humans, being a competitive athlete has been linked with increased risk of SD, suggesting the cardiac strain associated with intense exercise can exacerbate VA.

Signalment

Arrhythmogenic right ventricular cardiomyopathy is most common in the boxer breed. Males tend to be overrepresented. The average age at diagnosis is 5–7 years but younger and older dogs may be affected. Multiple cases are now also reported in the English bulldog. Isolated cases of a similar RV cardiomyopathy have been reported in a dachshund, bullmastiff, Labrador retriever, Siberian husky, Shetland sheepdog, Dalmatian, and Weimaraner.

History and Clinical Signs

Many boxers present without any clinical signs and are detected incidentally through identification of an arrhythmia on physical exam or through active screening programs. Roughly one-third to two-thirds may have a history of syncope, and roughly one-quarter experience exercise intolerance. Few present with respiratory signs typical of CHF, whereas this appears to be more common in English bulldogs. It is important to note that there are other causes of syncope in the boxer apart from ARVC.

Physical examination may be normal since the VA are intermittent. Alternatively, intermittent premature beats may be heard on auscultation, or rather the "pause" after a premature beat may be more apparent than the premature beat itself. Bursts of tachycardia may also be noted in more severely affected dogs. Dogs with arrhythmias may have pulse deficits. Soft left base murmurs are common in boxers and not specifically indicative of myocardial disease.

Diagnosis

There is no gold standard for antemortem diagnosis of ARVC in dogs. However, Holter recording is the most valuable diagnostic tool, and should be performed in any boxer with an auscultable arrhythmia, with a history of exercise intolerance or syncope, for active screening in any asymptomatic adult boxer especially with a family history of ARVC or positive genotype (starting at >3 years of age), or for those in breeding programs. Diagnostic criteria have yet to be clearly defined. Greater than 100 VPCs per 24 hours of RV origin (LBBB configuration, "upright" orientation in lead II) is suspicious for ARVC in the absence of another identifiable cause, particularly if there is increased complexity like couplets, triplets, or VT, and >300 VPCs/24h is a more suggestive threshold.

One study proposed three diagnostic criteria (>100 VPCs/24h, presence of couplets, and presence of R-on-T phenomenon) with the presence of two out of three possibly being a more robust way to identify the disease. However, these or any other cut-offs have yet to be validated prospectively, and to rely solely on the total VPC count may be erroneous. The complexity of the arrhythmia and the complete clinical presentation should be considered when making the diagnosis. Holter recordings can have a high degree of day-to-day variability (as much as 80%) and therefore may need to be repeated in dogs with high suspicion yet equivocal results.

Myocardial biopsy is not typically used for diagnosis owing to anesthetic requirements and invasiveness, as lesions may be missed given the epicardial and patchy distribution of pathology, and the risk of adverse effects including provocation of arrhythmias or cardiac puncture.

Unlike in humans, imaging modalities including echocardiography have low diagnostic yield as they are often normal. In few boxers will RV or LV dilation and systolic dysfunction be appreciable whereas in a case series of English bulldogs, 59% had subjective RV dilation. Cardiac MRI may have utility in detecting the fatty infiltration that characterizes the disease, but this remains to be investigated thoroughly in dogs.

Circulating biomarkers including cTnI and NT-proBNP are not useful for detection of ARVC, based on studies in boxers. While cTnI levels did correlate with degree of arrhythmia, the degree of overlap with presumably normal boxers renders it an unsatisfactory screening tool.

A genetic test for the striatin mutation in boxers is available through the Veterinary Genetics laboratory at North Carolina State University (https://cvm.ncsu.edu/nc-state-vet-hospital/small-animal/genetics/). Interpretation and breeding recommendations are as for the DCM genetic tests outlined above, and genetic screening cannot replace clinical screening.

Therapy

While AAs have been shown to reduce VA frequency and syncope, it is uncertain whether they decrease risk of SD because studies are lacking. Nevertheless, AA therapy remains the mainstay of ARVC treatment. A consensus on arrhythmia threshold necessitating treatment is lacking, and each patient must be approached on a case-by-case basis. Even asymptomatic dogs may be at risk of SD, but this must be balanced with proarrhythmic risk of AA drugs and owner factors including commitment to long-term therapy. Suggested candidates for AA therapy include dogs with a history of syncope, those with VT regardless of total VPC number, those with >300 VPC/24h and increased complexity including couplets, triplets, or R-on-T (rapid VPCs), or those with >1000 VPC/24h.

For immediate treatment of VT or VA causing weakness or collapse, intravenous lidocaine is recommended. The most common and effective oral AAs are sotalol, mexiletine, or a combination of the two in more refractory cases (see Table 26.2). Note that therapy may be indicated prior to Holter recording, as in instances where there is a history of syncope and VT is identified on ECG. Therapy should be monitored by Holter examination within 1–2 weeks of AA initiation, and periodically thereafter (every six months). Therapeutic efficacy is supported by a >80% reduction in arrhythmia number and complexity. An increase in syncope post treatment may suggest a proarrhythmic effect and should be evaluated with Holter promptly.

There is some evidence that oral supplementation with omega-3 fatty acids may also be beneficial (see Table 26.2).

For the minority that experience CHF (left, right, or biventricular), therapy with ACEI, pimobendan, and diuretics is indicated as described above for DCM, in addition to AA therapy. L-carnitine may also be added given positive response in a small family of boxers.

Prognosis

While all dogs with ARVC are at risk of SD, many remain symptom free for years. In one prospective study of boxers, the median survival time after identification of >300 VPC/24h was just over four years, and in fact overall survival of the affected group was not significantly different from the control boxer group (survival to 10–11 years of age), whereas a retrospective study of boxers with more advanced disease suggested a median survival time of 365 days (range 7–1971 days). The probability of death within a year was almost five times greater with a history of syncope, just over five times greater with >10 000 VPCs/24h, and 20 times greater with >200 runs VT/24h. In a case series of English bulldogs, a median survival time of 8.3 months was reported, but whether the prognosis is truly worse in that breed is not known, as it is likely that these dogs had more advanced disease at the time of diagnosis than other boxer studies.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is a primary myocardial disease characterized by symmetric or asymmetric concentric hypertrophy (thickening) of the LV in the absence of a stimulus for hypertrophy (e.g., stenosis or hypertension), leading to diastolic dysfunction and arrhythmias that may result in CHF or SD. In humans, 50% or more of cases are related to familial genetic mutations. While common in the cat, HCM is very rare in dogs. Like in the cat, dynamic LV outflow tract obstruction (LVOTO) caused by systolic anterior motion of the mitral valve (SAM) is described in some cases.

Many cases of canine HCM appear to be in young dogs, with males overrepresented. This has raised the question as to whether the disease may be congenital and furthermore, whether LVOTO may represent a form of mitral valve dysplasia predisposing to SAM and secondary hypertrophy. Many affected breeds have been reported and include the pointer, golden retriever, Rottweiler, German shepherd, and shih tzu, amongst others. Cases are frequently evaluated for the presence of an incidental murmur which may be dynamic. Echocardiography is necessary for diagnosis. Treatment is targeted at reducing dynamic LVOTO with beta-blockade (atenolol), and treating CHF or arrhythmias in severe cases. A number of cases in young dogs have been noted to resolve with maturity, while others have persisted and resulted in CHF or SD. It is difficult to estimate prognosis based on the sparse reports of this disease in dogs.

Feline Myocardial Disease

Virginia Luis Fuentes, MA, VetMB, PhD, CertVR, DVC, MRCVS, DACVIM (Cardiology), DECVIM (Cardiology)

Department of Clinical Sciences and Services, Royal Veterinary College, University of London, Hatfield, Herts, UK

Myocardial disease is extremely common in cats and will be encountered regularly by any feline clinician, but can be hard to recognize. Feline myocardial disease is very heterogeneous in presentation, clinical findings, and prognosis. Without skilled echocardiography, identifying the different subclassifications of cardiomyopathy is usually difficult. Fortunately, this is not usually necessary, as the main priorities for the clinician are to identify those cats with a specific treatable cause of myocardial disease, and to identify cats at high risk of congestive heart failure (CHF) or aortic thromboembolism (ATE).

Etiology

The term "myocardial disease" includes a range of conditions with varied etiologies. Cardiomyopathies are usually classified according to a phenotype based on cardiac structure and function (Figure 27.1).

The myocardium can be affected by systemic conditions such as hyperthyroidism, systemic hypertension, and anemia, where disturbances in hemodynamic loading conditions may alter cardiac structure and function. The myocardium has a limited range of responses to injury or insult, so that different underlying causes can result in the same phenotype. For example, dietary taurine deficiency, an uncontrolled tachyarrhythmia or doxorubicin toxicity can all result in an identical "dilated cardiomyopathy phenotype" characterized by systolic dysfunction and ventricular dilation. In other cats, no obvious underlying cause is identified, although a genetic predisposition is suspected in some.

Traditionally, feline cardiomyopathies have been classified according to contemporary human classifications, but controversy currently exists over whether human myocardial disease should be classified according to etiology or phenotype. The most commonly recognized phenotype is hypertrophic cardiomyopathy (HCM), characterized by thickened left ventricular (LV) walls. Other phenotypes include restrictive cardiomyopathy (RCM), defined as relatively normal LV walls but with atrial enlargement and increased atrial pressures; dilated cardiomyopathy (DCM), recognized by atrial and ventricular dilation with global LV hypocontractility; and arrhythmogenic right ventricular cardiomyopathy (ARVC), which is typically manifested by fibrofatty replacement of predominantly the right heart. There is considerable overlap between phenotypes, so an additional category of "unclassified cardiomyopathy" or "non-specific phenotype" is sometimes used to describe patients with a phenotype that does not correspond with any of the above criteria.

Unless a causative systemic disease or myocardial insult can be identified, the etiology is unknown for most cats with myocardial disease, although familial HCM is recognized. A genetic cause has been established for HCM in Maine Coon and ragdoll cats, where two different genetic mutations have been identified in the myosin-binding protein C gene. In contrast, an HCM phenotype has been associated with over 1400 different mutations in humans, although a genetic cause is not identified in all human HCM patients.

Pathophysiology

The functional disturbance and consequent pathophysiology vary according to type of cardiomyopathy and severity of disease. With mild myocardial abnormalities, affected cats may not experience any obvious adverse consequences. With severe or advanced myocardial disease, congestive heart failure is the most commonly recognized sign. Sudden death is also a potential sequela, but the prevalence is unknown and probably underestimated. Systemic or arterial thromboembolism is recognized in many advanced cases of cardiomyopathy with left heart involvement.

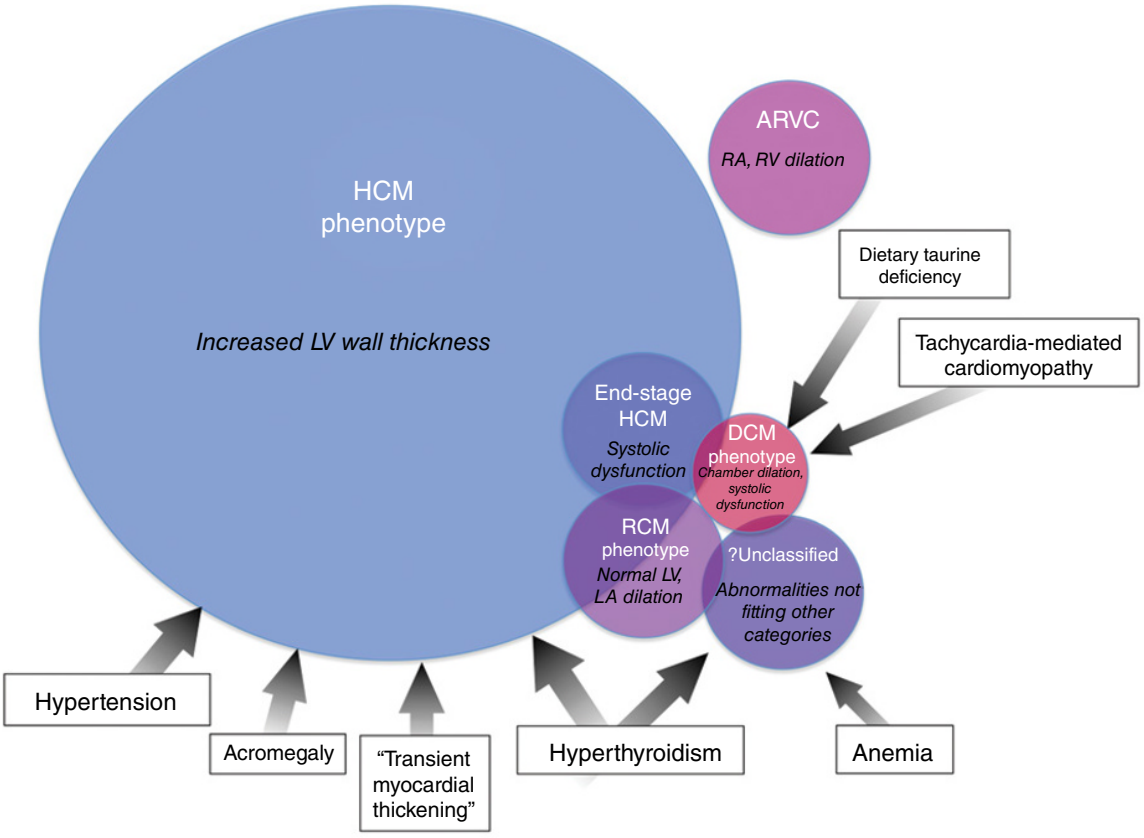

Figure 27.1 Myocardial disease phenotypes. There is overlap in the cardiac characteristics between the different "classic" forms of cardiomyopathy, and it can be difficult to differentiate cardiomyopathies with a genetic or unknown etiology from cardiomyopathies caused by systemic disease on the basis of cardiac characteristics alone. Hypertrophic cardiomyopathy (HCM) is defined as left ventricular (LV) hypertrophy in the absence of an obvious cause, but hypertension, acromegaly, "transient myocardial thickening," and hyperthyroidism can all result in a phenotype that is identical to classic HCM. A minority of cats with severe (primary) HCM develop systolic dysfunction, and are described as "end-stage HCM," overlapping with dilated cardiomyopathy (DCM). A DCM phenotype can be produced by taurine deficiency or a tachycardia-mediated cardiomyopathy though no underlying cause is found in most cats with dilation of all four cardiac chambers and global systolic dysfunction. The classic form of restrictive cardiomyopathy (RCM) is defined as normal LV dimensions with biatrial enlargement, but there is overlap with the above phenotypes. Not all cats fit into one of the categories listed above. Those with predominantly right heart enlargement without an obvious cause are usually presumed to be arrhythmogenic right ventricular cardiomyopathy (ARVC), but others do not fit any category and are sometimes called "unclassified cardiomyopathy" or "non-specific phenotype".

HCM

Key pathologic features of HCM include increased LV mass associated with myocyte disarray, interstitial myocardial fibrosis, and narrowing of small coronary arteries. Myocardial hypertrophy may result in delayed LV relaxation, but this is usually well tolerated under normal circumstances and is not likely to result in clinical signs. Many cats with HCM will remain clinically stable provided they are not subjected to a sudden change in hemodynamic load. Examples of such triggers include the stress of a visit to the veterinarian, which increases myocardial oxygen demand; general anesthesia, which can reduce cardiac output; or intravenous fluid therapy, which can result in volume loading. Any of these short-term hemodynamic stressors can cause a sudden increase in left atrial (LA) pressures and acute pulmonary edema. The cats with subclinical HCM that are most vulnerable to these stressors are likely to be those with LA enlargement. Cats with massive LV hypertrophy may also be at increased risk, but the relationship between LV wall thickness and risk is not linear, and LA enlargement is a better global indicator of advanced disease.

Many cats with well-compensated HCM exhibit dynamic LV outflow tract obstruction, which can be either persistent or only induced by excitement/exertion. Outflow tract obstruction is usually caused by systolic anterior motion (SAM) of the mitral valve, where movement of the anterior mitral leaflet towards the interventricular septum during mid to late systole causes obstruction to ejection of blood flow, as well as mitral

regurgitation. Outflow tract obstruction can be severe enough to result in a pressure gradient across the LV outflow tract of over 100 mmHg for much of systole. In human HCM patients, the additional myocardial oxygen consumption associated with outflow tract obstruction can cause myocardial ischemia, which is further exacerbated by the concurrent narrowing of small coronary arteries that is a feature of HCM in both humans and cats. Clinical signs of outflow tract obstruction in human HCM patients include exertional dyspnea and chest pain. The exact clinical effect in cats is difficult to determine, as chest pain could easily pass unnoticed by owners, and the majority of affected cats appear to be subclinical. Some owners report open-mouth breathing during play, despite an absence of documentable pulmonary edema.

With progression of HCM, diastolic filling of the LV may be further impaired as interstitial fibrosis worsens, and the LV myocardium becomes stiffer. Ischemic episodes can result in focal areas of myocardial damage, resulting in replacement fibrosis. Neurohormonal activation adds to the problem by causing plasma volume expansion through sodium and water retention, and signs of chronic congestive heart failure become more likely. Signs include pulmonary edema, pleural effusion or both. Cats at this stage are also at risk of arterial thromboembolism, as LA contractile function deteriorates with chronic LA enlargement. A minority of cats will develop generalized LV systolic dysfunction, or large areas of ventricular "scarring" with regional wall thinning and replacement fibrosis. Cats with increased wall thickness but systolic dysfunction are sometimes described as "end-stage HCM" (ES-HCM). Although these cats may start with a nondilated hypertrophied LV, over time the LV wall thickness may decrease and LV diameter increases, so that ultimately they may bear little resemblance to the classic HCM phenotype.

Occasionally, cats with HCM will present with acute signs of cardiogenic shock, including hypotension, hypothermia, and, often, bradycardia. These low-output signs may or may not be accompanied by congestive signs.

RCM

Two forms of RCM have been reported: an endomyocardial form characterized by LV bridging scar (eRCM); and a myocardial form where the LV appears structurally normal but is poorly compliant (mRCM). Varying degrees and distribution of myocardial fibrosis are common to both forms. Biatrial enlargement and increased atrial pressures are also common to both. Cats diagnosed with RCM usually demonstrate clinical signs, which can include congestive heart failure, arrhythmias, arterial thromboembolism, or low-output signs. It is difficult to differentiate RCM from the more advanced forms of HCM with myocyte loss or ES-HCM, and they may in fact be part of the same wide spectrum of HCM.

DCM

This form of cardiomyopathy is now very uncommon in cats, despite being the most common phenotype in dogs. A DCM phenotype is characterized by systolic dysfunction with normal or reduced LV wall thickness and is associated with an increase in diastolic and systolic ventricular dimensions. An association was identified in the late 1980s between DCM in cats and dietary taurine bioavailability, and since that time, a change in pet food manufacturing processes has resolved this problem. Accordingly, most cats with a DCM phenotype are found to have normal plasma taurine concentrations. Congestive heart failure, arterial thromboembolism, and low-output signs are all common presentations for DCM.

Arterial Thromboembolism

All of the above forms of cardiomyopathy may lead to intracardiac thrombus formation if disease is sufficiently advanced (i.e., with left atrial enlargement and dysfunction). Arterial embolization of thrombus (ATE) into the systemic circulation causes vascular occlusion and acute ischemia of downstream tissues, resulting in severe pain, electrolyte disturbances, acute renal injury, and for those surviving the initial embolic episode, a high long-term risk of ATE recurrence or CHF. Nevertheless, a minority of cats can survive for periods in excess of a year if they recover from the acute crisis.

ARVC

Arrhythmogenic right ventricular cardiomyopathy also occurs in humans and dogs, and is characterized by fibrofatty replacement of myocytes. The extent and distribution of myocyte replacement are variable, and may result in tachyarrhythmias and/or right atrial and right ventricular dilation. Affected cats may be presented with signs of syncope associated with tachyarrhythmias, but can also develop right-sided congestive signs with ascites.

Epidemiology

The prevalence of HCM in cats is high; approximately 15% of apparently healthy cats are affected, with a prevalence increasing to nearly 30% of cats over 9 years of age. The prevalence of RCM, DCM, and ARVC is harder to gauge, but is likely considerably lower. HCM is the most common type of feline cardiomyopathy, regardless of age, breed or presenting signs. In the absence of longitudinal epidemiologic studies, it is impossible to determine

whether RCM is a separate form of cardiomyopathy or an advanced stage variant of HCM.

Signalment

There is a male predominance in cats with HCM. Most cats with HCM are domestic nonpedigree cats, but a number of pedigree breeds are said to be predisposed, including the Maine Coon, ragdoll, Persian, British shorthair, sphynx, Cornish rex, and Norwegian forest cat. Siamese and Oriental cats may be predisposed towards eRCM. Age at diagnosis varies widely, as any age of cat can be affected with HCM, including kittens and geriatric cats, but the prevalence of LV hypertrophy increases with age.

History and Clinical Signs

Cats with advanced myocardial disease are often perceived by their owner to be healthy until shortly before the onset of CHF, ATE, syncope or sudden death. Typical presenting signs for CHF include respiratory distress and tachypnea, whereas acute limb paralysis/paresis is the most common presentation with ATE. Some cats may develop open-mouth breathing only with stress or exertion, and may be found to have dynamic LV outflow tract obstruction.

Physical examination findings are varied. Murmurs are common in cats with HCM but also in healthy cats with normal hearts, so a murmur should not always be assumed to indicate heart disease. Murmurs are less common in the more severe forms of cardiomyopathy than in well-compensated HCM. A minority of cats with cardiomyopathy have an audible gallop or arrhythmia, and these auscultation findings are more likely to indicate advanced disease, though can also be detected in some geriatric cats with only mild abnormalities. A prominent apical impulse may be apparent in cats with cardiomegaly or a hyperdynamic LV.

Physical exam findings in cats with congestive heart failure will include tachypnea with increased respiratory effort, crackles on pulmonary auscultation with severe pulmonary edema, or absent breath sounds ventrally with a pleural effusion. The presence of a gallop sound in a cat with tachypnea and respiratory distress should prompt treatment for congestive heart failure until further confirmatory tests are possible.

Diagnosis

From the above descriptions, it is clear that establishing a diagnosis of a particular type of cardiomyopathy in an individual cat is challenging. To differentiate end-stage HCM, RCM, and UCM requires a high level of echocardiographic skill and experience. A precise diagnosis can be challenging even for experienced cardiologists unless a cat has a classic HCM or ARVC phenotype, due to poor consensus on the definitions of each cardiomyopathy type. Moreover, the labels "end-stage HCM," "RCM," and "UCM" might not actually reflect distinct disease entities but rather different stages of a single condition. Instead, diagnostic tests should be focused on confirming the presence of heart disease; identifying any underlying systemic cause of cardiomyopathy that should be treated; and identifying cats at high risk of CHF and ATE.

Is Heart Disease Present?

In practical terms, the clinician's first priority when presented with a cat with clinical findings suggestive of heart disease is to establish whether or not cardiac disease is present. The approach will be different for cats with respiratory distress versus those that are asymptomatic.

Tachypneic Cats

Heart disease should always be considered in cats with tachypnea, and the presence of a murmur, gallop or arrhythmia should increase this suspicion (Figure 27.2).

Differentiation of congestive heart failure from other causes of respiratory distress may require diagnostic imaging, but the potential value of radiography or echocardiography must be weighed against the possible risk of subjecting the patient to further stress that could prove fatal. Ultrasound is generally better tolerated than radiography, and has the advantage that patient positioning is less critical. Thoracic ultrasound can demonstrate pleural effusion and can even be used to indicate pulmonary parenchymal changes as with pulmonary edema (B-line artifacts). If sufficient expertise is available, the most useful way to increase confidence of a cardiac cause of respiratory distress is to demonstrate LA enlargement with echocardiography. Thoracic radiography can be used to identify pleural effusion, pulmonary infiltrates, and assess cardiac size, but must be obtained with great care to avoid compromising patient safety. A point-of-care test is available to measure plasma NT-proBNP, providing a simple way to help differentiate cats with respiratory distress due to heart failure versus noncardiac causes.

Asymptomatic Cats

Myocardial disease should be considered in an otherwise healthy cat when a murmur is detected, and should be strongly suspected when a gallop or arrhythmia is auscultated (Figure 27.3). A very loud murmur (i.e., with a precordial thrill) is usually associated with congenital heart disease.

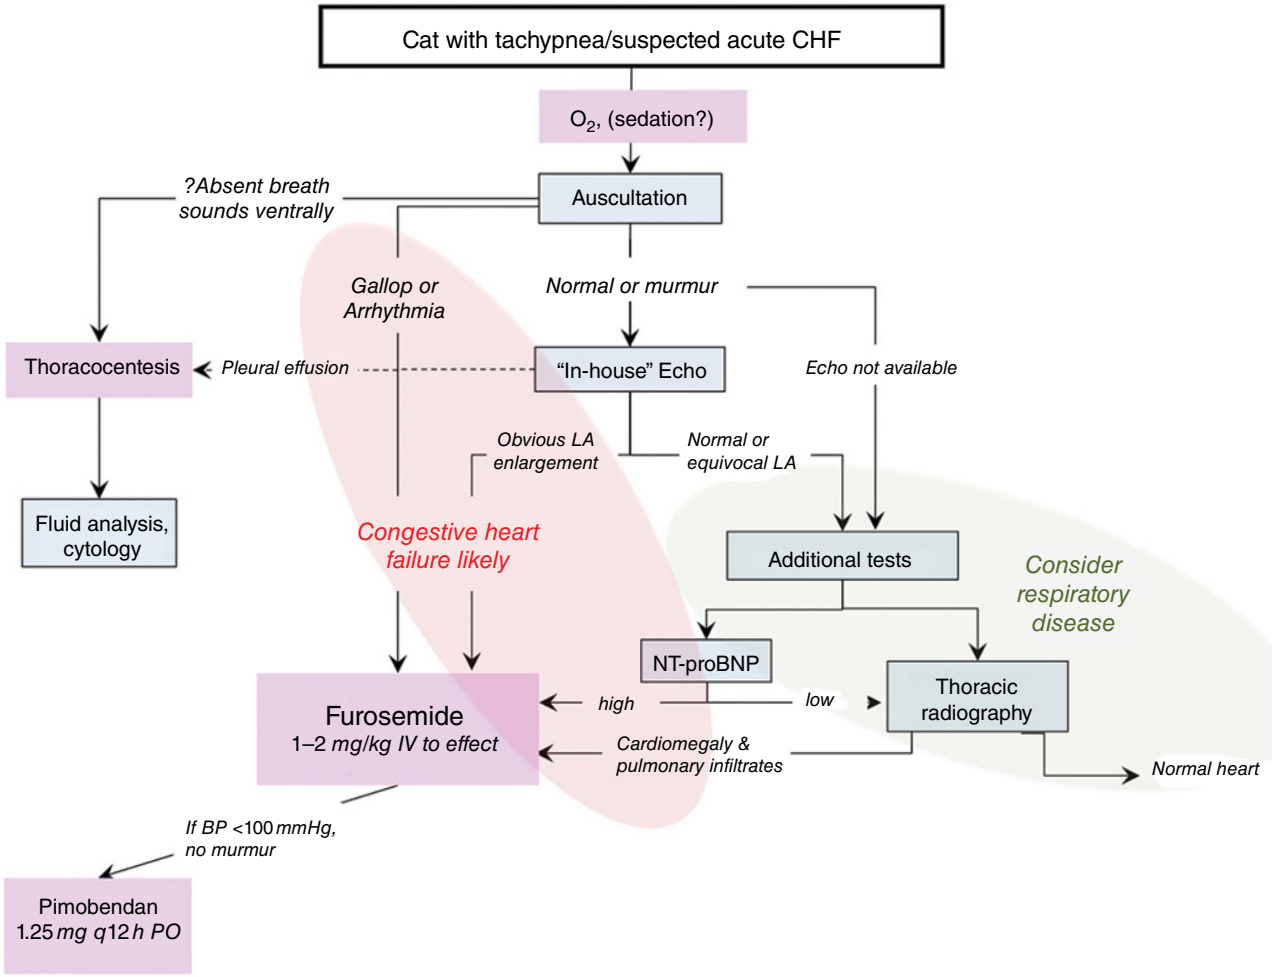

Figure 27.2 Initial approach to the cat with tachypnea and suspected heart disease. Diagnostic tests are shaded in blue, therapy is shaded in pink. A combination of auscultation, rapid and focused "in-house" ultrasound examination, and other diagnostic tests can provide information on probability that the cat's tachypnea is due to congestive heart failure (CHF) or noncardiac disease. BP, blood pressure; Echo, echocardiography; LA, left atrium.

Other common causes of a heart murmur in cats include physiologic (or nonpathologic) murmurs, as well as anemia, hyperthyroidism, and hypertension.

Is There an Underlying Systemic Cause of Myocardial Disease?

It is helpful to view feline myocardial disease in terms of those with and without a specific systemic cause, as treatment of any underlying cause is essential. It is vital to identify hypertension, hyperthyroidism or anemia, as specific treatment requirements will differ for each. Blood pressure should be measured in all cats with suspected heart disease, and T4 concentrations measured in older cats. Hematocrit should be checked if there is any concern that anemia may be responsible for a murmur. For those cats where no cause is identified or can be treated, it is important to evaluate the potential risk of cardiac complications such as CHF or ATE. Classifying cats as either "low risk" or "high risk" facilitates management.

Heart Disease Present; High Risk or Low Risk?

One of the most useful prognostic indicators for cats with cardiomyopathy is LA size. Cats with HCM and normal LA size can be considered to be at low risk of CHF and ATE. Cats with LA enlargement fall into a higher risk category. If echocardiography is not available to assess LA size, thoracic radiographs are reasonably specific but poorly sensitive to detect LA enlargement. ARVC is an exception, as LA size is an indicator of risk for left heart disease and ARVC predominantly affects the right heart. Plasma biomarkers such as NT-proBNP and troponin-I can help provide an indication of the severity of heart disease.

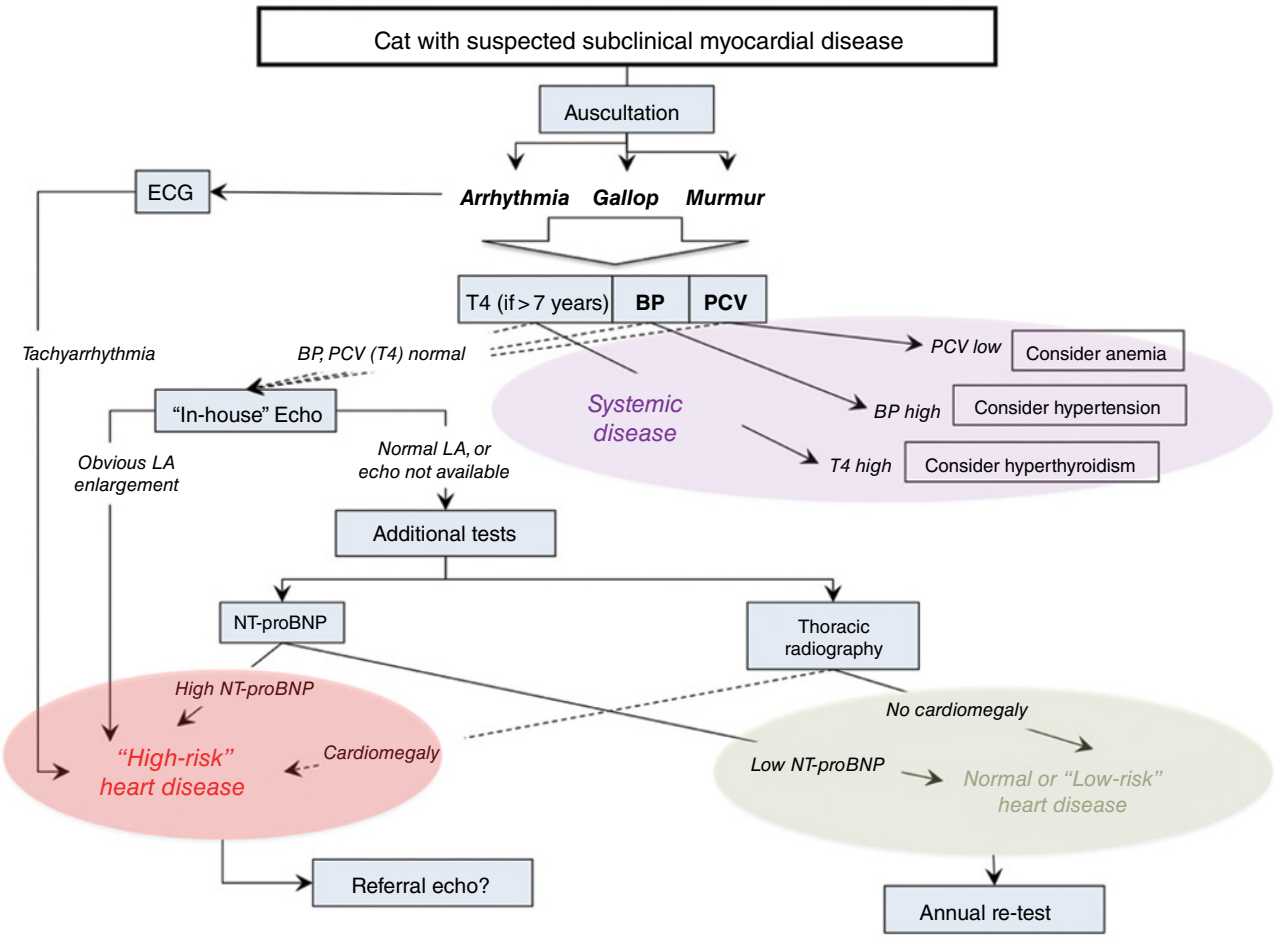

Figure 27.3 Initial approach to the cat with suspected subclinical heart disease. Diagnostic tests are shaded in blue. Secondary systemic causes of myocardial disease should be identified, as further specific testing may be indicated and therapy will be specific for the underlying cause. A combination of auscultation, rapid "in-house" echocardiography, biomarkers, and radiographs can be used to differentiate cats at high risk of congestive heart failure and thromboembolism, versus those at low risk of these complications. More advanced echocardiography can be considered for "high-risk" cats to further characterize the myocardial disease and rule out congenital heart disease. Cats with "high-risk" cardiomyopathy may benefit from antiplatelet treatment, such as clopidogrel. BP, blood pressure; echo, echocardiography; ECG, electrocardiogram; LA, left atrial; PCV, packed cell volume; T4, serum thyroxine concentrations.

Which Cardiomyopathy is This?

Echocardiography is a difficult technique in cats, and it takes an experienced echocardiographer to differentiate many of the more advanced cardiomyopathy phenotypes. Severe forms of ARVC may be easy to differentiate from other cardiomyopathies, but hard to differentiate from tricuspid dysplasia or conditions associated with severe pulmonary hypertension. Milder or atypical forms of any of the cardiomyopathies can be difficult to classify on echocardiography, and can sometimes be challenging even for cardiologists. At the other end of the spectrum, it can be challenging to differentiate cats with mild HCM from those with physiologic murmurs.

There are few clinical consequences in the short term for incorrectly distinguishing normal cats from those with mild HCM (apart from when screening prebreeding pedigree cats for cardiomyopathy), providing these "low-risk" cats continue to be monitored over subsequent years. The rate of progression from normal to mild HCM, or mild HCM to "high-risk" HCM is variable, so such cats should be reevaluated at least annually. Biomarkers can be helpful in this context, as low NT-proBNP concentrations should provide some reassurance that a cat continues to be low risk.

Therapy

Cats with CHF

For cats with life-threatening signs, therapy is focused on relieving critical hypoxemia using a combination of parenteral furosemide, oxygen, and sedation as needed

(butorphanol 0.3 mg/kg, IM or SC) for cats in distress. Initially, furosemide should be given IV at 2 mg/kg, but may be given IM until IV access can be secured. Repeated doses are given every 30–60 minutes, to effect. Response is assessed by monitoring respiratory rate and effort, with the goal of returning respiratory rates to normal (or at least <40 breaths/min). Renal function and electrolytes should also be monitored, as hypokalemia and elevations in BUN are common. Although the effect of therapy on renal function and electrolytes should be considered, the principal goal should be the elimination of congestive signs. Intravenous fluids should be avoided in the presence of congestive heart failure, even in hypotensive cats (systolic blood pressure <100 mmHg). For hypothermic, hypotensive cats without a heart murmur, pimobendan (1.25 mg PO per cat) can be considered.

Hospitalized cats are often stressed, and once respiratory distress is controlled they may benefit from being returned to their home environment.

Cats with "transient myocardial thickening" (TMT) warrant a specific mention, as they have a better than expected prognosis. The cause of TMT is unknown, but affected cats are often young and have a history of a recent stressful event. They usually present with CHF associated with thickened LV walls, but if treated appropriately for their heart failure can make a full recovery, with return to a normal cardiac phenotype.

For outpatient management, parenteral furosemide can be replaced with oral furosemide. The goal of long-term management is to maintain control of congestive signs and to prevent ATE. Evidence-based selection of therapeutic agents for CHF management in cats suffers from the absence of clinical trial data. Angiotensin converting enzyme inhibitors (ACEI), spironolactone, and pimobendan are all currently used off-label in the treatment of CHF in cats. ACEIs have not been associated with any adverse effects in cats with cardiac disease and in theory should counteract furosemide-mediated activation of the renin-angiotensin-aldosterone system (RAAS). Spironolactone should also act on the RAAS and has been reported to have favorable effects in experimental models of HCM, but its use was reported to result in skin lesions in a small minority of cats. Pimobendan is considered contraindicated in cats with HCM and outflow tract obstruction, but is a logical choice for treatment of cats with systolic dysfunction. Diltiazem is rarely used, and beta-adrenergic antagonists such as atenolol are generally considered contraindicated in the presence of congestive heart failure.

Cats with recurrent or persistent CHF despite appropriate doses of diuretics are generally managed by increasing diuretic doses and adding medications such as an ACEI and spironolactone. Cats that have experienced an episode of CHF are likely to be at risk of ATE, so should also receive antiplatelet treatment. Clopidogrel is the first-choice treatment for prevention of ATE (18.75 mg per cat q24h PO), as aspirin (at either 5 mg/kg or 75 mg q72h) does not appear to be as effective, though is well tolerated.

Administering multiple medications is a problem with many cats, so combining tablets in a single gelatine capsule can be helpful.

Asymptomatic Cats

Low-Risk Cats

Many asymptomatic cats will have normal survival times whether or not they receive treatment. It is debatable whether extending survival is possible in low-risk cats, although improving quality of life might be a worthwhile aim. In human HCM patients, LV outflow tract obstruction can be associated with chest pain and exertional dyspnea, which can be relieved with atenolol in some patients. Although atenolol does not seem to confer an obvious survival benefit in cats with HCM and LV outflow tract obstruction, there are anecdotal reports that atenolol might improve activity levels in some cats.

High-Risk Cats

There are currently no therapies that are known to reduce the risk of developing CHF in cats with myocardial disease, apart from treating hyperthyroidism, hypertension, and anemia when present. As high-risk cats are at risk of ATE, they should receive antiplatelet treatment.

Prognosis

Feline myocardial disease has a very varied prognosis, ranging from a benign condition with minimal influence on morbidity and mortality in many cats, to a disabling and potentially fatal condition associated with respiratory distress, sudden death, and pain and paralysis. Factors such as gallop sounds, arrhythmias, LA enlargement, and systolic dysfunction are indicators of a poor prognosis and high risk of cardiac complications, and absence of these factors is likely to indicate a more benign outcome. Of these factors, LA enlargement is the most important predictor and the ability to assess LA size with echocardiography is extremely useful. By focusing on potential risk, the complex issues of cardiomyopathy classification are avoided and therapy can be directed at cats that are in most need.

Pericardial Disease

Ashley B. Saunders, DVM, DACVIM (Cardiology) and Sonya G. Gordon, DVM, DVSc, DACVIM (Cardiology)

Department of Small Animal Clinical Sciences, College of Veterinary Medicine & Biomedical Sciences, Texas A&M University, College Station, TX, USA

The pericardium is a multilayered structure surrounding the heart that isolates the heart from the remainder of the thorax. It creates a potential space that can be filled by fluid, tissue, or air/gas. While pericardial disease is relatively uncommon, it can lead to life-threatening conditions when intrapericardial pressure rises and cardiac output is compromised. A combination of restricted filling, reduced diastolic function, partial obstruction to inflow into the atria, and reduced cardiac output can manifest clinically as weakness, collapse, tachycardia, jugular venous distension, and ascites. Pericardiocentesis is recommended to alleviate clinical signs of pericardial effusion and cardiac tamponade. Congenital and acquired pericardial diseases in cats and dogs will be discussed in detail.

Congenital

Etiology/Pathophysiology

Peritoneopericardial diaphragmatic hernia (PPDH) occurs during development in dogs and cats when the septum transversum does not form or fuse normally, resulting in a communication that allows abdominal contents to displace into the pericardial space. The tissues and organs herniated most often are omentum, liver, gallbladder, and small intestine. Concurrent congenital abnormalities including portosystemic shunt are often present in animals with PPDH.

Intrapericardial cysts have been rarely reported in dogs and cats and in some cases were associated with PPDH.

Epidemiology

The overall prevalence of PPDH at two veterinary institutions was 0.025%, with a greater prevalence in cats than dogs.

Signalment

Although these are congenital abnormalities, they can be detected incidentally in adults so the age at presentation can vary greatly.

History and Clinical Signs

PPDH

Clinical signs with PPDH depend on which abdominal organs herniate. Up to 69% of animals have clinical signs including tachypnea/dyspnea, cough, vomiting, anorexia, and exercise intolerance. Common physical examination abnormalities include muffled heart and lung sounds, borborygmus auscultated in the thorax, and heart murmur.

Intrapericardial Cysts

Symptomatic animals have presenting signs similar to those with pericardial effusion and cardiac tamponade (see Pericardial Effusion section).

Diagnosis

Thoracic radiograph findings include enlarged or globoid cardiac silhouette and, in the case of PPDH, a loss of distinction between the cardiac silhouette and diaphragm or abnormal densities (gas or fat) within the cardiac silhouette (Figure 28.1a,b). Ultrasound confirms the presence of effusion and which organs have herniated. The diagnosis of PPDH can be an incidental finding during diagnostic imaging for another reason.

Therapy

Surgical repair of PPDH is recommended more often for young animals (median age 1.1 years) and those with clinical signs. Successful surgical management of

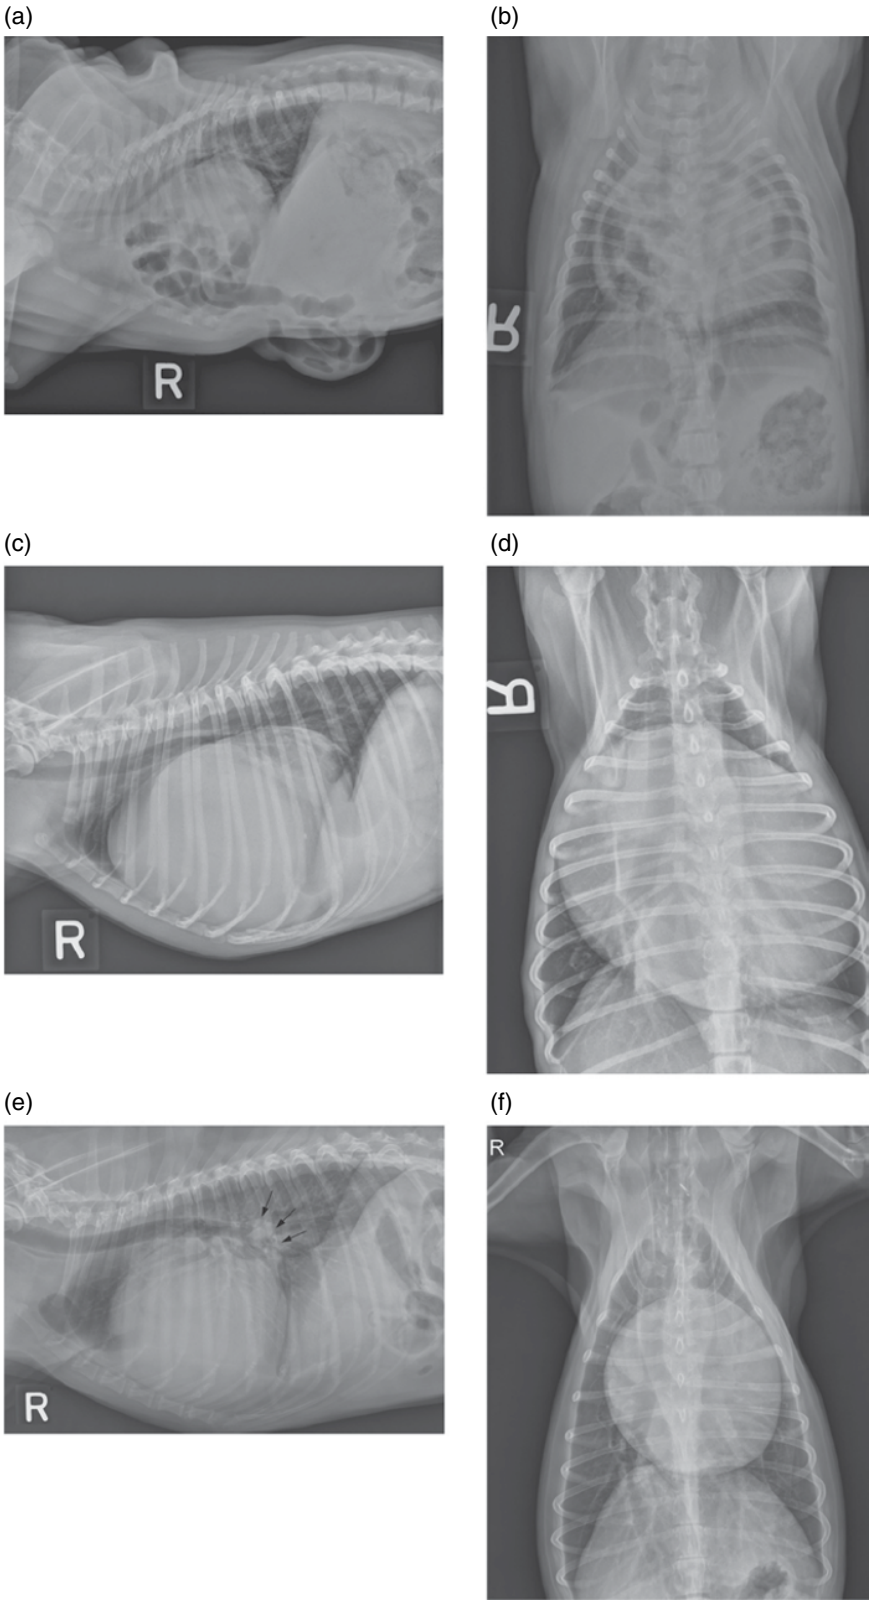

Figure 28.1 Lateral and dorsoventral thoracic radiographs in three dogs with pericardial disease. (a,b) A 4-month-old English bulldog with a peritoneopericardial diaphragmatic hernia seen as an abnormal gas pattern consistent with bowel loops within the cardiac silhouette. (c,d) Severe enlargement of the cardiac silhouette with a large-volume pericardial effusion in a dog that presented for cough. The trachea is dorsally deviated. (e,f) The cardiac silhouette is enlarged with rounded borders in a dog with degenerative mitral valve disease. Left atrial enlargement can be noted as straightening of the caudal aspect of the cardiac silhouette (*arrows*). The left atrium was severely enlarged on echocardiography and a small-volume pericardial effusion was documented that resolved with heart failure management.

pericardial cysts, with repair of a PPDH when present, has been reported.

Prognosis

The majority of animals with clinical signs will improve following surgical correction. The mortality rate following surgery for PPDH varies between 5.1% and 14%. The mortality rate following surgical repair of PPDH is higher if reexpansion pulmonary edema or hemorrhage occurs, although improvements in anesthesia and postoperative management have most likely improved the prognosis.

Pericardial Effusion

Etiology/Pathophysiology

Accumulation of fluid within the pericardial space can cause hemodynamic abnormalities depending on the volume and rate of fluid accumulation as well as intracardiac filling pressures and compliance. The resulting hemodynamic changes and decrease in cardiac output create a clinical syndrome called cardiac tamponade, where increased intrapericardial pressure equals or exceeds intracardiac pressure, with the right side of the heart most susceptible to compromise.

The most common causes of pericardial effusion in dogs are neoplastic and idiopathic with rare cases of infectious pericarditis (bacterial, fungal), coagulopathy, left atrial tear, heart failure, foreign body, and uremia.

The most common causes of pericardial effusion in cats are heart failure, neoplastic and infectious (viral) with rare cases of coagulopathy, foreign body, and uremia.

Dogs

Neoplastic

Primary or metastatic neoplasia is the most commonly reported cause of pericardial effusion in dogs. The incidence of hemangiosarcoma and aortic body tumors (chemodectoma) is higher than mesothelioma with infrequent reports of thyroid carcinoma, myxoma, and others.

Hemangiosarcoma has a 10-fold greater incidence than aortic body tumors in dogs. They are typically located in the right atrium/auricle and are highly malignant. The mean age at presentation is 9.8 years and mean weight is 32 kg. Golden retrievers are overrepresented. Survival times with combinations of pericardiocentesis, pericardiectomy, tumor resection, and/or chemotherapy are short.

Heart base tumors, most often chemodectoma or thyroid carcinoma, are located near the aorta and main pulmonary artery. Chemoreceptor cells are found in groups at the ventrolateral surface of the aorta and the bifurcation of the carotid artery near the base of the heart. The chemoreceptor system responds to changes in pH and the partial pressure of arterial oxygen and carbon dioxide in the blood. These tumors tend to be slow growing and locally invasive, causing compression or infiltration of adjacent structures. Chemodectomas can occur in any breed but brachycephalic breeds appear predisposed (boxer, bulldog, Boston terrier). Mean age at presentation is 10 years. Heart base tumors are intimately associated with vascular structures, making complete surgical excision and radiation therapy problematic. In dogs with heart base tumors assumed to be chemodectomas and clinically significant pericardial effusion, palliation with pericardiectomy significantly extends survival. In the absence of significant pericardial effusion, these tumors can be an incidental finding in dogs undergoing an echocardiogram for another indication.

Mesothelioma is a neoplasm of the pericardium and serosal surfaces. It is relatively uncommon and is not characterized by an easily identifiable discrete mass, making it difficult to diagnose. Diagnosis of mesothelioma requires histopathology of the pericardium and is therefore difficult to distinguish from idiopathic disease. Mesothelioma can develop secondary to chronic effusions. The mean age at diagnosis is 9.5 years.

Idiopathic

A cause for pericardial effusion cannot be identified in up to 23% of cases. Therefore, idiopathic is a diagnosis of exclusion. Affected dogs are typically medium to large breed and middle aged. The reported mean age is slightly less than that reported for dogs with a neoplastic etiology. Of note, reports have identified small tumors on necropsy and confirmed mesothelioma on histopathology of pericardial tissue in dogs initially diagnosed with idiopathic effusions.

Infectious

Rare reports of systemic fungal disease (*Coccidioides immitis*, *Aspergillus niger*), bacterial pericarditis (various bacteria including botryomycosis) and protozoal infection with *Leishmania chagasi* have been associated with pericardial effusion. In some cases, long-term survival can be achieved with a combination of surgical management and long-term antibiotic or fungal therapy.

Other

A left atrial tear can occur in dogs with degenerative mitral valve disease, most often resulting in acute clinical decompensation. An echocardiogram performed at the time may document evidence of a thrombus in the pericardial space. Pericardial effusion secondary to heart failure is uncommon in dogs with heart disease and if it does occur, the effusion is typically scant and does not

result in tamponade. Additional rarely reported causes of pericardial effusion in dogs include renal failure/uremia, coagulopathy, and migrating foreign bodies including grass awns, porcupine quills, and gun pellets.

Cats

Heart Failure

The most common cause of pericardial effusion in cats, it can develop with any significant underlying heart disease including hypertrophic cardiomyopathy. The volume of effusion is typically small with heart failure and resolves with heart failure management. Cats with heart failure-associated pericardial effusion have a shorter survival time than cats with pericardial effusion not caused by heart disease.

Neoplastic

This is a rare cause of pericardial effusion in the cat. The most common tumors reported in cats with pericardial effusion are lymphoma, thymoma, mesothelioma, and adenocarcinoma. The clinical effects of cardiac tumors are related principally to compression or obstruction of adjacent cardiac structures, infiltration of the myocardium, and development of pericardial effusion.

Infectious

In the past, infection was considered the most common cause of pericardial effusion in the cat related to the historical prevalence of feline infectious peritonitis (coronavirus). The prevalence of pericardial effusion in cats with feline infectious peritonitis (coronavirus) is 9.6–12.8%.

Other

Additional rarely reported causes of pericardial effusion in cats include renal failure/uremia, trauma, and coagulopathy.

Signalment

Dogs

In general, dogs are middle aged to older and large breed (golden retriever, German shepherd). Golden retrievers are the most overrepresented breed presenting with pericardial effusion. They are also the most commonly reported breed with hemangiosarcoma. Brachycephalic breeds are predisposed to heart base tumors (chemodectoma). A young adult dog of any breed would be more likely to have an infectious or idiopathic cause.

Cats

Irrespective of cause, the most reported breed is domestic shorthair although pure breeds can be affected. Median age at presentation is 6.0 years.

History and Clinical Signs

Patients can be affected to various degrees, ranging from no overt clinical signs to severe compromise. Clinical signs, when present, are often nonspecific and can include lethargy, anorexia, collapse, cough, and vomiting. Respiratory signs (tachypnea, dyspnea, cough) are common complaints in cats. Abnormal physical examination findings that are suggestive of pericardial effusion can include muffled or distant heart sounds, weak pulses or variation in pulse quality with respiration, and tachycardia. Signs of overt right heart failure (abdominal distension from ascites) and evidence of increased right heart pressures, including jugular venous distension, can also be present.

Diagnosis

A complete diagnostic work-up is recommended to assess clinical status and create a treatment plan. Evaluation includes but may not be limited to a complete blood count, biochemistries, coagulation testing, urinalysis, blood pressure, thoracic radiographs, electrocardiography, and echocardiography. In addition, point-of-care ultrasound in the emergency setting is helpful for rapidly detecting pericardial effusion. Infectious disease testing may be indicated in endemic areas or if one is suspected. Additional tests may be indicated depending on clinical status or presenting signs.

Thoracic Radiographs

An enlarged, globoid cardiac silhouette suggests the presence of pericardial effusion (Figure 28.1c,d). Small-volume pericardial effusions may not cause a rounded appearance. Additional findings include dorsal deviation of the trachea, caudal vena cava distension, and hepatomegaly. Some specific abnormalities indicative of the underlying diagnosis include abnormal bulges at the heart base suggestive of a mass, left atrial enlargement in degenerative mitral valve disease (Figure 28.1e,f), and pulmonary metastasis. When present, pleural effusion often impedes assessment of the cardiac silhouette. Pulmonary edema is uncommon in dogs with pericardial effusion but can be present in cats with heart failure.

Echocardiography

Echocardiography (cardiac ultrasound) provides a non-invasive means of imaging the heart and surrounding structures, and is superior to conventional radiography for identifying pericardial effusion, which appears as a hypoechoic space surrounding the heart (Figure 28.2). Additionally, echocardiography can identify the etiology of pericardial effusion, such as neoplastic or underlying heart disease. Pericardial effusion provides a source of ultrasonic contrast that is helpful when attempting to

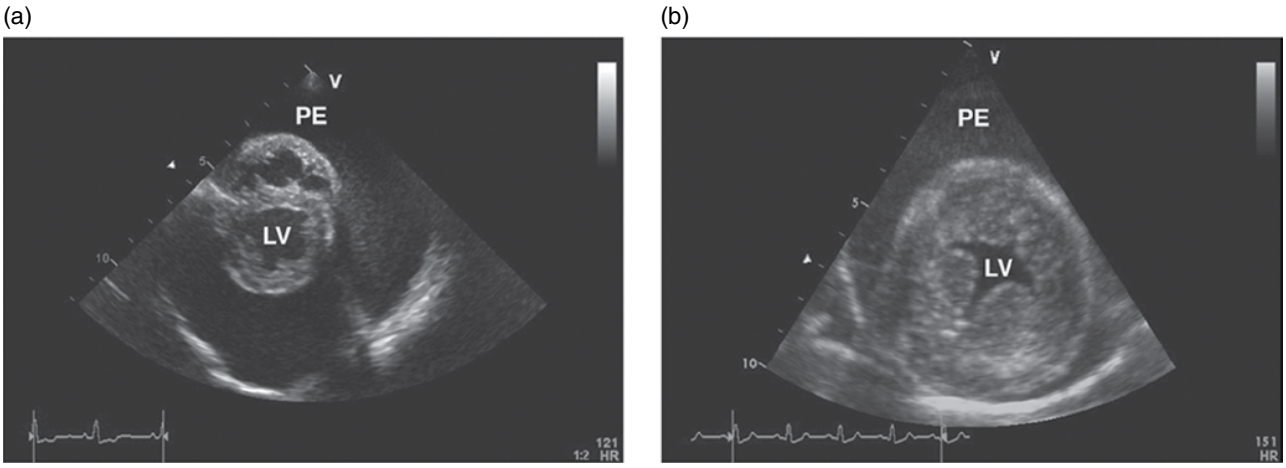

Figure 28.2 Transthoracic echocardiographic images of the left ventricle (LV) from a right parasternal short-axis view. (a) A large-volume pericardial effusion in a dog. (b) A small-volume pericardial effusion in a cat with hypertrophic cardiomyopathy and congestive heart failure. PE, pericardial effusion.

visualize cardiac tumors, but therapeutic pericardiocentesis should not be delayed for an echocardiographic examination in an unstable patient. Tumors are most often located in the right atrial or auricular wall in the case of hemangiosarcoma or at the heart base associated with the aorta or main pulmonary artery (Figure 28.3). They can also be found, more rarely, within the right ventricular myocardium and right ventricular outflow tract. Hemangiosarcomas frequently appear cavitary. Both the right and left imaging windows are recommended for identification and localization. In addition to identifying pericardial effusion, echocardiography can provide evidence of cardiac tamponade by documenting diastolic collapse of the right atrium and ventricle when intrapericardial pressures exceed right atrial or ventricular end-diastolic pressures (Figure 28.4). Left ventricular internal dimensions will measure small when pericardial effusion inhibits preload of the heart.

Pericardial Fluid Analysis

Pericardial fluid is typically hemorrhagic in appearance, although opaque fluid can be seen with chylous effusions and exudates. Most cardiac tumors do not exfoliate well, and for this reason pericardial fluid analysis and cytology often are unrewarding for the identification of cardiac tumors. Careful cytologic evaluation is required so that reactive mesothelial cells are not mistaken for neoplastic cells. Occasionally, lymphoma or an infectious cause can be documented. Culture and sensitivity are indicated for the identification of effusions secondary to infectious etiologies.

Electrocardiography

The most common finding is sinus tachycardia (Figure 28.5a), which is a physiologic compensatory mechanism to improve cardiac output. Low-voltage QRS complexes can be indicative of pericardial effusion in dogs (Figure 28.5b). It is important to recognize that QRS complexes are typically small in cats, making this an insensitive indicator of effusion. Electrical alternans, identified as a beat-to-beat variation in the QRS complexes, is highly suggestive of pericardial effusion, although it is only identified in a small number of dogs (Figure 28.5c). Lastly, a change (depression or elevation) in the ST segment associated with myocardial hypoxia (Figure 28.5d) may be documented. Ventricular arrhythmias are not uncommon and supraventricular arrhythmias can also occur. Most ECG abnormalities will resolve shortly after the removal of pericardial effusion.

Laboratory Work

Comprehensive laboratory evaluation including complete blood count, biochemical analysis, coagulation panel, and urinalysis can provide information regarding underlying etiology and the patient's clinical status. Abnormalities are not uncommon but are often nonspecific. Cardiac troponin I concentrations can be increased in dogs with hemangiosarcoma (>0.25 ng/mL) when compared to other causes of pericardial effusion.

Neoplastic Evaluation

Cardiac tumors are located adjacent to important vascular structures, making the diagnosis challenging. Definitive diagnosis is often made during surgery or at necropsy. Surgical excisional biopsy has been described for the diagnosis of hemangiosarcoma of the right auricle and for chemodectoma but is often not performed as a consequence of the overall risk to benefit ratio.

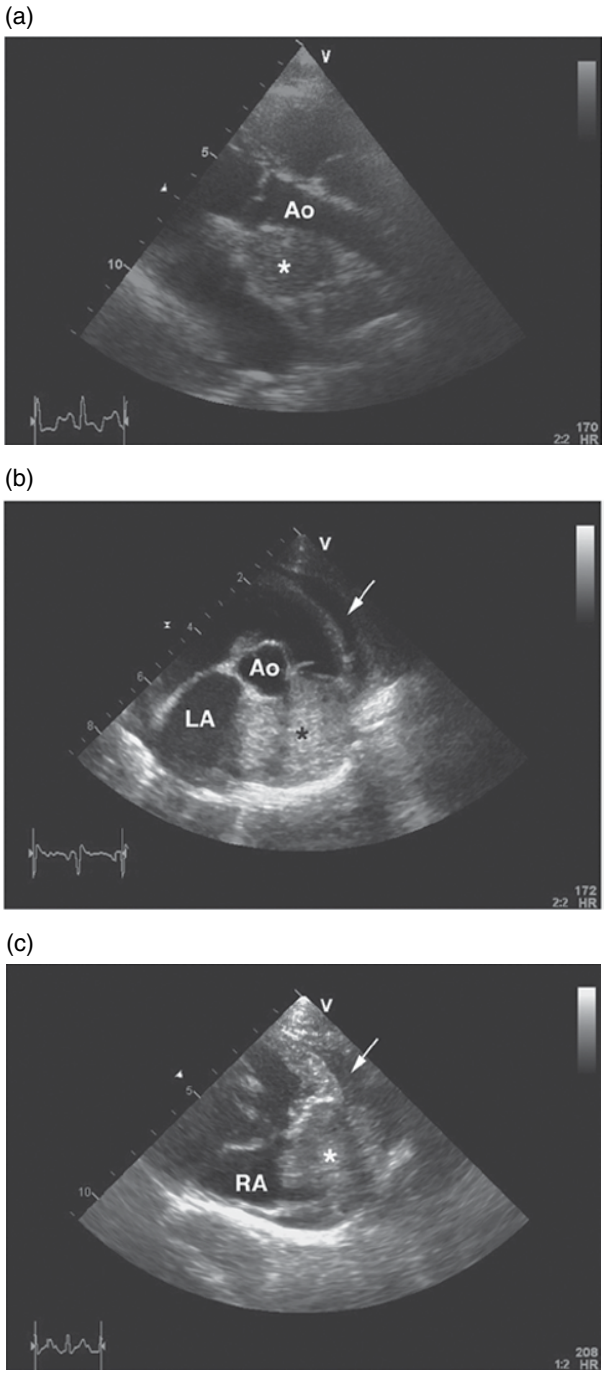

Figure 28.3 Transthoracic echocardiographic images from dogs with cardiac tumors and pericardial effusion. (a) Images obtained from the left cranial window document a mass (*) in direct apposition with the aorta typical of heart base tumors. (b) Right parasternal short-axis view of the heart base documenting a mass (*) near the aorta consistent with a heart base mass. (c) Images obtained from the left cranial window document a mass (*) within the right auricle, most likely a hemangiosarcoma based on location. Ao, aorta; LA, left atrium; RA, right atrium.

Advanced Imaging

Computed tomography and magnetic resonance imaging can provide additional information including tumor location and the presence of metastatic disease.

Therapy

The urgency of pericardiocentesis depends on the clinical status of the patient at the time of evaluation.

Acute Therapy

Critically ill animals require immediate stabilization with intravenous fluid therapy to help restore cardiac output, and pericardiocentesis to resolve tamponade. Dyspneic patients may benefit from a combination of oxygen supplementation and removal of pleural effusion and/or ascites if the volume(s) are significant enough to contribute to respiratory difficulty. Diuretic therapy with furosemide is generally contraindicated because diuretics do not consistently remove free fluid from the pericardium and can contribute to further hemodynamic compromise. One exception is the judicious use of furosemide in cats and dogs with pericardial effusion secondary to congestive heart failure.

Pericardiocentesis

Pericardiocentesis is performed primarily in dogs and is recommended when pericardial effusion is large volume and/or contributing to hemodynamic compromise (tamponade). The majority of cats have small volume effusions secondary to heart failure that resolve with heart failure management.

Several techniques for pericardiocentesis have been described and the technique selected depends on the clinical status of the patient, veterinarian comfort level with the procedure, equipment availability, and technical support. The objective of the procedure is to remove as much pericardial fluid as possible. Complications can occur during pericardiocentesis if the catheter contacts the heart, resulting in arrhythmias, or lacerates lung or other cardiac structures. Pericardial fluid removal typically provides an immediate clinical benefit noted by a reduction in heart rate to a more normal range and an improvement in pulse quality and blood pressure.

Equipment and Supplies

- Over-the-needle catheter with a length appropriate for the patient size (for example: 14 g × 5.25 inch, 16 g × 3.25 inch).
- Extension IV set.
- Three-way stopcock.
- Syringe (20–60 mL).

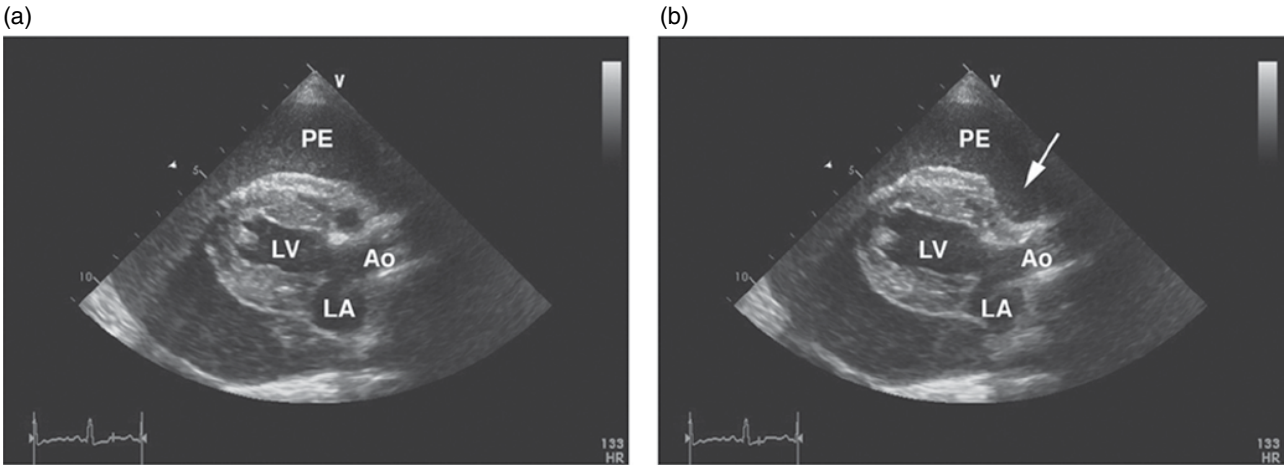

Figure 28.4 Echocardiographic images obtained from a right parasternal long-axis view in a dog with pericardial effusion and collapse of the right atrium (*arrow*) caused by elevated intrapericardial pressure. Ao, aorta; LA, left atrium; LV, left ventricle; PE, pericardial effusion.

- Scalpel blade.
- Collection bowl and graduated cylinder or other volume measuring tool.
- Red-top tube containing no anticoagulants or preservatives.
- Purple- or lavender-top tube containing EDTA as an anticoagulant.
- Sterile gloves.
- Local anesthetic block.
- Continuous ECG – recommended for detecting arrhythmias generated by contacting the heart when advancing the catheter into the pericardial space.
- Echocardiogram/ultrasound machine – useful for identifying a location on the right side of the thorax for obtaining the most direct access to pericardial fluid.
- Sedation – may be required to facilitate the procedure in some cases.

Preparation

Prior to performing the procedure, gather the supplies appropriate for the patient's size, demeanor, and clinical status. Putting together a prestocked kit that contains the necessary supplies for pericardiocentesis is very useful, especially for immediate access in an emergency situation. Light sedation may be required to facilitate the procedure in some cases. The local anesthetic block can be drawn into a syringe, and the right side of the thorax can be shaved in preparation for the procedure.

Procedure (Figure 28.6)

Pericardiocentesis is routinely performed on the right side of the thorax to utilize an approach through the cardiac notch between lung lobes and to avoid damage to the lung and coronary arteries.

1) For the procedure, the patient is positioned in sternal or lateral recumbency with continuous ECG attached.
2) Identify the ideal position for introducing the catheter into the thorax, which is often around the fifth or sixth intercostal space, mid-thorax at the costochondral junction. It can be found by flexing the right front limb and swinging the leg across the thorax and using the intercostal space where the point of the elbow crosses the costochondral junction (Figure 28.6a) or with ultrasound guidance (Figure 28.6b). A permanent marker can be used to identify the spot for catheter entry or to mark multiple spots on the perimeter of the shaved area to triangulate the position.
3) Following sterile preparation of the pericardiocentesis site, inject a local anesthetic block to the skin, intercostal muscles, and pleura (Figure 28.6c). The discomfort associated with the local block can limit its value in some dogs that would otherwise benefit from sedation. After approximately five minutes, use a scalpel blade to make a small stab incision in the skin to facilitate catheter insertion and advancement.
4) Attach the catheter to the extension set tubing with a three-way stopcock placed between the extension set tubing and a syringe. At the predetermined ideal pericardiocentesis site, advance the catheter through the skin, followed by the intercostal muscles, avoiding the caudal aspect of the rib where the intercostal vessels are located, and into the pleural space (Figure 28.6d). An assistant applying gentle negative pressure on the syringe may encounter pleural effusion that is typically straw colored in patients with right heart failure. Continue advancing the catheter until a scratching sensation is detected when the needle comes into contact with the pericardium. Continue to advance

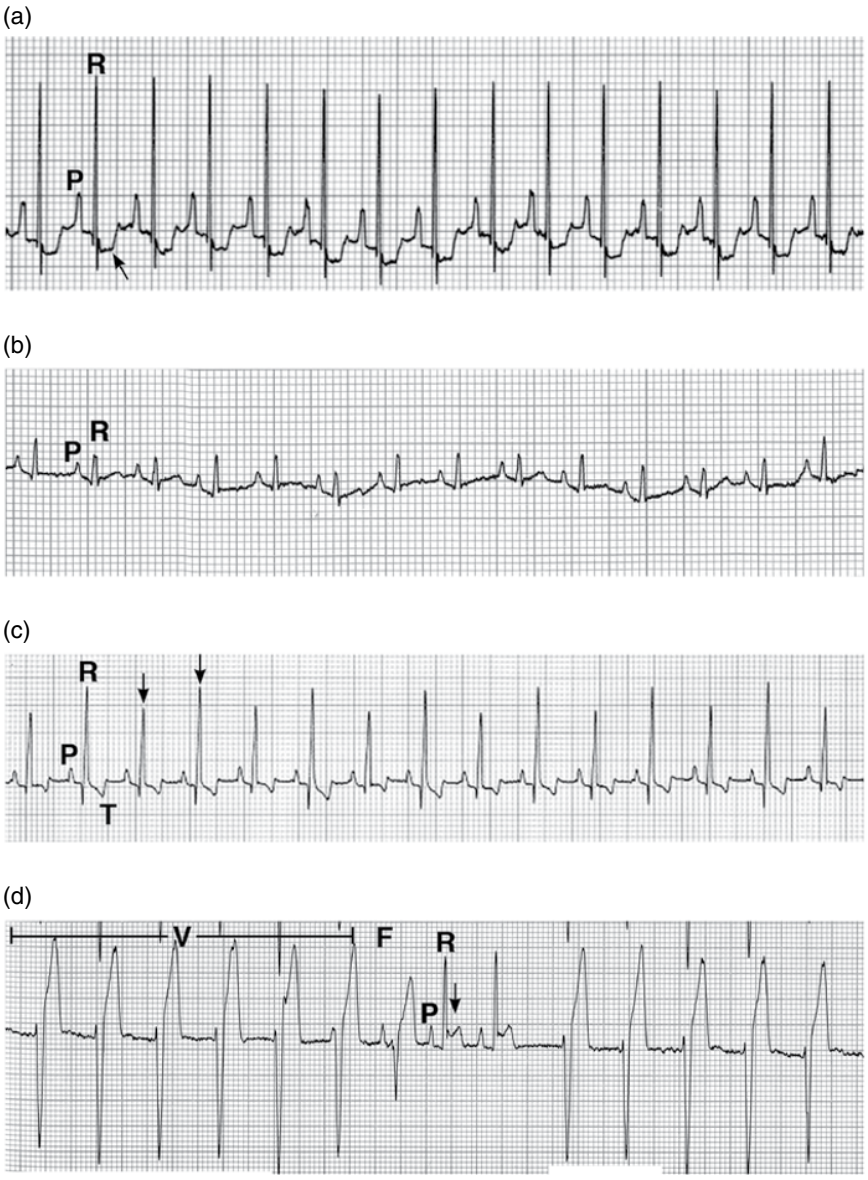

Figure 28.5 Electrocardiogram recordings from dogs with pericardial effusion. (a) Sinus tachycardia. (b) Sinus rhythm with small QRS complexes. (c) Sinus rhythm with electrical alternans, a beat-to-beat variation in R-wave amplitude (*arrows*). (d) Predominantly ventricular rhythm (V) with a single fusion beat (F). Sinus complexes have ST segment elevation (*arrow*). All traces are lead II recorded at 25 mm/s and 10 mm/mV.

the catheter into the pericardial space until fluid, typically hemorrhagic appearing (Figure 28.6e,f), is withdrawn into the extension set tubing. Contact with the heart will make the catheter move with the heartbeat and induce arrhythmias (typically ventricular) as noted on a simultaneous electrocardiogram. If either is encountered, the catheter should be withdrawn quickly. Alternatively, the catheter can be advanced without being attached to the extension set tubing and flash of hemorrhagic fluid will be detected when the catheter is introduced into the pericardial fluid, at which point the needle is removed and the extension set tubing connected.

5) Once pericardial effusion is encountered, detach the extension set tubing from the needle, remove the needle from the catheter, and reattach the extension set tubing directly to the catheter. Removing the needle prevents contact with the heart as the pericardial fluid is removed.
6) Place the initial sample of pericardial fluid in serum (red-top) and EDTA (purple-top) tubes for laboratory analysis. Fluid can be reserved for culture and sensitivity,

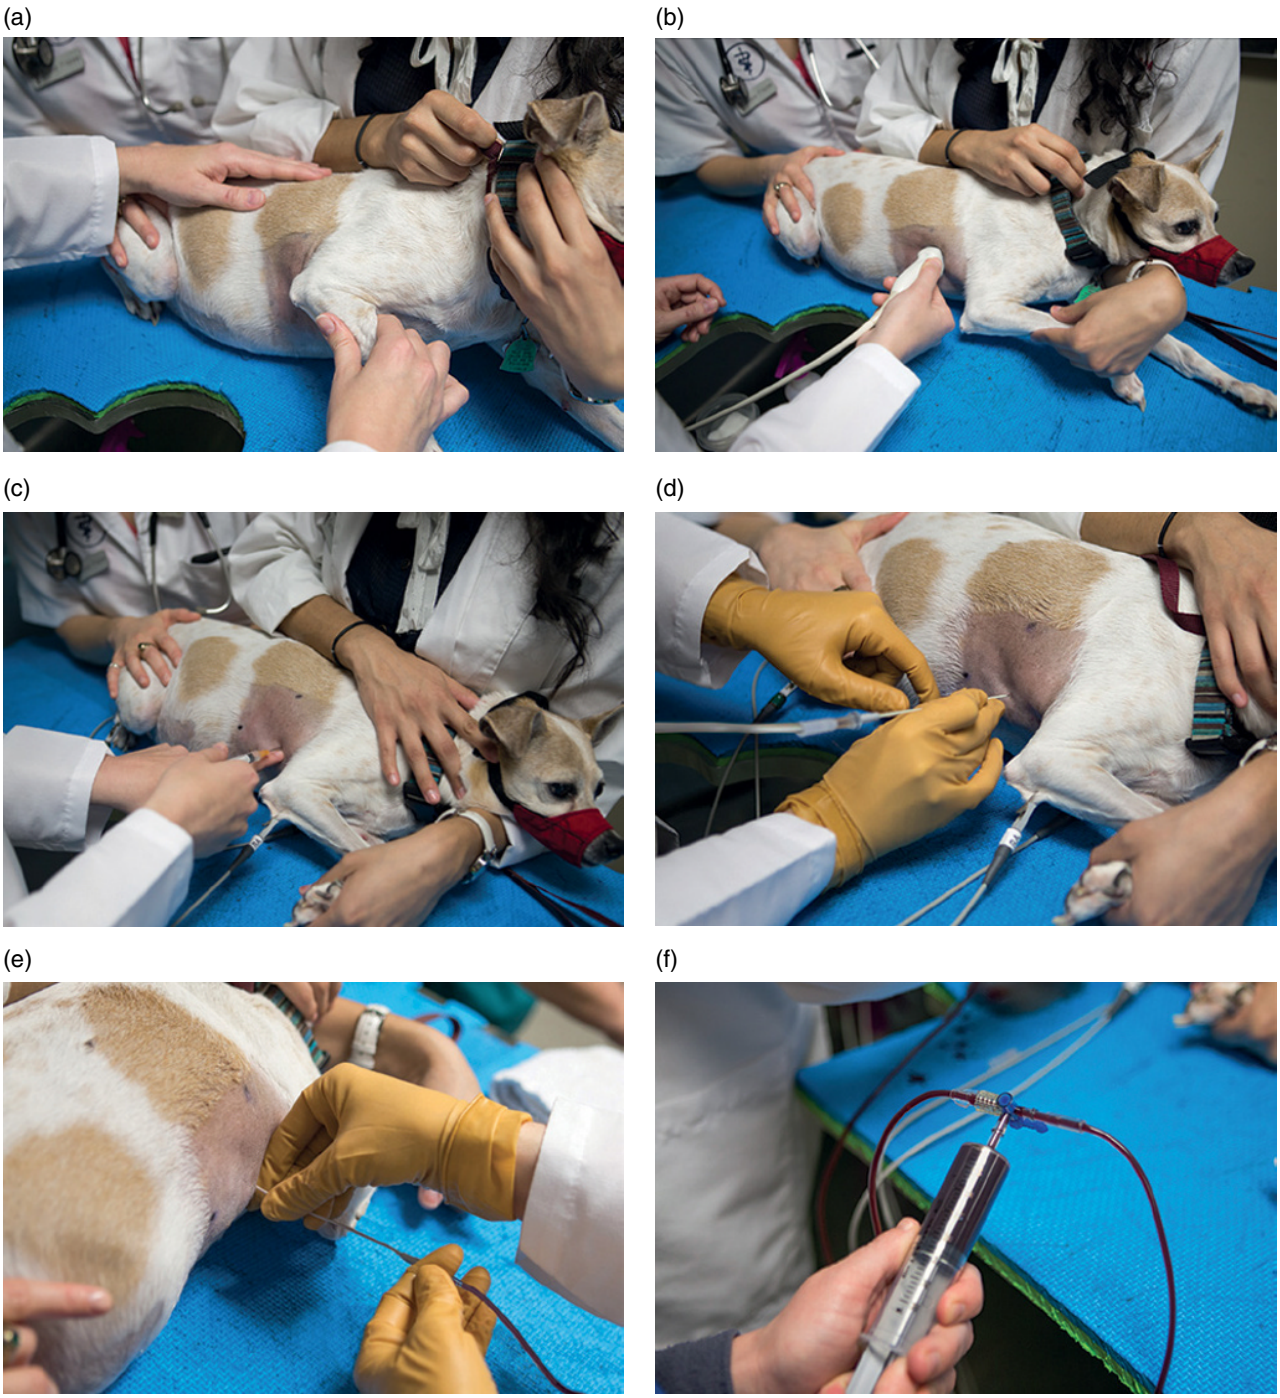

Figure 28.6 Pericardiocentesis in a dog. This dog had a history of biting and no clinical signs of dyspnea. A muzzle was placed as a precautionary measure along with gentle restraint for the procedure. (a) Identify the ideal position for introducing the catheter into the thorax, which is often around the fifth or sixth intercostal space near the costochondral junction. It can be found by flexing the right front limb and swinging the leg across the thorax and using the intercostal space where the point of the elbow crosses the costochondral junction. (b) Locating the ideal site for catheter entry using ultrasound guidance. (c) Following sterile preparation of the pericardiocentesis site, inject a local anesthetic block into the skin, intercostal muscles, and pleura. After approximately five minutes, use a scalpel blade to make a small stab incision in the skin to facilitate catheter insertion and advancement. Note multiple spots were marked on the perimeter of the shaved area to triangulate the position for the anesthetic block and subsequent catheter entry site. (d) At the predetermined ideal pericardiocentesis site, advance the catheter through the skin, followed by the intercostal muscles, avoiding the caudal aspect of the rib where the intercostal vessels are located, and into the pleural space. Note the leads have been attached for monitoring the electrocardiogram during the procedure. (e) The catheter was advanced until a scratching sensation was detected when the needle contacted the pericardium. Once pericardial effusion was encountered, the extension set tubing was detached from the needle, the needle removed from the catheter, and the extension set tubing reattached directly to the catheter. Removing the needle prevents contact with the heart as the pericardial fluid is removed. (f) Two extension sets are connected with a three-way stopcock. One extension set tubing is connected to the end of the catheter and the second is emptying into a collection bowl. Note the fluid is hemorrhagic in appearance, characteristic of pericardial effusion.

when indicated. The fluid in the red-top tube should be monitored for clotting, which could indicate inappropriate intracardiac placement of the catheter. Pericardial fluid does not routinely clot. A packed cell volume (PCV) on the effusion can be obtained to confirm that the fluid is not blood.

7) Once pericardial effusion is no longer withdrawn, ultrasound can be used to confirm the pericardial effusion has been removed or has drained into the thoracic cavity. Pleural effusion can be removed prior to withdrawing the catheter from the thorax.

Monitoring and Follow-Up

Pericardiocentesis often results in immediate clinical improvement. Careful monitoring of the patient for further hemodynamic collapse or clinical improvement is recommended following the procedure. Ideally, dogs should not be sent home immediately after pericardiocentesis and are monitored in the hospital for 12–24 hours. Rapid (minutes to hours) reaccumulation of pericardial fluid and significant arrhythmias are possible following pericardiocentesis. If pericardiectomy is not scheduled (see Surgical Management for recommendations), recheck within 2–4 weeks and consider pericardiectomy if the pericardial effusion has reaccumulated.

Cancer Therapy

Palliative or definitive cancer therapy rarely is successful with cardiac neoplasia. Complete surgical excision can rarely be achieved because of tumor proximity to vital structures. There are reports of a positive response to chemotherapy for lymphoma and hemangiosarcoma. Consultation with an oncologist is recommended for the most current therapeutic strategies.

Surgical Management

Despite fluid removal and immediate clinical improvement, pericardial effusion is likely to recur in most instances. Surgical pericardiectomy (partial or subtotal) allows improved visualization for the surgeon to identify the underlying etiology and/or biopsy a tumor. Echocardiography is very specific for identifying a tumor but not 100% sensitive, particularly for small tumors that may be readily identified by a surgeon. A small pericardial window provides palliation but can potentially lead to constrictive pericarditis of the remaining pericardium or allow herniation of a portion of the heart through the pericardial opening. Pericardiectomy can be curative for idiopathic and infectious etiologies and extend survival for dogs with chemodectomas. Thoracoscopic pericardiectomy has the benefit of offering lower patient morbidity but requires a skilled operator to achieve optimum results. Balloon pericardiotomy has been described as a palliative procedure for neoplastic effusions.

Prognosis

Prognosis depends on the underlying cause of the effusion. Pericardiectomy can result in clinical improvement or cure in idiopathic cases and in infectious cases when combined with appropriate antibiotic or antifungal therapy. Pericardiectomy extends survival time in dogs with heart base tumors and is associated with minimal improvement with hemangiosarcoma and mesothelioma. In cats, prognosis with effusion secondary to heart disease and heart failure is guarded to poor due to the presence of severe underlying heart disease.

Constrictive Pericarditis

Etiology/Pathophysiology

Constrictive pericarditis is characterized by a stiff, fibrous pericardium that impairs ventricular diastolic filling even if no fluid is present. Although considered uncommon, the diagnosis is difficult to make and can be overlooked. It is characterized by an absence of pericardial effusion though combined constrictive-effusive disease does occur. Chronic pericardial and pleural effusion including chylous effusion and infectious pericarditis secondary to fungal organisms can result in constrictive pericarditis.

Signalment

Similar to pericardial effusion.

History and Clinical Signs

Similar to pericardial effusion with a high incidence of signs of elevated right heart pressures.

Diagnosis

Echocardiography

Pericardial effusion is often absent or small volume. Tamponade may be documented with only a small volume of effusion. The pericardium can appear thickened. Advanced Doppler studies show respiratory changes in the peak velocities of mitral and tricuspid valve inflow profiles highly suggestive of constrictive physiology.

Cardiac Catheterization

Characteristic patterns in atrial and ventricular pressure profiles are indicative of constrictive physiology although administering a fluid bolus may be required to generate

the pattern. Right atrial pressure traces are characterized by a prominent Y descent. Right ventricular pressure traces have a characteristic dip and plateau (square root sign) with elevated end-diastolic pressure.

Therapy

Surgical management with subtotal pericardiectomy to remove the fibrotic pericardium is generally required to resolve clinical signs. If the epicardium is involved, epicardial stripping is more difficult and associated with important complications.

Prognosis

Prognosis is poor without surgical management and associated with an increased rate of complications with epicardial involvement.

Respiratory Disease

29

A Respiratory Pattern-Based Approach to Dyspnea

Christopher G. Byers, DVM, DACVECC, DACVIM (SAIM), CVJ

CriticalCareDVM.com, Omaha, NE, USA

The initial approach to a patient with respiratory distress is of the utmost importance as it can determine whether these critical patients live or die. Classic clinical signs of respiratory distress include tachypnea, head and neck extension, open-mouth breathing, anxiety, cyanosis, nares flaring, abducted elbows, orthopnea, and paradoxical movement of the chest and/or abdomen. Overt signs of respiratory distress are more commonly seen in dogs than cats. Unfortunately, cats readily mask disease severity, and commonly the only evidence of respiratory dysfunction may be tachypnea and prominent respiratory motions in sternal recumbency.

The first step in examining a patient with a respiratory emergency is to perform a primary survey, efficiently evaluating airway, breathing, and circulation (ABCs). If the airway is not patent, it must be cleared of obstruction and immediate orotracheal intubation performed. If an upper airway obstruction prevents orotracheal intubation, an emergency tracheostomy must be performed. If there are no airway patency issues, a clinician should evaluate the patient's breathing pattern and work of breathing. Particular attention should be given to the phase of breathing affected, and effort should be made to determine if the breathing pattern is obstructive or restrictive.

Anatomical localization of the cause of respiratory distress is assessed through a "look, listen and feel" approach, and may be a very powerful tool for assessing underlying structural changes. Increased inspiratory effort is commonly associated with extrathoracic disorders while increased expiratory effort is most often due to intrathoracic diseases. An obstructive breathing pattern indicates inappropriate movement of air into and/or out of the lungs and is frequently associated with a slower respiratory rate and deeper breaths than normal. A restrictive breathing pattern is characterized by inadequate expansion of the chest wall and/or lungs, resulting in shallow tachypnea. The initial evaluation of a patient should ideally begin from afar, as the breathing pattern may change with manipulation. Making an accurate assessment after handling can be far more challenging.

Upper Airway

The upper respiratory tract, that includes the nares, nasal cavity, pharynx, and larynx, is simply a conduit from the nares to the glottis. Diseases of the upper respiratory tract are relatively common in both dogs and cats (Table 29.1). Upon presentation, the owner may report that a patient snores and/or has exercise intolerance, dysphagia, regurgitation, and/or posttussive retching. They may also report that these clinical signs are associated with and/or exacerbated by excitement, humidity, and/or elevated ambient temperatures. Physical examination may identify referred upper airway sounds, orthopnea, bilateral elbow abduction, restlessness, dysynchronous breathing, and cyanosis. Affected patients commonly have abnormal respiratory sounds and pattern of breathing; the classic upper airway breathing pattern is characterized by increased inspiratory time and effort compared to expiration. Increased nasal noise (stertor) and/or laryngeal noise (stridor) may also be present, depending on the site of airflow turbulence. Occasionally, pulmonary crackles that form due to noncardiogenic pulmonary edema may be auscultated.

Diseases of the upper airway commonly cause at least partial airway obstruction that markedly reduces proper airflow. The resultant turbulent airflow promotes the formation of edema and inflammation that subsequently increases the work of breathing and further narrows the affected airway, creating a vicious cycle. Combined with a reduced ability to effectively eliminate heat from the body via evaporation, affected patients may readily

Table 29.1 Common diseases affecting the upper airway

Site	Examples
Nares	Stenotic nares
Nasal cavity	Inflammation, neoplasia, infection (bacterial, fungal, parasitic), granuloma, foreign body
Pharynx	Neoplasia, polyp, abscess, granuloma, elongated soft palate, foreign body, stenosis/stricture
Larynx	Paralysis, collapse, neoplasia, abscess, granuloma, everted saccules, foreign body

develop severe secondary hyperthermia. Patients affected by upper airway disorders should always be handled with minimal restraint, as they may experience respiratory arrest with minimal manipulation.

Patients with upper airway diseases with partial obstruction should be given appropriate sedation and supplemental oxygenation as soon as possible in an effort to reduce the work of breathing and anxiety. The least stressful method of supplemental oxygen provision should be employed, and viable options include flow-by, facemask, oxygen cage, nasal cannulation, modified Elizabethan collar (i.e., Crowe collar), and transtracheal catheterization. A commonly used sedative protocol for cardiovascularly unstable patients is the combination of a pure mu opioid (i.e., fentanyl 2–4 µg/kg IV; oxymorphone 0.05–0.1 mg/kg IV/IM; methadone 0.2–0.5 mg/kg IV; hydromorphone 0.1–0.2 mg/kg IV) with a benzodiazepine (i.e., diazepam 0.1–0.5 mg/kg IV; midazolam 0.2–0.4 mg/kg IV). Acetylpromazine (0.02–0.1 mg/kg IV/IM) and butorphanol (0.1-0.2 mg/kg IV/SQ) may be appropriate for cardiovascularly stable patients.

While provision of sedation and supplemental oxygen is sufficient to relieve clinical signs for many patients with upper airway diseases, some will not meaningfully respond. These patients must have their airways captured via orotracheal intubation immediately, and the astute clinician must be prepared to perform an emergency tracheostomy for those patients with complete oropharyngeal and/or laryngeal obstruction. Passive and active cooling measures should be employed for patients with body temperatures greater than 40.5 °C (105 °F), but should be discontinued with body temperatures reach 39.4 °C (103 °F).

Once stable, a thorough physical examination should be performed in an effort to determine the underlying cause of the upper airways signs (if not obvious). Diagnosis of specific airway abnormalities in an individual patient requires thorough evaluation of the nares, oral and nasal pharynx, and larynx. Diagnostic investigation may include a sedated orolaryngeal examination, aural and otoscopic examination, thoracic and cervical radiography, tracheal fluoroscopy, and nasal computed tomography with rhinoscopy. Arterial blood gas analysis commonly identifies hypoxemia with hypercapnia.

Lower Airway

The lower airway is composed of the intrathoracic trachea, primary and lobar bronchi, and bronchiolar arborization. Dogs may be affected most commonly by intrathoracic tracheomalacia, bronchomalacia, and chronic bronchitis, while feline patients are most commonly diagnosed with asthma. Foreign body obstruction must be considered. While neoplasia may affect the lower airway, they rarely induce acute dyspnea due to their chronic, insidious nature. Owners may report a chronic and/or progressive history of coughing that is frequently productive although the sputum is most often swallowed. Affected patients commonly have a respiratory pattern characterized by prolonged expiration despite normal inspiratory time and effort; additionally, a clinician may observe abdominal effort during expiration (abdominal push) and/or auscultate expiratory wheezes. Patients may display orthopnea, and feline patients may breathe with an opened mouth. A murmur is not expected unless lower airway disease has contributed to the development of cor pulmonale. Tracheal sensitivity may be noted in dogs with tracheobronchomalacia and chronic bronchitis.

Feline bronchial asthma is a common respiratory condition caused by altered immunosensitivity of the respiratory tract to inhaled allergens. This hyperresponsiveness causes various structural and chemical changes in the tracheobronchial tree, including adrenergic–cholinergic imbalance and abnormal mucus production. No pathognomonic clinical signs and/or laboratory assays have been identified, and definitive diagnosis is based on history, physical examination findings, and exclusion of other disease entities from the list of differential diagnoses.

The cause of canine chronic bronchitis is not definitively known, and is typically considered idiopathic in nature. Establishment of a clear link between this disease and environmental pollutants, hypersensitivity reactions, and/or poor dental health has been challenging. Accordingly, a definitive diagnosis is currently made with documentation of lower airway inflammation and elimination of other potential causes. Tracheobronchomalacia is characterized by progressive flaccidity of the tracheal cartilages that results in collapse of the tracheal and/or bronchial lumina. The definitive cause of this disease has not yet been identified, and possible contributing factors include airway allergies inducing chronic inflammation, genetic predisposition, and cartilage matrix degeneration. During exhalation, the intrathoracic trachea and/or

bronchi collapse, contributing to common clinical signs, most notably coughing. Definitive diagnosis is made via imaging that may include thoracic and cervical radiography, fluoroscopy, and/or tracheobronchoscopy.

Clinicians should follow a standard and consistent protocol for assessing and hopefully stabilizing a patient suspected of having lower airway disease, focusing initially on performing an efficient primary survey. Patients should be given appropriate sedation and supplemental oxygenation as soon as possible in an effort to reduce the work of breathing and anxiety. Minimal handling is advocated, as the stress of manipulation may be lethal. The least stressful method of supplemental oxygen provision should be employed, and viable options include flow-by, facemask, oxygen cage, nasal cannulation, modified Elizabethan collar (i.e., Crowe collar), and transtracheal catheterization.

A commonly used sedative protocol for cardiovascularly unstable patients is the combination of a pure mu opioid (i.e., fentanyl 2–4 µg/kg IV; oxymorphone 0.05–0.1 mg/kg IV/IM; methadone 0.2–0.5 mg/kg IV; hydromorphone 0.1–0.2 mg/kg IV) with a benzodiazepine (i.e., diazepam 0.1–0.5 mg/kg IV; midazolam 0.2–0.4 mg/kg IV). Acetylpromazine (0.02–0.1 mg/kg IV/IM) and butorphanol (0.1-0.2 mg/kg IV/SQ) may be appropriate for cardiovascularly stable patients. Inhaled albuterol (90–180 µg), a rapidly acting beta-2 agonist, should be administered; terbutaline (0.01 mg/kg SC) is a reasonable alternative if a metered-dose inhaler is not available. Corticosteroids are commonly used for chronic management of feline asthma and canine chronic bronchitis, but their use is not necessarily warranted in the initial management of these diseases; a brief (i.e., 7–10 days) tapering regime of antiinflammatory corticosteroid may be beneficial in the acute management of tracheobronchomalacia to help break the cycle of coughing commonly present in affected patients.

Once stable, a thorough physical examination should be performed in an effort to determine the underlying cause of the lower airways signs. High-quality, three-view thoracic radiographs are an essential part of the diagnostic investigative process. Indirect visualization via fluoroscopy and/or direct visualization of the lower airways via tracheobronchoscopy may be invaluable, and lower airway cytology and culture should be pursued to rule out infectious diseases.

Pleural Space

The pleural cavity is the potential space between the parietal pleura associated with the body wall and visceral pleura associated with lungs. When this potential space is occupied by air, fluid, masses and/or viscera, the lungs are unable to expand normally. As a result, intrapleural pressure increases and ultimately exceeds the intrapulmonary pressure, effectively reducing tidal volume. Accordingly, a patient must breathe rapidly to maintain adequate minute ventilation. Classically, affected patients manifest a restrictive breathing pattern characterized by shallow tachypnea. With reduced tidal volume, alveoli progressively collapse to cause hypoventilation and hypoxemia due to ventilation–perfusion mismatch.

Thoracic auscultation varies depending on the nature of the pleural disease. Pneumothorax may develop secondary to blunt or penetrating thoracic trauma, but may also occur spontaneously due to primary pulmonary parenchymal disease. A patient with pneumothorax has lung sounds that are most audible ventrally. Pleural effusion may occur secondary to accumulation of blood (hemothorax), infectious exudate (pyothorax), neoplasia, chyle (chylothorax), and heart failure; hypervolemia and hypovolemia are rare causes of pleural effusion. A patient with pleural effusion commonly has dull ventral lung sounds with audible and possible increased lungs sounds dorsally. Borborygmi may be heard in those patients with a congenital or traumatic pleuroperitoneal diaphragmatic hernia. A cardiac murmur and/or dysrhythmia may be auscultated in those living with heart disease.

Patients with pleural disease should be provided supplemental oxygenation as soon as possible via the least stressful method. Sedation should also be administered, ideally prior to thoracocentesis; this is not always feasible if imminent respiratory arrest is anticipated. A commonly used sedative protocol for cardiovascularly unstable patients is the combination of a pure mu opioid (i.e., fentanyl 2–4 µg/kg IV; oxymorphone 0.05–0.1 mg/kg IV/IM; methadone 0.2–0.5 mg/kg IV; hydromorphone 0.1–0.2 mg/kg IV) with a benzodiazepine (i.e., diazepam 0.1–0.5 mg/kg IV; midazolam 0.2–0.4 mg/kg IV). Diuretic therapy is not indicated for the emergency management of pleural space disease.

Thoracocentesis should generally be performed prior to thoracic radiography if pleural space disease is suspected. A thoracocentesis is typically performed at the seventh to ninth intercostal space. If a pneumothorax is suspected, the site of pleural puncture is perpendicular to the body wall just ventral to the thoracic hypaxial musculature; the level of the costochondral junction is the site of pleural puncture for those patients with suspected or confirmed pleural effusion. If available, thoracic focused assessment with sonography for trauma, triage and tracking (tFAST[3]) may be used to confirm pneumothorax and pleural effusion, help determine site of pleural puncture, and may be performed in lateral or sternal recumbency. Thoracocentesis has been uncommonly associated with hemorrhage, pulmonary parenchymal injury, and iatrogenic infectious disease

transmission. Rapid and fatal reexpansion pulmonary edema may rarely occur in patients with chronic pleural effusion. Ideally, pleural fluid and/or air should be removed until negative pressure is achieved, but this is not always possible. If negative pressure cannot be achieved, if more than two thoracocenteses are required in a one-hour period, or more than three thoracocenteses are required in a 24-hour period, a thoracostomy tube should be placed.

Once stable, a thorough physical examination should be performed in an effort to determine the underlying cause. Traumatic pneumothorax commonly resolves without surgical intervention, but injuries may require several days to heal. The presence of pneumothorax without a history of trauma should always prompt a search for pulmonary parenchymal disease. Pleural effusion should be immediately evaluated in-house for obvious sepsis and/or neoplastic cells, and one should submit samples (i.e., pleural fluid sample in EDTA-containing tube, unstained slide, fluid sample on appropriate culture media) to a veterinary reference laboratory for evaluation by a board-certified veterinary clinical pathologist. Echocardiography and cardiac biomarker (i.e., NT-proBNP) measurement may be helpful in those patients suspected of living with cardiac disease, and diaphragmatic hernias should be surgically repaired as soon as the patient is cardiovascularly and metabolically stable.

Pulmonary Parenchyma

The pulmonary parenchyma may be affected by a number of diseases, and a thorough history will help the astute clinician develop an appropriate diagnostic investigation and therapeutic interventions. Dogs frequently have a history of a cough that may or may not be productive, but cats rarely manifest this clinical sign. A history of laryngeal paralysis or recent vomiting should raise concern for aspiration pneumonitis, and patients with trauma may develop pulmonary contusions and/or noncardiogenic pulmonary edema. Recent generalized seizure activity, electrocution, traumatic brain injury, and/or strangulation should also raise concern for noncardiogenic pulmonary edema that develops secondary to endothelial injury and vascular leakage into alveoli. Conversely, patients with primary cardiac disease are at risk for developing cardiogenic pulmonary edema.

Performing a complete physical examination is invaluable for patients with suspected pulmonary parenchymal disease. Affected patients do not have a specific respiratory pattern, and frequently manifest respirations that are rapid and deep. They may be presented with cyanosis and dyspnea, and increased abdominal effort is relatively common. Auscultation commonly reveals end-inspiratory crackles, adventitious lung sounds that represent the sudden opening of fluid-filled alveoli. Alveolar fluid may be blood, purulent exudate or transudate. Alveolar hemorrhage may occur secondary to trauma and/or coagulopathy. A patient with cardiogenic pulmonary edema secondary to left-sided heart disease may have a systolic murmur and hypothermia while a patient with pneumonia or aspiration pneumonitis may have pyrexia. Patients should be efficiently examined for evidence of ecchymoses, obvious soft tissue and/or orthopedic injury and thermal injury (i.e., lingual or oral commissure).

Patients should be given appropriate sedation and supplemental oxygenation as soon as possible in an effort to reduce the work of breathing and anxiety. The least stressful method of supplemental oxygen provision should be employed. A commonly used sedative protocol for cardiovascularly unstable patients is the combination of a pure mu opioid (i.e., fentanyl 2–4 µg/kg IV; oxymorphone 0.05–0.1 mg/kg IV/IM; methadone 0.2–0.5 mg/kg IV; hydromorphone 0.1–0.2 mg/kg IV) with a benzodiazepine (i.e., diazepam 0.1–0.5 mg/kg IV; midazolam 0.2–0.4 mg/kg IV). A single dose of furosemide (dogs: 2 mg/kg IV/IM; cats: 1 mg/kg IV/IM) may be provided to those in which primary heart disease is suspected to be contributing to clinical signs until a definitive diagnosis is made. While provision of sedation and oxygen is sufficient to relieve clinical signs, some will not meaningfully respond; these patients must have their airways captured via orotracheal intubation immediately and mechanical ventilation should be initiated. Provision of positive end-expiratory pressure (PEEP) at a level of 3–5 cm H_2O may promote recruitment of collapsed alveoli.

Diagnostic imaging should be performed once the patient has been appropriately stabilized. Commonly employed thoracic imaging modalities include tFAST[3], veterinary bedside lung ultrasound examination (VetBLUE), and thoracic radiography. A tFAST[3] evaluation may be used to detect chest wall, lung, pleural and/or pericardial pathology, and may be performed in lateral or sternal recumbency. Five points are evaluated, and fur is not shaved but rather is simply parted with alcohol or sonographic gel (Table 29.2). Patients with pulmonary parenchymal disease may have B-lines (aka: comet tail artifacts, lung rockets) that suggest interstitial disease or interlobar edema is present; thus a clinician should be suspicious of pulmonary edema (cardiogenic and noncardiogenic) and pneumonia/pneumonitis. A VetBLUE scan is similar to a tFAST[3], as it is performed rapidly in sternal recumbency, measures the presence of B-lines and does not require hair coat shaving; in contrast, eight locations (four per hemithorax) are evaluated during the scan (see Table 29.2). The absence of B-lines in all evaluated lung fields rules out pulmonary edema and suggests a nonrespiratory cause of distress.

Table 29.2 Areas evaluated during tFAST[3] and VetBLUE examination

tFAST[3]		VetBLUE	
Right hemithorax	Left hemithorax	Right hemithorax	Left hemithorax
Chest tube site (CTS)	Chest tube site	Caudodorsal lung lobe (CdLL)	Caudodorsal lung lobe
Pericardial site (PCS)	Pericardial site	Perihilar lung lobe (PHLL)	Perihilar lung lobe
Diaphragmatic-hepatic (DH)		Middle lung lobe (MDLL)	Middle lung lobe
		Cranial lung lobe (CrLL)	Cranial lung lobe

Table 29.3 Common etiologies based on thoracic radiographic patterns of distribution

Pattern of distribution	Common underlying etiology
Cranioventral	Pneumonia, aspiration pneumonitis
Perihilar	Cardiogenic pulmonary edema (dogs)
Caudodorsal	Noncardiogenic pulmonary edema, hematogenous pneumonia
Nodular	Pulmonary mycoses, neoplasia

One must understand that VetBLUE and tFAST[3] scans do not replace the diagnostic utility of thoracic radiography when evaluating patients with pulmonary parenchymal disease. Indeed, evaluation of soft tissue parenchymal patterns may be uniquely helpful in determining the underlying disease process (Table 29.3). Interstitial, interstitial-to-alveolar, and alveolar patterns are most commonly reported in patients with pulmonary parenchymal diseases.

Animals with primary left-sided cardiac disease may have cardiomegaly, left atrial enlargement, and pulmonary venous dilation. While a perihilar radiographic distribution is highly suggestive of cardiogenic pulmonary edema in dogs, cats do not have classic radiographic patterns for most parenchymal diseases. The choice of additional diagnostic investigation should be based on patient history and physical examination. Tracheal washing or bronchoalveolar lavage for airway cytology and culture (bacterial & fungal) may be appropriate for patients with suspected infectious pneumonia or aspiration pneumonia/pneumonitis. Metastatic screening via abdominal radiography and/or ultrasonography may be indicated for those patients suspected of living with neoplasia, and fungal urine antigen and serology should be performed in those with suspected pulmonary mycoses. Definitive treatment is based on a patient's ultimate diagnosis.

Pulmonary Thromboembolism

Pulmonary thromboembolism (PTE) occurs when venous thrombi formed in large, deep veins travel through the right side of the heart and lodge in the pulmonary arterial bed. The caudal lung lobes are more likely to be involved as they receive most of the right ventricular output. Consequences of PTE include hypoxemia, bronchoconstriction, ventilation–perfusion (V–Q) mismatch, and hyperventilation. With time, further complications arise, including atelectasis, pulmonary edema, and pleural effusion. Hemodynamic complications from PTE depend on the extent to which the pulmonary vasculature is occluded and the amount of preexisting cardiac and pulmonary compromise. If pulmonary vasculature reserve capacity is exceeded, pulmonary vascular resistance increases to augment right ventricular afterload and ventricular oxygen demand. If the oxygen supply is exceeded, ischemia, dysrhythmias, and/or right ventricular failure may occur. Decreased cardiac output is caused by reduced pulmonary venous return induced by pulmonary blood flow obstruction.

Diagnosing PTE is difficult. Clinical signs commonly include tachypnea, dyspnea, and hypoxemia, none of which is pathognomonic for PTE. Initial assessment should include thoracic radiography, abdominal ultrasonography, arterial blood gas analysis, a complete blood count, biochemical profile, urinalysis and heartworm testing. Reported radiographic abnormalities associated with PTE are pleural effusion, regional oligemia, alveolar infiltrates, cardiomegaly, hyperlucent lung regions, and enlargement of the main pulmonary artery. While the majority of patients with PTE will have radiographic abnormalities, radiographs may also be normal in 9–27% of dogs and 7% of cats with PTE. Arterial blood gas (ABG) analysis is frequently a very useful diagnostic tool. In one canine PTE study, hypoxemia was documented in 80% of affected patients and increased alveolar-arterial (A-a) gradients on room air in all dogs. Basic blood and urine testing is performed in an effort to identify predisposing conditions, including hyperadrenocorticism, protein-losing nephropathy, protein-losing enteropathy, hypothyroidism, and/or diabetes mellitus.

If these tests fail to identify an underlying disease process, echocardiography and measurement of prothrombin and partial thromboblastin times may be helpful.

Echocardiography may show a right-sided thrombus or a thrombus in the main pulmonary artery, or may also demonstrate changes suggestive of pulmonary hypertension. A normal echocardiogram does not rule out PTE. Measurement of D-dimers may have diagnostic utility in patients with PTE. A 2003 study determined that D-dimer concentrations >500 ng/mL were 100% sensitive for predicting thromboembolic disease but specificity was 70%; conversely, D-dimer concentrations greater than 1000 ng/mL had 80% sensitivity and 94% specificity. The sensitivity of D-dimer in the diagnosis of PTE is more important than specificity, as false negatives may have fatal consequences. Tests for hypercoagulability, such as antithrombin, fibrinogen, and thromboelastography, should also be considered. Advanced imaging such as V–Q scans, spiral computed tomography, and/or pulmonary angiography might ultimately be required for definitive diagnosis of PTE.

Pulmonary thromboemboli dissolution may begin without treatment within hours of formation and completely dissolve within days. Nevertheless, a prothrombotic tendency persists to promote continued formation of pulmonary thromboemboli. Goals of treatment are reversal of the prothrombotic state and correction of hemodynamic and pulmonary changes responsible for morbidity and mortality. Treatment usually consists of supportive care, oxygen supplementation, and anticoagulant therapy; systemic or locally delivered thrombolytic agents may be used, but the benefits must be weighed against potential serious risks. Oxygen administration aims to correct hypoxemia caused by V–Q mismatch, alveolar hypoventilation, and/or diffusion impairment. However, the response to oxygen depends on the degree of vascular obstruction; pulmonary shunt occurs when more than 50% of the circulatory bed surface area is occluded, yielding venous admixture and decreased oxygen responsiveness. Resolution of the underlying disease process should always be the primary goal.

Chest Wall

The chest wall is composed of bone and soft tissue structures, including skeletal muscles, external fascia, costal parietal pleural nerves and vasculature; all play structural and functional roles in respiration. The craniodorsal external intercostals and parasternal intercostals promote inspiration by pulling ribs in a cranial direction. The interosseous portion of the internal intercostals and the caudalmost external intercostals contribute to expiration by pulling the ribs caudally. Given the normal negative pressure within the pleural space, it is potential in nature with the parietal pleura held in constant contact with the visceral pleura in the absence of disease. As thoracic cavity dimensions are increased in response to respiratory muscle action, the lungs expand because of the constant negative intrapleural pressure.

Common thoracic wall injuries include blunt trauma, penetrating trauma, and flail chest. Blunt trauma may cause crush and shear injuries to both soft tissues and skeletal structures; advantageously, the skeletal structures of the chest wall are relatively resistant to blunt force trauma. However, muscle is uniquely sensitive to crushing injury, and when damaged in low-velocity accidents may become edematous and inelastic, and may lose the ability to efficiently and effectively contract. Accordingly, thoracic wall compliance decreases and work of breathing subsequently increases. This may manifest as tachypnea but breaths may be shallow or deep; subsequent hypoxemia and/or hypoventilation are relatively common. High-velocity accidents are also associated with shearing injury. While soft tissue damage to the thoracic wall rarely contributes to patient morbidity, energy may be readily transmitted to intrathoracic organs to induce both crush and shearing injuries at these sites. Additionally, a blunt force applied laterally to the thoracic wall may cause rib fractures. However, pressure applied dorsoventrally to the thoracic cage infrequently results in rib and/or sternebrae fractures but such injuries may contribute to reduced thoracic compliance.

Penetrating injuries to the thoracic wall are relatively common in domestic dogs and cats, and common examples include bite injuries and missile (i.e., bullet, arrow) trauma. These wounds readily induce stretching and crushing of tissues in the direct path of penetration. While the actual chest wall penetration is frequently a minor issue in affected patients, one must be acutely aware of the potential underlying pleural and intrathoracic injuries caused by the penetrating trauma. The type and severity of injury directly influence how a patient is presented, and the medical team must be prepared to triage a patient in profound respiratory distress that is in need of immediate orotracheal intubation and intrathoracic stabilization.

Flail chest results from the segmental fracture and/or dislocation of two or more adjacent ribs. This type of injury is uncommon in dogs and cats because of the inherent compliance and anatomic shape of the thoracic cage. Blunt trauma and bite injuries are the most common causes of flail chest, and concurrent pulmonary damage, most notably pulmonary contusions and direct injury from costal fractures, is a major contributor to morbidity associated with this condition; these contusions may lead to decreased pulmonary compliance, hypoventilation, and shunting, all of which cause hypoxemia. The pathognomonic respiratory pattern is paradoxical movement of the unstable ribs (flail

segment) during respiration. Splinting due to pain associated with respiration leads to a decreased cough reflex, hypoventilation, hypoxemia, and atelectasis. Several techniques for stabilization of flail chest have been reported, but the primary focus should be on oxygen supplementation, underlying intrathoracic injuries, and multimodal analgesia.

Diaphragm

As a major respiratory muscle responsible for the creation of subatmospheric intrathoracic pressure, the diaphragm is essential for adequate oxygen and ventilation. Many conditions may induce partial or complete diaphragmatic paralysis, including pleuroperitoneal hernias, botulism, and phrenic nerve damage or degeneration. The classic respiratory pattern of a patient with a dysfunctional or ruptured diaphragm is tachypnea with marked inspiratory excursion of the cranial half of the thorax. Paradoxical abdominal movement is also common, and may be due to either thoracic displacement of abdominal viscera during vigorous inspiration or an inability to maintain abdominal girth during inspiration.

Nonrespiratory Causes

There are multiple causes of tachypnea and dyspnea that do not directly arise from the respiratory tract. Perhaps the most common example is nonpyogenic hyperthermia which may be the sole cause of respiratory signs or be secondary to a concurrent medical condition. Accordingly, measurement of body temperature is essential in patients presented with respiratory signs, and appropriate cooling measures should be implemented when hyperthermia is documented.

Intracranial diseases may directly stimulate the respiratory center located in the medulla. Patients with traumatic brain injury, intracranial neoplasia, and/or inflammatory/infectious central nervous system diseases may have abnormal respiratory patterns. Neurological examination typically identifies other deficits that may aid in determining a definitive diagnosis. Pain and acid–base disorders may also induce tachypnea without hypoxia in patients. Distension of the abdominal cavity is another common cause of tachypnea and dyspnea in dogs and cats, chiefly through elevation of intraabdominal hypertension and development of abdominal compartment syndrome; specifically, intraabdominal hypertension impairs diaphragmatic contraction, thereby impeding the ability to generate subatmospheric intrathoracic pressure. Additionally, pulmonary parenchyma may be compressed, leading to decreased oxygen transport across the pulmonary capillary membrane, increased alveolar dead space, and alveolar atelectasis.

Common examples of intraabdominal pathology that may cause and/or contribute to respiratory compromise include severe paralytic ileus, marked abdominal discomfort inducing splinting of abdominal musculature, large-volume peritoneal effusion, intraabdominal neoplasia, and gastric dilation-volvulus. Whenever possible, abdominal decompression should be performed, and possible decompression methods include peritoneocentesis, therapy for ileus and capillary leak, adequate analgesia to allow for abdominal muscle relaxation, and surgical decompression.

Feline Bronchial Asthma

Christine M. Serafin, DVM, DACVIM (SAIM)

The Animal Surgical Center of Michigan, Flint, Michigan, USA

Feline bronchial asthma is one of the most commonly recognized diseases of the lower respiratory tract of cats and is estimated to affect up to 5% of the cat population. The broad range of clinical manifestations that characterizes this condition, its similarities to the human form of the disease, the challenges inherent to its diagnosis, and the necessity for life-long treatment warrant significant consideration of feline bronchial asthma in both human and veterinary respiratory medicine.

Etiology and Pathophysiology

Feline bronchial disease is a general term that has been applied to inflammatory disease of the lower airways that does not have an apparent etiology. Feline asthma is considered to be a specific form of bronchial disease that is distinguished from other inflammatory airways diseases by reversible airflow limitation. This airflow obstruction is caused by smooth muscle hyperreactivity and hypertrophy, increased mucus production, inflammation, and permanent airway remodeling. Airflow restriction reverses either spontaneously or in response to pharmacological intervention. Intermittent bronchoconstriction, predominantly eosinophilic lower airway inflammation, and an allergic immunopathogenesis differentiate feline asthma from chronic bronchitis, which is typified by neutrophilic airway inflammation in response to a previous insult. Accordingly, asthma is recognized by its three hallmark features: airway eosinophilic inflammation, hyperresponsiveness, and permanent remodeling.

Although the exact etiopathogenesis has not been determined, type I hypersensitivity response is widely accepted to be the basis for the development of feline bronchial asthma. This response begins with dendritic cells within the airways that process inhaled allergen. These cells migrate to the regional lymph nodes and present the antigen, bound to major histocompatibility complex class II receptors, to naïve CD4+ T helper cells, triggering these cells to differentiate into T helper 2 cells. T helper 2 cells, in turn, produce interleukins (IL) 4, 5, and 13. IL-4 in particular induces B cells to switch from production of immunoglobulin (Ig) G to antigen-specific IgE that then binds to Fc receptors on the surface of mast cells. Allergen particles that are subsequently inhaled cross-link IgE molecules on the surface of mast cells, initiating an intracellular cascade of events that culminates in mast cell degranulation. Histamines and leukotrienes released from degranulating mast cells promote increased vascular permeability, smooth muscle contraction, and mucus production, generating the clinical manifestations associated with asthma. IL-4, IL-5, and IL-13 that are also released by mast cells recruit eosinophils to the airways. Major basic protein, eosinophil peroxidase, and cationic proteins released by degranulating eosinophils induce the tissue damage that characterizes asthma.

Epidemiology

Cats of any age can develop asthma but young to middle-aged cats are most often affected. A predilection for the Siamese breed has been proposed.

History and Clinical Signs

A wide spectrum of clinical signs characterizes feline asthma. Acute manifestations arise from bronchoconstriction and can include severe dyspnea, orthopnea, tachypnea, cyanosis, open-mouth breathing, and wheezing. Episodes of dyspnea may occur on a daily basis or as infrequently as once or twice yearly. Chronic manifestations are typified by paroxysmal episodes of coughing.

The cough is usually described as harsh and "gagging" and results from activation of bronchial cough receptors by inflammatory debris, mucus, and smooth muscle spasm. Inhalation of mechanical or chemical irritants can trigger cough, leading to the sporadic nature of the clinical signs. Further, acute exacerbations may be observed in patients with chronic signs, which can result in periodic wheezing or dyspnea in patients with a long-standing history of occasional cough. Clinical signs referable to the upper airways, including sneezing, nasal discharge, and stertor, have been anecdotally reported in asthmatic cats. In fact, histopathologic inflammatory changes have been documented in the nasal passages of cats with experimentally induced asthma. Inspiratory stridor and dyspnea associated with dynamic upper airway obstruction have also been described in an asthmatic cat. Signs of systemic illness, including inappetence, lethargy, and depression, are not typically reported.

Physical examination findings in asthmatic cats are likewise variable. Due to the intermittent nature of the clinical signs, physical examination may yield no abnormalities. Alternatively, observation of the respiratory pattern may reveal an end-expiratory "push" as air trapped within the lungs following inspiration is forcefully expelled through narrowed airways during expiration. In severely affected patients, air trapping can lead to lung hyperinflation, resulting in decreased compliance of the thoracic wall and, subsequently, a "barrel-shaped" appearance to the thorax. Tachypnea with prolongation of the expiratory phase may be observed at rest. Resistance to airflow caused by reduced intraluminal airway diameter results in turbulence, which is exhibited clinically as wheezing that may be audible with or without a stethoscope. Inspiratory crackles, increased bronchial sounds, and/or rhonchi may also be identified on thoracic auscultation, or no abnormal sounds may be appreciated. In some patients, palpation of the trachea elicits cough. Stress associated with restraint can greatly exacerbate the clinical signs.

Diagnosis

In human patients, asthma is definitively diagnosed on the basis of pulmonary function testing such as spirometry that requires a voluntary expiratory maneuver. Since such maneuvers are not feasible in feline patients, there remains at present no gold standard diagnostic test by which feline asthma is diagnosed.

Currently, clinical diagnosis relies on compatible clinical signs, pathology noted on thoracic radiography, airway cytology abnormalities, and exclusion of other causes of similar findings. In an acute setting, conditions such as congestive heart failure and pleural space disease can lead to respiratory distress that resembles signs of severe asthma on initial evaluation. Plasma levels of N-terminal pro-brain natriuretic peptide (NT-proBNP) can be used to differentiate between congestive heart failure and primary respiratory disease in cats with acute dyspnea when specific cut-off values are used. Parasitic bronchitis caused by *Aelurostrongylus abstrusus*, *Capillaria aerophila*, *Paragonimus kellicotti*, or pulmonary migration of *Toxocara cati* is characterized by eosinophilic lower airway inflammation and can be associated with clinical signs that mimic chronic manifestations of asthma. Heartworm-associated respiratory disease complex should also be considered a differential diagnosis for feline bronchial asthma. Specific testing (i.e., Baermann fecal examination, fecal flotation, heartworm antibody testing) should be performed to exclude these conditions before a diagnosis of feline asthma is reached.

Laboratory abnormalities seen with feline asthma are nonspecific but can include a peripheral eosinophilia, occurring in 20–57% of patients. A peripheral neutrophilia can also be noted in moderately to severely affected cats. Hyperproteinemia due to hyperglobulinemia may develop consequent to chronic inflammation. Results of serum biochemistry analysis are typically unremarkable.

Thoracic radiography is standardly employed in the diagnostic evaluation of suspected asthmatics. However, thoracic radiography should not be solely relied upon for diagnosis, as findings can be variable and nonspecific. A bronchial pattern is most commonly seen, consistent with airway inflammatory infiltrates. Interstitial, alveolar, and mixed patterns have also been documented in asthmatic patients. Consolidation of the right middle lung lobe may be observed and results from obstruction of the bronchus by mucus plugging that preferentially occurs in this lung segment due to its perpendicular orientation to the mainstem bronchus. Hyperinflation of the lungs, identified by flattening of the diaphragm, is also consistent with asthma. Importantly, no pulmonary abnormalities may be detected in as many as 25% of cases.

Bronchoscopy provides additional information that can be used to support a diagnosis of feline asthma. The most common bronchoscopic finding identified in cats with lower airways disease is airway obstruction by mucus. Nodular irregularities of the epithelium, airway hyperemia, static or dynamic airway collapse, and bronchial stenosis are also frequently seen. As with radiography, these findings are not specific for feline asthma. Complications ranging from hemoglobin desaturation to pneumothorax have been documented in up to 24% of cats undergoing bronchoscopy. Pretreatment with terbutaline has been associated with a lower incidence of these complications. When the necessary precautions are taken, bronchoscopy can be performed safely in

asthmatic cats and can provide evidence that is crucial in reaching a diagnosis.

Airway cytology remains the most definitive means of diagnosing feline bronchial asthma after other conditions are excluded. Bronchoalveolar lavage (BAL) can be accomplished with bronchoscopic guidance to collect samples from specific segments of the lower airways for cytologic analysis. Alternatively, BAL can be performed using an unguided technique in patients with diffuse distribution of disease when bronchoscopy is not available or feasible. The procedure is performed under general anesthesia that is induced and maintained with short-acting injectable anesthetic agents such as propofol. Prior to inducing anesthesia, the patient is preoxygenated for 5–10 minutes with flow-by or mask oxygenation methods. The procedure is performed with the patient in sternal or lateral recumbency with the most diseased side positioned ventrally. While avoiding oropharyngeal contamination as much as possible, the patient is intubated with a sterile endotracheal tube. A sterile red rubber or polypropylene catheter is then inserted through the lumen of the endotracheal tube and advanced until resistance is met, indicating that the catheter is wedged within a distal airway. Using a syringe, a 5 mL/kg bolus of warmed, sterile 0.9% saline or phosphate buffered saline is instilled through the catheter followed by a 5 mL bolus of air. The empty syringe is then used to aspirate the fluid from the airways. This may be repeated twice to obtain an adequate sample. Retrieval of 46–68% of the total infusate has been reported. The caudal half of the patient may be elevated during aspiration to facilitate retrieval of fluid. Supplemental oxygen is administered postprocedurally for 5–10 minutes. Samples reserved for cytologic analysis should be kept on ice and processed within one hour of collection to avoid deterioration of cells. Hypoxemia is a significant complication associated with BAL but can usually be reversed with oxygen supplementation. Bronchospasm may also occur as a consequence of BAL and can be managed with bronchodilators.

Increased numbers of eosinophils are classically noted in cytologic samples collected from the airways of asthmatic cats. However, a significant neutrophilic component has also been reported in cats with both naturally occurring and experimentally induced asthma. Discrepancy exists regarding the percentage of eosinophils considered abnormal within feline airway cytology samples. Eosinophil proportions ranging from 16% to 28% have been documented in airway samples collected from healthy cats. As such, cytologic findings must be interpreted in light of other diagnostic results in order for a diagnosis of asthma to be verified.

Bacterial culture of airway lavage samples collected from cats with lower airways disease produces variable results. Bacterial growth has been found in airway samples collected from healthy cats, though growth of *Mycoplasma* spp. has not been documented. Therefore, a diagnosis of secondary bacterial infection in an asthmatic patient must be based on growth of a large number of colonies of a single organism or intracellular bacteria seen cytologically. Organisms that have been detected on airway samples collected from cats with bronchopulmonary disease include *Pasteurella multocida*, *Streptococcus* spp., *Staphylococcus* spp., *Mycoplasma* spp., *Moraxella* spp., and *Bordetella* spp.

Due to the degree of invasiveness, lung biopsies are not routinely performed in the diagnostic evaluation of cats with lower airways disease. Histopathology of postmortem lung samples from cats with experimentally induced asthma revealed epithelial hypertrophy and hyperplasia, marked smooth muscle hypertrophy of the terminal and respiratory bronchioles, and mucous cell metaplasia.

Pulmonary function testing, though not employed standardly in clinical settings, has been investigated as a means of assessing asthmatic cats. Specifically, barometric whole-body plethysmography (BWBP) has been employed to assess airway responsiveness in cats with experimentally induced asthma. This noninvasive technique measures pressure changes generated by an awake, spontaneously breathing cat in a transparent, ventilated chamber. Pause and enhanced pause are variables used to estimate lung resistance. These values have been shown to increase significantly following bronchoprovocation in healthy cats and cats with artificially induced asthma. Tidal breathing flow-volume loops have also been utilized to assess lung resistance in cats with bronchial disease. These loops are generated in awake cats using a facemask attached to a pneumotachograph to assess airflow. Cats with bronchial disease have reduced expiratory flows and tidal breathing expiratory volumes and prolonged expiratory time compared to healthy cats. Additionally, ventilator-acquired mechanics have been used to measure airway resistance, positive end-expiratory occlusion pressure, and end-expiratory breath hold pressure following bronchoprovocation in anesthetized cats with experimentally induced asthma.

Advances in the diagnostic approach to feline asthma have included the development of minimally invasive methods that may have utility in a future clinical setting. In particular, exhaled breath condensate (EBC) can be collected from nonanesthetized cats briefly housed within an acrylic chamber and analyzed for hydrogen peroxide, a marker of oxidative stress. The concentration of hydrogen peroxide in the EBC of artificially sensitized cats has been shown to correlate with the degree of eosinophilic lower airway inflammation, suggesting that analysis of EBC may prove to be a useful screening tool for suspected asthmatics.

Identifying the allergens responsible for inciting the asthmatic response in individual cats is a critical step in devising targeted therapies. Methods have been developed to detect IgE that is specific for the allergens used in sensitization in the serum of cats with experimentally induced asthma. Moreover, intradermal skin testing, a practice most often used in the diagnosis of atopic dermatitis, has been shown to be a sensitive means of detecting aeroallergen sensitization in experimental models of asthma. Other minimally invasive immunodiagnostic methods that have been investigated in asthmatic patients include the use of flow cytometry to detect proliferation of allergen-specific T lymphocytes in the peripheral blood.

Treatment

Supplemental oxygen, stress reduction, and bronchodilation are the tenets of therapy for the asthmatic cat in acute crisis. For the patient presenting with dyspnea and cyanosis, supplemental oxygen should be provided immediately at a FiO_2 of 40%. This can be effectively accomplished by placing the patient in an oxygen cage, which also minimizes restraint and handling that can exacerbate dyspnea, with fatal outcomes in some instances.

Beta-2-adrenergic agonists such as terbutaline are most commonly used to induce bronchodilation in an acute setting. Bronchodilation results from airway smooth muscle relaxation triggered by stimulation of beta-2-adrenergic receptors. Activation of these receptors triggers adenylyl cyclase to increase production of cAMP, which sequesters intracellular calcium, thereby reducing smooth muscle contraction. Other potentially beneficial effects of these agents include inhibition of mast cell mediator release and airway microvascular leakage, increased mucociliary clearance, decreased neutrophil activation and endothelial adhesion, and induction of neutrophil apoptosis. Adverse effects associated with beta-2-adrenergic agonist therapy include tachycardia, CNS stimulation, hypokalemia, and tremors. For this reason, these agents should be used with caution in patients with co-morbid cardiac disease, hypertension, hyperthyroidism, seizure disorders, and diabetes mellitus. Beta-2-adrenergic agonists can interact with tricyclic antidepressants such as amitriptyline and clomipramine and should be used with caution in patients receiving these medications. Terbutaline sulfate can be administered IM or SC at an initial dose of 0.1 mg/kg to induce bronchodilation in an acute setting. Decreased respiratory rate is expected within 15–30 minutes of dosing, and repeated doses can be administered as needed.

Albuterol sulfate is a beta-2-adrenergic agonist that may be administered in inhalant form to cats presenting with severe, acute dyspnea. A metered dose inhaler is used to deliver the medication into a chamber device attached to a facemask (Aerokat® Feline Aerosol Chamber, Trudell Medical International). This apparatus facilitates inhalation of the aerosolized particles into the lower airways. An initial dose of one 90 µg puff can be administered to dyspneic patients that will tolerate having the facemask held over the nose and mouth for the 7–10 seconds necessary for the complete dose to be inhaled. This dose may be repeated every 30 minutes for up to four hours. Albuterol can also be dispensed for at-home administration as a "rescue inhaler" for management of acute exacerbations in established asthmatics until veterinary care can be provided. However, chronic use of racemic albuterol should be avoided as the S-enantiomer in this mixture has been shown to cause airway inflammation in healthy and experimentally asthmatic cats.

Status asthmaticus is defined in human medicine as severe, acute asthma that is refractory to repeated doses of beta-agonists. Severely dyspneic feline asthmatics that do not respond to bronchodilators and supplemental oxygen may stabilize only after initiating antiinflammatory therapy with a rapidly acting glucocorticoid such as dexamethasone sodium phosphate. An initial dose of 0.25–2 mg/kg can be administered IM or IV to quickly reduce airway inflammation if necessary.

Lifelong glucocorticoid therapy is the key to chronic management of feline asthma. Because the aeroallergen that provokes the asthmatic response usually cannot be identified or completely removed, avoidance of the offending allergen is often impossible in feline patients. Thus, it is postulated that lower airway inflammation is continually present in asthmatic cats, even in the absence of clinical signs. Lower airway inflammation has been shown to persist in feline asthmatics treated with high-dose glucocorticoid therapy despite resolution of clinical signs. To minimize the permanent airway remodeling that ensues from long-standing inflammation, continuous antiinflammatory therapy is necessary.

Glucocorticoids are the most effective antiinflammatory agents used in the management of feline asthma. They exert their antiinflammatory effects by binding to a cytosolic receptor, then translocating to the nucleus where the glucocorticoid–receptor complex binds to a glucocorticoid response element on the genes that regulate production of inflammatory cytokines such as IL-3 and IL-5. Glucocorticoids also increase vasoconstriction to reduce airway edema; decrease airway hyperresponsiveness over time; decrease mucus secretion; inhibit macrophages, T cells, eosinophils, and mast cells; increase the synthesis of secretory leukocyte protease

inhibitor to reduce airway remodeling; and prevent the downregulation of beta-adrenergic receptors.

Orally administered glucocorticoids are used in the initial management of stable asthmatics. Prednisolone is preferred over prednisone in cats because of impaired hepatic bioconversion of prednisone. No standardized dosing regimen and tapering schedule exists for the use of glucocorticoids in the management of feline bronchial asthma. Patients are typically started on therapy at doses near or at the immunosuppressive range (1–2 mg/kg PO q12h). Long-term therapy with systemic glucocorticoids can be associated with numerous undesirable effects such as polyuria, polydipsia, polyphagia, weight gain, alopecia, thinning of the skin, increased susceptibility to infections, and the development of diabetes mellitus. Systemic steroids can also exacerbate underlying cardiac disease. To minimize these complications, the initial prednisolone dose is tapered by 25–50% once clinical signs have resolved and after at least seven days of therapy.

Inhaled glucocorticoids are associated with negligible adverse effects compared to those seen with systemic therapy and are a very effective means of managing feline asthma long term. Inhaled steroids are minimally absorbed into the systemic circulation and undergo extensive first-pass metabolism. Fluticasone propionate is the most commonly prescribed inhaled glucocorticoid in veterinary medicine. It has the longest receptor residency time and greatest lipophilicity of the inhaled glucocorticoids as well as a high therapeutic index. Treatment with inhaled fluticasone has been shown to reduce airway inflammation and hyperresponsiveness in cats with naturally occurring lower airways disease and in cats with experimentally induced asthma. Suppression of the hypothalamic-pituitary-adrenocortical axis has been demonstrated in healthy cats following treatment with inhaled glucocorticoids, but significant suppression of the systemic immune response was not noted. Fluticasone doses of 44 µg, 110 µg, and 220 µg q12h were shown to reduce airway inflammation in experimental models of feline asthma with similar efficacy. Fluticasone is available in a metered dose inhaler formulation and can be administered to cats using a chamber and facemask as with inhaled albuterol. Systemic steroid therapy should be continued during the first 14 days of treatment with fluticasone to allow the inhaled glucocorticoid to reach full effect. The oral glucocorticoid dose can then be gradually tapered and eventually discontinued while inhalant therapy is continued long term. Inhaled budesonide (400 µg q12h) has also been evaluated in asthmatic cats and has been shown to reduce airway responsiveness while causing suppression of the hypothalamic-pituitary-adrenal axis in a subset of treated cats.

Methylxanthine bronchodilators can be used in conjunction with antiinflammatory therapy for chronic management of refractory disease. Theophylline is the methylxanthine derivative that has been studied most extensively in cats. The mechanism by which methylxanthines induce bronchodilation is postulated to be related to inhibition of phosphodiesterase, which leads to increased intracellular cAMP and, subsequently, smooth muscle relaxation. However, theophylline does not inhibit phosphodiesterase at therapeutic concentrations. Inhibition of adenosine or interference with intracellular calcium levels may instead explain the bronchodilatory effects of these agents. Theophylline also prevents mast cell degranulation, reduces microvascular leakage, and increases respiratory muscle strength. When administered in the evening, sustained-release theophylline achieves higher peak plasma concentrations compared to morning administration. The recommended dose of slow-release preparations is 20–50 mg/kg PO q24h. Adverse effects associated with methylxanthine derivatives include central nervous system stimulation, tachyarrhythmias, increased gastric acid secretion, and diuresis. Because of this, methylxanthines should be used cautiously in patients with preexisting cardiac disease, seizure disorders, hyperthyroidism, and gastric ulcers. Long-acting bronchodilators such as theophylline should be used adjunctively with steroid therapy to achieve improved control of clinical signs in patients that do not completely respond to glucocorticoid therapy alone.

Ciclosporin has been promoted for management of feline asthma that is refractory to glucocorticoid and bronchodilator therapy. A calcineurin inhibitor, ciclosporin inhibits T cell activation and proliferation by interfering with the transcription of genes related to cytokine production, particularly IL-2. In an experimental model of feline asthma, treatment with ciclosporin prior to and during chronic antigen challenge decreased the amount of IL-2 secreted from peripheral blood lymphocytes, prevented an increase in airway hyperresponsiveness after chronic antigen stimulation, and resulted in reduced airway smooth muscle thickness and mucosal eosinophil infiltration histologically compared to untreated cats. Following acute antigen challenge in the same model, pretreatment with ciclosporin did not prevent mast cell degranulation or an increase in lung resistance. Despite this, tracheal smooth muscle harvested from these artificially sensitized cats did not contract in response to antigen exposure when incubated with ciclosporin *in vitro*. Given these differential findings, ciclosporin should be reserved for patients with a poor response to standard asthma therapies. An initial dose of 10 mg/kg PO q12h is recommended with the goal of achieving blood trough levels of 500–1000 ng/mL. Adverse effects associated

with ciclosporin use in cats include anorexia and gastrointestinal upset. Nephrotoxicity and hepatotoxicity may develop at high blood levels.

Antiserotonergics, antileukotrienes, and antihistamines have been investigated for use in feline asthma to reduce airway inflammation while circumventing the adverse effects associated with systemic glucocorticoid therapy. Serotonin released during mast cell degranulation mediates airway smooth muscle contraction in cats. Cyproheptadine, a serotonin receptor antagonist, has been shown to attenuate constriction of airway smooth muscle from antigen-sensitized cats *in vitro*. In live cats experimentally sensitized to aeroallergen, cyproheptadine did not uniformly diminish airway responsiveness, degree of airway eosinophilic inflammation, plasma or BAL fluid serotonin concentrations, or serum content of allergen-specific IgE following allergen challenge. Similarly, cysteinyl leukotrienes are produced by mast cells as well as eosinophils and contribute to many of the pathophysiologic processes underlying asthma, including bronchoconstriction, smooth muscle proliferation, mucus production, and inflammatory cell influx. The leukotriene receptor antagonist zafirlukast was evaluated in an experimental model of feline asthma and was demonstrated to have no effect on airway eosinophilia, airway reactivity, or serum levels of allergen-specific IgE compared to placebo. In another study, urine concentrations of cysteinyl leukotrienes in allergen-sensitized cats did not increase after allergen challenge. These results suggest that leukotrienes may not be a critical factor in the generation of the feline asthmatic response. Histamine plays a crucial role in inducing bronchoconstriction in human asthmatics, though its importance in mediating the feline asthmatic response remains questionable. Cetirizine is a second-generation histamine 1 receptor antagonist that has been evaluated in cats with experimentally induced asthma and was shown to have no effect on eosinophilic airway inflammation or plasma histamine concentrations. Until additional studies are conducted, pharmaceutical agents that inhibit serotonin, leukotrienes, and histamine are not recommended as monotherapy in the management of feline asthma.

Allergen-specific immunotherapy holds promise as the only potentially curative therapy for feline asthma. This form of therapy, which is most commonly employed in veterinary medicine in the management of atopic dermatitis, is proposed to alter the immune response so as to reestablish tolerance to a specific allergen. In particular, rush immunotherapy (RIT) is a modified version of allergen-specific immunotherapy that involves subcutaneous administration of gradually increasing doses of a specific antigen over an accelerated period of time, generally a couple of days or less. The immunomodulatory effects of RIT are hypothesized to be related to production of IgE-blocking antibodies, induction of T cell unresponsiveness, shift from a T helper 2 to a T helper 1 cell response, elaboration of immunosuppressive cytokines such as IL-10 from T regulatory cells, and decreased lymphocyte proliferation in response to allergen. In cats experimentally sensitized to Bermuda grass allergen (BGA), RIT significantly decreased eosinophilic airways inflammation, induced lymphocyte hyporesponsiveness to BGA, increased mRNA transcription of IL-10 in BAL fluid, and decreased mRNA transcription of IL-5 in BAL fluid. Adverse effects associated with RIT in this model included localized swelling around the injection site, increased heart and respiratory rate, hyperthermia, vomiting, agitation, and systemic anaphylaxis noted in one cat. These adverse effects were less severe when RIT was adjuvanted with CpG oligodeoxynucleotides, immunostimulatory DNA sequences that induce a polarized Th1 response. Intranasal administration of RIT has also been evaluated in an experimental model of feline asthma and was shown to be equally effective in reducing the degree of eosinophilic airway inflammation as subcutaneously administered RIT, although subcutaneous RIT more consistently abolished the clinical signs induced by aeroallergen challenge. Both antiinflammatory and immunomodulatory therapy may be necessary in severely affected cats. When administered concurrently with RIT, oral glucocorticoid therapy has been shown to dampen the long-term effectiveness of RIT, which may limit the benefits of RIT as monotherapy in patients with severe disease.

The challenge in applying RIT to cats with naturally occurring asthma lies in elucidating which antigen is triggering the asthmatic response. Intradermal skin testing has been employed to identify the inciting antigens in veterinary patients with atopic dermatitis. This method has been shown to be highly sensitive in detecting a known inciting antigen in cats artificially sensitized to a specific allergen. Concurrently, detection of allergen-specific IgE in the serum of experimentally sensitized cats was shown to be highly specific in identifying the antigen used for sensitization. When evaluated in cats with naturally occurring small airway disease, significantly more positive allergen reactions on serum IgE testing and intradermal skin testing were noted compared to cats without airways disease, though the clinical relevance of these allergens could not be determined. Even though isolating the specific inciting antigen is the ideal means of guiding immunotherapy, RIT using antigens that did not completely match those used to induce the asthmatic phenotype in experimental feline models was shown to reduce eosinophilic airways inflammation. Immunotherapy is likely to play a prominent role in the management of feline asthma in the future, but additional studies in patients with naturally occurring disease

are necessary before allergen-specific immunotherapy can be employed standardly in clinical practice.

Several novel therapies have been investigated using cats with experimentally induced asthma and may be applicable to the management of patients with naturally occurring disease. Specifically, the antiinflammatory effects of omega-3 polyunsaturated fatty acids (ω3 PUFAs) extracted from New Zealand green-lipped mussel have been evaluated in artificially sensitized cats. Airway responsiveness but not eosinophilic inflammation decreased following treatment, suggesting that ω3 PUFAs may have some benefit as adjunctive therapy in the management of feline asthma. Masitinib, a tyrosine kinase inhibitor, has been demonstrated to reduce eosinophilic airway inflammation and improve respiratory compliance in cats with experimental asthma and may emerge as an effective treatment strategy for patients with glucocorticoid intolerance or refractory disease. Stem cell therapy has also been investigated as a means of reducing airway remodeling, one of the hallmarks of feline asthma. Administration of allogenic mesenchymal stem cells to cats experimentally sensitized to a common aeroallergen resulted in attenuation of changes consistent with chronic lung remodeling based on computed tomography. Nebulized lidocaine has been evaluated in cats with experimentally induced asthma and was shown to reduce airway hyperresponsiveness without adverse effects, indicating that it may be effective as palliative therapy when used in combination with glucocorticoids.

Monitoring

Response to therapy is most effectively evaluated by assessing clinical signs. Due to the intermittent nature of clinical signs in some patients, overall improvement in clinical condition should be judged after at least a few weeks of therapy. Decreased frequency of episodes of coughing and/or dyspnea is the expected outcome of successful treatment. A more objective assessment of clinical improvement involves "cough counts" performed by owners at home prior to and after starting therapy. Due to permanent airway remodeling, radiographic manifestations of asthma may not change significantly with treatment, limiting the use of repeated thoracic radiography to monitor response to therapy. The exception is radiographic evidence of atelectasis of the right middle lung lobe, which is expected to resolve with antiinflammatory and mucolytic therapy. The limited availability of pulmonary function testing prohibits its practical application as a means of assessing response to treatment, but it may prove useful for this purpose in the future.

Prognosis

Most asthmatic patients that receive appropriate treatment demonstrate a favorable response with a good long-term prognosis. However, continuing antiinflammatory therapy for life is crucial to prevent further permanent airway remodeling unless the inciting allergen can be identified and exposure prevented. Severe, refractory forms of feline asthma do exist and can present management challenges. Moreover, even patients with apparently well-controlled asthma are at risk for potentially life-threatening episodes of severe, acute bronchoconstriction. The adverse effects associated with systemic glucocorticoid therapy can complicate prognosis and lead to the development of life-limiting complications, including congestive heart failure and diabetes mellitus. Long-term treatment can be further impaired by patients that will not tolerate oral administration of medications or placement of the facemask required for administration of inhalant therapy. In addition, the expense associated with inhaled medications may prevent their use in some patients. Despite these challenges, feline asthma is a readily manageable condition, and successful treatment can prevent acute death and significantly improve quality of life in the majority of patients.

Canine Chronic Bronchitis

Kevin Kumrow, DVM, DACVIM (SAIM)

Orchard Park Veterinary Medical Center, Orchard, Park, NY, USA

Etiology/Pathophysiology

Canine chronic bronchitis (CCB) is the most common cause of a chronic cough. It is characterized by a cough that is present for at least two months, inflammation in the airways, and a lack of an identified underlying disease that may cause a cough. There is some evidence that environmental pollutants, second-hand smoke or other inhaled noxious chemicals may be contributors to the etiology. A specific role of bacteria in CCB has not been established. The diagnosis of CCB is largely through exclusion, and treatment is based on a patient's clinical history, diagnostic results and response to therapy.

Canine chronic bronchitis airway inflammation is neutrophilic, and there is an increase in the production of mucus. The inflammatory response perpetuates the coughing cycle, which in turn stimulates continued inflammation. This positive feedback sets up a vicious cycle that ultimately leads to permanent changes in the airways, including hyperplasia of mucous glands and goblet cells, hypertrophy of smooth muscle, and fibrosis of the lamina propria. These changes are often accompanied by obstruction of small airways and airway collapse. Some cases of chronic bronchitis can progress to permanent dilation of the bronchi and destruction of the structural integrity of the bronchial walls. This condition is known as bronchiectasis. Cocker spaniels have an increased risk of bronchiectasis. Left unidentified and untreated, the aforementioned changes to the airway can contribute to a progressive decline in lung function. Box 31.1 gives a list of many of the common differentials for CCB.

Epidemiology

The most common signalment for CCB is middle-aged to older, small-breed dogs.

History and Clinical Signs

The history and clinical signs of patients with CCB are similar to those presenting for collapsing trachea and mitral valve insufficiency. Patients with collapsing trachea have a chronic cough associated with narrowing of the airway combined with chronic tracheal inflammation, and a perpetual dry honking cough. Mitral valve insufficiency can lead to enlargement of the left atrium and subsequent compression of the mainstem bronchi that stimulates a chronic coughing reflex. CCB is less commonly diagnosed in large-breed dogs. Exhaustive consideration of alternative causes of a chronic cough in these patients should occur. For example, a Doberman with a history of cough should be thoroughly evaluated for dilated cardiomyopathy, and heart failure should be suspected until proven otherwise. A 12-year-old Labrador with a history of cough should be evaluated for laryngeal paralysis with intermittent aspiration pneumonia or pulmonary metastatic disease. It is imperative that the clinician be astute in differentiating between the potential causes of chronic cough as a misdiagnosis could result in inappropriate treatment and a worsening of the patient's condition.

A thorough history can assist in the differentiation of CCB from other causes of chronic cough. Patients that have had exposure to other dogs in any setting for any period of time should be suspect for canine infectious respiratory disease (CIRD). Commonly, exposure occurs at a groomer, boarding facility, doggie day-care, or dog park, or via a visiting family pet or a new puppy in the household; however, any known interaction, even limited, should raise suspicion. These patients can be any age or breed, and can have clinical signs that range from a mild dry-hacking cough to systemic illness. Pets with evidence of systemic disease that have a history of cough are unlikely to have CCB as their primary ailment, and

Box 31.1 Common differential diagnoses for CCB

- Bacterial pneumonia – *Escherichia coli*, *Klebsiella*, *Pasteurella*, *Pseudomonas* sp., *Streptococcus*, and *Staphylococcus* are commonly associated with pneumonia in dogs.
- Canine infectious respiratory disease complex – *Bordetella bronchiseptica*, canine influenza, *Mycoplasma*, etc.
- Congestive heart failure
- Fungal pneumonia – histoplasmosis, blastomycosis, and coccidiomycosis.
- Interstitial lung disease.
- Parasitic pneumonia – *Aelurostrongylus* sp., *Capillaria aerophila*, *Crenosomavulpis*, *Filaroides hirthi*, and *Paragonimus kellicotti*. *Oslerus osleri* can result in coughing, but is found in the trachea rather than the lower airways. *Dirofilaria immitis* (heartworm disease) also results in cough.
- Pleural effusion.
- Protozoal infections – *Neospora caninum* and *Toxoplasma gondii*.
- Pulmonary neoplasia.
- Tracheal collapse.
- Upper airway dysfunction (laryngeal paralysis).

attention should be focused on investigating their systemic illness. Questions about weight loss, anorexia, lethargy, and other behavior changes could lead to the detection of a systemic illness. A clinical history should also include questions that discuss potential exposure to passive (second-hand) smoke, the presence of excessive environmental odors/perfumes, and prior prescriptions or home remedies and their clinical effect on the cough.

Physical examination of most patients with CCB is relatively unremarkable. Patients tend to be systemically well, with the only major clinical sign being coughing. Patients are often seen due to an acute exacerbation in their coughing secondary to exposure to environmental irritants or allergens, secondary development of a bacterial infection, or the unveiling of an unrelated concurrent disease. Some dogs will present with tachypnea or increased expiratory effort (labored breathing). Physical examination should focus on the cardiopulmonary system and signs of systemic illness (weight loss or gain, anorexia, lethargy, etc.). Careful auscultation of the lungs can provide clues to lower airway disease, and the presence or absence of a murmur should be noted. Although heart disease and CCB can coexist, the presence of a sinus arrhythmia supports the airway/pulmonary system as the primary cause of coughing.

Sometimes a cough can be elicited with palpation of the trachea due to nonspecific inflammation of the airways. This may assist with characterization of the cough by the clinician and exclude other conditions such as reverse sneezing or other upper airway noises that may be mistaken for a cough. Whether a cough can or cannot be produced during physical examination, a descriptive history should be gathered from the owners – is it dry or productive, paroxysmal or intermittent, is there a relation to eating or certain activities, does it occur at specific times during the day/night, has there been any voice change or reluctance to bark? Some dogs may have syncopal events associated with coughing. This is known as the cough-drop syndrome, which is most likely associated with high vagal tone.

- NT pro-BNP

Diagnosis

Diagnostic evaluation should be tailored to the individual patient, and prioritized with regard to clinical assessment and history.

Recommended laboratory tests can be found in Box 31.2. These diagnostic evaluations are typically normal in patients with CCB but they assist with the general assessment of the patient's health. A CBC may be suggestive of an infectious component to the cough, while appropriate fecal evaluation may lead to the identification of lungworm larva or eggs, and a NT-proBNP has been shown to be useful in the identification of left atrial enlargement/congestive heart failure.

Thoracic radiographs are essential in the evaluation of a coughing dog. In patients where diagnostic testing is limited, thoracic radiographs have been shown to be the most useful test. Patients with CCB may show findings consistent with bronchial thickening, evidenced by increased "donuts and tramlines" (Figure 31.1). Additional findings consistent with CCB include hyperinflation and bronchiectasis. Although radiographs are relatively insensitive for the diagnosis of CCB, they provide the benefit of assisting with the exclusion of other conditions that result in coughing, such as cardiomegaly, lung masses, pleural effusion, and interstitial lung disease. It is important to remember that normal chest radiographs do not exclude a diagnosis of CCB.

Fluoroscopy may be useful in evaluation for tracheal and bronchial collapse, but does not typically provide benefit for evaluation of chronic cough unless concurrent

Figure 31.1 Thoracic radiographs with a diffuse bronchial pattern evidenced by increased "donuts and tramlines."

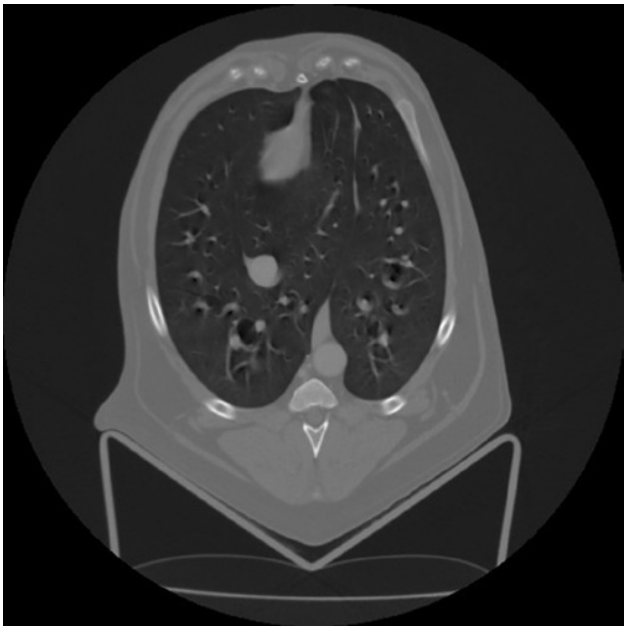

Figure 31.2 Computed tomography slice of the thorax showing a "ground-glass" appearance.

airway collapse is suspected. Ultrasound of the thoracic cavity may assist with diagnostic sampling of isolated lesions that are observed on radiographs (masses or consolidation), or when pockets of pleural effusion are identified; however, it does not assist in the diagnosis of CCB.

Computed tomography (CT) is widely used in people with airway disease, and is becoming more popular in veterinary medicine for the evaluation of canine bronchial disease. The increased resolution of CT compared to radiographs and the ability to perform 3D reconstructions may prove to be more sensitive for the diagnosis of CCB, and allow earlier detection and treatment of the disease (Figure 31.2). Diagnostic CT scanning in veterinary medicine does require brief general anesthesia, and if permissible should be combined with evaluation of laryngeal function, collection of airway cytology samples, and bronchoscopy for a complete airway evaluation.

If available, bronchoscopy is the preferred technique to evaluate and visualize the airway. A recent study showed that patients with CCB often demonstrate an irregular mucosal surface without the glistening seen in healthy airways. Most airways were also noted as having a granular mucosal appearance with a roughened texture, increased amounts of mucus, hyperemia of mucosal vessels, and partial collapse of larger airways during expiration secondary to weakened walls. Bronchial dilation in patients with bronchiectasis can also be noted in CCB patients. Bronchoscopy is also beneficial for the diagnosis or exclusion of some other large airway diseases such as collapsing trachea/bronchi, obstructive intraluminal masses or granulomas caused by some parasites, and foreign bodies.

Transtracheal washes, endotracheal washes, and blind or visualized bronchoalveolar lavages are very useful in characterizing the type of inflammation present in the airways, and for the diagnosis of CCB. Samples should be submitted for bacterial cultures and cytology (fungal cultures should be submitted when appropriate). The airway sampling technique chosen often reflects clinician preference, and availability of supplies and equipment (see Box 31.3 for a detailed description of techniques).

Cytologic samples should be immediately placed into EDTA tubes, and processed promptly to avoid changes in cell counts and appearance. In cases where analysis will be delayed, a small portion of the sample should be centrifuged, decanted, and a direct smear of the supernatant and precipitation should be prepared. Evaluation of respiratory cytology from dogs with CCB typically reveals a predominant neutrophilic infiltrate with excessive mucus (Figure 31.3), small numbers of lymphocytes, eosinophils, goblet cells, ciliated and epithelial cells, and a variable number of alveolar macrophages. Samples that show a marked eosinophilia should be suspected of having an eosinophilic bronchopneumonopathy, rather than CCB. Bacterial cultures should be submitted in all cases; however, the role of bacteria is unclear, as colonization is common, but may not reflect a clinical infection.

Pulmonary function testing is widely used in human medicine to better characterize the severity of and specific

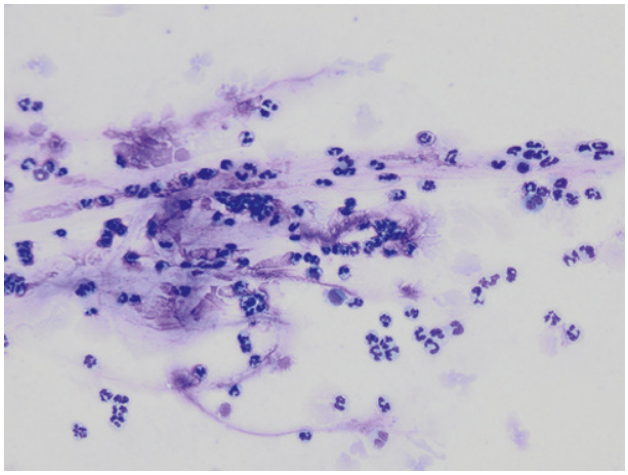

Figure 31.3 Photomicroscopy from a patient diagnosed with chronic bronchitis showing a typical cytologic representation with abundant mucus and neutrophils, and prominent "Curschmann spirals." *Source:* Image courtesy of Eric J. Fish, DVM, DiplACVP.

defects associated with chronic bronchitis. Although tidal breathing flow-volume loops have been described in veterinary medicine, they are not widely used due to lack of patient cooperation. Forms of pulmonary function testing that are more practical and may be used in dogs include the collection of arterial blood gas samples, the measurement of oxygen saturation with pulse oximetry, and use of the six-minute walk test (6MWT). Arterial blood gas analysis may document hypoxemia (PaO_2 <80 mmHg) or an increased alveolar-arterial (A-a) gradient (>15), although due to difficulty with technique and a lack of necessary equipment, this is not commonly performed in the clinical setting. Pulse oximetry is widely available in practice, and may be used to estimate arterial saturation with a value of >97% considered normal. Pulse oximetry may also be assessed after a short walk, as desaturation may be more commonly observed after exercise in patients with more mild compromise to their airway function. The 6MWT formally measures the distance that a dog can walk over six minutes; distances less than 400 meters are supportive of significant lung disease. The 6MWT may also be combined with pre- and post-walk pulse oximetry to evaluate for exercise-induced oxygen desaturation.

Treatment

Due to the lack of a definitive treatable etiology for CCB, the treatment options are limited to therapy to ameliorate known clinical signs and co-morbid conditions. Primary treatment focuses on limiting inflammation, limiting cough, and improving exercise stamina.

Possible environmental causes should be identified and eliminated. Owners should be advised not to smoke indoors, or in closed environments with affected pets. Any air-borne irritants should be eliminated such as perfumes, incense, scented detergents, and aerosolized cleaners. Owners should also be encouraged to remove as much dust from the environment as possible. Cloth furniture should be cleaned or removed, carpets cleaned or removed, and frequent vacuuming/dusting should be encouraged. If extensive remodeling is planned that is likely to produce potentially noxious fumes or a large amount of aerosolized particles then plans should be made for CCB patients to stay with friends or family. Exposure to potentially sick puppies should be avoided as well as trips to dog parks, grooming parlors, and boarding facilities. If a patient is obese, an appropriate weight loss program should be established. Activities that incite excess barking or strenuous exercise should be curtailed. The importance of replacing neck collars with harnesses should be emphasized.

Antiinflammatory medications are typically employed to assist with reducing inflammation in the airway, and glucocorticoids are still the mainstay of treatment. Reducing inflammation can limit cough and assist in reducing the positive feedback cycle that perpetuates CCB. Glucocorticoids may be administered orally or via inhalation. Prednisone is the most commonly used glucocorticoid. Initial dosing of prednisone is 1–2 mg/kg/day though it should be tapered to the lowest effective dose that controls clinical signs. Inhaled glucocorticoids have been widely used in people, and there is growing frequency of their use in veterinary medicine. Inhaled steroids are delivered via a spacer chamber and facemask designed specifically for dogs (e.g., AeroDawg, wwww.trudellmed.com). Inhaled glucocorticoids are more expensive than oral steroids, but the benefits include a directed therapy approach that limits systemic absorption and subsequent steroid side-effects. One study demonstrated benefits of therapy with fluticasone at 125 µg q12h.

Bronchodilators are commonly prescribed for dogs with CCB and evidence supports an improvement in clinical signs in approximately half of treated dogs. Theophylline (extended release, 10 mg/kg PO q12h) has been shown to have nonspecific effects that may benefit patients with CCB. These include decreasing diaphragmatic fatigue, increasing mucociliary clearance, and enhancing the efficacy of glucocorticoid activity. Beta-2-agonists, such as terbutaline, may be less effective due to the lack of reversible bronchoconstriction in some patients. The use of theophylline versus beta-2-agonists is still a clinical preference. It should be noted that beta-2-agonists might cause some anxiety and restlessness when initiated although these signs often resolve within a few day.

Box 31.3 Airway sampling techniques

Cytologic samples can be obtained from the airway via a tracheal wash, blind bronchoalveolar lavage, or with bronchoscopy.

Transtracheal wash (TTW) is best suited for tolerant medium- or large-sized dogs. This technique should be avoided in brachycephalic breeds, and obese patients where easy palpation of the trachea is limited.

- TTW is performed in unsedated or lightly sedated dogs.
- After aseptic preparation of a small area over the cervical trachea or larynx and a local anesthesia block is performed, a through-the-needle catheter is passed through the cricothyroid ligament or between tracheal rings; the catheter is fed down the trachea (beveled edge down).
- Two to three aliquots of 5–10 mL 0.9% sterile saline are flushed into the trachea, and promptly retrieved. Retrieval volume is typically about 50%, and the remaining fluid is rapidly absorbed from the airway.
- Collection of a diagnostic sample is facilitated by a patient's ability to cough resulting in an increased likelihood in retrieving a representative cytology from more areas of the airway.

Endotracheal wash (ETW) is commonly performed in smaller patients, patients that are less amenable to restrain, brachycephalic breeds, and obese patients.

- ETW is performed by briefly anesthetizing the dog with propofol then performing a clean intubation with a sterile endotracheal tube. Lubricating gel should not be used.
- In a sterile fashion, a 5–8 Fr catheter is fed through the endotracheal tube and sterile saline is infused and reaspirated. Alternatively, a modified technique using suction, a Lukens specimen container, a three-way stopcock, and a red rubber or Argyle feeding tube can be used (Figure 31.4a,b).
- 0.9% saline aliquots of 3, 5, and 10 mL are used for dogs <5 kg, 5–15 kg, and >15 kg, respectively.
- A sterile collection cup may be used to collect any additional samples that may be expectorated.

(a)

(b)

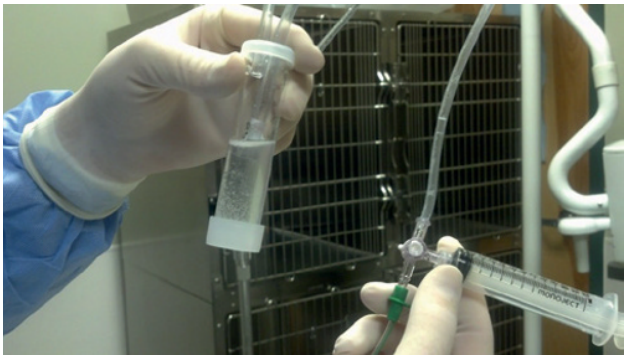

Figure 31.4 Equipment set-up for a modified technique to perform bronchoalveolar lavage or endotracheal tube lavage using suction, a Lukens specimen container, a three-way stopcock, and a red rubber or Argyle feeding tube.

- Supplemental oxygen should be available during this procedure and for recovery.

Blind bronchoalveolar lavage (BAL) is performed similarly to an ETW with the exception of the following.

- The flexible catheter is advanced until it is lodged in the lower airways.
- A larger volume of 0.9% saline is used, dependent on the patient's size.
- A simple technique using a modified stomach tube has been used successfully.

Bronchoscopic bronchoalveolar lavage can be used to collect samples via bronchoscopy by flushing sterile 0.9% saline through the chamber of a sterilized scope and reaspirating it back through the biopsy channel.

Antibiotics are warranted in dogs with an acute exacerbation of their clinical signs of CCB, or in those with evidence of an infection on airway cytology and/or culture. Doxycycline and azithromycin have antiinflammatory and antimicrobial properties, and should be considered in CCB patients with no specific bacterial culture and sensitivity data. Clinician preference is often influenced by cost, formulation, and availability of products. Fluoroquinolones are also a good choice for patients with CCB due to their high airway tissue concentrations although it is important to remember that concurrent administration of fluoroquinolones and theophylline may results in theophylline toxicity. If simultaneous administration of both drugs is necessary then the theophylline dose should be reduced by approximately 30–40%.

Cough suppressants are typically used to reduce the positive feedback cycle of cough begets inflammation and inflammation begets cough, and to improve the quality of life of the patient and owners. Over-the-counter cough suppressants are rarely effective in dogs. Narcotic cough suppressants are the most effective, with hydrocodone (0.22–0.5 mg/kg PO q6–12h) the most widely used. Butorphanol (0.5 mg/kg PO q6–12h) may also be considered as a primary cough suppressant. A human study has recently reported on the efficacy of gabapentin for control of cough in humans though data in dogs are lacking.

Prognosis

The clinical course of CCB is highly variable. In the majority of patients, permanent changes are present in the airways at the time of diagnosis, and as a result treatment is not curative. Appropriate medical management can typically help ameliorate the clinical signs and palliate the disease by stopping or slowing progression of bronchial damage. Periodic relapse of cough is not uncommon, and will frequently respond to temporary or permanent adjustment in the therapeutic regimen, or treatment of a developed concurrent illness such as pneumonia. As techniques are developed to screen for and diagnose CCB at earlier stages and more directed medical therapy is established, the prognosis for and probability of cure of CCB will improve.

Pulmonary Thromboembolism

Robert Goggs, BVSc, PhD, DACVECC, DECVECC

Cornell University College of Veterinary Medicine Companion Animal Hospital, Ithaca, NY, USA

Pulmonary thromboembolism (PTE) refers to obstruction of a pulmonary vessel or vessels by a thrombus and encompasses both *in situ* thrombus formation and embolization from elsewhere in the vasculature. In small animals, PTE is the preferred term because these mechanisms are difficult to differentiate clinically and both share a common pathophysiology. PTE is associated with numerous diseases and disorders in small animals (Table 32.1) and many patients with PTE have more than one predisposing condition. These underlying conditions can be categorized by how they affect Virchow's triad, although formation of thrombi *in vivo* typically involves more than one such effect.

The true incidence of PTE in dogs and cats is unknown but it is probably more common than the literature suggests. Difficulties definitively diagnosing PTE antemortem, limited numbers of postmortem examinations being performed, and rapid postmortem fibrinolysis mean some cases are missed. In a retrospective case series of 29 dogs with confirmed PTE, there was antemortem suspicion in less than 40% of dogs in which it was subsequently identified at necropsy. This study suggested a prevalence of PTE in dogs of 0.9% over a 10-year period. In cats, PTE was suspected in ~25% cats with respiratory signs and in only 14% of cats in which it was subsequently diagnosed postmortem. Subsequently, a 24-year prevalence of 0.06% was reported for PTE in cats.

Pathophysiology

Pulmonary thromboembolism frequently results in hypoxemia, hyperventilation, and dyspnea. Arterial hypoxemia in patients with PTE is secondary to abnormal ventilation/perfusion (V/Q) ratios within affected lungs, potentially complicated by diffusion impairment due to interstitial and alveolar edema. The V/Q mismatches occur due to small airway constriction, reduced surfactant production, and development of pulmonary edema and atelectasis. Small airway constriction occurs in both nonperfused and nonembolized areas of lung, which may lead to airway closure and alveolar collapse. Surfactant production is reduced in dogs with experimental PTE, leading to fluid transudation into alveoli (pulmonary edema). Edema may also develop in nonembolized regions due to increased hydrostatic pressure combined with increased microvascular permeability resulting from neutrophil activation. Rarely, pulmonary infarction and pleural effusion may result from complete occlusion of distal pulmonary vascular branches.

The cardiovascular consequences of PTE are dependent upon the extent of vessel occlusion. There is substantial reserve capacity in the pulmonary vasculature, which likely accounts for the subclinical nature of many PTE events. In healthy dogs, >60% of the pulmonary vasculature must be occluded before alterations in pulmonary vascular resistance (PVR) reduce pulmonary arterial flow. Reflex vasoconstriction secondary to alveolar hypoxia, humoral factors such as serotonin released from activated platelets, and neurogenic reflexes may also contribute. Significant pulmonary vascular occlusion leads to pulmonary hypertension and increased right ventricle (RV) afterload. Severe, acute changes in RV afterload result in dilation and dysfunction. As the RV dilates, the interventricular septum shifts leftward, impairing filling and reducing diastolic distensibility, a concept known as ventricular interdependence. Consequent reductions in left ventricular filling decrease cardiac output and may lead to signs of forward failure (hypotension, cardiogenic shock). If the patient survives an acute crisis but has residual pulmonary hypertension, then clinical signs of backward failure (hepatomegaly, ascites, pleural effusion) may develop over the medium to long term.

Clinical Signs

The clinical signs of PTE are variable, inconsistent, and nonspecific. The degree of physiologic impairment and thus the severity of clinical signs reflect both the magnitude of the PTE and the patient's ability to compensate. The most common signs are dyspnea, tachypnea, and depression. Other signs include coughing, hemoptysis, cyanosis, syncope, collapse, and sudden death. In dyspneic patients, physical examination may reveal harsh lung sounds and crackles suggestive of pulmonary edema. Occasionally, lung and heart sounds may be muffled due to pleural effusion or in very rare cases pneumothorax. In eupneic patients, lung field auscultation will likely be normal. On cardiac auscultation, tachycardia with a split second heart sound may be noted or, more commonly, a loud second heart sound associated with pulmonary hypertension. Signs compatible with backward heart failure (jugular distension or pulsation, ascites) or forward heart failure (poor peripheral pulse quality, pallor, prolonged capillary refill time) may be present. Complicating the picture may be clinical signs attributable to the predisposing intercurrent disease.

Clinicians should suspect PTE in patients with no history of cardiopulmonary disease who develop respiratory distress acutely, particularly where known risk factors exist.

Diagnosis

Suggested Diagnostic Approach

Pulmonary thromboembolism is commonly suspected but infrequently conclusively diagnosed, probably because of variability in clinical signs, low test specificity, and limited availability of definitive diagnostics. Establishing a clear diagnosis of PTE remains a challenge in veterinary medicine, even with a logical approach. In human medicine, where definitive diagnostics are widely available, the major challenge is to identify which patients to prioritize for definitive imaging studies. This need has driven the development of clinical prediction rules and diagnostic algorithms.

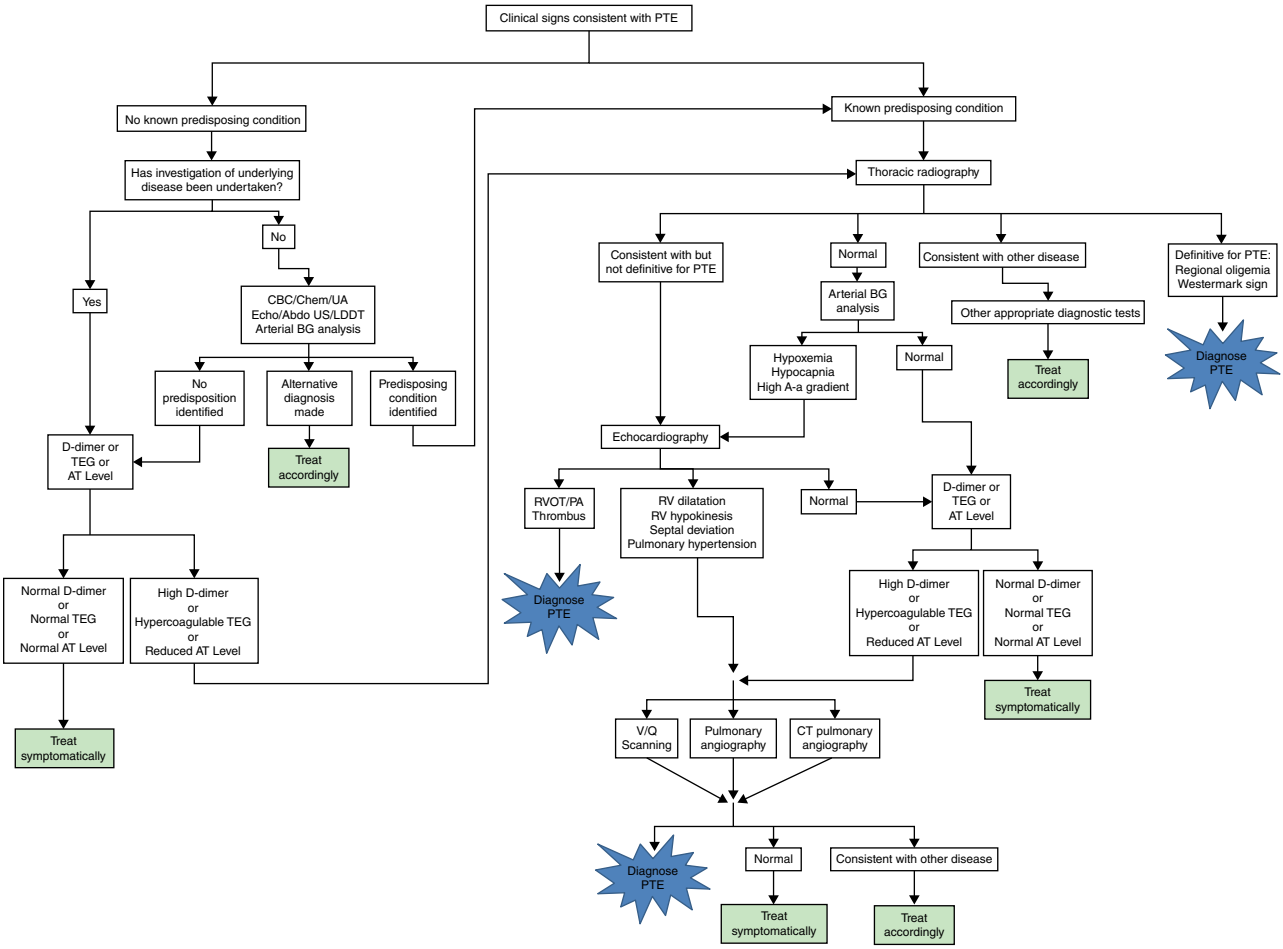

Figure 32.1 A possible diagnostic algorithm for the investigation of small animals with suspected PTE.

Patients at high risk must be identified for expedited diagnostic evaluation. A possible diagnostic schema for small animals is proposed in Figure 32.1. All patients with consistent clinical signs should undergo thoracic radiography, ideally in combination with arterial blood gas analysis. Occasionally, thoracic radiography will be diagnostic but most patients will require additional tests, particularly if arterial blood gas analysis is consistent with PTE. Echocardiography is a reasonable next step. It is noninvasive, can be performed bedside, and eliminates key differentials, clarifying which patients require advanced imaging. Cardiac biomarkers may also contribute to decision making. In patients with clinical signs but without known risk factors, coagulation testing with D-dimers, antithrombin (AT) activity, or thromboelastography (TEG) may help identify patients with evidence of thrombin activation, AT depletion or hypercoagulability, respectively. Recognition of a dyspneic, hypercoagulable patient should prompt reevaluation for predisposing conditions and mandates imaging studies for PTE.

Initial Diagnostics

Survey Thoracic Radiography

Up to 30% dogs with PTE have normal thoracic radiographs, but most small animals in the literature with confirmed PTE had abnormalities visible. This finding might reflect an inability to detect small emboli, as abnormal thoracic radiographs might only occur in severe PTE. It has therefore been suggested that PTE should be suspected in all markedly dyspneic patients with normal thoracic radiographs. Similarly, where risk factors are present, PTE should be considered as the cause of unexplained pulmonary infiltrates on thoracic radiographs.

Various radiographic abnormalities can be seen in PTE. Pulmonary infiltrates are the most common finding and are typically alveolar or alveolar-interstitial in appearance, present focally or multifocally. These infiltrates likely represent edema, atelectasis, hemorrhage or infarction and often have indistinct borders. Hypovascular lung areas are hyperlucent regions

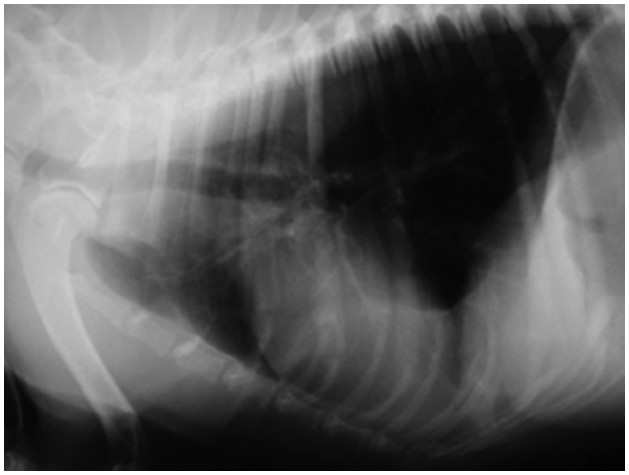

Figure 32.2 A lateral thoracic radiograph from a dog with pulmonary thromboembolism showing an area of regional oligemia (Westermark sign) affecting the right caudal lung field.

representing zones of reduced blood flow distal to sites of vascular occlusion. This finding, known as the Westermark sign (Figure 32.2), is rare but pathognomonic for PTE. Pulmonary infarcts appear as distinct pleural-based, wedge-shaped densities. Other potential abnormalities include uneven vessel diameter, pulmonary arterial enlargement, lobar vein or artery attenuation, pleural effusion, and right-sided cardiomegaly.

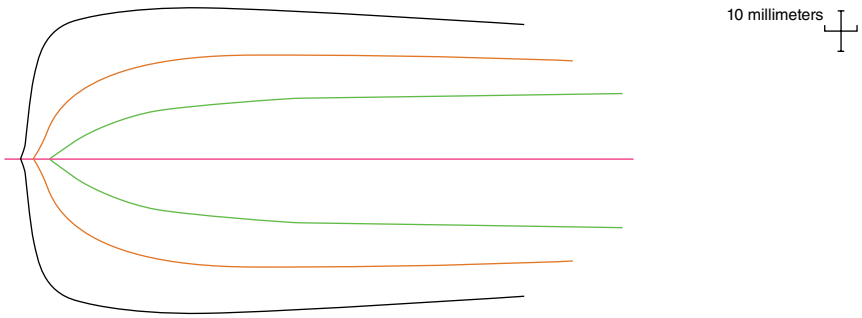
Arterial Blood Gas Analysis

Typical blood gas abnormalities associated with PTE in dogs are hypoxemia, hypocapnia, and an increased A-a gradient. In some cases, this hypoxemia may respond poorly to oxygen therapy due to intrapulmonary shunt. These findings are not specific for PTE, however, and should be interpreted in light of other data. Similarly, normal blood gas values do not rule out PTE. Using the A-a gradient may be more sensitive than solely looking for hypoxemia, since the degree of hypoxemia is proportional to the extent of thromboembolic occlusion. Arterial blood gas analysis may be useful in assessing disease severity, monitoring response to therapy, and determining prognosis. The ratio of PaO_2:$PaCO_2$ in PTE patients was highly predictive of outcome in a recent human study. Blood gas values in cats with PTE have not been reported to date but are expected to mirror those in dogs.

Risk Profiling

Antithrombin and D-Dimers

Antithrombin inhibits coagulation factors IIa, IXa, Xa, XIa, and XIIa. In patients with active thrombin production, plasma AT activity is reduced by consumption and urinary AT loss has been linked to the hypercoagulable states associated with protein-losing nephropathy and hypercortisolemia. Measuring patient levels of AT activity may allow thrombosis risk stratification. Based on extrapolations from humans, reductions of AT activity between 50% and 75% moderately increase risk, while activities below 30–50% markedly increase thrombosis risk.



Increased plasma D-dimer concentrations indicate plasmin-mediated cleavage of factor XIII cross-linked fibrin. Since D-dimers require activation of both thrombin and plasmin for their formation, they are considered more specific for thrombosis than fibrin degradation products (FDPs). Rapid, accurate, bedside D-dimer assays are integral to decision making in humans with possible PTE. People with high clinical probability scores (previous TE disease, deep vein thrombosis, dyspnea) undergo thoracic imaging without a D-dimer test. For all other people presenting with compatible clinical signs, rapid, quantitative D-dimer enzyme-linked immunosorbent assays (ELISAs) are performed prior to selection of further diagnostic testing. Positive D-dimer tests prompt thoracic imaging, while negative tests suggest no further investigation for PTE is required.

Similar guidelines for small animals cannot be formulated currently because we lack sufficient data and, more fundamentally, a convenient and highly accurate D-dimer assay is not available for small animals. Although semiquantitative latex agglutination D-dimer assays perform well for disseminated intravascular coagulation (DIC) in dogs, their sensitivity and specificity for thrombosis vary widely depending on the cut-off used. As such, this assay may be best suited to testing patients with a high index of suspicion for PTE, and a cut-off of >1000 ng/mL to minimize false positives. Unfortunately, the latex agglutination assay has limited availability and is laboratory based.

Point-of-care (POC) tests allow determination of analyte values at the bedside, enabling them to be used for clinical decision making in unstable patients. Several canine D-dimer POC tests have been evaluated for the detection of D-dimers in patients with thromboembolic disease. Of these, the NycoCard system performed the best, but all of these assays suffer from a lack of specificity for thromboembolic disease. Irrespective of the assay chosen, D-dimers should be evaluated within 1–2 hours of the suspected embolic event because in experimental canine PTE, D-dimers were increased by 30 minutes, peaked at >2000 ng/mL at 1–2 hours before falling back to control levels after 24 hours.

Viscoelastic Coagulation Testing

Whole-blood tests of coagulation such as thromboelastography (TEG), thromboelastometry (ROTEM), and the Sonoclot system graphically represent the

Events at time of trace	R time (min) 3.0–8.0	K time (min) 3.1–6.7	α angle (°) 28.0–58.9	MA (mm) 38.8–59.0	G (d/s) 3.2–7.2 k
At time of PTE	2.3	0.8	78.6	77.1	16.8 k
On LMWH	7.2	9.5	26.1	29.8	2.1 k
PLE stable on Tx	4.2	2.8	54.9	51.4	5.3 k

Figure 32.3 Tissue factor-activated thromboelastography tracings from a patient with PTE secondary to PLE. The black tracing is a markedly hypercoagulable TEG run at the time of the patient's PTE. Note the shortened reaction (R) and clot formation (K) times and the increased alpha angle (α), maximum amplitude (MA), and clot elasticity (G) values. The patient was treated with low molecular weight heparin, which significantly prolonged the R and K times and reduced the alpha and MA values (*green tracing*). A baseline (pink) is displayed for comparison. After stabilizing on therapy, a normal-looking TEG tracing was produced (*orange tracing*).

viscoelastic properties of clotting blood during clot formation and lysis. These different systems produce comparable but not interchangeable results. These techniques have been validated in small animals and are now commonly used in veterinary medicine. Using TEG/ROTEM, hypercoagulability has been identified in multiple settings in veterinary patients.

Hypercoagulable patients produce characteristic TEG/ROTEM tracings (Figure 32.3). These patients typically have short reaction and clot formation times, steep alpha angles, and large maximum amplitudes. In people, MA values derived from conventional TEG and from a rapid-TEG assay have been demonstrated to predict thrombotic risk in human surgical patients, and risk of PTE following trauma. It is unclear which (if any) of these parameters best relates to thrombotic risk in veterinary patients. It is also essential to recognize that preanalytical variables such as patient hematocrit and fibrinogen concentration in addition to sample handling and assay parameters contribute to the final TEG/ROTEM tracings.

To date, only one study has reported viscoelastic coagulation testing in small animal PTE. That study did not identify any correlation between TEG variables and PTE, but the sample size was limiting. A recent study evaluated TEG in dogs with thrombosis in various anatomic locations. This study found that although the TEG G-values of dogs with thrombosis were significantly greater than controls, half of the dogs' TEG tracings were classified as normocoagulable, suggesting that TEG may not have the discriminant power necessary to diagnose PTE. These tests likely have a place in the diagnostic work-up of possible PTE patients, but more work is needed to identify which test protocols and which parameters are most predictive of thrombotic risk. The ability of these tests to identify hypercoagulability at the point of care suggests they help identify at-risk patients who require further investigation, particularly once properly integrated into diagnostic algorithms.

Plasma-Based Coagulation Assays

Tests including the prothrombin time (PT), activated partial thromboplastin time (aPTT), activated clotting time (ACT), and fibrinogen concentration are of limited value in PTE because they may be normal, and any abnormalities are nonspecific. Similarly, abnormalities of FDPs have not been widely identified in small animals with PTE. These molecules indicate plasmin-mediated degradation of fibrinogen or fibrin has occurred. Increased FDP concentrations are present in thrombosis, but also occur in liver failure, dysfibrinogenemia, excessive fibrinolysis, and DIC, making FDPs less specific than D-dimers.

Complete Blood Counts/Serum Biochemistry

These tests are not discriminating for PTE, but serum biochemical testing may help identify predisposing conditions such as hyperadrenocorticism, protein-losing nephropathy, diabetes mellitus, or hypothyroidism. Complete blood counts may help identify a nonspecific inflammatory leukogram or myeloproliferative disorders such as polycythemia or essential thrombocytosis that can predispose to thrombosis. Secondary thrombocytosis does not predispose to PTE, although primary essential thrombocythemia may, particularly if other risk factors exist. Thrombocytopenia or schistocytosis, as markers of DIC, may increase the index of suspicion for PTE.

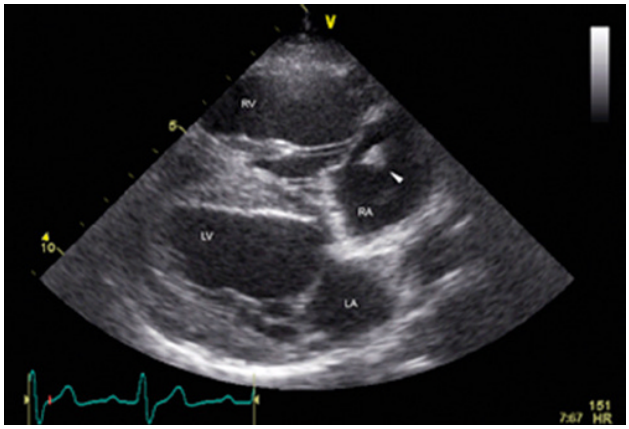


Figure 32.4 Long-axis four-chamber echocardiographic view showing a pendulous thrombus (*arrowhead*) adherent to the roof of the right atrium in this patient. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Cardiac Function Testing

Echocardiography

In people, echocardiography is not a routine diagnostic test for PTE, although case registries report echocardiography is performed in 47–74% patients. Although many echocardiography studies are normal in PTE, they may be diagnostic if cardiac or RV outflow tract thrombi are present (Figure 32.4). Where PTE is present, echocardiography can quantify the hemodynamic consequences of PTE and provides valuable prognostic information to guide patient management. Echocardiography can also identify differential diagnoses such as cardiomyopathy, endocarditis or pericardial tamponade noninvasively.

Typical echocardiographic findings in humans with PTE include right ventricular dilation and hypokinesis, septal flattening and paradoxical septal motion, diastolic left ventricular impairment, pulmonary arterial hypertension, right ventricular hypertrophy, and patency of the foramen ovale. The degree of right ventricular dysfunction is related to the cross-sectional area of the pulmonary vasculature affected; occlusion of >30% is frequently associated with RV hypokinesis. In people with severe PTE, the apex of the RV appears to be spared the hypokinesis that affects the remainder of the right ventricular free wall (RVFW). This apical sparing (the McConnell sign) is highly specific for the diagnosis of PTE in people.

There are currently few data regarding echocardiography in canine PTE because in recent retrospective studies <20% of dogs underwent echocardiography. However, it is reasonable to suspect many small animals with PTE will have abnormal echocardiograms. Typically reported findings in small animals include right atrial and ventricular enlargement, paradoxical septal motion, pulmonary hypertension, and thrombi in the heart or pulmonary artery (PA). To date, RV hypokinesis (apical sparing) has not been confirmed in dogs or cats with PTE.

Cardiac Biomarkers

In humans, echocardiographic RV dysfunction secondary to PTE is associated with elevated cardiac troponin (cTn) concentrations. A recent metaanalysis of 20 studies suggested that humans with PTE and an increased cTn level are at high risk of short-term death and adverse events. Cardiac troponins are increased in veterinary patients with primary, ischemic, congenital and degenerative cardiac and pericardial diseases, but also in gastric dilation-volvulus (GDV) syndrome, sepsis, trauma, uremia, and hyperthyroidism. Serum cTn concentrations are related to the magnitude of myocardial injury in myocarditis, GDV syndrome, and blunt chest trauma. In dogs with PTE secondary to dirofilariasis, cTnI values were significantly higher than in controls, and in dogs with experimental PTE, cTnI levels increase in proportion to the severity of occlusion as indicated by PVR and mean pulmonary artery pressure (MPAP). There is only one report on cTnI in dogs with PTE. In that small study, patients with CT-confirmed PTE did not have significantly increased cTnI values compared to dogs without PTE, but the sample size was limiting.

It seems unlikely that cTn values will be sufficiently specific to enhance the diagnosis of PTE and they may prove most valuable in assessing PTE severity and predicting complications, rather than differentiating PTE from other disease processes. In contrast to D-dimers, which peak at 1–2 hours after PTE, cTnI levels peak at eight hours post embolism in people and are most diagnostically accurate at this time point. The availability of POC tests for cTn in dogs makes accurate timing of this assay a viable proposition.

Atrial and B-type natriuretic peptides are produced by cardiac muscle and released in response to volume overload, hypertrophy, and hypoxia to elicit natriuresis and vasodilation. Assays of BNP or the metabolic by-product NT-proBNP are used to diagnose cardiac disease, differentiate respiratory from cardiac disease, assess severity, and guide management. In PTE, NT-proBNP concentrations are closely related to the degree of RV dysfunction, and this likely underpins their relationship with adverse events and outcome in people with PTE. No studies on NT-proBNP measurement in small animal PTE have been reported to date. As with cTn, it is likely that concentrations of NT-proBNP will be increased. The discriminant ability of this test in small animal PTE remains an open question. Currently, the principal limitations of the NT-proBNP test are the *ex vivo* stability of the analyte which is time and temperature dependent, and the lack of a POC test for dogs. Once a bedside test for dogs

becomes available, NT-proBNP may become integral to the evaluation of these patients.

Electrocardiography

Electrocardiographic abnormalities are likely uncommon in acute PTE. The most likely alteration is sinus tachycardia secondary to sympathetic stimulation associated with hypotension or hypoxemia. Myocardial hypoxia or cardiac hypertrophy may cause ST segment depression or slurring. Only with chronic pulmonary hypertension will ECG morphology changes occur, reflecting right ventricular compromise (right axis deviation, increased amplitude of S-, T- or P-waves).

Definitive Diagnostic Imaging

Computed Tomography Pulmonary Angiography

Rapid, multislice helical CTPA is key to diagnosis of PTE in human medicine, and is now integral to PTE diagnosis in small animals too. These studies are obtained by performing rapid, spiral thoracic CT concurrent with bolus injection of contrast media. The contrast agent is infused through a peripheral catheter using a pressure injector, linked electronically to the scanner to ensure peak enhancement of the pulmonary arteries.

Diagnostic criteria for PTE using CTPA are failure to enhance the entire arterial lumen due to occlusive filling defects, partial filling defects surrounded by contrast material, producing the "polo mint" or "railway track" signs, and peripheral intraluminal filling defects that form acute angles with the arterial wall (Figure 32.5). A normal CTPA study essentially rules out PTE as the cause of the patient's respiratory distress, unless the index of suspicion is very high.

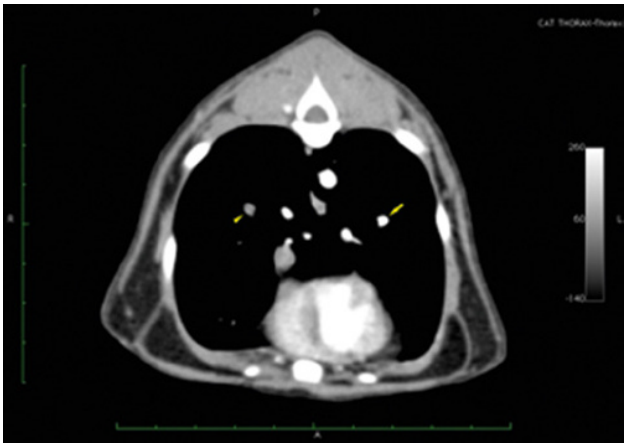

Figure 32.5 A transverse CT angiographic image of the heart and main pulmonary arteries from a cat with PTE. Right is on the left of the image. There is a strongly attenuating signal from contrast medium in the heart and in the left pulmonary artery (*arrow*), but there is substantially lower attenuation by the right pulmonary artery (*arrowhead*) due to an occlusive thrombus, which has prevented the entry of contrast material.

Single-channel CTPA has been used for experimental PTE diagnosis and investigation of PTE following total hip arthroplasty. No emboli were identified in the arthroplasty patients, but the authors stated that the CTPA protocol enabled consistent diagnostic quality acquisition visualization down to fifth-generation PA branches.

Multidetector row CT is also increasingly available in veterinary medicine. These multislice CT scanners permit imaging of the whole thorax in sedated patients without the need for breath-hold techniques to eliminate motion artifact. Multidetector CTPA has been reported in dogs using 16-slice and 64- slice scanners, and protocols to maximize PA contrast enhancement have been published. Although the majority of publications to date have focused on normal patients, multidetector CT angiography has been successfully used to detect PTE in experimental dogs, to identify a descending aortic thrombus secondary to spirocercosis in a dog and in dogs with PTE secondary to immune-mediated hemolytic anemia (IMHA).

MRI and Clot-Labeling Techniques

The use of magnetic resonance imaging (MRI) in the diagnosis of PTE is still in its infancy, but recently this technology has been used for angiography in dogs. The safe, noninvasive nature of MRI offers potential advantages over CT – lack of ionizing radiation and no need for iodinated contrast material. However, the need for cardiac gating and, more importantly, a requirement for general anesthesia limit the utility of MRI-based techniques in unstable veterinary patients. Nevertheless, MR angiography appears comparable to CTPA in experimental studies in dogs.

Direct thrombus imaging techniques have also been developed. Clots can be imaged by identifying the thrombus degradation product methemoglobin via a heavily T1-weighted image. Clot-labeling techniques utilizing radiolabeled antibodies against P-selectin, D-dimers or GPIIIa have been performed experimentally in dogs. The feasibility and utility of these techniques remain uncertain and they may be best suited to more stable patients, patients in whom CTPA is equivocal or those with specific contraindications to iodinated contrast material use.

Other Imaging Modalities

Selective pulmonary angiography is now largely obsolete in human medicine. Since selective pulmonary angiography involves the risk of general anesthesia and

the technical difficulty of PA catheter placement, it has been largely supplanted by CTPA in small animals.

Ventilation–perfusion (V–Q) scanning has been used for the detection of PTE in small animals. Perfusion scanning is performed after IV injection of technetium-labeled macroaggregated albumin (^{99m}Tc-MAA). Inhomogenous pulmonary vascular distribution of activity from the decay of ^{99m}Tc-MAA is consistent with PTE. Although radionuclide labeling of inspired air to assess ventilation is possible, typically perfusion scans are compared against thoracic radiographs to identify pulmonary pathology. Photopenic wedge-shaped, pleural-based defects with a lobar or segmental distribution are classic for PTE, but entire lung lobes may appear photopenic, or if multiple small emboli are present, then a mottled pattern may result.

Computed tomography pulmonary angiography has largely replaced V–Q scanning in human medicine. A prospective evaluation of PTE diagnosis (PIOPED II) suggested that V–Q scanning was indicated for just a small subset of the population presenting with suspected PTE. In light of this, and the limited availability of equipment and expertise, it is likely few V–Q scans will be performed in small animals in future.

Management

In people, risk stratification based on clinical assessment, oxygenation status, anatomic clot size, cardiac function, and biomarkers underpins successful treatment. Anticoagulant therapy alone is recommended for low-risk patients, while patients with hypotension secondary to PTE are treated with thrombolytics followed by anticoagulation. The optimal strategy for management of PTE in small animals is not known because of the scarcity of specific information in the veterinary literature. Tailored supportive treatment for PTE patients is easy to recommend. When PTE is definitively diagnosed or the index of suspicion is sufficiently high then antithrombotic therapy is also warranted. Successful treatment for acute PTE is typically followed by chronic antithrombotic therapy and should be accompanied by management of any underlying predisposing disorder.

Supportive Therapy

For some patients, PTE is rapidly fatal irrespective of therapy. In normal dogs, thrombi lyze rapidly so supportive therapy buys time for fibrinolysis to occur. All dyspneic patients should receive oxygen therapy. Positive pressure ventilation (PPV) should be considered as a last resort if oxygen therapy cannot resolve hypoxemia, with efforts made to minimize the detrimental impact of PPV on PVR, which will already be increased in these patients. Caution must be exercised with fluid therapy, because RV overdistension impairs coronary perfusion and LV preload. Echocardiography to determine RV filling may help determine if fluid administration is likely to be beneficial.

Theophylline may be beneficial as a bronchodilator and through pulmonary vasodilation, improved diaphragmatic contractility, and reduced respiratory muscle fatigue. Positive inotropes such as dobutamine may be necessary in cardiogenic shock, but can increase MPAP and cause arrhythmias. Reflex pulmonary vasoconstriction increases PVR in PTE. Inhaled nitric oxide (NO) acts as a vasodilator, decreasing MPAP and improving hemodynamics in PTE, but has not been used clinically in small animals as yet, and is cost-prohibitive. In dogs, sildenafil has beneficial effects in pulmonary hypertension, and in canine PTE models it reduces MPAP through selective pulmonary arterial vasodilation. In people, sildenafil has beneficial effects in both acute PTE and the treatment of chronic PTE-induced pulmonary hypertension. Although sildenafil has not been reported in small animal PTE to date, it should be considered if pulmonary hypertension is documented echocardiographically. Potential side-effects include vomiting and systemic hypotension, and co-administration with heparin may increase the risk of hemorrhage.

Thrombolysis

Therapeutic thrombolysis is the administration of supraphysiologic doses of plasminogen activators systemically or directly at the thrombus site to accelerate plasmin generation and induce thrombus dissolution. Thrombolysis in PTE aims to reverse right heart failure, improve systemic and pulmonary hemodynamics, limit neurohumoral activation, and reduce recurrence. Available drugs include alteplase, reteplase, and tenecteplase. These drugs have distinct pharmacokinetics, thrombolytic activities, and fibrin specificities. Veterinary experience with thrombolytics is limited and is predominantly in the field of feline aortic thromboembolism (ATE). A recent prospective clinical trial of tissue plasminogen activator (t-PA) in cats with ATE highlighted the risks of side-effects associated with these agents. Although efficacious in >50% cats, all 11 patients in the study suffered side-effects, many attributable to reperfusion injury.

The t-PA products are fibrin specific, activating fibrin-bound plasminogen more rapidly and more effectively than plasminogen in circulation. At pharmacologic concentrations, however, a systemic lytic state can still occur and all t-PA products are associated with a risk of hemorrhage in humans. Alteplase has the shortest half-life of the available recombinant thrombolytics.

Alteplase has been successfully used in one dog with ATE, and experimentally induced canine PTE has been treated with t-PA therapy.

Currently, the American College of Clinical Pharmacology (ACCP) recommends thrombolytic therapy for people with hypotension secondary to acute PE. Thrombolysis in PTE in the absence of hypotension is not currently recommended, but could be considered in patients with echocardiographic evidence of cardiac dysfunction or in those with high cTnI or NT-proBNP concentrations. A recent trial of normotensive PTE patients with biomarker and echocardiographic evidence of myocardial damage and dysfunction evaluated thrombolysis with tenecteplase. Thrombolysis in these patients significantly reduced the rate of death due to hemodynamic collapse, but at the cost of a significant increase in major bleeding events.

Where thrombolytic agents are used, the ACCP recommend they be administered over a short time period via a peripheral catheter rather than a PA catheter. Case registry data suggest thrombolytics are used in only 30% of people with massive PTE. In veterinary medicine, no consensus on their administration exists and clinicians must determine the potential benefits and risks of administration for individual patients. Recent advances in small animal interventional radiology may provide novel methods or routes for thrombolysis in future. Based on the ACCP guidelines, thrombolytic therapy should only be considered in veterinary patients with hemodynamically unstable acute PTE and where continuous hemodynamic monitoring is available. In appropriate cases, fibrin-specific drugs with short half-lives (e.g., alteplase) are preferred.

Antithrombotic Strategies

In PTE anticoagulants and antiplatelet agents are administered to minimize thrombus propagation, which can be stimulated by embolization, and to reduce risk of recurrence. However, the optimal antithrombotic strategy for small animals is not known. Some suggest that PTE should be managed with anticoagulant drugs and that antiplatelet agents are not appropriate. Viewing arterial and venous thrombosis as separate pathophysiologic entities is likely an oversimplification, however, and there is evidence of overlapping efficacy of antiplatelet and anticoagulant agents in the treatment of both venous and arterial thromboembolic conditions. Platelets are integral to the cell-based model of hemostasis, and thrombocytosis is associated with an increased risk of PTE in people. In venous thrombosis, tissue factor-mediated secondary coagulation precedes platelet activation, but both arms of the hemostatic system are activated, which correlates with the architectural and pathophysiologic features shared by both venous and arterial thrombi.

Anticoagulants remain the mainstay of antithrombotic therapy for people with PTE, however. In people with PTE, the ACCP recommends initial parenteral anticoagulation with low molecular weight heparin (LMWH) or fondaparinux except where renal insufficiency, thrombolytic therapy or poor perfusion mandate the use of IV unfractionated heparin (UFH). Ongoing anticoagulation for people with PTE is recommended for three months, although this may be extended in certain cases. Since the advent of the orally active direct Xa inhibitors and direct thrombin inhibitors, most people are now maintained on these newer medications. The direct oral anticoagulants (DOACs) have equivalent efficacy to warfarin but are associated with significantly lower bleeding risk.

To date, there are no clinical trials of anticoagulants in PTE in small animals on which to base recommendations. Although there is not universal consensus on dosage, frequency of administration or monitoring strategy for antithrombotics in small animals, ongoing efforts by the American College of Veterinary Emergency and Critical Care led to guidelines being published in January 2019. As a result of improved understanding and the availability of the DOACs, long-term anticoagulation in veterinary medicine is becoming increasingly common. The narrow therapeutic index of warfarin has led to increasing use of the DOACs in dogs and cats. Individual patient monitoring and dose adjustment of UFH and LMWH may enhance efficacy and improve safety and is possible using commonly available assays.

Anticoagulants

Unfractionated heparin, a heterogenous mixture of polysaccharides, complexes with and amplifies the inhibitory activity of AT against factor IIa (thrombin) and factor Xa, although factors IXa, XIa, XIIa, and XIII are also inhibited. Thrombin inactivation prevents fibrin formation and reduces thrombin-induced platelet activation. Variation in the size distribution of heparin molecules in UFH and unpredictable bioavailability in critical illness cause variation in heparin dose–responses, necessitating therapeutic monitoring since severe bleeding complications can result from exceeding the therapeutic range. Therapeutic monitoring can be performed using the ACT, aPTT, thrombin generation, viscoelastic testing, or anti-FXa levels. This need for therapeutic monitoring reduces the cost benefit of UFH, but individually adjusted dosing may offer benefits over fixed dosing.

Low molecular weight heparins derive from depolymerization of UFH and were developed to provide more consistent pharmacokinetic/pharmacodynamic (PK/PD) profiles than UFH. The reduced size of the LMWH polysaccharides limits their ability to simultaneously bind AT

and thrombin. Thus, LMWHs are principally anti-FXa agents and are probably best monitored with anti-Xa assays, although tissue factor (TF)-activated TEG can also be used. LMWHs are less protein bound than UFH, and have more predictable PK profiles and better bioavailability after SC injection. The PK profiles of distinct LMWHs preparations are not interchangeable, however. LMWH PKs have been evaluated in normal healthy dogs and therapeutic anti-Xa levels extrapolated from people are achievable. LMWH PKs in cats are less predictable, however, with frequent administration of high dosages necessary to achieve target anti-FXa activities. A recent study evaluated the *ex vivo* antithrombotic effect of enoxaparin in a venous stasis model in cats, comparing it to anti-Xa activity. The study found that at peak (but not at trough) plasma levels, enoxaparin significantly reduced thrombus formation, but in this model there was little correlation between antithrombotic effect and anti-Xa activity. Clearly, well-designed clinical studies evaluating LMWH in naturally occurring PTE in dogs or cats are urgently needed.

Fondaparinux is a synthetic, AT-dependent selective FXa inhibitor with no anti-FIIa activity. In people with acute PTE, fondaparinux administration reduces PTE recurrence rate compared with UFH without increases in major bleeding, and is at least as effective as enoxaparin in this setting. In dogs to date, fondaparinux has only been studied in experimental settings. In cats, a recent dose-finding study found that SC administration of 0.06–0.20 mg/kg q12h was sufficient to achieve peak plasma anti-Xa activity deemed therapeutic in humans.

Warfarin is an oral anticoagulant that inhibits vitamin K epoxide reductase, interrupting the recycling of vitamin K epoxide to hydroquinone and depleting the supply of carboxylated clotting factors II, VII, IX, and X. Warfarin is the mainstay for oral anticoagulation in people but maintaining adequate anticoagulation without hemorrhagic complications is challenging. The drug has a narrow therapeutic index, variable patient dose–response and numerous interactions with other drugs, necessitating close therapeutic monitoring. As a result, the Consensus on the Rational Use of Antithrombotics in Veterinary Critical Care (CURATIVE) guidelines published in January 2019 advise against the use of warfarin in small animals.

The difficulties associated with the clinical use of vitamin K antagonists generated a need for effective, safe, novel oral anticoagulants. Rivaroxaban is an oral, small molecule, direct FXa inhibitor that can inhibit both free and prothrombinase complex-associated FXa. This drug can be monitored using the PT or aPTT. Rivaroxaban was recently approved by the FDA for PTE following demonstration of equivalent efficacy to standard therapy with enoxaparin and warfarin. The pharmacokinetics of rivaroxaban has been studied in dogs, and it is reported to be an effective anticoagulant in healthy dogs. Its clinical use has been reported in a small case series, but it has not been evaluated in a randomized clinical trial.

The oral prodrug dabigatran etexilate is a potent, reversible direct thrombin inhibitor. This class of drugs do not require AT as a co-factor for their anti-IIa activity and are also able to inhibit thrombin bound to formed clot. Dabigatran can be monitored with the PT, aPTT or the preferred ecarin clotting time (ECT) in canine plasma. Dabigatran is FDA approved for thromboembolism in AF and in other countries for VTE and has a similar efficacy and safety profile to warfarin for the treatment of acute symptomatic VTE. To date, no studies have examined the effects of dabigatran in small animals.

Antiplatelet Agents

In small animals, antiplatelet agents are principally used for long-term oral maintenance therapy or as thromboprophylaxis for at-risk patients. Oral antiplatelet agents available for small animals include aspirin, ticlopidine, and clopidogrel, although concerns over myelotoxicity associated with ticlopidine have led to it being largely superseded by clopidogrel. There is limited evidence of efficacy for either aspirin or clopidogrel in veterinary medicine, however.

The COX-1 inhibitor aspirin irreversibly inhibits platelet thromboxane A_2 (TXA_2) synthesis, inhibiting platelet function. Aspirin is the primary antithrombotic therapy for people with atherosclerotic disease, but the populations of small animals which would most benefit from aspirin therapy are unknown. Aspirin has been recommended for dogs with protein-losing nephropathy, nephrotic syndrome, and IMHA. The use of aspirin in IMHA is contentious, however.

To date, no studies have been performed in veterinary medicine evaluating the efficacy of aspirin against objective measures of thrombosis or comparing the efficacy of aspirin against other antithrombotic therapies, but one such study is reportedly under way. The dose required to cause *in vitro* or *ex vivo* inhibition of canine platelet function varies with the assay used, but is in the range of 0.5–20 mg/kg. This wide range may be related to heritable variability in canine thromboxane responsiveness. A recent study suggested that 1 mg/kg/day aspirin consistently inhibited platelet function in only a third of dogs and higher dosages may be required to obtain a consistent effect.

The thienopyridines ticlopidine and clopidogrel are both produgs that rely on active metabolites for their *in vivo* efficacy. The active metabolite of clopidogrel causes cumulative inhibition of platelet function following repeated daily administration. In humans, clopidogrel may be marginally more effective than aspirin,

while combining both agents may produce beneficial additive effects. The clinical activity and pharmacodynamics of clopidogrel have been evaluated in cats and in dogs and significant antiplatelet effects are achievable in both species. A recent multicenter double-blinded prospective study comparing aspirin with clopidogrel in cats with ATE demonstrated superior efficacy for clopidogrel compared to aspirin, suggesting that clopidogrel should be the first-choice antiplatelet agent in cats.

The parenteral GPIIb/IIIa inhibitors abciximab, eptifibatide, and tirofiban, which antagonize the platelet fibrinogen/vWF receptor, have been used in canine experimental model settings of myocardial infarction and coronary stent thrombosis. Of these agents, only abciximab has been used safely in cats. Eptifibatide causes fatal cardiotoxicity in cats and should be avoided. All three drugs effectively inhibit canine platelet aggregation, but none has been used in veterinary medicine. Barriers to their clinical use include cost, risk of hemorrhage, and the need for administration by continuous infusion.

Conclusion

Despite recent advances in human and veterinary medicine, PTE remains a challenging diagnosis to confirm. A thorough, logical diagnostic approach should incorporate assessment of clinical probability, identification of risk factors and disease biomarkers, and appropriate application of diagnostic imaging, principally echocardiography and multislice CTPA. Many of these diagnostic steps remain to be prospectively investigated in veterinary medicine.

Since PTE carries a poor prognosis and is potentially fatal, the importance of early detection cannot be overstated. Once we can more consistently confirm the diagnosis of PTE in small animals, therapeutic clinical trials of thrombolytics, anticoagulants, and antiplatelet agents will be essential in order to improve our treatment of this condition. Until such time, therapy for PTE should consist of close monitoring, good supportive therapy and judicious, individualized empiric use of thrombolytics and antithrombotic agents.

Surgical Approaches to Thoracic Disease

Raegan Wells, DVM, DACVECC

Phoenix Veterinary Referral and Emergency Center, Phoenix, AZ, USA

Thoracotomy is commonly performed in critically ill small animal patients with disease of the pulmonary parenchymal structures, intrathoracic cardiovascular system, pleural space, thoracic wall, mediastinum, or esophagus. Aside from the underlying disease process, the thoracotomy procedure has the potential to induce several negative effects that can be detrimental without appropriate intensive monitoring and care. This chapter discusses the pathophysiologic effects of thoracic surgery, thoracostomy tube care, postoperative monitoring, overall case management strategies, and potential complications incurred in postoperative thoracotomy patients.

Pathophysiology of Thoracotomy

The most common surgical approaches to the thoracic cavity include intercostal thoracotomy, median sternotomy, and transdiaphragmatic incisional thoracotomy. Regardless of technical approach, some pathophysiologic consequences of entering the thoracic cavity may include atelectasis, hypoxemia, hypoventilation, hypotension, hypothermia, cardiac arrhythmias, pain, and continual pneumothorax or effusion.

The four distending forces of the lungs that prevent collapse under normal conditions are transpulmonary pressure (the difference between alveolar and pleural pressure), tethering of the lungs to the surrounding structures, pulmonary surfactant, and the nitrogen skeleton. During thoracotomy, there is disruption of the natural subatmospheric pleural and transpulmonary pressure. Thoracotomy induces a positive pleural pressure which exceeds the alveolar pressure and this alteration from normal physiology rapidly leads to atelectasis. Nitrogen wash-out occurs secondary to oxygen supplementation, which results in absorption atelectasis. This occurs as the native nitrogen skeleton is washed out by the greater than 21% FiO_2, leading to a loss of the natural nitrogen skeleton that helps maintain normal alveolar distension. It is important to emphasize that oxygen supplementation is necessary during the thoracotomy procedure, and strongly recommended in the postoperative period. Nitrogen wash-out is, however, an important pathophysiologic contributing factor to atelectasis in the thoracotomy patient. Prolonged lateral recumbency may lead to pressure atelectasis, which results in significant low ventilation–perfusion (V–Q) mismatching and intrapulmonary shunting. Hypoxemic pulmonary vasoconstriction is the natural defense mechanism to improve V–Q mismatching under such conditions. This emphasizes the importance of body positioning and frequent rotation of recumbent patients in the immediate postoperative period.

Hypoxemia and Hypoventilation

Postthoracotomy hypoxemia can result from many etiologies, including hypoventilation, V–Q mismatching, and diffusion impairment. Delivery of oxygen (DO_2) is the product of arterial oxygen content (CaO_2) and cardiac output. In relation to hypoxemia, arterial oxygen content is dependent upon hemoglobin concentration (g/dL) and saturation as well as the partial pressure of dissolved oxygen (PaO_2).

Hypoventilation is defined as a $PaCO_2$ greater than 45 mmHg in the dog or 40 mmHg in the cat. Common causes of hypoventilation in postthoracotomy patients include pain, residual anesthetics, respiratory fatigue, loss of chest wall elasticity, decreased total pulmonary compliance, increased airway resistance, and increased dead space ventilation. There is an approximate 1:1 ratio to explain hypoxemia due to hypoventilation. That is, for every 1. mmHg elevation in $PaCO_2$, there is a corresponding 1.0 mmHg decrease in PaO_2. Calculation of the alveolar to arterial oxygen gradient can be performed to rule out pulmonary pathology as the cause for hypoxemia.

Decreased transpulmonary pressure, pain, and recumbency impede proper ventilation via atelectasis and decreased tidal volume. As previously mentioned, gravitational forces may cause significant atelectasis and decreased alveolar ventilation within the dependent lung, but perfusion is maintained (or even increased) within these pulmonary segments. The overall net result in this situation is moderate to low V–Q mismatching and hypoxemia.

Finally, hypoxemia following thoracotomy may also result from a combination of diffusion impairment and low V–Q mismatch secondary to reexpansion pulmonary edema or increased pulmonary vascular hydrostatic pressure. The pulmonary vasculature possesses significant permeability to protein compared to the extrapulmonary blood vessels. Since there is less intravascular oncotic pressure within this vascular circuit, elevated intrapulmonary hydrostatic pressure will favor the movement of fluid into the alveolar and interstitial space relatively quickly. Thus, pulmonary hydrostatic pressure is the main determinant for the development of pulmonary interstitial fluid accumulation and subsequent edema.

Net filtration in the pleural cavity (pleural effusion) is dependent upon the capillary hydrostatic pressure of the visceral and parietal pleura, intrapleural hydrostatic pressure, plasma oncotic pressure, and intrapleural oncotic pressure. Unlike the low pulmonary interstitial to vascular space oncotic gradient, a substantial gradient is generated within the pleural space. The normal colloid osmotic pressure (COP) of the pleural space is 3.2 cmH_2O (compared to 24.5–27.0 peripherally) with the average pleural pressure being –5 cmH_2O.

Hypothermia

Hypothermia is a common occurrence during and immediately following thoracotomy. With either median sternotomy or lateral thoracotomy, the pleural (visceral and parietal) body surface area is exposed to relatively cool ambient temperatures. This results in loss of body heat via evaporation and to some extent convection. Unimpeded hypothermia can have serious detrimental cardiovascular, respiratory, acid–base, and coagulopathic effects.

Arrhythmias

Cardiac arrhythmias may be observed during and subsequent to thoracotomy. Intraoperative cardiac arrhythmias may result from manual cardiac manipulation and are typically ventricular in origin. Postoperative arrhythmias, however, are classically secondary to underlying pathophysiology including pain, hypoxemia, or physical irritation from thoracostomy tube(s). Common arrhythmias include sinus tachycardia, accelerated idioventricular rhythm, bundle branch blocks, and ventricular tachycardia.

Hypotension

Postoperative hypotension is a common challenge for clinicians caring for patients following thoracotomy. Similar to the transpulmonary pressure gradient, subatmospheric pleural pressure is also important to maintain vascular distension within the thoracic cavity.

During a normal breath, the elastic recoil of the lungs upon inhalation allows distension of the large intrathoracic vessels (caudal and cranial vena cava), promoting venous return and thus increasing preload. Positive intrathoracic pressure exerted during exhalation causes mild collapse of these vessels, resulting in slight changes in pulse pressure between inspiration and expiration. During mechanical ventilation, the opposite effect occurs. With positive pressure ventilation, the majority of venous return occurs during expiration, not inspiration. Anesthesia along with underlying pulmonary pathology often necessitates the use of positive end-expiratory pressure (PEEP). Baseline PEEP is generally set at 5.0 cm H_2O, but decreased pulmonary compliance and atelectasis often require higher values of PEEP. Constant, low-grade, positive intrathoracic pressure, as PEEP increases, further impedes venous return, resulting in significant reductions in cardiac preload. Decreased preload leads to compromised stroke volume, cardiac output, and subsequent reduced delivery of oxygen. Positive pressure ventilation also has beneficial effects as it decreases afterload during inspiration, although this can be offset by dramatic decreases in preload.

Pain

Postoperative pain control is of critical importance following median sternotomy or lateral thoracotomy. Both of these procedures induce pain. In addition to surgical trauma, all postthoracotomy patients have an indwelling thoracostomy tube(s) that is a frequent source of pain. Hypoventilation and hypoxemia may be a direct result of pleurodynia, incisional pain, or thoracostomy tube-induced discomfort. Some patients are unwilling or unable to maintain an adequate tidal volume due to painful thoracic expansion. Hypoventilation secondary to pain may also contribute to significant atelectasis resulting in hypoxemia secondary to V–Q mismatching.

Continual Effusion and Pneumothorax

The goal of thoracic surgery is generally to palliate or resolve the underlying disease process to improve cardiopulmonary, vascular, or esophageal function. Often, the underlying disease process may not be immediately terminated post thoracotomy, such as chylothorax,

pyothorax, or pneumothorax. In such cases, thoracostomy tubes remain in place for several days following surgery for continual thoracic evacuation and fluid sampling. Occasionally, continual effusion or pneumothorax occurs postoperatively, exceeding expected volumes.

Predictable pleural effusion secondary to an indwelling thoracostomy tube should approximate 2.0 mL/kg/day. Fluid production above this may represent continual disease. Fluid analysis, including cell counts and cytology, can help the clinician assess if the fluid is reflective of ongoing disease. If cell counts and cytology do not support ongoing inflammation, infection or neoplasia, then it is possible that the ongoing fluid production is related to a systemic vasculitis, low oncotic pressure or elevated hydrostatic pressure. The pleural space volume is approximately 100–140 mL/kg in small animals. As such, when volumes of air or fluid exceed this value, it can be classified as a continuous process (e.g., continuous pneumothorax).

Thoracostomy Tubes

Thoracostomy tubes are a mainstay in the management of postthoracotomy patients. Depending on patient stability, a thoracostomy tube may be placed preoperatively or intraoperatively. Patients with viscous thoracic effusions or large-volume pneumothoraces may require bilateral thoracostomy tube placement.

Conventional thoracostomy tubes consist of large-bore plastic tubing made from silicone or polyvinyl chloride. Soft, small-bore thoracostomy tubes (e.g., Mila®, Mila International) that can be placed using a percutaneous catheter and guidewire are preferred by many emergency and critical care clinicians. The small bore tubes can be placed with ease and minimal risk to the patient either pre or intra-operatively. The smaller diameter low profile thoracostomy tubes are effective for all disease processes, including viscous effusions such as pyothorax. A cadaver study evaluating traditional large bore chest tubes to small bore tubes in efficiency to remove air, low viscosity fluid and high viscosity fluid found that small bore tubes were as effective as large bore tubes. It is the authors' opinion that the more traditional larger diameter tubes should be very rarely utilized, and that these tubes contribute to patient discomfort without providing any significant advantage with regards to evacuating the pleural space.

Postoperative Monitoring

Intensive postoperative monitoring is imperative following thoracotomy. Ideal monitoring would include electrocardiography, direct arterial blood pressure measurement, pulse oximetry, and arterial blood gas analysis, as well as end-tidal CO_2 and tidal volume in patients requiring continued mechanical ventilation.

Electrocardiography

Electrocardiographic monitoring provides early detection and continuous monitoring of cardiac arrhythmias. Postoperative arrhythmias may be observed primarily as a result of surgical trauma, prior manual cardiac manipulation, or direct pericardial or epicardial irritation from the indwelling thoracostomy tube. Arrhythmias may also occur secondary to pain, hypoxemia, hypovolemia, or electrolyte imbalances. Observation of hemodynamically significant postoperative atrial or ventricular arrhythmias necessitates therapeutic intervention including supplemental oxygen therapy, aggressive analgesia, correction of hypovolemia and electrolyte imbalance, and possibly antiarrhythmic medications. Diagnostic evaluation of postoperative arrhythmias may include electrolyte measurement, arterial blood gas analysis, and echocardiography.

Arterial Blood Pressure

As mentioned, changes in transpulmonary and pleural pressures can have significant hemodynamic effects. Direct arterial blood pressure measurement is the gold standard for monitoring patient stability and diagnosing changes in intrathoracic pressure. A sudden reduction in blood pressure may indicate an acute increase in pleural pressure, such as pneumothorax, warranting immediate investigation. Central venous pressure (CVP) monitoring can guide fluid therapy for postthoracotomy patients, but CVP is known to be affected by changes in intrathoracic pressure due to respiration, PEEP, and abdominal hypertension as each of these is known to decrease right ventricular compliance and thus artificially augment CVP. For these reasons, routine measurement of CVP in the postoperative patient with significant pleural space disease is not recommended.

Pulse Oximetry and End-Tidal CO_2

Pulse oximetry can provide valuable information regarding arterial hemoglobin saturation but it can also be affected by multiple patient factors. End-tidal CO_2 ($ETCO_2$) and tidal volume are helpful monitoring tools in the postthoracotomy patient requiring extended intubation and mechanical ventilation. Changes in $ETCO_2$ may be the first indicator of acute deterioration such as a large pulmonary thromboembolism or cardiopulmonary arrest in these critical patients, emphasizing the importance of capnography.

Arterial Blood Gas Analysis

Arterial blood gas analysis is paramount in patients with pulmonary dysfunction, as it will provide rapid identification of hypoxemia, hypoventilation, and respiratory failure. When arterial access is unobtainable, central venous ($S_{cv}O_2$) or mixed venous (S_vO_2) oxygen saturation as well as venous CO_2 ($PvCO_2$) can be extrapolated to evaluate respiratory function. Normally, $S_{cv}O_2$ is 10–15% higher than S_vO_2 but in states of circulatory shock or failure, these two measurements closely parallel one another. The normal arterial-venous gradient for PCO_2 is 4–6 mmHg, but it may approach 10 mmHg in some patients. This allows for serial ventilatory monitoring via venous blood sampling.

Postoperative Management

Intense postoperative management following thoracic surgery comprises adequate analgesia, appropriate thoracostomy tube care, intravenous fluid therapy, and intensive nursing care. Supplemental oxygen therapy is often implemented in the immediate postoperative period and occasionally continued mechanical ventilation is required.

Analgesia

Optimal analgesic protocols are critical for the postthoracotomy patient to prevent secondary hypoxemia, hypoventilation, and cardiac arrhythmias. Multimodal analgesia is preferred to avoid noxious effects of single-agent protocols. Combination therapy of systemic analgesics allows for synergistic analgesia and lower dosing of each chosen drug. Local analgesia including intercostal nerve blocks, incisional diffusion catheters, and intrapleural infusion of local anesthetics via the thoracostomy tube provides effective adjunctive analgesia. Intercostal nerve blocks can provide very effective analgesia when utilized for lateral thoracotomy. It is recommended to perform the procedure at the intercostal space of the incision, one space cranial and one space caudal to the incision. As discussed later, much of the postoperative pain seems to be associated with large-bore thoracostomy tubes.

Thoracostomy Tube Management and Pleural Drainage

Thoracostomy tubes generally remain in place for 12–24 hours post thoracotomy in patients without ongoing pleural space disease, but certain circumstances may necessitate maintenance beyond this timeframe due to continual effusion, residual pneumothorax, and for therapeutic lavage or delivery of chemotherapeutics. Pleural drainage may be passive or active, but active drainage is more commonly implemented in veterinary patients. The normal transpulmonary pressure is 4–8 mmHg, which is equivocal to 5–10 mL of suction in a syringe. Intrapleural infusion, via the thoracostomy tube, of lidocaine and bupivacaine (1.0 mg/kg each) provides local analgesia following intermittent suction and may be performed every 4–6 hours. The rationale behind using both lidocaine and bupivacaine is that the lidocaine provides immediate relief and allows for a more comfortable infusion of the longer-acting bupivacaine. This method of analgesia delivery has been investigated and deemed safe in patients following pericardectomy.

Intermittent active suction is applied often postoperatively, but continuous active suction may be necessary for larger volumes of air or effusion which compromise ventilation. The pleural space in small animals can accommodate approximately 100–140 mL/kg of fluid or air. Beyond this volume, continuous pneumothorax or hydrothorax (usually hemothorax) should be suspected. Obstruction of the thoracostomy tube may rarely occur, depending on tube diameter and viscosity of the thoracic effusion. The Mac technique consists of turning the thoracostomy tube 180° in each direction and observing whether the tube returns to the prior position. This method can be used to evaluate kinking of the tube when persistent negative pressure is observed despite evidence of significant pleural effusion or pneumothorax. If the tube consistently spins back into the initial position, tube kinking should be suspected.

The thoracostomy tube itself will induce approximately 2.0 mL/kg/day of pleural effusion. Once the volume of pleural effusion drops below this value, removal of the thoracostomy tube may be considered. Ideally, consistent negative pressure should be observed for 24 hours following pneumothorax prior to thoracostomy tube removal.

Fluid Therapy

Fluid therapy is a mainstay of postthoracotomy therapy. Most postoperative patients will require, at minimum, maintenance fluid therapy, as they may be unwilling to drink following surgery. Of further importance, continual fluid losses via the thoracostomy tube should be accounted for, and at least a percentage of this loss should be replaced with IV fluids to avoid hypovolemia due to third spacing. Postthoracotomy patients may experience significant protein loss with pleural effusion. The ideal

therapy for protein replacement in critically ill patients is to provide enteral nutrition in order for the patient to synthesize albumin.

Oxygen Therapy

Oxygen therapy may be provided intermittently via facemask or continuously by nasopharyngeal insufflation, nasal prongs, oxygen cage, or intubation and mechanical ventilation. Provision of intermittent supplemental oxygen at an FiO_2 of 50–60% can be achieved via facemask with oxygen flow rates of 8.0–12.0 L/min. Nasopharyngeal insufflation or nasal prongs may be utilized with oxygen flow rates of 50–150 mL/kg/min to achieve an FiO_2 of 30–70%. More commonly, postoperative thoracotomy patients are maintained in an oxygen cage with flow rates of 0.5–1.0 L/min to maintain a FiO_2 of 40–60%. Patients requiring an FiO_2 above 60% to maintain normoxemia will likely require intubation and mechanical ventilation. Caution must be exercised to avoid oxygen toxicity when supplemental oxygen levels are maintained above 60% for more than 24 hours.

When mechanical ventilation is utilized, PEEP ventilation can be beneficial to prevent atelectasis and augment work of breathing. In contrast to the spontaneously breathing patient, permissive hypercapnia is tolerated in mechanically ventilated postthoracotomy patients. Arterial PCO_2 may rise to 50 mmHg before intervention is necessary, as long as normoxemia is maintained. Proper humidification is an important component of oxygen therapy for preservation of proper mucociliary function and clearance of respiratory secretions.

Dyspnea

Dyspnea is the perceived feeling of breathlessness. The pathophysiology of dyspnea is multifactorial and is described elsewhere. Multiple therapeutic targets have been investigated to decrease the perception of dyspnea in human patients. In human studies, nebulized or aerosolized furosemide has been found to prevent bronchoconstriction and inhibit the cough reflex in addition to reducing pulmonary vascular hydrostatic pressure and edema when absorbed systemically. Furosemide has been shown experimentally and clinically in people to reduce bronchial slow-acting receptors (SARs), thereby reducing the sensation of dyspnea. Furosemide exerts a diuretic effect when administered by the enteral or parenteral route via inhibition of the Na:K:2Cl co-transporter within the thick ascending loop of Henle. A similar mechanism is postulated for the antidyspneic effect of nebulized furosemide causing a local increase in sodium ion concentration within the airways, increasing pulmonary stretch receptor activity.

Hypothermia

Hypothermia is an inevitable occurrence during and immediately following thoracic surgery. Warming IV fluids prior to administration can help diminish large reductions in intraoperative body temperature. Postoperative temperature monitoring, either intermittent or continuous, is recommended to ensure euthermia and active warming using warming blankets or heat lamps should be performed until the patient's temperature has reached 99.5 °F.

Arrhythmias

For hemodynamically significant, multifocal, sustained, or R-on-T phenomena ventricular arrhythmias, lidocaine remains the mainstay therapy. Lidocaine may also be useful to slow the heart rate, allowing differentiation of ventricular tachycardia from sinus tachycardia with bundle branch block. The waveform of the latter often will not change following lidocaine bolus (2.0 mg/kg IV), but P-waves may be appreciable once the heart rate has decelerated. For lidocaine-responsive arrhythmias, a constant rate infusion of 60–80 μg/kg/min may be implemented postoperatively. A beta-blocker may also be considered for patients that do not have known underlying cardiac disease with compromised contractility. Anecdotally, sotalol 2.0 mg/kg PO BID has favorable postoperative antiarrhythmic properties for patients with supraventricular and ventricular tachyarrhythmias.

Nursing Care

Nursing care is a critical yet often underemphasized aspect of postthoracotomy care. Patients undergoing median sternotomy often prefer lateral recumbency in the immediate postoperative period due to incisional pain. Turning or rotating the patient every 4–6 hours prevents atelectasis and V–Q mismatching secondary to gravitational forces in lateral recumbency. Turning the patient also promotes patient comfort and hygiene. Optimal analgesia aids in patient well-being and may promote tolerance of sternal recumbency and therefore improved oxygenation and ventilation.

Complications

Complications post thoracotomy may include edema formation, hypoproteinemia, continual pleural effusion,

secondary infection, hemorrhage, residual or continuous pneumothorax, seroma formation, sternal osteomyelitis, pyrexia, iatrogenic chylothorax, fibrosing pleuritis, surgical dehiscence, and ipsilateral thoracic limb lameness (lateral thoracotomy). Crystalloid fluid therapy, anorexia, vasculitis, and postoperative inflammation can contribute to peripheral edema formation.

The most common complication involving the thoracostomy tube is improper placement. Insufficient subcutaneous tunnel formation with large-bore thoracostomy tubes can lead to continuous air leakage and pneumothorax. The thoracostomy tube percutaneous insertion site should be inspected carefully when continuous pneumothorax is observed. Continual pleural effusion may be primary or secondary in origin, depending on the etiology requiring thoracotomy. Pyothorax, chylothorax, and neoplastic effusion represent sources of continual pleural effusion during the postoperative period. Pleural drainage is important to maintain proper ventilatory function as well as oxygenation. However, excessive pleural effusion can lead to significant systemic protein and fluid loss with subsequent intravascular volume depletion. Vasculitis and surgical inflammation are contributors to this protein-losing pleuropathy and third spacing, which may encourage perpetual effusion. Resolution of the underlying disease process will likely terminate the cause of effusion.

Infection is an undesirable complication in any postoperative patient. Preoperative infection may be present in some patients, such as pyothoraces, in which septic effusion necessitated surgical intervention. Continual monitoring of thoracic fluid cytology and cell counts aids in determining resolution of pyothorax. Responsible antimicrobial administration is of paramount importance in the care of critically ill patients. A full discussion on this topic can be found elsewhere. Generally speaking, clinicians should be familiar with antibiotic sensitivity patterns of common bacterial isolates from their hospitals and deescalate coverage to single-agent therapy as soon as possible. Infection may be introduced intrathoracically via the thoracostomy tube or surgical incision. This may be due to bacterial contamination associated with prolonged surgical exposure, improper handling of the thoracostomy tube, or bacterial invasion of the thoracostomy tube insertion site and/or surgical incision. Appropriate samples should be obtained for bacterial culture and antimicrobial susceptibility testing when infection is suspected.

Proper intraoperative hemostasis ensures minimal postoperative hemorrhage, therefore significant hemorrhagic pleural effusion is not expected in the postthoracotomy patient. Serosanguinous pleural effusion (PCV <25% of peripheral PCV) is a common and expected occurrence with an indwelling thoracostomy tube(s). However, hemothorax is diagnosed when the pleural PCV exceeds peripheral PCV by 25% and warrants immediate investigation. When the volume of thoracic hemorrhage exceeds 10 mL/kg, autotransfusion should be considered.

Proper postoperative incisional care can reduce patient discomfort and surgical inflammation while minimizing risk of infection. During the initial postoperative period, the thoracotomy incision as well as thoracostomy tube insertion site(s) should be covered with an impermeate adhesive dressing. This provides a seal preventing air leakage with resultant pneumothorax while protecting against environmental contamination. Cold and warm compresses following surgery can reduce incisional pain, swelling, and inflammation. Cold compresses are usually applied during the immediate postthoracotomy period for 24–48 hours, with warm compresses used thereafter.

An elevation in body temperature above normal in any postoperative patient warrants immediate concern and investigation. Hyperthermia may be secondary to decreased heat dissipation (inability to pant due to pain, excessive cage bedding), pharmacologic (mu opioid use in cats), or pain induced. Postthoracotomy pyrexia may be observed with infection, inflammation, or neoplasia. Indwelling catheter sites should be inspected for hyperemia, warmth or discomfort upon palpation. Thoracostomy tube insertion sites should also be interrogated in a similar fashion. Complete blood count and thoracic radiographs may also be considered when an obvious etiology of pyrexia cannot be determined from physical examination.

Surgical reexploration is rarely necessary following thoracotomy, but is required for continuous pneumothoraces or hemothoraces that do not respond to medical management. Pneumothoraces, which fail to seal despite continuous active suction, are an indication for prompt reexploration to evaluate the pulmonary parenchyma (bullae or pneumatocele rupture) and previous surgical sites (complete or partial lobectomy). Chronic pleural effusion, despite prior thoracotomy, may also necessitate a second surgery due to fibrosing pleuritis or restrictive fibrin plaque formation on the surface of the visceral pleura of the lung. Decortication may be necessary if significant inelastic fibrin plaque formation has occurred restricting lung expansion. For perpetual pleural effusion, pleurodesis may also be considered.

Pleural Effusion

Ashley Allen, DVM, DACVECC and Gareth Buckley, MA, VetMB, MRCVS, DACVECC

College of Veterinary Medicine, University of Florida, Gainesville, FL, USA

Pleural effusion is the pathologic collection of fluid within the pleural space resulting from one of three primary mechanisms: disruption of pleural pressure homeostasis, diminished lymphatic drainage, or increased mesothelial and capillary endothelial permeability. Given the dynamic state of the pleural space, overlap can occur between the mechanisms of effusion, depending on the underlying disease. Dogs and cats with pleural effusion present with various clinical signs including lethargy, hyporexia, tachypnea, dyspnea, and a paradoxical breathing pattern, regardless of precipitating cause. History and physical examination may help to formulate a differential diagnosis for pleural effusion, but ultimately collecting a sample of the effusion for cytologic analysis and additional tests provides the most important information to obtain an accurate diagnosis. Treatment options and prognosis are dependent on the underlying cause of pleural effusion.

Anatomy and Physiology

The pleura lines the thoracic cavity and is a thin, serous membrane with five layers: an outer fibroelastic layer, an extensively vascularized subpleural loose connective tissue layer, an elastic superficial tissue layer, a loose connective submesothelial tissue layer, and a mesothelial layer. The visceral pleura line the lungs, whereas the parietal pleura line the thoracic wall with the potential space between the two known as the pleural space. The visceral pleura functions to provide mechanical lung support, limit lung expansion, and contribute to elastic recoil and deflation of the lung. The parietal pleura is subdivided into the costal, mediastinal, and diaphragmatic parietal pleura and contains numerous lymphatic vessels that form stomas between mesothelial cells for lymphatic drainage. Lacunae are dilated lymphatic vessels in the submesothelial parietal pleura where stomas form and transport fluid back through the lymphatic system. Compared to other species, dogs and cats have a thin pleural surface, approximately 15 μm thick. The mediastinum divides the pleural space into a right and left pleural cavity, although in dogs and cats the mediastinum may not be complete, allowing for bilateral disease from a unilateral origin. The highly metabolically and immunologically active multipotent mesothelial cells line the entire pleural cavity and play an active role in pleural fluid production and reabsorption. Sialomucins are negatively charged glycoconjugates which coat the free mesothelial surface, functioning to repel opposing membranes as well as organisms, abnormal cells, and particles.

In healthy animals, a small volume of fluid is present in the pleural space which facilitates smooth gliding of the lung over the thoracic wall and transmission of forces during normal respirations. Normal pleural fluid is low in protein (<1.5 g/dL) and cellular content (1500–2500 cells/μL), consisting of mesothelial cells (9–30%), monocytes (61–77%), lymphocytes (7–11%), and neutrophils (<2%). Healthy dogs and cats produce approximately 0.01–0.02 mL/kg/h of pleural fluid via microvascular filtration from pleural capillaries. Fluid crosses the pleural capillary endothelium followed by the interstitium. Pleural capillary endothelium imparts most of the resistance to flow; however, the resistive properties of the endothelium and interstitium are additive, which becomes significant during some disease processes that interfere with the resistive properties of these layers. The production and reabsorption of pleural fluid are multifactorial, dependent on Starling forces, solute flux, hydraulic conductivity (the resistive properties of the two pleural surfaces), total surface area, the solute reflection coefficient (ability of the surface to restrict larger molecules), membrane diffusive permeability, pleural lymphatic drainage via stomata in the parietal pleura, and cellular mechanisms of transport by mesothelial cells (Table 34.1).

Table 34.1 Starling Law applied to pleural membrane

$$Q_b = LA[(P_c - P_{pl}) - \sigma_o(\pi_c - \pi_{pl})]$$

Q_b	Filtration rate across the capillary endothelial barrier in series with the pleural membrane (interstitium)
LA	Filtration coefficient = [hydraulic conductivity (L) * surface area (A)]
σ_o	Reflection coefficient to protein of the combined endothelial-interstitial barrier
P_c	Capillary hydrostatic pressure
P_{pl}	Pleural hydrostatic pressure
π_c	Capillary oncotic pressure
π_{pl}	Pleural oncotic pressure

Source: Adapted from Lai-Fook 2004.

Normal pleural pressure is approximately −3 to −5 cmH_2O at functional residual capacity, becomes greater (more negative) with deeper breaths, and is more negative in the dorsal space compared to the ventral space, decreasing by 0.5–0.7 cmH_2O/cm in dogs. This subatmospheric pleural pressure results from elastic recoil forces of the lung exerting a force inward with the propensity of the chest wall to expand outward and serves to maintain lung inflation while decreasing the work of breathing. Although reported as a single number, pleural pressure is a result of the dynamic nature of the pleural space and represents a summation of the pressure exerted by pleural fluid, regional pleural surface deformation, and weight of the lung in dependent areas of the thoracic cavity.

Pathophysiology of Pleural Fluid Accumulation

Pleural fluid volume depends on Starling forces, mesothelial cell activity, and lymphatic drainage; however, the exact contribution of each of these mechanisms remains somewhat elusive and varies during disease processes. Starling forces which favor the formation of pleural fluid include increased capillary hydrostatic pressure, decreased capillary oncotic pressure, and increased capillary permeability. Mesothelial cells have apical microvilli that increase the surface area for exchange and vesicles that allow for transcytosis of proteins from the pleural space to the pleural interstitium. In addition, indirect evidence suggests mesothelial cells are involved in solute-coupled liquid transport across the pleural surface. Lymphatics communicate directly with the pleural cavity through openings between the mesothelial layer in the parietal pleura, called stomas, and allow cells, protein, and larger particles to be absorbed into the lymphatic system through channels called lacunae. The maximal reabsorption rate through pleural lymphatics is estimated to be 0.2–0.3 mL/kg/h, which is considerably more than the normal daily rate of fluid accumulation. Therefore, the accumulation of pleural fluid occurs when the disease process overwhelms fluid reabsorption capacity, reduces the ability of lymphatics to reabsorb fluid, or increases production of fluid while simultaneously decreasing lymphatic clearance.

Pathologic fluid effusions are classified in two broad categories: transudates and exudates. Transudative effusions typically accumulate secondary to an increase in hydrostatic pressure or a reduction in plasma oncotic pressure while the pleura remains normal, whereas exudative effusions typically accumulate secondary to various pleural pathologic conditions leading to increased vascular permeability and/or diminished lymphatic fluid reabsorption. Mesothelial cells play a pivotal role in the development of exudative effusions by synthesizing inflammatory cytokines, growth factors, and extracellular proteins. A classic example of increased systemic venous hydrostatic pressure leading to a transudative effusion is congestive heart failure. In addition, pulmonary thromboembolism, cardiac tamponade, heartworm disease, and neoplasia can all lead to increased venous hydrostatic pressure and therefore transudative pleural effusion. In comparison, a classic example of an exudative effusion is pyothorax with an influx of inflammatory cells, which can increase vascular permeability and decreased lymphatic drainage (Table 34.2).

Regional changes in pleural pressure occur with the accumulation of pleural effusion and the mechanism of pressure change is controversial. Proposed theories to explain the pressure difference center around the hydrostatic pressure contribution of a column of fluid in the thorax and the changes in deformation forces as the lung and thoracic wall become separated by fluid. The hydrostatic theory divides the pleural space into three distinct pressure zones: the upper (dorsal) zone, middle zone, and lower (ventral) zone. In the upper (dorsal) zone, the pleural liquid thickness is normal and the pleural liquid pressure is less than the pleural surface pressure. In the middle zone, the pleural liquid thickness increases and pleural liquid pressure equalizes with pleural surface pressure at zero. In the lower (ventral) zone, the pleural fluid thickness increases substantially and the pressure becomes positive, displacing the lung from the thoracic wall. In the other predominant theory, the pleural liquid pressure is always equal to pleural surface pressure such that pressure gradients caused by gravity and regional differences in pleural surface pressure drive a small viscous flow of fluid in the normal pleural space and surfaces are never in contact. As pleural effusion

Table 34.2 Causes of pleural effusion in dogs and cats

Physical agents

Others
- Feline infectious peritonitis
- Coagulopathy (rodenticide or factor deficiency)
- Allergic hypersensitivity conditions
- Cholecystectomy

accumulates, the viscous resistance to flow quickly decreases and the pleural pressure gradient approaches the hydrostatic pressure gradient. Both theories contend that pleural effusion increases pleural pressure by 1 cm H_2O/cm effusion height.

Measuring pleural liquid pressure and pleural surface can be challenging because the space is small and the insertion of any device will cause an artifact by deforming the surface. In the diseased thorax with an appreciable amount of pleural effusion, these challenges become less significant and pleural pressure measured is an accurate representation of hydrostatic pressure at the level of the catheter or transducer. During thoracocentesis or if an indwelling thoracostomy tube is in place, pleural pressure can be monitored in veterinary patients with a minimal amount of equipment using a water manometer or pressure transducer. If using a pressure transducer, measurements are recorded in mmHg and should be converted to be interpreted appropriately (1 mmHg = 1.36 cmH_2O). Pleural pressure monitoring may be beneficial with chronic effusions when draining the effusion does not necessarily equate to return to normal pleural physiology because the pleural surface remains diseased. If the lungs cannot expand appropriately after thoracocentesis, creating a situation of entrapped lung, the supraphysiologic negative pressure created in the pleural cavity by removing the fluid may increase the risk of pneumothorax.

Clinical Signs and Physical Examination

Rapid intervention with minimal patient stress is paramount in patients with respiratory distress so it is important to be familiar with clinical signs and physical examination findings indicative of certain disease processes. Time of onset, volume of fluid accumulation, and inciting cause of pleural effusion all contribute to the patient's history and clinical signs.

Pleural effusion is a consequence of an underlying disease and vague historical clinical signs are often reported including lethargy, exercise intolerance, weight loss, and hyporexia or anorexia. In a retrospective study, tachypnea and dyspnea were the most commonly reported complaints by owners, present in 95% of dogs with pleural effusion. Additional complaints, which may or may not be an indication of the underlying disease, include cough, polydipsia, vomiting, fever, collapse, diarrhea, restlessness, reluctance to lie down, cervical extension, hemoptysis, abdominal distension, melena, hematemesis, and halitosis. Severe pleural effusion may present as open mouth breathing and cyanosis, especially if onset is acute.

On physical examination, a restrictive breathing pattern seen as rapid and shallow breathing has historically been reported but recent literature suggests an asynchronous (paradoxical) or inverse breathing pattern and decreased lung sounds on auscultation are more common clinical findings in dogs and cats. Paradoxical breathing refers to increased inspiratory effort strong enough to pull the abdominal contents toward the thorax, leading to a sunken flank appearance during inspiration and a bulging flank appearance on expiration. Additional physical examination findings include muffled heart sounds, decreased ventral lung sounds, shallow breathing, and inspiratory dyspnea. Patients with cardiac disease, such as heart failure, pericardial effusion, or caval syndrome, may have a murmur or crackles on thoracic auscultation, jugular pulses, a positive hepatojugular reflex, and/or pulse deficits. Patients with a coagulopathy causing pleural effusion, such as anticoagulant rodenticide toxicity, may have bruising, pale mucous membranes, weak pulses, or tachycardia on physical examination. Masses found on abdominal palpation, oral or dermatologic examination may indicate a neoplastic cause for pleural effusion. Mediastinal neoplasia should be suspected with an incompressible cranial thorax in cats or Horner syndrome in cats or dogs. Pain in the right cranial abdominal quadrant with gastrointestinal signs may be suggestive of pancreatitis as an underlying cause of pleural effusion (Table 34.3).

Table 34.3 Classification of effusions in dogs and cats

	Total protein (g/dL)	Cells per microliter	Cell types	Special features
Transudate	<2.5	<1500	Mononuclear	Low cellularity
Modified transudate	2.5–7.5	1000–7000	Mononuclear	Cell type varies with etiology
Exudate	>3.0	>3000	Neutrophils or specific to underlying disease	Subcategories: hemorrhage, bile, chyle, septic, aseptic

Diagnostics

Patient presentation, stability, and available resources will often guide the diagnostic approach in patients with pleural effusion. The cyanotic cat with open mouth breathing will have a different initial diagnostic and treatment plan from a dog presenting for vomiting or diarrhea with scant pleural effusion found during routine testing for underlying gastrointestinal disease. Regardless of the underlying pathology, the goal should be patient stabilization first followed by a thorough investigation into the inciting cause of pleural effusion using imaging techniques, pleural fluid tests, and, if necessary, histopathology.

Imaging

Ultrasonography, radiography, and computed tomography (CT) are currently available imaging techniques in dogs and cats with pleural effusion. In general, the patient requiring emergent treatment for respiratory distress due to pleural effusion is likely to have an ultrasound in the emergency department initially followed by thoracocentesis prior to the pursuit of additional imaging techniques whereas a stable patient will likely have thoracic radiographs with or without a thoracic ultrasound followed by advanced imaging if necessary.

Although the name implies a single subset of patients, which benefit from the test, the thoracic focused assessment with sonography for trauma (TFAST) is the most common initial test in an emergency situation due to pleural space disease because it allows for rapid assessment of the thoracic cavity with a therapeutic goal. TFAST is performed with the patient in sternal or right lateral recumbency and assessing five areas of the thoracic cavity: the right and left chest tube site (dorsolateral 7th–9th intercostal spaces), right and left pericardial site (ventrolateral 5th–6th intercostal space), and the diaphragmatico-hepatic (subxiphoid) site. Pleural effusion is recognized as anechoic or echogenic fluid in the pleural space and its presence may allow better visualization of some mediastinal masses. In people, the diaphragmatico-hepatic site is the most sensitive and specific area to diagnose pleural effusion because it has less air interface than the pericardial sites; however, with breed conformation and size variation of veterinary patients, this has yet to be prospectively evaluated. Thoracic ultrasound is useful for the detection, characterization, and subjective quantification (by depth) of pleural fluid, in addition to guiding therapeutic intervention. Abdominal ultrasound and echocardiogram may also help determine the cause of pleural effusion.

Thoracic radiographs are useful to evaluate for the presence of pleural effusion and survey the thoracic cavity for an underlying etiology. Radiographic signs of pleural effusion include retraction of the lung margins from the thoracic wall and sternum with increased opacity in the pleural space, widened interlobar fissures, rounding of lung margins, pleural thickening, and obscuring of the diaphragm and cardiac silhouette by radiopaque fluid. Pleural fluid will often obscure structures in the thoracic cavity, including the heart, mediastinum, and diaphragm; therefore, in patients with significant pleural effusion it is advantageous to perform thoracocentesis, ideally ultrasound guided, prior to radiographs to allow better evaluation of intrathoracic structures. Since the pleura cannot normally be seen on radiographs, if pleural lines are seen, horizontal beam radiographs, in addition to the standard three-view series, may help differentiate pleural thickening from pleural effusion because vertical beam projections are limited by superimposition of fluid and soft tissue structures. In addition, more pleural effusion is present than predicted based on vertical beam (standard-view) radiographs because large fluid pockets are not struck head-on by the X-ray beam; however, a horizontal beam allows fluid to collect ventrally such that the X-ray beam strikes the fluid–lung interface tangentially. However, ultrasound remains the most sensitive test for detection of small amounts of fluid.

Thoracic CT has become increasingly available in veterinary practice; CT allows better lesion delineation and characterization than conventional radiography for many thoracic disorders. Prior to thoracic CT,

thoracocentesis should be performed to remove as much fluid as possible to enhance visualization of intrathoracic and extrathoracic structures. Patients are maintained in dorsal or ventral recumbency, manually hyperventilated immediately preceding the helical scan to decrease respiratory drive during a forced breath hold, and the entire thorax is acquired using a slice collimation of 3–7 mm, depending on patient size. During a single inspiratory hold not exceeding one minute, the entire thorax is scanned which determines the slice thickness of the images, reserving the ability to make thinner slices of areas of pathologic importance if needed. Both ultrasound and conventional radiographs are poorly sensitive to determine vascular invasion, displacement of normal anatomic structures, or invasion of adjacent structures by mediastinal masses; however, CT enhances the ability to determine the aggressiveness of the tumor prior to surgical exploration. Regarding chylothorax, CT may be superior to traditional radiographic lymphangiography to show contrast enhancement of the thoracic duct. Thoracic CT may also be indicated in dogs and cats with pyothorax not responding to conventional management or if a pleural or pulmonary foreign body or abscess is suspected because this imaging technique eliminates superimposition and silhouetting of intrathoracic structures. Pleural abscesses on CT often appear as ring-enhancing cystic structures with a fluid-attenuating core. Additional benefits of thoracic CT include identifying pleural thickness, small-volume pneumothorax, parenchymal lung masses, and peripheral bronchopleural fistulae.

Pleural Fluid Evaluation

Thoracocentesis is therapeutic and has the potential to be diagnostic in any dog or cat with pleural effusion. In the emergent respiratory patient, thoracocentesis should be the first step after pleural effusion has been confirmed by TFAST with a goal to remove as much fluid as possible, the exception being the coagulopathic patient. There are no absolute contraindications to perform thoracocentesis but in coagulopathic patients, extreme caution should be used if thoracocentesis is necessary and should be reserved for patients in moderate to severe respiratory distress. In the absence of ultrasound availability, thoracocentesis can be carefully performed in a dyspneic patient prior to radiographs. The small risk associated with thoracocentesis is outweighed by the major risk of prolonged restraint for radiographs of a patient in severe respiratory distress. Unilateral or bilateral thoracocentesis may be needed and is ideally performed with ultrasound guidance.

Gross appearance of aseptically collected pleural fluid should be recorded, as well as protein content and cytologic characteristics. Samples should also be saved in ethylenediaminetetraacetic acid (EDTA, lavender top), serum (red top) tubes, sterile tubes for culture, and/or other tubes for effusion-specific tests such as polymerase chain reaction (PCR). Information gained from protein content and cellularity may help guide future diagnostics or treatment. Gram stain should be performed if pyothorax is suspected on preliminary diagnostics to guide antimicrobial therapy while cultures are pending. Sterile samples can be stored for bacterial, fungal, and/or *Mycoplasma* culture followed by antimicrobial susceptibility. Fluids are typically divided into three categories based on protein content and nucleated cell count: transudate, modified transudate, and exudate. Subcategories of exudative effusions include hemorrhage, bile, chyle, septic and aseptic (Table 34.4).

Pure transudates are low in protein (<2.5 g/dL) and total nucleated cell count (<1500 cells/μL) with a clear, colorless, or straw-colored appearance. Cytologic examination shows predominantly mononuclear cells such as lymphocytes, macrophages, and mesothelial cells with low to absent numbers of nondegenerate neutrophils. Transudative pleural effusion is a consequence of either increased hydrostatic or decreased oncotic pressure. Liver disease, protein-losing enteropathies and nephropathies, malnutrition, maldigestion, and malabsorption can cause profound hypoalbuminemia with or without hypoglobulinemia, leading to decreased oncotic pressure. In addition, chronic blood loss, intestinal parasitism, and

Table 34.4 Pyothorax bacterial isolates

intestinal neoplasia can also cause significant hypoproteinemia. In general, albumin concentrations less than 1.0 g/dL cause oncotic pressure to be low enough for a transudate to develop; however, if increased hydrostatic pressure is also present, a pure transudate can be seen with a higher albumin concentration.

Modified transudates are variable in protein content (2.5–7.5 g/dL) and cell count (1000–7000 cells/μL). Grossly, they can be tan and slightly turbid, to pink, or opaque and white in appearance depending on the underlying etiology. Most of the nucleated cells are mononuclear (macrophages, lymphocytes, or a combination of both) with a lower number of mesothelial cells and nondegenerate neutrophils. Modified transudates result from increased vascular or lymphatic permeability with or without increased hydrostatic pressure. They are modified by the addition of proteins, cells, or chyle, and classifying a fluid as a modified transudate implies the disease process causing fluid to accumulate is noninflammatory. Most modified transudates are a consequence of obstructed venous or lymphatic drainage secondary to numerous underlying diseases, with right-sided heart failure being most common. Some modified transudates may become exudative effusions, especially with chronicity because fluid in the pleural space is inflammatory. Chylous effusion has been classified as both a modified transudate and an exudate for this reason. Initially, chylous effusions contain a predominant population of mononuclear cells (lymphocytes) and fluid accumulates due to lymphatic obstruction from noninflamed vessels. In cats, chylous effusion can result from congestive heart failure or heartworm disease. Additional causes in veterinary species include lung atelectasis, neoplasia, diaphragmatic or peritoneal-pericardial hernias, lung lobe torsion, lymphangiectasia, cranial vena cava thrombosis, trauma, restrictive pericarditis, pericardial disease, and mediastinal disease. Often, an underlying disease for chylous effusion is not identified and is therefore idiopathic.

Exudates have a high protein concentration (>3.0 g/dL) and nucleated cell count (>3000 cells/μL). Exudates vary in gross appearance from white to amber to pink depending on etiology and are typically turbid. The predominant cell type is the neutrophil, which may be nondegenerate (aseptic) or degenerate (septic), with macrophages, lymphocytes, eosinophils, and mesothelial cells in lesser quantities. Exudative effusions usually result from an inflammatory process in the pleural cavity causing release of cytokines and other vasoactive mediators, leading to increased capillary permeability (filtration coefficient). The initial inflammatory process can be due to endogenous (chyle, neoplastic cells) or exogenous (bacteria, fungi) mediators. Eosinophilic effusions determined cytologically with >10% eosinophils are infrequently reported in veterinary medicine; however, if present, cancer is the most common underlying etiology, followed by thoracic wall trauma, pneumothorax, congestive heart failure, and allergic hypersensitivity conditions. Pyogranulomatous inflammation may indicate fungal or foreign body reaction. Cytologic slides should be closely evaluated for the presence of intracellular bacteria and aerobic and anaerobic cultures with antimicrobial susceptibilities should always be submitted when degenerate neutrophils are present. Nondegenerate neutrophils typically indicate a nonseptic process and may be secondary to neoplasia, chronic diaphragmatic hernia, lymphatic obstruction or leakage, and infectious processes. If the patient has a history of recent cholecystectomy or trauma and yellow, nonseptic exudate is collected, bilothorax should be a differential and further diagnostics performed.

Specific Pleural Fluid Tests

When chylothorax is suspected, triglyceride concentration should be analyzed in the pleural effusion and patient's serum. Diagnosis of chylothorax is confirmed if the triglyceride concentration in the pleural fluid is higher than the triglyceride concentration in the patient's serum. Decreased glucose (<60 mg/dL) in pleural fluid is due to decreased transport of glucose to the pleural fluid or increased utilization of glucose by mononuclear cells, neutrophils, bacteria, or malignant cells. If the effusion appears hemorrhagic, the packed cell volume (PCV) of the pleural effusion should be compared to the PCV of the patient, with hemothorax present if the pleural fluid PCV is at least 25% of the patient's PCV. Bilirubin should be quantified in the pleural fluid and blood if bilothorax is suspected, such as those patients with recent biliary surgery or known/suspected trauma. If bilirubin in the pleural fluid is higher than in the patient's blood, bilothorax is diagnosed.

Pleural Pressure Monitoring

Normal pleural pressure in a dog or cat is negative with respect to the atmosphere and functions to facilitate lung inflation and reduce the work of breathing. Negative intrapleural pressure is generated by the lymphatic system as it drains the normal, physiologic small volume of pleural fluid present. As pleural effusions accumulate, lung parenchyma collapses and intrathoracic pressure increases. Dyspnea and tachypnea result due to collapsed parenchymal lung tissue and pleural pressure becomes less negative, or positive to the atmosphere. When the fluid is removed by thoracocentesis, the expectation is that intrapleural pressure returns to its normal negative pressure and the lungs can reexpand but this is not always the case, especially with chronic effusions. The pleural surface can become fibrinous,

thickened, and inflamed by chronic effusions, thus inhibiting reexpansion of the lungs once the effusion is removed. In humans, this is termed lung entrapment as the intrapleural pressure has become negative, but the lungs cannot expand due to the formation of a visceral pleural peel and persistent pleural effusion. This imparts a large negative pressure on the diseased visceral pleural surface, which may cause pain or increase risk of spontaneous pneumothorax.

Intrapleural pressure can be measured during thoracocentesis with several techniques, including a U-shaped water manometer, an "overdamped" water manometer, or electronic pressure transducer systems such as those used for invasive blood pressure monitoring. The role of intrapleuaral pressure monitoring in veterinary medicine is an expanding area of interest and research.

Thoracoscopy

Thoracoscopy is a minimally invasive technique which is becoming more widespread in veterinary medicine and can be used as both a diagnostic and therapeutic technique in veterinary patients with pleural effusion. Advantages of thoracoscopy include obtaining pleural biopsies, visualization of intrathoracic pathology, and minimally invasive approach (Figure 34.1).

Properly collected thoracoscopic pleural biopsies are adequate in quality and quantity to obtain a definitive histopathologic diagnosis (Figure 34.2). Disadvantages include general anesthesia, risk of pneumothorax, hemorrhage, infection, and potential need for thoracotomy if unable to achieve definitive treatment (depending on underlying disease) with thorascoscopy alone.

Pyothorax

Pyothorax is the accumulation of purulent exudative effusion in the pleural space caused by infection. Young (3–6 years) male dogs are more likely to be diagnosed with pyothorax, with performance breeds being overrepresented. Dyspnea, tachypnea, pyrexia, lethargy, and anorexia are the most common clinical signs in dogs. In cats, pyothorax is more common in young (2–4 years) domestic shorthairs, with no sex predilection, and the most common initial clinical signs include hyporexia or

anorexia, lethargy, and/or dyspnea. Although more common in young animals, pyothorax can occur at any age, with rare reports in neonatal dogs and cats. Additional clinical signs include weight loss, nasal or ocular discharge, hypersalivation, coughing, and exercise intolerance. Clinical signs can be acute or chronic. Physical examination findings often include tachypnea, dyspnea, decreased ventral lung sounds, muffled heart sounds, and restrictive respiratory pattern. Severe sepsis and associated signs could occur in either species, with pyothorax being the most common cause in a retrospective paper on cats with severe sepsis.

In dogs, causes include bite wounds, penetrating thoracic injury, foreign body inhalation, lung abscess, parasitic migration, hematogenous spread, esophageal or tracheal perforation, diskospondylitis, neoplasia with lung abscessation, previous thoracic surgery, and thoracocentesis. In cats, causes include extension from a lung parenchymal infection, foreign body migration, esophageal rupture, and penetrating thoracic wounds. Cats with pyothorax are 3.8 times more likely to live in multiple cat households, *Pasteurella* spp. are the most common bacterial isolate, and 14.5–40% of cases have a history of bite wounds, thus adding support to the theory that bite wounds are a common route of infection. Migrating grass awns can be a common cause of pyothorax in dogs and cats, depending on geographic location, but in many cases the cause of infection is not identified.

Diagnosis is based on presence of an exudate, cytologic slide evaluation, and positive bacterial cultures of aseptically collected pleural fluid. Intracellular bacteria identified on cytologic review confirms the diagnosis but if intracellular bacteria are not seen and degenerate neutrophils are present, then bacterial cultures (aerobic and anaerobic) should be performed (Figure 34.3). If the patient has already been on antibiotics prior to collection of pleural effusion, diagnostic test results may not be reflective of disease and a nonseptic exudate may be seen. Many feline pyothorax infections are due to multiple organisms and common bacterial isolates in feline pyothorax include *Pasteurella* spp., *Clostridium* spp., *Fusobacterium* spp., *Bacteroides* spp., *Peptostreptococcus* anaerobius, *Porphyromonas* spp., *Prevotella* spp., and *Actinomyces* spp. In dogs, enteric organisms are more common than in cats and common bacterial isolates include *Escherichia coli*, *Enterobacter cloacae*, *Pasteurella* spp., *Actinomyces* spp., *Streptococcus canis*, *Peptostreptococcus anaerobius*, *Bacteroides* spp., *Fusobacterium* spp., and *Porphyromonas* spp. Additional clinicopathologic findings seen in patients with pyothorax include elevated liver enzymes, electrolyte disturbances, hypoglycemia or hyperglycemia, hypoalbuminemia, mild anemia, and leukocytosis due to neutrophilia.

Imaging techniques include thoracic ultrasound, radiographs, and CT. In clinical practice, thoracic ultrasound is typically utilized initially because it is noninvasive, does not require sedation, and can be used rapidly in patients with respiratory disease for diagnosis and to localize an area for therapeutic thoracocentesis. With pyothorax, pleural fluid is often echogenic and wispy, fibrinous strands can be seen along pleural margins. Radiographs may be helpful once fluid has been removed to determine if an underlying cause can be identified, such as a lung mass lesion, focal pulmonary opacity, or foreign body; however, as previously mentioned, an underlying cause is rarely found. The use of CT is becoming more widespread in veterinary medicine but the role of CT in canine pyothorax is controversial. A retrospective study in dogs with spontaneous pyothorax showed that common CT findings include bilateral pleural fluid, pleural gas (due to preimaging thoracocentesis or thoracostomy tube placement), pleural thickening, pulmonary parenchymal abnormalities, and mediastinal involvement. Of the surgically managed dogs in this study, CT correctly predicted the extent of disease in only 62.5% and correctly identified the underlying cause in only 50%; therefore, surgical exploration remains the gold standard to identify underlying pathology.

Treatment includes administration of appropriate antimicrobials, intermittent or continuous thoracic drainage, thoracic lavage, and surgery. Intravenous broad-spectrum antimicrobials with adequate anaerobic coverage should be started once culture samples have been collected and adjusted accordingly based on culture and susceptibility results. Potentiated beta-lactams are reasonable first-line therapy because they have efficacy against *Actinomyces* spp., anaerobes, and some gram-negative organisms. Enrofloxacin is often added to improve gram-negative coverage while awaiting culture results. Deescalation of antimicrobial therapy should be

considered once susceptibility data are available. Medical management involves thoracocentesis alone (repeated as needed) or placement of unilateral or bilateral indwelling thoracostomy tubes with intermittent or continuous suction and thoracic lavage along with appropriate antimicrobial therapy and supportive care. In general, large-bore trocar or surgically placed thoracostomy tubes are preferred in larger patients; however, smaller thoracostomy tubes placed using a modified Seldinger technique have been reported for management of pyothorax in dogs. Surgical management involves exploratory thoracotomy, usually by median sternotomy, to lavage and debride the pleural space, and break down any adhesions causing pocketing of fluid, then insertion of thoracostomy tubes for postoperative care, in addition to appropriate antimicrobial therapy and supportive care.

Appropriate treatment of pyothorax is controversial and there is no consensus on ideal therapy for all cases. Failure of medical therapy or presence of a focal lesion (abscess, tumor, or granuloma), foreign body, or evidence of esophageal rupture found on imaging are indications for surgical management in dogs or cats. In dogs, some advocate for early surgical treatment regardless of whether an underlying cause is identified, with the premise being that any other infectious disease such as peritonitis, septic arthritis, or abscess is best treated by aggressive debridement and drainage. In a retrospective paper on medical versus surgical treatment canine pyothorax, medical management was 5.4 times more likely to fail compared to surgical treatment and more dogs were free of disease at one year if treated surgically. In contrast, other studies have not shown a survival benefit of surgery versus medical management and reported success of medical management has ranged from 29% to 100%. If *Actinomyces* spp. are suspected on cytology or cultured from dogs with pyothorax, surgical management is warranted because medical treatment has a high rate of failure and a grass awn foreign body is a likely underlying cause. In cats, medical management with indwelling thoracostomy tubes is reported to have a survival rate of 73–95%, whereas surgical management has been reported to have a 100% survival rate. Successful management of chronic pyothorax in cats with unilateral pneumonectomy has been reported.

With medical management alone or during the postoperative period, thoracic lavage is often recommended to facilitate drainage of exudative fluid; however, there are no large-scale canine or feline studies to evaluate outcome with this method. Theoretical advantages of lavage include minimizing bacteria and inflammatory mediators in the pleural space and dilution of exudative fluid, which could clog the thoracostomy tube. Potential disadvantages include electrolyte disturbances such as hypokalemia, which has been reported in a cat undergoing thoracic lavage, and nosocomial infection if aseptic technique is not followed. Pleural lavage is performed by slowly infusing 10–20 mL/kg of warmed, 0.9% saline into the pleural space, waiting 10–15 minutes, and then withdrawing the fluid. If bilateral thoracostomy tubes are in place, some advocate for using one side as an infusion port and the opposite side as a withdrawal port. Thoracostomy tubes are generally removed when fluid production decreases to 3–5 mL/kg/day, in addition to clinical improvement of the patient and cytologic confirmation of absence of infectious organisms. Time to resolution of disease is generally 5–8 days and patients should be rechecked frequently as recurrence is possible.

Chylothorax

Chylothorax is a syndrome characterized by the accumulation of chyle, the milky fluid consisting of lymph and emulsified fat formed in the small intestines during digestion, in the pleural space and is often idiopathic in nature. Additional reported causes include traumatic or surgical thoracic duct rupture, cranial vena cava thrombosis, lymphatic obstruction by cancer or fungal granuloma, cardiomyopathy, congenital defect, diaphragmatic hernia, peritoneopericardial diaphragmatic hernia, lung lobe torsion, pericardial effusion, tetralogy of Fallot, tricuspid dysplasia, cor triatriatum dexter, constrictive pericarditis, and heartworm disease. Although trauma has been a reported cause of chylothorax in the literature, it could not be experimentally reproduced in dogs by laceration or transection of the thoracic duct as the effusion resolved within 10 days. Reported neoplasms associated with lymphatic obstruction causing chylothorax include thymoma, lymphosarcoma, lymphangiosarcoma, and aortic body tumors. The rate of chyle production and drainage in normal dogs is approximately 2–4 mL/kg/h.

Most of the body except the right forelimb and right side of the head and neck drain into the thoracic duct in dogs and cats. Intestinal lymphatics drain chyle into the mesenteric lymph nodes, which then form larger ducts that continue on to form the cisterna chyli, which is a lymphatic reservoir located ventral to the first four lumbar vertebrae. The cisterna chyli continues cranially to become the thoracic duct and eventually empty into the brachiocephalic trunk. In dogs, the cisterna chyli and caudal thoracic duct are located on the right side of the mediastinum; however, the duct crosses from right to left in the mid-mediastinum to empty into the brachiocephalic trunk. In cats, the thoracic duct is typically only located to the left side of the mediastinum. Thoracic duct anatomy can vary within the same species. Obstruction of the thoracic duct or cranial vena cava causes lymphatic flow stasis and dilation. It is thought

that increased pressure causes chyle to leak out of dilated lymphatics, as would occur in other parts of the body with lymphedema. With cardiac disease, chylous effusion can develop due to impaired lymph drainage to the venous circulatory system. In addition, hepatic congestion occurs with heart failure, which significantly increases hepatic lymph production and therefore thoracic duct flow. Pathophysiologic mechanisms for idiopathic chylous effusion are not well elucidated.

Chylothorax can occur in any breed or age of dog or cat, with Afghan hounds being overrepresented because of the association between lung lobe torsion and chylothorax. Clinical signs are those typical of pleural effusions, including lethargy, hyporexia or anorexia, weight loss, tachypnea, cough, and paradoxical or restrictive breathing pattern. Diligent cardiothoracic auscultation should be performed because of the association between cardiac disease and chylothorax. Additional physical examination findings include muffled heart sounds, decreased ventral lung sounds, and increased dorsal lung sounds. There are no consistent laboratory findings for dogs or cats with chylothorax.

Diagnosis of chylothorax is based on examination of pleural fluid, which grossly appears milky white to opaque pink-white, but can vary depending on nutritional status of the patient. Pleural fluid from thoracocentesis should be saved in EDTA for cytologic examination and a serum separator tube for triglyceride concentration analysis. The fluid is most often classified as an exudate, but may be classified as a modified transudate depending on the protein and cell count. Cytologic examination shows predominantly lymphocytes, small numbers of macrophages, and nondegenerate neutrophils, which increase in numbers with chronicity of pleural effusion (Figure 34.4).

Definitive diagnosis is made by demonstrating higher triglycerides in pleural fluid than in serum samples, collected at the same time. If the effusion triglyceride concentration is >100 mg/dL, chylomicrons are seen microscopically on a wet-mount preparation, pleural cholesterol concentration is less than serum cholesterol concentration, or Sudan stain verifies lipid in the sample, then it is also classified as chylous. Once the diagnosis of chylothorax has been made, additional diagnostics, including complete blood count, chemistry profile, heartworm test, thoracic radiographs, thoracic ultrasound, echocardiogram, thoracic CT, +/− abdominal imaging, should be considered to determine if an underlying disease can be found. Cats should also be tested for retroviral diseases.

Treatment of chylothorax should be directed at the underlying disease but as the disease is often idiopathic, targeted treatment is rarely possible. Resolution of respiratory distress by removing the pleural effusion should be initial treatment, regardless of etiology. Chylous effusion is rich in lymphocytes, protein, lipid, and electrolytes and removal of large quantities of chylous effusion can cause hypovolemia, hyponatremia, hyperkalemia, hypoproteinemia, lymphopenia, weight loss, and immunosuppression. Conservative medical treatment involves pleural evacuation and nutritional management. Surgical treatment for idiopathic chylous effusion involves ligation of the thoracic duct with or without various adjunctive procedures including subtotal pericardectomy, cisterna chyli ablation, and thoracic omentalization.

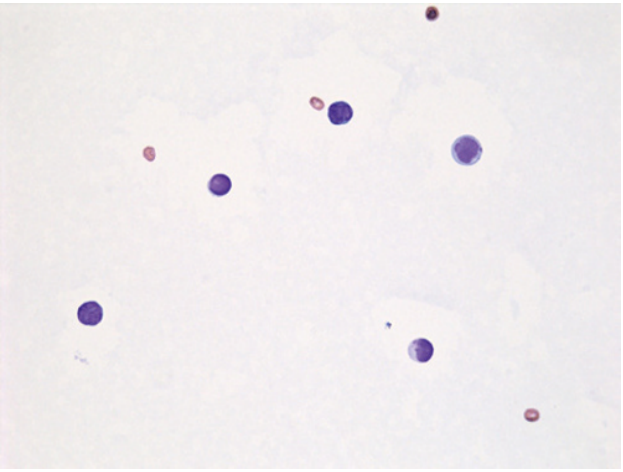

Figure 34.4 Chylothorax cytology. Chylothorax in a cat consisting of a mixture of mostly mature small, well-differentiated lymphocytes and intermediate-sized lymphocytes. Diets low in fat have been recommended for medical management of chylothorax in dogs and cats to decrease the volume of chyle production and therefore flow through the thoracic duct; however, this has not been experimentally validated in dogs or cats. Rutin is a commercially available benzopyrone nutritional supplement used in humans for treating lymphedema and commonly recommended for medical management of idiopathic chylothorax, although no proven beneficial effects have been demonstrated in dogs and cats. Theoretical beneficial actions of rutin include edema uptake by lymphatic vessels, reduction of blood vessel permeability, and enhancement of tissue macrophage number and function to promote phagocytosis of protein in chylous fluid. Octreotide, a somatostatin analogue, inhibits biliary, pancreatic, and gastric secretions, and is recommended in humans with chylothorax to decrease thoracic duct flow; however, use in dogs and cats requires further research.

Prior to surgical treatment, some form of thoracic duct imaging is typically recommended to allow for surgical planning given the anatomic variation within and between species. Mesenteric lymphangiography, or the use of aqueous contrast material injected into a

mesenteric lymph node to highlight the thoracic duct, has been utilized for over 30 years in veterinary medicine to guide surgical planning and assess postoperative success. Mesenteric lymphangiography is an invasive procedure as it requires an exploratory laparotomy and injection of contrast medium into a mesenteric lymphatic vessel or lymph node, followed by radiographs or CT under general anesthesia; therefore less invasive procedures have since been developed for thoracic duct imaging. More recent minimally invasive imaging modalities include percutaneous mesenteric lymphadenography, laparoscopic mesenteric lymphadenography, percutaneous popliteal lymphangiography, and subcutaneous or submucosal lymphography, and CT has largely replaced conventional radiography as the ideal imaging technique.

Surgical treatment is recommended if chylothorax is persistent despite medical therapy because chyle is inflammatory and can cause severe fibrosing pleuritis or pericarditis. Thoracic duct ligation at the entry point of the duct into the thorax is the most commonly performed surgical technique for dogs and cats with idiopathic chylothorax. The premise behind thoracic duct ligation is to create a stimulus for new lymphaticovenous connections to the caudal vena cava or azygous vein outside the pleural space, thereby bypassing the thoracic duct and preventing intrathoracic flow of chyle. Surgical approach to the thoracic duct can be through a caudal intercostal thoracotomy, paracostal or ventral midline celiotomy with transdiaphragmatic extension, median sternotomy, or using thoracoscopy.

Several adjunctive surgical procedures have been combined with thoracic duct ligation in an effort to increase success rate of treatment. Cisterna chyli ablation was developed because hypertension within the cisterna chyli is thought to cause collateral lympathic vessels to form around the thoracic duct ligation site. Adjunctive subtotal pericardectomy is rationalized because chronic chylous effusions can cause pericarditis, which in turn can increase right-sided venous pressure and possibly impede chyle drainage from new lymphaticovenous anastomoses. Other adjunctive or alternative procedures are thoracic omentalization to provide lymphatic drainage, pleurodesis to abolish the pleural space, and cisterna chyli and thoracic duct embolization, with the latter being a salvage procedure if previous surgical attempts have failed. Surgical (conventional or thoracoscopic) success rates vary between 50% and 100% in dogs and 14.3% and 80% in cats. Persistence of chylous or nonchylous pleural effusion is the most common surgical complication. If surgical treatment fails, then implantation of an active pleuroperitoneal shunt or PleuralPort device should be considered to manage long-term effusion.

Hemothorax

Hemothorax is defined as an exudative effusion in the pleural space with a PCV that is at least 25% of peripheral blood. Iatrogenic hemorrhage during thoracocentesis should be suspected if the sample contains platelets and lacks erythrophagocytosis on cytology. In general, causes of hemothorax can be divided into coagulopathic and noncoagulopathic. Anticoagulant rodenticide toxicity is the most common cause of coagulopathic hemothorax in veterinary patients but disorders of primary hemostasis could also result in hemothorax. Reported noncoagulopathic etiologies include neoplasia, thoracic trauma, lung lobe torsion, pancreatitis, pulmonary parasitic disease (*Spirocerca lupi*, *Dirofiliaria immitis*, or *Angiostrongylus vasorum*), esophageal foreign body, and pulmonary infarction. Therapeutic thoracocentesis should only be performed in patients with hemothorax if respiratory distress is present on physical examination because most of the blood will be reabsorbed once the underlying cause is treated. Coagulation tests should be performed prior to thoracocentesis and blood products should be readily available. Fresh frozen plasma should be administered to coagulopathic patients with hemothorax, prior to or during therapeutic thoracocentesis, if this is deemed necessary on patient evaluation. Thoracic ultrasound, echocardiography, and CT may be utilized to determine the underlying cause along with standard blood tests, heartworm test, and fecal examination. Treatment is directed at the underlying cause and emergency surgical treatment may be necessary in some dogs or cats that are nonresponsive to conservative management.

Bilothorax

Bilothorax is the accumulation of a nonseptic, exudative effusion high in bilirubin within the pleural space and is rare in both veterinary and human medicine. It has only been reported in a few veterinary patients, all of which had recent hepatobiliary trauma (gunshot wound or penetrating trauma) or biliary surgery. In one cat, the penetrating trauma was iatrogenic; pleurobiliary fistulae occurred secondary to thoracotomy tube placement. The theorized mechanism of bilothorax formation is from pleurobiliary formation, with a presumptive diaphragmatic incongruity; however, bile can also be carried across an intact diaphragm by way of the lymphatic system. Diagnosis is confirmed if the ratio of bilirubin in pleural fluid to serum is greater than 1:1. Given the rarity of bilothorax, optimal treatment is controversial. Medical management by placing thoracostomy tubes with frequent pleural fluid drainage is recommended to minimize bile pleuritis. If medical management fails, surgical exploration is recommended. Bilothorax in dogs and cats appears to have a good prognosis, with a combined 100% survival rate of currently reported cases.

Conclusion

Pleural effusion is a common consequence of several underlying pathophysiologic processes in dogs and cats. Historical findings can be acute or chronic and clinical signs are variable, with many dogs and cats presenting with a primary complaint related to lethargy, hyporexia, and/or respiratory distress. A thorough diagnostic approach is often needed to determine the underlying disease and subsequently guide treatment options and overall prognosis.

Critical Care Medicine

35

Approach to the Patient in the Critical Care Setting

Sarah Allen, DVM, DACVECC

Massachusetts Veterinary Referral Hospital, Woburn, MA, USA

Patients presenting to a veterinary emergency room represent a diverse array of illness and injury, ranging from mild to life threatening. The use of a triage system allows these patients to be systematically evaluated and prioritized based on presenting signs, history, and initial vital parameters. While no triage system is perfect, success is enhanced when staff are well trained. Every facility and emergency team should have a standard triage system, appropriately trained staff to perform triage, and a reliably equipped area to allow for efficient and prompt care of these patients' needs.

A clinician's relationship with a critical patient often begins upon presentation to the hospital or, in the case of a referral center, upon admission to the intensive care unit (ICU). As the direct definition of the word "critical" states, a critical patient is one that is at a stage of disease when an abrupt change for better or worse may be expected, or that has an illness or condition involving danger of death. Due to this unstable position, these patients require intense and continuous assessment and care and may benefit from consultation with a critical care specialist.

Physical Exam

A thorough initial physical exam, as well as frequent sequential exams, should be performed with the goal of promptly identifying current and evolving problems. Advanced diagnostics may become necessary in order to fully illuminate clinical findings but should never be used in place of a physical exam. While each clinician should have a routine by which they approach an exam, it may be required that the order of the exam be varied in critically ill patients, based on each patient's current condition and stability. Care must be taken to ensure that all systems are assessed due to possible variation in exam sequence. The exam may need to be performed in multiple phases to allow for patient comfort and safety.

Due to the critical condition of these patients, initial exam time should be spent on evaluating critical systems, particularly airway and breathing, heart and circulation, and neurologic status. For patients in respiratory distress, brief attempts at an exam may need to be interspersed between periods of rest in an oxygen chamber. Observation of the patient's respirations with attention to chest wall and abdominal movement may also provide information as to the cause of distress. Emphasis should be placed on thoracic auscultation to help discern the cause of distress, noting stridor, air movement or increased/decreased lung sounds. If the patient is not breathing or is ineffectively moving air, intubation and manual ventilation is required.

The heart should be ausculted while peripheral pulses are palpated. If heartbeat and pulses are absent, CPR must be instituted immediately (see Chapter 37). If the heart is beating and pulses are absent or irregular, further investigation and intervention are required to restore effective circulation. During heart auscultation, the heart rate and rhythm should be noted and heart sounds should be evaluated for presence of murmurs or muffled nature.

The patient's neurologic status should be evaluated and continuously monitored for alterations or deterioration. Particularly with trauma, signs of spinal cord injury should be sought and appropriate stabilization initiated prior to further manipulation of the patient. If traumatic brain injury is suspected, efforts to increase cerebral perfusion and decrease intracranial pressure (ICP) should be instituted, including blood pressure support, head elevation, and minimal jugular vein occlusion. Judicious IV fluid therapy is recommended to restore blood pressure to a minimum of a systolic of 90 mmHg or a mean of 60 mmHg.

Companion website: www.wiley.com/go/bruyette/clinical

Occasionally, emergency interventions are necessary at the time of examination to stabilize the patient so that further examination and diagnostics can be performed and an overall treatment plan composed. If it is possible to complete a comprehensive exam at the time of initial evaluation, it should done.

History

A complete history is required for appropriate care of a critical patient. During triage and emergency presentation, the need for speed and efficiency often prevents the gathering of a thorough history. Once the patient's condition allows, further history to be discovered includes past medical problems, past and recent surgical interventions, origin and travel history, and general wellness and preventive care (vaccines, flea/tick/parasite prevention) schedule. Medications administered by the owner should be determined, with specific questioning about vitamins, supplements, and over-the-counter medications. Efforts should be made to obtain copies of medical records from other veterinary facilities where the patient has been treated recently and in the past. These records should be carefully reviewed to identify areas in the patient's history that the owner may have forgotten or misunderstood.

Assessment

After the history and physical exam have been completed, time should be taken to document the information and to form an active problems list. The initial list may consist of an identified problem without an underlying cause. Initial therapeutic interventions directed at the current problem(s) should be initiated and the problem list and eventual diagnosis list updated as indicated by response to therapy or results of additional diagnostics. While a written problem list is commonly used by beginning clinicians and then discarded as clinicians gain experience, with complicated cases it remains essential to ensure best patient care.

Record Keeping

Not only are formal medical records required by law, they help the clinician keep the case documented and organized and assist in transfer between clinicians and facilities. Medical records also provide information for follow-up care after discharge and in the future. The medical record should consist of the presenting history and physical exam, a problem list, a diagnosis list, and results of laboratory and imaging procedures. For the duration of hospitalization, a minimum of one physical exam should be documented daily as well as an updated problem/diagnosis list and an updated treatment and diagnostic plan. The ideal medical record will also document communications between the treating veterinarian and owner and any consulting veterinarians that have been involved.

Client Communication

The assessment and medical management of a critical patient are complicated and challenging enough. Adding to the difficulty is the need for the clinician to communicate effectively and compassionately with the owner. As the case evolves, the client needs to be informed of the working diagnosis, financial costs, and short- and long-term prognosis for the current condition. Apprising the owner of the risks and benefits of each proposed treatment or therapy is necessary in order for them to make an informed decision. As many of these patients are unstable, a CPR resuscitation code is a required topic of conversation to ensure that the owner's wishes are followed in the event of an arrest. Detailed written client communications should be kept as part of the formal medical record. These notes help all clinicians involved with a case to know what has been discussed and when. They are also invaluable should a case go to litigation.

Referral

When treating a critically ill patient, a large consideration is whether the current facility can offer the patient and client the level of care that they need and want. While many facilities may be able to meet the minimum standard of care, it is always best to inform the owner of the option of referral, making sure to communicate the pros and cons of transfer as well as the expected financial cost of treatment at another facility. While some owners may opt to not pursue referral, many will elect to transfer to a hospital that has 24-hour doctor care or other advanced capabilities. For many general practitioners, referral to a 24-hour facility for any patient requiring overnight IV fluids or observation is common. Cases may also need referral for advanced diagnostics including imaging (ultrasound, computed tomography, magnetic resonance imaging), advanced surgical procedures (soft tissue and orthopedic), or for advanced therapeutics (long-term ventilation, transfusion, dialysis).

Prior to referral of critically ill patients, the treating clinician should call the intended receiving facility and speak to the specialist who will be taking control of the case to ensure the transfer is made as safe and efficient as possible. All available medical records should be copied and should accompany the pet in a hard copy format.

The "Rule of 20"

In addition to serial physical exams and frequent reevaluation of the active problem list, there are a multitude of critical parameters that need to be evaluated at least daily in the critical patient. Developed by Rebecca Kirby, a founding Diplomate of the American College of Veterinary Emergency and Critical Care, the "Rule of 20" provides a comprehensive tool to guide the continuous evaluation and integration of a patient's organ systems, laboratory findings and treatment and many critical care specialists find it useful to refer to the "Rule of 20" on a daily basis with critically ill patients. Each element will be discussed below, many of which will be covered in detail in other chapters.

Fluid Balance

Fluid therapy is a common treatment in critical patients with a goal to reestablish and maintain hydration and to ensure circulating volume is maintained. Often dehydration and hypovolemia require rapid fluid replacement in the form of boluses. After initial volume expansion and rehydration, each patient's "maintenance" fluid needs will differ due to underlying conditions, ongoing losses, and variations in metabolism. Each patient will also have a unique ability to tolerate administered fluids. The consequences of overhydration or inappropriate fluid redistribution include pulmonary edema, peripheral edema, and third spacing of fluids within body cavities. Assessment of response to administered fluids requires monitoring of many parameters, including mucous membrane color and moistness, skin turgor, heart rate, and body weight. Each of these parameters should be assessed several times per day. Monitoring of blood pressure and urine output can provide additional information on a patient's needs. Monitoring of central venous pressures and changes in blood gas variables (lactate, base deficit) are used for advanced monitoring of fluid therapy.

Blood Pressure and Perfusion

There are many methods to monitor blood pressure, including direct (via an arterial catheter and pressure transducer) and indirect (Doppler and sphygmomanometer or oscilllometric measurements) options. A good general goal is to maintain a mean arterial blood pressure >60 mmHg and a systolic blood pressure >90 mmHg for optimal organ and tissue perfusion. Hypotension that is nonresponsive to fluid therapy may indicate the presence of an underlying acid–base or electrolyte disorder or the need to begin therapy with a vasoactive agent. Central venous pressure and lactate monitoring can provide additional information on the need for vasopressor therapy. While less commonly encountered clinically, monitoring for and treatment of hypertension are useful to prevent complications including retinal detachment, neurologic impairment, and end-organ injury.

Cardiac Function

Heart function should be evaluated not only by heart rate and rhythm but also ability to effectively pump blood forward through evaluation of peripheral limb temperatures and capillary refill time. Electrocardiographically confirmed arrhythmias should be treated if perfusion is compromised. Echocardiography is helpful in identifying underlying structural heart disease as well as visualizing cardiac filling and contractility. Additional treatments directed at optimizing cardiac function, including IV fluids, inotropic support or afterload reduction, should be introduced as indicated.

Albumin

Albumin is a blood protein produced by the liver that plays an essential role in a multitude of physiologic processes, including fluid balance, drug transport, tissue healing, and coagulation. Synthetic colloids can be used to maintain fluid in the intravascular space but they do not substitute for albumin's other roles in the body and may be associated with acute kidney injury. Albumin levels <2 g/dL have been associated with a poor prognosis in critically ill patients and may indicate the need for replacement with plasma (frozen or fresh frozen) or canine albumin transfusions.

Oncotic Pull

Adequate oncotic pressure is required to maintain appropriate intravascular volume and prevent interstitial fluid loss that can propagate hypovolemia and edema formation. Oncotic pressure changes in direct correlation with albumin concentration and can therefore be augmented with administration of natural colloids.

Oxygenation and Ventilation

Oxygenation can be assessed by arterial blood gas measurement (PaO_2) or pulse oximetry (SpO_2), and allows a clinician to evaluate how well a patient is moving oxygen into the blood. A PaO_2 <80 mmHg or a SpO_2 <96% indicates the need for supplemental oxygen which can be provided by flow-by oxygen, nasal oxygen cannula, an oxygen chamber or endotracheal intubation with 100% oxygen. Ventilation is evaluated by assessing the arterial $PaCO_2$ or indirectly by using end-tidal CO_2 concentration. End-tidal CO_2 monitoring can be used on intubated as well as nonintubated patients using a tight-fitting facemask or a nasal cannula. In situations of hypoventilation, hypercarbia ($PaCO_2$ >60 mmHg) should be treated with supplemental oxygen and mechanical ventilation if needed. Repeated measurements are required to monitor response to therapy.

Glucose

Ideally, glucose should be maintained in the normal range (75–120 mg/dL). Hypoglycemia can manifest as peripheral weakness, altered neurologic function (obtundation, stupor or seizures), and hypotension. Severe infection, synthetic liver failure, neoplasia, and hypoadrenocrticism are common causes of hypoglycemia in critical patients. Young and undernourished animals are predisposed to developing hypoglycemia. Administration of supplemental dextrose in IV fluids is indicated if normoglycemia cannot be maintained via enteral nutrition. Hyperglycemia due to diabetes requires exogenous insulin administration to prevent ketoacidosis, hyperosmolarity, and dehydration due to osmotic diuresis. Hyperglycemia associated with trauma is associated with a worsening prognosis. Although well described in the human medical literature, the benefits of tight glycemic control for hyperglycemia in veterinary medicine are unproven and should only be attempted at a 24-hour critical care facility.

Electrolyte and Acid–Base Balance

Critically ill patients often have significant acid–base and electrolyte disorders that contribute to their overall clinical condition. Important electrolytes to be monitored include sodium, potassium, ionized calcium, chloride, magnesium, and phosphorus. Many disease states are associated with particular electrolyte arrangements and care should be taken to customize monitoring to an individual patient's signs and diagnosis. Critical patients should have electrolytes monitored at least once daily while on IV fluid therapy. Acid–base derangements can be the result of metabolic or respiratory conditions, or a combination of the two. In addition to pH, PCO_2 and HCO_3^-, lactate levels should be evaluated to assist in identifying the origin of an acid–base disorder. Most hyperlactatemia is the result of impaired oxygen delivery and rapid resolution is generally associated with better patient outcome.

Mentation and Intracranial Pressure

Close monitoring and documentation of a patient's mentation is necessary to allow prompt detection of any changes that may indicate progression of intracranial disease or a hemodynamic or metabolic disease with neurologic consequences. Elevated ICP is common in patients with head trauma and inflammatory encephalitides. It should be remembered that not all mentation changes are due to structural changes or ICP alterations. Hypotension and hypoglycemia can manifest as altered mentation. Hepatic diseases resulting in encephalopathy can lead to neurologic signs that may indicate progression of a disease process.

Coagulation

Impaired coagulation in the critical patient due to thrombocytopenia or clotting factor deficiency is easy to identify. It is more difficult to evaluate patients for hypercoagulability, which can result in thromboembolic sequela and secondary complications. Hypercoagulability can be due to systemic inflammation from trauma, infection or neoplasia as well as a multitude of underlying metabolic and endocrine disorders. Advanced diagnostics, including thromboelastography, are required to fully evaluate a patient for hypercoagulability. As underlying conditions predisposing to a hypercoagulable state are identified, clinicians should weigh the benefits versus risks of initiating thromboprophylaxis.

Red Blood Cell and Hemoglobin Concentration

Adequate oxygen delivery is important for all patients, but is especially crucial for critical patients whose systems are already taxed by underlying conditions. Hemoglobin is necessary for oxygen transport and delivery and red blood cell transfusions should be administered in response to clinical signs associated with anemia, including tachycardia, increased respiratory rate, hypotension, and weakness. While there is no standard transfusion "trigger" point, each patient should be individually assessed for the need for a transfusion based on clinical signs, underlying disease processes, and anticipated losses. Evaluation of venous oxygen saturation may allow early identification of inadequate oxygen delivery.

Utilizing a goal-directed approach, red blood cell transfusion to maintain a hematocrit >30% is recommended if central venous oxygen saturation ($S_{cv}O_2$) >70% is not maintained despite supplemental oxygen and normalization of intravascular volume and systemic blood pressure.

Renal Function and Urine Output

Kidney function should be frequently evaluated in critically ill patients as hypotension, thrombosis, and nephrotoxic medications can cause temporary or permanent injury resulting in renal insufficiency. Urine output should be at least 1 mL/kg/h but oliguria should be evaluated in light of fluid input for an individual patient. An indwelling urinary catheter, and recording fluid in and fluid out, assists in evaluating a patient's overall fluid status. In addition to urine output, insensible losses, losses from surgical drains, chest tubes or wounds should also be accounted for. Commonly accepted insensible loss rates are 10–20 mL/kg/day. Fluid input includes IV fluids (crystalloids and colloids) as well as nutritional support in the form of parenteral or enteral nutrition. In patients with possible renal impairment, close monitoring of fluid ins/outs may assist in maintaining fluid balance. Daily monitoring of serum BUN and creatinine is recommended to detect potential renal injury early. Especially in patients with normal renal values at the time of presentation, even mild changes in BUN or creatinine (even within the reference range) can be a harbinger of renal injury or multiorgan failure. Early detection and aggressive treatment can have a dramatic impact on patient outcome. Analyzing urine for casts, glucose, and protein is also used to identify renal injury and dysfunction.

Immune Status and Antibiotic Coverage

Critically ill patients are often battling infections and may have overextended or overwhelmed immune systems. Empirical antibiotic therapy is recommended for patients with suspected infections and antibiotic selection should be based on presumed site of infection, likely organism involved, and hospital surveillance profiles. When empirical antibiotics are used, initial broad-spectrum coverage is recommended with deescalation based on results of culture and sensitivity panels. In addition to bacterial infections, clinicians should be aware of the concern for rickettsial, protozoal, fungal, and parasitic infections that may require additional antimicrobial therapies. In all critical patients, care should be taken to practice aseptic techniques when examining and treating them. Clinicians and nurses should practice good hygiene with frequent hand washing. Exam gloves should be worn at all times when handling any patient and the use of isolation gowns should be considered if the patient is severely immunocompromised.

Gastrointestinal (GI) Motility and Integrity

Many underlying conditions can result in gastric and intestinal ileus and compromise of the GI mucosal barrier. Decreased intestinal motility results in stasis of intestinal contents and overgrowth of normal bacterial flora. An altered mucosal barrier results in an increased risk for bacterial translocation and subsequent sepsis. Gastric and small intestinal stasis may result in vomiting, while large intestinal derangements may lead to diarrhea, which can create and/or exacerbate hypovolemia. Medical intervention (promotility medications, physical activity) to increase GI motility and protect the mucosal barrier is recommended. If possible, enteral nutrition is recommended to maintain enterocyte health, decrease villous atrophy, increase GI motility, and improve mucosal integrity.

Drug Metabolism and Dosage

Medication doses and routes should be reviewed daily for accuracy, safety (side-effects, metabolism, and drug interactions) and continued necessity. In the face of altered renal or hepatic function, it may be prudent to reduce the dose or increase the interval of medications to decrease the risk of toxicity and side-effects. Highly protein-bound drugs should be used with caution in hypoalbuminemic patients due to the potential for higher than expected plasma levels.

Nutrition

All attempts should be made to provide appropriate nutritional support to critical patients in order to avoid a negative energy balance contributing to organ dysfunction, delayed healing, immunocompromise, and GI dysfunction. Enteral nutrition is ideal and can be accomplished by voluntary patient eating or feeding tubes (e.g., nasogastric, esophageal, gastrostomy or jejunostomy tubes). Total or partial parenteral nutrition is an option for providing nutritional support to patients with a contraindication to enteral nutrition (severe ileus, intractable vomiting, malabsorptive conditions).

Analgesia

Appropriate pain management is necessary to improve patient comfort and decrease the secondary effects of pain. Common signs of pain include increased heart rate, agitation, and discomfort upon palpation of wounds. Multiple pain scoring systems have been validated for

use in veterinary medicine and provide a systemic and repeatable approach to evaluating pain and a patient's response to pain medications.

Nursing Care and Patient Mobility

While focusing on the medical care of a critically ill patient, it is easy to overlook patient comfort and husbandry. In patients that require extensive nursing care, these measures may be skipped due to the time and staffing they require, especially in larger patients that may require multiple people to move and support them. Many of these patients are nonambulatory and physical therapy should be provided several times a day. Passive range of motion of limbs keeps muscles and joints flexible and can improve circulation. For patients with peripheral limb edema, tissue massage from distal to proximal can assist in resolution. Deep bedding and frequent repositioning are necessary to prevent pressure sores, lung atelectasis, and edema formation. Standing sessions are useful and allow patients to attempt supported ambulation. If possible, underwater treadmill therapy is an option for assisted mobility to increase flexibility, strength, and circulation. Efforts should be made to frequently take nonambulatory patients out of their cages and, if feasible, outside for a "visual vacation." For patients with lung consolidation from pneumonia or other conditions, positional coupage based on afflicted region can be useful in resolving consolidation. In patients with surgical incisions or traumatic tissue injury, cold laser therapy can be considered to improve tissue blood supply and increase healing. Patients should be diligently cleaned to prevent skin irritation and burns from urine and feces soiling.

Bandage and Wound Care

All IV catheters should be routinely changed and catheter insertion sites evaluated for infection and inflammation. Each facility should establish a protocol for the placement and maintenance of peripheral IV catheters and advanced catheters such as central IV catheters and arterial catheters. At a minimum, daily bandage changes should be required but other considerations include acceptable indwelling duration, flushing/locking procedures, level of sterility during placement and handling, and a protocol for investigation and treatment of suspected catheter site infections. Indwelling urinary catheters also require set protocols for placement and maintenance including prepuce/vulva flushing, collection system handling/changing, acceptable indwelling duration, and a protocol for investigation of suspected infections due to catheterization. Bandages placed on wounds require frequent changing to evaluate for changes in underlying wounds. During critical illness, peripheral edema can rapidly develop and cause wraps or bandages to become tight and constricting. Soiled or wet bandages should be immediately changed as they provide an excellent source of infection. Wounds and incisions should be closely monitored for healing and any changes that occur, including bruising, odor, swelling, and discharge, should be immediately investigated.

Tender Loving Care

Amongst all the medications, procedures, and treatments, time should be taken to simply sit with a patient to provide comfort and affection. Once again, this is an area that is easy to omit when a patient has intense medical treatments and support staff is spread thin. Patients that require many treatments are often mislabeled as being "difficult cases" rather than appreciated for the multiple levels of complex care they require to support their severe disease states. Many times patients will only eat when being petted. Owner visits should be encouraged and efforts made to allow visits to occur outside the hospitalization area to allow patients stress-free periods during which they may eat or rest. In 24-hour care facilities, efforts should be made to allow the patients to have treatment-free periods during which uninterrupted rest can occur. Clinicians should attempt to arrange treatments in groupings to establish greater intervals of time when the patient is not being handled or interacted with. Especially during evening hours, further emphasis should be placed on treatment-free periods. During these evening times, lights should be dimmed and attempts made to decrease ambient noise. There may be benefit to playing relaxing music such as soft classical or nature sounds.

Euthanasia

For many critical patients, compassionate euthanasia may be the most humane treatment available. As a case progresses, lines of communication regarding euthanasia should remain open between owners and the medical staff. Despite being common in veterinary medicine, some owners may not know it is an option for their pets. Broaching the subject of euthanasia can be difficult and needs to be handled with special attention. Even in cases with a grave or guarded prognosis, owners may not consider euthanasia due to religious or ethical beliefs.

Conclusion

Each critical patient will require a unique and customized approach to every element of their care. While the

care for these cases is more complicated, with it comes a greater feeling of success when a patient is discharged to its family. Many critically ill patients will not have a positive outcome and often the deciding factor in outcome is determined by the attention provided to the patient and owner. It is easy to influence a client to terminate care for a patient with a guarded prognosis, but experience and clinical knowledge should be used to assist clients in making the best decision for them and their pet.

The care of critical patients can be exhausting for the entire medical team. Clinicians should take the time to frequently discuss the details of these cases with support staff to ensure that they understand the importance and motivation behind medical treatments and owners' decisions.

Fluid Therapy

Teresa Rieser, DVM, DACVECC

Veterinary Specialty Care, Mt. Pleasant, SC, USA

Intravenous fluids are a commonly used treatment in small animal medicine. A full understanding of the indications and potential fluid choices allows clinicians to reap the maximum benefit from fluid therapy while minimizing possible complications.

Vascular Access

Catheter Types

Fluid therapy can be administered via a number of different routes, including intravenous, subcutaneous, and intraosseous. In order to administer fluids intravenously, venous access must first be established. Most commonly, this involves the placement of a catheter within a peripheral vein or within the jugular vein. There are a variety of catheter types currently available, including winged needle (butterfly catheters), over the needle, through the needle and catheters that are placed using a guide wire. When placing an intravenous catheter, a number of questions should be considered to ensure the most appropriate catheter is selected.

Butterfly-type catheters are rigid needles with a plastic "butterfly" at the needle hub to make handling easier. The needles are then attached to a length of tubing that can be connected to a syringe for bolus drug delivery or blood sample collection. This type of catheter is useful for instances where the catheter does not need to be maintained within the vein. An example would be an IV bolus injection of medication or a single episode of venipuncture to collect blood samples.

If a catheter needs to be maintained within a peripheral vein for any duration of time then an over-the-needle type catheter is most commonly used. Theses catheters are relatively easy to place and can be maintained within a vessel for a number of days with diligent nursing care. If placed in the critically ill, emergent or surgical patient, the short length of the catheter coupled with a reasonable diameter allows for rapid bolusing of fluids. This type of catheter is usually secured in place with medical tape.

Through-the-needle catheters are also widely available. This type of catheter tends to be greater in length and is used when central venous access is desired for repeated blood sampling or the administration of a hyperosmolar solution such as total parenteral nutrition. Catheters placed using a guide wire can be single lumen or multilumen and are placed into a central vein. This type of catheter allows for blood sampling, fluid administration, including the concurrent administration of noncompatible fluids through separate lumens, as well as the administration of hyperosmolar solutions that would cause significant phlebitis if administered peripherally. Placement of a central venous catheter also allows for monitoring of central venous pressure in patients to guide fluid therapy.

Intravenous catheters may be made of a number of different materials, including polyurethane, Teflon®, and silicon elastomer (silastic). Polyurethane and Teflon catheters are most commonly used, as they are cost-effective and relatively easy to insert. Silicon elastomer (Silastic®) catheters are very flexible and less likely to result in catheter-related thrombophlebitis but they are more expensive and technically challenging to place. Silastic catheters are used for long-term catheterization, while Teflon or polyurethane catheters are reasonable choices for shorter term catheterization.

The placement of intravenous catheters is common in small animal veterinary medicine. Peripheral catheters are most commonly placed in the cephalic, medial or lateral saphenous or femoral vein. In some animals, the veins of the ear can also be used for catheterization. Central catheters are placed within the jugular vein or threaded from a peripheral vein into the vena cava. In order to preserve the integrity of the catheter and minimize discomfort and inflammation, catheters should not cross a joint. Common sense would also dictate that the

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

patient's disease process might make one catheterization site preferred over another. An example is the parvoviral enteritis patient with voluminous diarrhea; a hind leg catheter should not be the first choice, as it would probably become soiled in short order.

The area selected for placement should be clipped and aseptically prepared, taking care not to abrade the skin, as this can increase the rate of catheter-related complications. In addition to preparing the patient, staff members should also wash their hands and wear gloves. Once the catheter is seated within the vein, it is flushed with sterile saline. There has been no proven benefit to using heparinized saline in lieu of sterile saline as a catheter flush. Peripheral catheters are secured to the limb with medical tape. It is common to suture central lines in place and then to protect them further with a bandage. Catheter sites should be kept clean and dry and inspected at least daily for evidence of inflammation.

Catheter-Related Complications

Catheter-related complications are common but can be minimized with relative ease. Any material used for an intravenous catheter will cause some inflammation within a vessel so it is important to diligently assess catheter sites for indication of not only infection but also thrombophlebitis. Catheter sites should be inspected daily for swelling, pain, or induration of the vessel. An indurated vessel will feel firm and ropey when palpated. It is also important to monitor patient response when infusing medications. As catheter integrity degrades, the animal may object when drugs are infused.

The possibility of infection or thrombophlebitis should be suspected in any patient who has an intravenous catheter and develops signs of infection or exhibits a reaction to injections that were previously well tolerated. A patient who develops a low-grade fever in hospital without another potential nidus of infection or inflammation should have all catheter sites promptly inspected. While in the past it has been recommended that catheters be removed after 72 hours to prevent infection, multiple studies have shown that the rate of infection does not increase if catheters are allowed to remain in place for longer periods of time and that it is more important to keep the area clean and the catheter dressing unsoiled.

Infiltration occurs when a catheter moves out of a vein into the surrounding tissue. Any fluids or drugs administered through the catheter are therefore infiltrated into that area instead of being delivered to the vein. Most commonly, infiltration is identified by swelling and tenderness at the catheter site. If vesicant medications are administered perivascularly, the term used is *extravasation*. The sequelae of extravasation can be more severe and may include heat, pain, redness, swelling, and induration. Sloughing of the skin and the perivascular tissue can then follow. If the catheter is a central line, it may not be immediately evident that the position of the catheter has changed. Infiltration of fluid in this instance can result in mediastinal or pleural fluid accumulation that can be severe enough to cause dyspnea.

The key to preventing catheter-related complications is vigilance. Place catheters away from joints and avoid using rigid materials, like a butterfly catheter, for prolonged infusion. Inspect the catheter site frequently. Before infusing drugs, aspirate the catheter for blood (a "flash") and then flush with saline to ensure proper placement and patency of the catheter.

Catheter foreign bodies occur when a portion of the catheter becomes free within a vessel and lodges (most commonly) in the heart or a pulmonary artery. Catheter foreign bodies may occur when catheters are accidently cut during removal or when a through-the-needle catheter is cut off by the introducer needle. It can also occur when an over-the-needle catheter is partially advanced and then replaced on the needle while seated within a vein. Infrequently, the shaft of a catheter can become disconnected from the catheter hub. These types of mishaps can be associated with serious complications, including cardiac perforation, endocarditis, pulmonary embolism, sepsis, and arrhythmias. Options for management of catheter foreign bodies include surgical retrieval, endovascular retrieval, or leaving the catheter *in situ*. In human medicine, attempted retrieval of the foreign body is preferred. Successful retrieval of intravascular foreign bodies using endovascular techniques has been reported in five dogs, a goat, and a horse.

Air emboli occur when air is introduced into the vascular system through a catheter. This can be seen when a central line is advanced into the thoracic cavity and the change in pressure draws air into the system. More commonly, air can be introduced through incorrectly prepared IV lines or when air is injected into rigid fluid containers to speed an infusion. Small emboli are usually clinically silent. Large air emboli can result in a dramatic increase in pulmonary vascular resistance followed by pulmonary edema formation and dyspnea. If a large enough bolus of air is delivered, the right ventricular outflow tract can be obstructed. If a central line is in place when an air emboli occurs, aspirating the air out of the heart is the best choice for treatment.

Body Fluid Compartments

Body Water Distribution

Approximately 60% of body weight is water. This percentage can change based on age, gender or body

composition. Both humans and dogs have been shown to have a decrease in total body water with age. Body composition also plays a role and it is useful to base fluid therapy recommendations on lean body mass as opposed to body weight. In the normally fleshed animal, the lean body mass is approximately 80% of total body weight. In obese patients, fat (which has a lower water composition than other tissues) is abundant, so lean body mass can be estimated as 70% of body weight. By contrast, in the underconditioned animal, measured body weight is equivalent to the lean body weight.

Total body water is further divided into body fluid compartments. The largest portion of total body water is found within the cells, with the intracellular fluid (ICF) compartment accounting for roughly two-thirds of total body water. The remaining one-third is found in the extracellular fluid (ECF) compartment. The ECF compartment is further divided into the interstitial space, which contains roughly 75% of the water of the ECF, and the vascular space, which contains the remaining 25% as plasma volume. While it is useful to describe total body water based on its location, it is important to remember that fluid balance is dynamic and movement between fluid compartments is occurring constantly.

Body fluids contain varying concentrations of solutes in addition to water. The ECF and ICF have vastly different solute concentrations but the total numbers of cations and anions in all body fluids must be equal to maintain electroneutrality. In the ECF, sodium is the major cation and chloride and bicarbonate are the most common anions. By contrast, within the cell, the most common cations are potassium and magnesium and the most common anions are phosphates and proteins. Body fluid compartments are dynamic and the relative volume within the fluid compartments is dependent on the number of osmotically active particles present within the space. The normal plasma osmolality (tonicity) is 300 mOsm/kg in the dog and 310 mOsm/kg in the cat. Approximately 95% of total serum osmolality in the normal animal results from the presence of sodium, potassium, chloride, bicarbonate, urea, and glucose while large molecules such as albumin have little effect on osmolality.

The body must balance daily fluid losses with intake. In addition to pathologic fluid losses, all animals have insensible fluid losses via the urinary tract, gastrointestinal tract, and respiratory system. When fluid and solutes are lost from the body, the relative effect on the different body compartments is dependent on the tonicity of the fluid lost. Lost fluid can be hypertonic to plasma, isotonic, or hypotonic. Usually fluid is lost from the ECF. When hypotonic fluid is lost from the ECF, the ECF becomes hypertonic relative to the ICF. Because the solutes (sodium, potassium, and chloride) are effective osmoles, the majority of equilibration will occur by the movement of water from the ICF to the ECF. This results in a decrease of the ICF volume but a bolstering of the ECF. An example of hypotonic fluid loss would be polyuria seen with renal disease. When isotonic fluid is lost, there is no change in the tonicity between the ECF and ICF. For this reason, there is no net fluid movement between fluid compartments and the volume lost results in an absolute decrease in the volume of the ECF. An example of isotonic fluid loss would be acute hemorrhage. Finally, in the case of hypertonic fluid loss from the ECF, the ECF becomes hypotonic relative to the ICF and water moves from the ECF into the ICF, which further exacerbates the volume loss. It is important to recognize that an animal can have hypovolemia without dehydration but dehydration cannot occur without some degree of hypovolemia.

Water Movement

Movement of fluid between body fluid spaces is governed by Starling's law.

$$\text{Fluid flux} = k_f\left[\left(P_c - P_i\right) - \left(\pi_c - \pi_i\right)\right]$$

In this equation, k_f is a filtration coefficient unique to each tissue bed that reflects the relative permeability of the capillary wall within that tissue bed, P_c refers to the hydrostatic pressure within the capillary and P_i refers to the hydrostatic pressure within the interstitium. Similarly, π_c and π_i refer to the oncotic pressure in the capillary and interstitium respectively. Recall that oncotic pressure differs from osmolality/osmolarity and refers to the force exerted by large, impermeant molecules to hold water within either the capillary or interstitial space. Clinically, oncotic pressure is referred to as colloid osmotic or colloid oncotic pressure (COP). The balance between these opposing forces determines the direction and degree of net fluid movement.

When fluids are administered too aggressively, the intravascular space is overexpanded. This results in an increase in hydrostatic pressure within the capillaries that exceeds the oncotic pressure in the vessels and favors the movement of fluid into the interstitium, which is composed of a meshwork of collagen and glycosaminoglycans as well as proteins and electrolytes in solution. There are three mechanisms, known as tissue safety factors, that prevent fluid accumulation within the interstitium and their relative importance varies between tissue types. As fluid moves in, the hydrostatic pressure rises rapidly due to the nondistensible nature of the interstitium and opposes further fluid accumulation. Opposition to the movement of fluid into the interstitium also occurs as interstitial oncotic pressure drops due

to dilution. Finally, as the hydrostatic pressure increases in the interstitium, lymphatic drainage is increased. If increased capillary hydrostatic pressure persists, however, these safety factors can be overwhelmed and the meshwork within the interstitium can be disrupted. When this occurs, the resistance to further fluid accumulation becomes minimal and manifests clinically as pitting edema, chemosis, and, in rare circumstances, pulmonary edema.

Fluid dynamics in pulmonary tissue have unique characteristics. The pulmonary capillary pressure is usually lower than in other tissues and the interstitial pressure is more negative (some tissues actually have a negative interstitial pressure) while the COP is higher than other tissues. The fact that the pulmonary capillaries are relatively permeable to protein contributes to this higher COP. In addition, the alveolar epithelial cells actively transport sodium into the interstitial space, promoting movement of fluid out of the alveolar space and into the interstitium. The net result of these characteristics is that fluid movement from the alveoli into the interstitium and then to the lymphatics is favored. This tendency is overcome when the pulmonary capillary pressure exceeds 25 mmHg, at which point fluid will accumulate within the alveoli. If the animal also has an increase in pulmonary capillary permeability such as occurs in sepsis or systemic inflammatory response syndrome (SIRS), or if the animal is hypoalbuminemic, pulmonary edema will occur at lower hydrostatic pressures.

Intravenous Fluid Types

In order to make logical choices with fluid therapy, it is important to understand the components and behavior of the different classes of intravenous fluids available in clinical practice.

Crystalloid Fluids

Crystalloid fluids are the most common type of fluids used in veterinary medicine. Crystalloids are defined as fluids containing electrolyte and nonelectrolyte solutes that are capable of entering all the body fluid compartments. They can further be described as "balanced" or "unbalanced." A balanced crystalloid has a composition similar to that of the ECF. An example would be lactated Ringer's solution (LRS) or Normosol-R®. An unbalanced crystalloid's composition does not mimic that of the ECF. An example would be 0.9% NaCl.

Crystalloids can also be described by their osmolarity. An isotonic crystalloid has an osmolarity similar to normal plasma osmolarity (300–310 mOsm/L) while the osmolarity of a hypotonic solution is less than that of normal plasma and a hypertonic solution is greater than normal plasma. An example of this can be seen with the different sodium chloride-based crystalloids: 0.9%NaCl is an isotonic crystalloid solution (308 mOsm/L), 0.45% NaCl is a hypotonic crystalloid (154 mOsm/L), and 7.2% NaCl is a hypertonic crystalloid (2464 mOsm/L).

Finally, crystalloids can be described as replacement fluids or maintenance fluids. The composition of these two categories is quite different and warrants a brief explanation. When a crystalloid fluid is administered intravenously, the majority of the volume given will move out of the vascular space and into the interstitium. When a 1 L bolus of an isotonic crystalloid is given, it can be anticipated that after one hour only 25% of the delivered volume remains within the vascular space. The majority of the delivered volume has moved into the interstitium and for this reason, a replacement fluid is designed to approximate the fluid composition of the ECF. By contrast, a maintenance fluid is designed to meet the ongoing insensible losses of the patient and has a lower sodium concentration and usually a higher potassium concentration. A unique crystalloid fluid that does not fall within the replacement versus maintenance classification scheme is 5% dextrose in water (D5W) that is composed entirely of dextrose and water. When given, D5W is effectively equivalent to administering pure water, as the dextrose is rapidly metabolized to CO_2 and water.

Specific clinical presentations may respond most effectively to specific crystalloid choices but in the majority of instances, a balanced, isotonic crystalloid is appropriate for initial fluid therapy. Some of the clinical presentations where one fluid may be preferred over another include hypochloridemic metabolic alkalosis and Addisonian crisis (0.9% NaCl) and urethral obstruction (LRS or Normosol-R), among others.

Additives such as 50% dextrose, potassium chloride, magnesium sulfate, and calcium gluconate can be incorporated into crystalloid fluids to meet specific patient needs; however, not all fluid additives are compatible with all isotonic crystalloids. Investigation into compatibility is required before fluid supplementation is undertaken. Certain crystalloids such as 0.9% NaCl and D5W are often used as carriers for a variety of drugs, including anesthetics, inotropes, vasopressors, and insulin, but compatibility should always be verified before administration.

Hypertonic saline is available in a variety of concentrations ranging from 3.0% to 7.5% and is a potent expander of the vascular volume. With an osmolarity of 2567 mOsm/L, 7.5% NaCl will effectively increase the extracellular fluid volume by five times the administered volume due to the movement of water from the intracellular and interstitial spaces into the intravascular space

in response to the profound osmotic gradient created. However, like other crystalloid solutions, the intravascular volume expansion will not remain for long if administered alone. For this reason, hypertonic saline is often combined with a synthetic colloid to extend the duration of effect. Because the action of hypertonic saline is dependent on movement of volume from the interstitial space to the intravascular space, it is relatively contraindicated in dehydrated patients. Hypertonic saline is a popular choice for small-volume resuscitation and is the preferred choice for the resuscitation of the hypotensive head trauma patient. In addition, it may also be used in patients with intracranial hypertension with, or in lieu of, mannitol.

Synthetic Colloids

Colloids are molecules of high molecular weight, which exert osmotic activity and thus promote the movement of fluid from the interstitium into the vascular space. Colloids can first be described as natural or synthetic. An example of a natural colloid is the albumin molecule. Synthetic colloids can further be divided into three classes: gelatins, dextrans, and hydroxyethyl starches (HES). The most commonly used class of synthetic colloid is the hydroxyethyl starches, which are plant-derived proteins that have undergone modification to prevent rapid degradation.

When describing hydroxyethyl starches, a number of parameters are used. First is the molecular weight, which affects the degree of "oncotic pull" exerted by the solution, with lower molecular weight solutions generally exerting a greater effect. Molecules in HES formulations tend to be polydisperse and can range in size from a few thousand to a few million kilodaltons. The distribution within a solution follows a bell-shaped curve. By convention, the molecular weight used to describe the solution is the average molecular weight.

The second parameter used in description of HES solutions is the degree of substitution, determined by measuring the number of substituted glucose molecules and dividing by the total number of glucose molecules. HES solutions with a higher rate of substitution resist hydrolysis more effectively than molecules with lower substitution rates and thus persist in the body for a longer period of time, extending duration of action. The rate of substitution is used to describe the fluid and while it is common in veterinary medicine to refer to all hydroxyethyl starches as "hetastarch," this is a misnomer; in fact, a substitution rate of 0.6 is termed a hetastarch, 0.5 is a pentastarch, and 0.4 is a tetrastarch.

The final parameter that can be considered when evaluating HES solutions is the carrier solution. Classically, the majority of HES solutions are provided in 0.9% NaCl. Some solutions are also available in balanced crystalloid solutions such as LRS.

The use of synthetic colloids is somewhat controversial. Studies in both the human and veterinary literature have shown impaired coagulation and decreased platelet clump strength as determined by thromboelastography. The higher the rate of substitution, the greater effect on coagulation. For this reason, HES solutions with a lower rate of substitution such as the tetrastarches are considered theoretically safer as their effect on coagulation is less.

Overzealous administration of any of the HES solutions can still result in a dilutional coagulopathy. In addition to effect on coagulation, synthetic colloids can impact serum total protein and urine specific gravity (USG) measurements. The administration of HES (670/0.75) has been previously shown to elevate the urine specific gravity. In one study, the largest increase in USG occurred 150 minutes following administration with a mean USG of 1.070 +/– 0.021.

Both hydroxyethyl starch and dextran 70 have been shown to affect total solids measured by refractometry. When evaluated using a refractometer, HES will yield a reading of 4.5 g/dL, therefore when administered *in vivo*, the refractometric measurement of total solids will trend to 4.5 g/dL. For this reason, total solids should be interpreted with caution in patients receiving synthetic colloids. In addition, serum amylase may be elevated 200–250% due to binding with hydroxyethyl starch molecules, leading to a decrease in clearance.

Ideally, the efficacy of synthetic colloids is monitored through serial measurement of the COP using a membrane osmometer. In practice, this technology is not widely available and the response to therapy is used instead to guide treatment.

Finally, in human medicine, in particular in the subset of patients with refractory sepsis, concerns have been raised about HES administration and renal injury based on an increase in the need for renal replacement therapy in patients receiving hydroxyethyl starches. At this time, this concern appears to be related to the cumulative dose of HES administered. There have been some studies examining the issue in small animal medicine but the topic remains controversial.

Dextrans are neutral glucopolysaccharides based on glucose monomers. Dextrans are described based on their average mean molecular weight as well as the tonicity of the fluid. Examples of dextrans include products such as dextran 40, dextran 60, and dextran 70. In humans, dextran administration has been associated with anaphylactoid reactions as well as being implicated in the development of renal failure in critically ill patients. This has not been documented in veterinary patients.

The last class of synthetic colloid is the gelatins – polydisperse molecules derived from bovine collagen. These solutions have a mean molecular weight of 35 000 daltons and are rapidly excreted upon infusion. As a result, they are far less effective than the hydroxyethyl starches or dextrans for sustained volume expansion. In addition, the gelatins are associated with the highest rate of anaphylactoid reactions among the synthetic colloids. As a class, gelatins are not available in the United States.

Albumin

Physiologically speaking, albumin is an extremely important protein. It contributes roughly 80% of the COP within the vascular space. In addition to its osmotic activity, albumin has many other roles in the body and functions as a carrier for a variety of substances, including bilirubin, as well as many different drugs. Albumin also plays a role in platelet function and in the scavenging of free radicals. The ability of albumin to create colloid osmotic pressure is enhanced by its negative charge as well as the Gibbs–Donnan effect that describes how charged molecules may not be equally dispersed across a semipermeable membrane due to the relative permeability of the membrane.

Indications for Fluid Therapy

Rapid Volume Expansion

The rapid administration of IV fluids is indicated for the treatment of hypoperfusion. Rapid volume expansion is not appropriate if hypotension is the result of forward cardiac failure for any reason other than cardiac tamponade. The goal of rapid volume expansion is to restore the effective circulating volume (ECV) to levels that permit adequate perfusion and thus tissue oxygenation. Serial monitoring of perfusion parameters is used to guide therapy during rapid volume expansion. Parameters that are commonly monitored include physical examination parameters such as heart rate, pulse rate, pulse quality, mucous membrane color, and capillary refill time (CRT). In addition, monitoring may also include toe-web to core body temperature gradient, urine output, central venous pressure, and blood lactate measurements. A full discussion of end-points of resuscitation can be found in Chapter 37.

The dosing of IV fluids for the treatment of shock varies with the type of fluid chosen for resuscitation as well as the patient's response to therapy. The most common fluid types used for rapid volume expansion are isotonic crystalloids. Classically, a full "shock" bolus is considered to be 90 mL/kg in the dog and 45–60 mL/kg in the cat. These amounts approximate one blood volume. Boluses can be administered over a specific amount of time (for example, a 250 mL bolus of 0.9%NaCl over 10 minutes), or in profoundly compromised patients as rapidly as possible. Frequently, one-quarter of the calculated shock bolus is administered as a starting point for resuscitation. After the bolus is complete, the animal is reassessed. If their perfusion parameters have not responded adequately, additional fluid therapy is indicated. It should be remembered that when using an isotonic crystalloid for rapid volume expansion, that crystalloid should be devoid of fluid additives such as supplemental dextrose, potassium chloride or magnesium sulfate.

Synthetic colloids such as Hespan® or Vetstarch® can also be used for rapid volume expansion. Because synthetic colloids are osmotically active, they promote the movement of water from the interstitium into the vascular space. This movement of fluid between body fluid compartments as well as the volume of colloid administered collectively results in the expansion of the ECV. An initial shock bolus of synthetic colloid would be 5 mL/kg administered over 10–15 minutes.The total shock dose is equal to the recommended total daily dose of 20 mL/kg in the dog. In the cat, the total daily dose is somewhat lower at 10 mL/kg. Rapid administration of hydroxyethyl starch has been associated with nausea and vomiting in the cat. Again, reassessment of the patient following completion of the bolus will guide further fluid therapy. If the response to therapy has not been adequate, additional fluids should be administered until the animal has been stabilized. If the animal is unstable but is deemed to be volume replete, other therapies such as inotropes or vasopressors may be needed. It should be remembered that synthetic colloids are potent osmotic agents so overzealous administration can result in volume overload as well as dilutional coagulopathy.

Hypertonic saline can also be used for rapid volume expansion. Hypertonic saline is commonly supplied as a 7–7.5% NaCl solution. The initial shock bolus is 4–6 mL/kg over 10–15 minutes. Hypertonic saline should not be administered at a rate exceeding 1 mL/kg/min as vagally mediated bradycardia, hypotension, and bronchoconstriction may be seen with too rapid administration. If needed, this initial bolus can be repeated once; further administration of hypertonic saline can result in serious complications such as hypernatremia and hyperchloridemia. Hypertonic saline administered alone will not expand the vascular space for much time, and is usually combined with a synthetic colloid to prolong its volume-expanding effects. Hypotonic crystalloids such as 0.45% NaCl are *not* appropriate for rapid volume expansion.

In certain situations, fluid resuscitation with whole blood or blood component therapy may be indicated. This fluid choice not only provides volume expansion but, in the case of whole blood or packed red blood cells,

it also provides oxygen-carrying capacity that may be crucial in the anemic, hypoperfused patient.

One concern that has been visited many times over the years is the risk of aggressive volume resuscitation in patients that are actively bleeding. Concern centers on the disruption of immature clots and the worsening of bleeding. The classic example of this in veterinary medicine is the patient that presents with a hemoabdomen due to splenic trauma. The animal is aggressively resuscitated which results in a short-term improvement in hemodynamic stability (i.e., blood pressure) followed by a decline as the clots forming on the traumatized spleen are disrupted and active bleeding worsens.

"Delayed resuscitation" refers to the practice of not administering fluid support to correct hemodynamic instability until definitive control of hemorrhage has been achieved. "Hypotensive resuscitation" is the practice of administering rapid volume expansion to the hemodynamically unstable patient but only resuscitating to a mean arterial pressure of around 60 mmHg. Here, the goal is to strike a compromise between the need to perfuse vital organs and the desire to avoid supraphysiologic resuscitation that may worsen injuries such as pulmonary contusions and abdominal bleeding. Any of the fluids appropriate for rapid volume expansion can be used for hypotensive resuscitation. When considering the use of either hypotensive or delayed resuscitation, it is important to keep in mind that these techniques were designed for human trauma patients with penetrating injuries, where the time from presentation to definitive treatment rarely exceeds one hour. There has been limited research in veterinary medicine to examine their efficacy in small animal patients. If definitive treatment is not possible or will not be pursued then delayed or hypotensive resuscitation should not be attempted.

"Small-volume resuscitation," which is also known as limited-volume resuscitation, uses resuscitative fluids in small volumes to achieve moderate increases in hemodynamic stability. In this type of resuscitation, synthetic colloids and hypertonic saline take center stage as they allow for expansion of the effective circulating volume in excess of the administered fluid volume. Again, the goal here is to minimize the deleterious effects seen with overaggressive crystalloid resuscitations. Endpoints with this style of resuscitation include a mean arterial pressure of 70 mmHg, a systolic pressure of 90 mmHg, and clinical improvement of perfusion parameters.

Dehydration

The assessment and correction of dehydration remains one of the more challenging parts of fluid therapy. The challenge lies in the poor sensitivity of physical and laboratory parameters to quantify dehydration. It is important to grasp just how limited these parameters really are. It has been shown that an animal can range from 5% to 16% dehydrated based on body weight and yet have a normal skin turgor. This flies in the face of commonly accepted guidelines where the percentage of dehydration is estimated based on the presence or absence of certain physical parameters. In reality, all of these parameters are flawed to a greater or lesser degree.

As skin turgor essentially assesses the interstitium, it can be altered not only by the water balance within the interstitium but also by alterations in the other components of the interstitium. For example, in the geriatric or cachectic patient, changes in collagen content may alter the skin turgor so that the animal appears more profoundly dehydrated than it truly is. By contrast, the obese patient may have dehydration but a normal skin turgor. Skin turgor is also affected by the location at which it is assessed, the posture of the animal (standing versus supine), age, and body condition.

Although the use of percentage dehydration based on physical parameters is crude, it does still provide a starting point for selecting an initial fluid rate. Usually changes in skin turgor with normal hemodynamic parameters are consistent with mild dehydration of about 5–7% body weight. As dehydration becomes more severe and approaches 10–12% dehydration, hypovolemia may also be evident when perfusion parameters are evaluated. This is evidenced by tachycardia, poor pulse quality, prolonged capillary refill time, and cool extremities. Another indicator of profound dehydration is the presence of sunken eyeballs (enophthalmos).

If hypoperfusion is present, rapid volume expansion to stabilize the patient is indicated prior to attempting correction of interstitial or intracellular fluid deficits. When the tissue safety factors of the interstitium are understood, it is clear that rapid volume expansion is not effective for correcting interstitial deficits. This type of deficit must be corrected slowly over at least 12–24 hours. When fluids are administered at an aggressive rate in the hope of shortening the time needed for correction, the results are unrewarding. This is due to the characteristics of the interstitium which oppose rapid expansion. Aggressive fluid administration will result in rapid increases in interstitial hydrostatic pressure as well as decreases in interstitial oncotic pressure. This in turn will increase lymphatic driving pressure and promote lymphatic flow. The end-result is the clearance of volume via the kidneys instead of a more rapid rehydration of the interstitial space.

Commonly assessed laboratory parameters should provide more insight into fluid balance, but they, too, are limited. Alterations in hematocrit and total solids have

not correlated reliably with alterations in fluid balance based on weight. This may be due to a variety of reasons and is most probably a result of the patient's underlying disease process.

Serum sodium can be used as an indicator of free water balance in most situations. It should be kept in mind that serum sodium does not reflect total body sodium but instead is a reflection of the water balance within the body. Serum sodium is of no value in determining the presence of hypovolemia or the need for rapid volume expansion. The most common types of volume lost are isotonic or hypotonic fluid loss. In the case of hypotonic fluid loss, free water is lost in excess of sodium. As a result, serum sodium concentration elevates. To correct free water deficit, a solution providing free water such as 0.45% NaCl or D5W is used. Interstitial fluid deficits should be corrected before free water deficits are addressed. In addition, when correcting free water deficits, it is imperative to consider the duration of the free water deficit. When free water deficits are long-standing, the brain will synthesize idiogenic osmoles. These are osmotically active particles that oppose the movement of fluid out of the brain in response to hypertonicity. Idiogenic osmoles require several days to be metabolized so it is best to correct long-standing free water deficits slowly over a number of days. Overzealous correction of long-standing hypernatremia can result in cerebral edema. If hypernatremia is acute then it can be corrected more rapidly.

To replace the free water deficit, the volume of the deficit can be calculated using the following equation:

$$\text{Free water deficit} = \text{Weight}(\text{kg}) \times \left[\left(\text{Na}_{\text{present}} / \text{Na}_{\text{normal}}\right) - 1\right]$$

Example : A 10 kg dog with serum sodium concentration of 180 mEq / L

$$\text{Water deficit}(\text{L}) = 10 \times \left[(180/145) - 1\right] = 2.4$$

In this example, the patient had a free water deficit of 2.4 L. This volume will need to be replaced after the interstitium is replete and additional fluids are indicated to meet insensible losses as well as ongoing losses that may be quantifiable.

Maintenance Fluids

Maintenance fluids are designed to meet sensible and insensible losses. In a normal animal, these needs are met through the intake of food and water. In the patient where this is not possible, or intake is inadequate to meet fluid requirements, a maintenance fluid may be used.

As mentioned earlier, the composition of maintenance fluids is different from that of replacement fluids. In general, maintenance fluids have a lower sodium concentration and a higher potassium concentration than replacement fluid. Maintenance fluid requirements will vary with the size, age, and metabolic needs of the patient, taking physiologic derangements into consideration. Smaller and younger patients tend to have higher maintenance fluid requirements. These requirements may also be increased with pyrexia and panting. Diet composition may also affect daily fluid requirements due to the amount of water provided by the food source as well as the relative nutrient composition of the diet. In critically ill or sedentary animals, maintenance fluid requirements may be decreased.

The calculation of maintenance fluid requirements can be done in several ways. One commonly used shortcut is 40–60 mL/kg/day. When using this formula, it should be remembered that larger dogs will usually have maintenance needs near the lower end of the dose range while small dogs will likely have requirements toward the higher end of the range. Another way to consider maintenance requirement is to link it to daily energy requirements. With this approach, the maintenance requirement is roughly 1 mL of water per 1 kilocalorie (kcal) of energy expended. Maintenance energy requirements can be calculated using the following formula:

$$140\,\text{kcal} \times \text{body weight}(\text{kg})^{0.73}$$

Alternatively, the basal energy requirements can be calculated and then multiplied by a factor of 2 to approximate maintenance energy requirements. In critical patients, water requirements may be decreased and therefore the use of maintenance energy requirement calculation may overestimate what is required. In this instance, basal energy requirements may be more reflective of true water requirements. Basal energy requirements (BER) can be calculated using the following formula in the dog:

$$97 \times \text{body weight}(\text{kg})^{0.655}$$

In the cat, BER is roughly 50–60 kcal/kg/day.

Once the degree of dehydration has been estimated and the maintenance fluid requirement and free water deficit calculated, consideration must also be given to ongoing losses. This may be due to loss of volume from the GI tract, urinary tract or third space losses. Also remember to take into consideration the possibility of iatrogenic loss of volume. An example of this would be when residual gastric volumes are discarded following aspiration of a gastric tube. The volume of estimated ongoing losses is then added in to the fluid prescription.

Albumin Replacement

In critically ill veterinary patients, it may become necessary to address albumin deficiency due to ongoing albumin loss (e.g., protein-losing nephropathy, septic peritonitis) or decreased albumin production (e.g., acute phase response, liver failure). The majority of total body albumin actually resides within the interstitial space so correction of an albumin deficit can be difficult to achieve using albumin-containing products such as fresh frozen plasma. Existing interstitial albumin deficits must be replaced before improvement of plasma albumin concentrations will be seen.

Albumin concentrate is administered as either a 5% solution or a 25% solution. The 5% solution of human serum albumin (HSA) has a COP of about 20 mmHg and an albumin concentration approximately equal to plasma while the 25% solution has a much higher COP of about 70 mmHg and an albumin concentration five times that of plasma. In veterinary medicine, both 5% and 25% HSA have been administered for albumin replacement in both dogs and cats. Studies have shown both acute and delayed hypersensitivity reactions in dogs. The incidence of these reactions appears lower in critically ill patients but the studies that have investigated the use of these solutions have been limited. In patients with significant albumin deficits, the volume of plasma that would need to be administered to effect change in serum albumin often precludes its use as an effective therapy. For this reason, concentrated albumin products such as 25% HSA or canine lyophilized albumin (a canine albumin product has been introduced to the US market but little has yet been published regarding its use) are more effective in correcting albumin deficits. When correcting albumin, the following equation can be employed:

$$\text{Albumin deficit}\,(\text{grams}) = 10 \times [\text{desired albumin}\,(\text{g/dL}) - \text{patient albumin}\,(\text{g/dL})] \times \text{body weight}\,(\text{kg}) \times 0.3$$

As an example, to increase the albumin in a 10 kg dog from 1.5 to 2.0 g/dL:

$$\text{Albumin deficit} = 10 \times [2.0 - 1.5] \times 10 \times 0.3 = 15\ \text{grams}$$

Assuming an albumin concentration of 5 g/dL of canine plasma, this patient would require approximately 300 mL of plasma (identical volume to 5% HSA). By contrast, this patient would require 60 mL of 25% HSA. Given the current costs of HSA versus canine plasma, this could result in a significant saving to the client. The recommended dose for the lyophilized canine albumin product has been reported to be 800–884 mg/kg IV.

Constant Rate Infusions

In addition to their uses in volume expansion and the correction of dehydration, intravenous fluids are often used as carriers for drugs that are best administered by constant rate infusion (CRI). Examples include vasopressors, some inotropes, and some vasodilators. Also, CRIs for the administration of anesthetics and analgesics are commonplace. Before starting a CRI, the compatibility of the drug and carrier fluid must be determined. In most instances, 0.9% NaCl or 5% dextrose in water are acceptable choices.

Constant rate infusions are dosed based on both weight and time. For example, a CRI of dopamine might be started at a dose of 5 µg/kg/min. This dose of drug is then administered in a specific volume of fluid. The volume of fluid administered is determined based on the patient's body weight and fluid status, and the concentration of drug that requires delivery. To calculate a CRI, the following information must be known.

- Patient weight (kg).
- Drug dose (5 µg/kg/min, for example).
- Starting rate of fluid administration (5 mL/h, for example).
- Concentration of the drug administered.
- Total volume of carrier fluid to be supplemented.

To be precise, when formulating a CRI, an equivalent volume of carrier fluid should be removed and replaced by the drug being delivered. For examples of CRI formulation, the reader is referred to supplemental materials available online.

Monitoring of Fluid Therapy

One of the great challenges of fluid therapy is to meet the patient's ongoing requirements and replace deficits without overloading the body's ability to cope with the volume. An understanding of the behavior of fluids within the body as well as body fluid compartment dynamics helps to avoid complications. When attempting to assess the adequacy of fluid therapy, various parameters can be monitored.

Perfusion parameters such as heart rate, respiratory rate, capillary refill time, and pulse quality are valuable in determining the need for rapid volume expansion but they do not provide information regarding the correction of dehydration. Perfusion parameters can be normal in the dehydrated animal, although the profoundly dehydrated animal will exhibit signs of hypovolemia.

Patients should be weighed at least once daily to track alterations in fluid balance, keeping in mind that 1 L of water is effectively equivalent to 1 kg of weight. The

importance of body weight monitoring is especially true in the patient in which the potential for third space loss is a concern.

Quantification of urine output allows assessment of adequacy of urine output, especially if oligoanuria from renal injury or polyuria from underlying disease processes is of concern. In addition, serial measurements of USG may provide insight into fluid balance. For example, consider the patient on crystalloid fluid therapy who has a decrease in urine output. Once technical complications such as catheter patency and placement have been considered and it has been determined that perfusion is adequate, USG will help to differentiate between physiologic and pathophysiologic oliguria. Recall that the use of hydroxyethyl starches will invalidate the use of specific gravity measurement in the urine.

The venous side of the circulation is a capacitance system. As such, it has a relatively low pressure until fully replete and distended. Once the venous side of the circulation has no further ability to distend, pressure within the vasculature will rise. This can be correlated to the volumes and pressures within the heart. Based on Starling's law, it is known that initial expansion of ventricular volume will increase cardiac output and cardiac contractility. Overdistension of the ventricles proves maladaptive and results in decreased cardiac contractility as well as increased intravascular pressures. Central venous pressure is generally reflective of venous volume status and can be a useful invasive monitoring technique to guide fluid therapy. When measuring central venous pressure (CVP), a catheter is placed in the jugular vein in close proximity to but not within the right atrium of the heart. When measured in the absence of pulmonic obstruction or pulmonary hypertension, CVP approximates right atrial pressure. CVP can be measured manually using a water manometer or continuously using a pressure transducer. Normal CVP is considered to be 0–10 cmH_20 (1 mmHg is roughly 1.36 cmH_2O). CVP should ideally be measured at the end of expiration in the spontaneously breathing or mechanically ventilated patient but the use of positive end-expiratory pressure (PEEP) will increase CVP measurements.

Although serum lactate is used commonly as an indicator of hypoperfusion, its usefulness as an indicator of dehydration is limited since dehydration must be severe enough to result in decreased oxygen delivery to result in hyperlactatemia. Elevations in serum lactate can also occur due to severe liver dysfunction and spurious elevations in lactate can be seen when difficulty is encountered with sample acquisition.

Conclusion

Fluid therapy is an integral part of small animal practice. Approaching a patient's fluid needs in a logical fashion where the needs for rapid volume expansion versus correction of dehydration or electrolyte abnormalities are identified and then targeted will maximize the benefits of fluid therapy. Each patient is unique. Each of the commonly available fluid types has properties that can be leveraged to the advantage of our patients. This chapter illustrates how perfusion, hydration, and water and electrolyte balance affect not only the type of fluid therapy that is indicated but also the rate and route of fluid administration. By understanding the physiology of fluid balance in the body, clinicians can tailor their fluid prescription to address interstitial dehydration, correct free water and albumin deficits, and manage electrolyte abnormalities safely. This knowledge also allows fluid choices to be altered during rapid volume expansion to meet the special challenges of each case.

The decision to use a specific fluid should be based on the goals of therapy and how effectively that fluid choice will achieve that goal, instead of a knee-jerk response. Veterinary patients are dynamic and the unique needs of each patient vary. The need to identify our patients' fluid needs and to address them appropriately, even if their clinical presentation is unusual, cannot be overestimated.

Cardiopulmonary Resuscitation

Nathan Peterson, DVM, DACVECC

VCA West Los Angeles Animal Hospital, Los Angeles, CA, USA

Approximately 330,000 people die of acute cardiac arrest in the United States annually. The incidence of unexpected cardiopulmonary arrest (CPA) in veterinary patients is currently unknown. What is known is that survival rates for dogs and cats that receive cardiopulmonary resuscitation (CPR) range from 2.6% to 25%. The reported survival rates for people experiencing CPR are equally dismal, with overall survival rates following in-hospital arrest ranging from 3% to 27%. The reason for the wide range in outcomes is due in part to the variance in the nature or cause of cardiopulmonary arrest. What the literature generally agrees on is that the chance of a patient surviving to discharge after CPA is small. The likelihood of survival increases if CPA was due to an anesthetic event rather than the culmination of a chronic or traumatic disease process. While the survival statistics are dismal, the long-term neurologic outcomes of patients surviving CPA are generally good to excellent, making CPR a worthy endeavor.

In 2010, veterinary-specific CPR guidelines were developed using an evidence-based approach modeled on the American Heart Association's CPR guidelines. The result of this effort was the publication of the Reassessment Campaign on Veterinary Resuscitation (RECOVER) in 2011. The RECOVER initiative (http://onlinelibrary.wiley.com/doi/10.1111/vec.2012.22.issue-s1/issuetoc) has provided veterinarians for the first time with evidence-based clinical guidelines for performance of CPR.

The progression from severe illness to cardiopulmonary arrest in the veterinary patient is complex. Diseases that can lead to CPA in veterinary medicine include but are not limited to sepsis, pulmonary failure, neoplasia, polytrauma, head trauma, and cardiac failure. Although not all animals progressing toward CPA follow the same clinical course, some physical exam findings that may indicate impending CPA include decreasing level of consciousness, hypothermia, bradycardia, hypotension, and changes in respiratory patterns. Once CPA occurs, all patients will exhibit loss of consciousness, absence of spontaneous ventilation, absence of heart sounds during auscultation, and absence of palpable pulses.

The importance of recognizing CPA quickly is underscored when the hemodynamic impact is considered. Following the onset of CPA, the aortic blood pressure drops precipitously, with intrathoracic aortic pressure dropping from a normal of approximately 120 mmHg to 20 mmHg within 30 seconds. Additionally, carotid blood flow decreases from an average of 190 mL/min to 15 mL/min within 15 seconds and to 0 mL/min within four minutes. Coronary perfusion pressure likewise drops from 60 mmHg to 15 mmHg within 15 seconds and to 0 mmHg within four minutes.

Although the underlying cause of CPA may not be immediately apparent to the clinician, the nature or cause of the arrest can have an impact on the expected outcome and should be ascertained as soon as possible. If a patient is known to have suffered respiratory arrest prior to cardiac arrest, the likelihood of resuscitation may be diminished due to the continued depletion of oxygen from circulating blood resulting in severe hypoxemia at the onset of cardiac failure and institution of CPR. Conversely, if an animal suffers sudden cardiac arrest, the blood oxygen content would be expected to be high at the onset of CPA and subsequent CPR, possibly making successful resuscitation more likely than in the previous instance.

Principles of CPR

Cardiopulmonary resuscitation is intended to provide blood flow to the heart and brain, preserving them until return of spontaneous circulation (ROSC) is achieved. Subsequently, the quality of chest compressions is of the utmost importance, since this is the mechanism by which circulation is generated. Whatever the technique,

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

the provision of chest compressions is an inefficient way to move blood out of the heart and into systemic circulation. Even ideal chest compressions are only capable of generating 25–30% of normal cardiac output (CO). However, to maximize the efficiency of chest compressions, the provider should attempt to achieve 30–50% compression of the thoracic diameter. Good–quality chest compressions consist of a 50% duty cycle, meaning 50% of the entire compression cycle is spent with the chest wall being compressed and 50% is spent allowing the chest wall to recoil. Failure to allow complete recoil of the thoracic wall can result in severe impairment to cardiac filling during the noncompression phase. It is often helpful to lift the heel of the hand off the chest wall to ensure that complete recoil has been accomplished.

Hand position during CPR in veterinary patients is not standardized and is left to the individual providing compressions to find what works best for them. In small dogs and cats, a one-handed technique can be employed by placing the sternum in the palm of the hand with the thumb and fingers centered over the heart on opposite sides of the chest. The heart is then compressed between the thumb and fingers in a rhythmic pattern. For larger dogs, it may be necessary to use one or two hands to achieve the desired amount of chest wall compression. In small dogs (<15 kg) and cats, the compressions should be located directly over the heart in an effort to take advantage of direct compression of the ventricles forcing blood forward through the semilunar valves. This is termed the cardiac pump theory. In larger dogs (>15 kg), the compressions should be located at the widest part of the thorax, realizing that this may be at the caudalmost portion of the costal arch. In this case, the clinician is reliant on the intrathoracic pressure generated during chest compressions to compress the vascular structures in the thorax forcing blood forward. This is called the thoracic pump theory.

An oft-overlooked facet of chest compressions is patient positioning relative to the compression provider. It is important that the position of the provider is comfortable and will allow for the best-quality compressions with the least amount of fatigue. Therefore, having the patient at approximately waist level or lower is ideal. If the patient's position is fixed then the provider should stand on a step stool to achieve the desired amount of leverage. If compressions are provided on a table, the tabletop should be rigid and would ideally be incapable of conducting electricity. Wet tables should be avoided. Larger dogs can often be more comfortably resuscitated on the floor with the compression provider kneeling next to the patient. An adjustable height hydraulic table should be considered if CPR is performed on a regular basis.

Diagnosing Cardiopulmonary Arrest

Prompt recognition of cardiopulmonary arrest is paramount to the success of CPR. Therefore any nonresponsive, apneic patient should be immediately evaluated for CPA and resuscitative measures should be started. The clinician should spend no more than 10 seconds attempting pulse detection and cardiac auscultation before beginning chest compressions. The risk of causing serious injury to a patient by providing unnecessary chest compressions is quite small. In a study of human patients receiving unnecessary chest compressions, the injury rate was less than 2% with no life-threatening injuries present, leading to the conclusion that the provision of CPR is not harmful, while inaction may prove fatal.

If the patient is found to be only in respiratory arrest following the brief pulse evaluation then the clinician should proceed with securing an airway with an endotracheal tube or tracheostomy tube. After the airway is secure, the patient should be manually ventilated with 100% oxygen. If not already obtained, attempts at venous access should be made at this time and the patient should be monitored for progression to cardiac arrest. If, on the other hand, the patient is found to be in cardiac arrest at the time of the pulse check then basic life support (BLS) should be instituted immediately.

Basic Life Support

Chest Compressions

While the definitive order in which BLS measures are implemented is not established, it is reasonable to continue using the Airway, Breathing, Circulation approach in which ventilation precedes compressions. Practically, however, instituting compressions does not require any equipment and can often be started earlier than an airway can be secured. Therefore, BLS begins with high-quality chest compressions performed at a rate of 100–120 beats per minute, making every effort to avoid interruptions. During the first cycle (two minutes) of chest compressions, the patient should be instrumented with an electrocardiograph (ECG) and capnography if available. Attempts can also be made to achieve intravenous access if this has not already been done. Intubating or securing an airway can be attempted during this first round of compressions while minimizing interruptions. It is often easier to perform the first cycle of compressions while other members of the arrest team obtain proper sized endotracheal or tracheostomy tubes and laryngoscope and mobilize the crash cart to the location of the arrest.

Following the first round of compressions, the first ECG rhythm check will be performed and a definitive attempt will be made to secure an airway. The purpose of the rhythm check is to determine if a cardiac rhythm may be amenable to electrical conversion. If no such rhythm is identified then chest compressions are immediately resumed. Ideally, the chest compression provider is changed at this time. This two-minute cycle is repeated as needed, alternating the compression provider at each planned rhythm check (i.e., every two minutes) or sooner if fatigue occurs.

There are four arrest rhythms, two of which are responsive to electrical defibrillation: pulseless electrical activity (PEA), asystole, ventricular fibrillation, and pulseless ventricular tachycardia. The most common arrest rhythms in veterinary medicine are asystole, which accounts for 72% of arrest rhythms, and pulseless electrical activity, neither of which is responsive to defibrillation.

Interruptions in chest compressions must be minimized during CPR. Following each interruption in chest compressions, it takes approximately 60–90 seconds to return CO to the preinterruption level. Eliminating hands-off time is therefore a major focus in improving both veterinary and human CPR. Minimizing interruptions during CPR must be balanced with the need to prevent compression provider fatigue. Many studies in human CPR providers document a tendency to lean during the provision of chest compressions. This tendency increases as the duration of compressions increases. The effect of leaning on a patient during CPR decreases cardiac filling and the overall efficiency of CPR by at least 25%. CPR is hard work and two minutes of high-quality chest compressions on even a small to medium-sized dog should be exhausting.

Airway

Orotracheal intubation of dogs and cats is relatively easy, making rapid intubation possible in most circumstances. In the majority of patients that experience cardiopulmonary arrest, an airway can be secured via routine orotracheal intubation. Occasionally, the glottis is obscured by vomit, fluid or saliva. If suction is available, it can be helpful in clearing the oropharynx of excess fluid. If suction is unavailable a gauze 4 × 4 or paper towel can be used to swab the area free of fluid or debris. Care should be taken to avoid excessive manipulation of the epiglottis as this can induce a vagal response. A laryngoscope should be used to facilitate intubation.

If the glottis cannot be visualized, the orotracheal route may still be considered for intubation if the epiglottis can be palpated. A blind intubation is performed by palpating and depressing the tip of the epiglottis and directing the endotracheal tube through the glottis dorsally. Successful intubation can be confirmed by direct visualization of the endotracheal tube between the arytenoid cartilages or visualization of normal chest rise during positive pressure ventilation. Capnography may be useful but should not be used as the sole means of confirming correct placement of an endotracheal tube during CPA since end-tidal CO_2 in CPA patients may be 0 due to lack of pulmonary blood flow.

Once an endotracheal tube is placed and correct positioning is confirmed, the tube should be secured to the patient with tape, gauze tie or rubber band to prevent tube dislodgment. The cuff on the endotracheal tube should be inflated to ensure an airtight seal. This will allow the patient to be effectively ventilated with positive pressure during chest compressions. In some cases, orotracheal intubation may not be possible due to severe swelling, inability to open the mouth or severe facial trauma necessitating emergency tracheostomy.

Ventilation

Positive pressure ventilation with 100% oxygen is begun once an airway is secured. Breaths can be provided by a number of means, including rescue bag, anesthesia machine or mechanical ventilator. Hyperventilation is common in the clinical CPR scenario and can be caused by an excessive respiratory rate, tidal volume or inspiratory time. Regardless of the cause, hyperventilation is detrimental to outcome. During positive pressure ventilation, venous return occurs during the expiratory phase and if insufficient expiratory time is allowed (due to either excessive rate or inspiratory time), cardiac filling will be reduced. Hyperventilation can also lead to decreased cerebral carbon dioxide levels and subsequent cerebral vasoconstriction, further impairing blood flow to the brain during the critical time of resuscitation.

No clear association has been made regarding the timing of rescue breathing with compressions and it is not recommended to attempt to synchronize breaths with compressions. Current recommendations for ventilation are a rate of 8–10 breaths per minute with a tidal volume of approximately 10 mL/kg and an inspiratory time of one second. Assigning the role of rescue breathing to a single team member and providing them with clear instructions on ventilation rates is the best way to prevent hyperventilation.

Advanced Life Support

Advanced life support (ALS) consists of all resuscitative measures that are not included in the BLS algorithm, including vasopressor therapy, vagolytic therapy, fluid and electrolyte therapy, and electrical defibrillation.

The rationale for the use of vasopressor therapy is grounded in the fact that cardiac output during CPR is a fraction of that during spontaneous circulation, making it imperative that the limited cardiac output is directed to the organs that need it most. Therefore, the provision of vasopressors is intended to increase peripheral vascular resistance, forcing more blood into the central circulation and subsequently improving the perfusion of vital structures (i.e., brain and heart).

Stimulation of the alpha-1 receptor results in peripheral vasoconstriction whereas stimulation of the beta-1 receptor increases both inotropy and chronotropy. While epinephrine is a balanced alpha- and beta-adrenergic agonist, its utility during CPR comes primarily from its action at the alpha-1 receptor. In fact, the effects of beta-1 stimulation may be detrimental as they can lead to increased myocardial oxygen consumption and predispose to arrhythmias if ROSC is achieved. The best dose for epinephrine use during CPR has been a topic of debate for many years, with mixed evidence. High-dose epinephrine (0.1 mg/kg IV) has been shown to result in slightly higher rates of ROSC but has not been shown to confer a survival benefit. Based on the lack of documented improved survival, the use of low-dose epinephrine (0.01 mg/kg) is currently recommended early in CPR efforts, with high-dose epinephrine being reserved for cases of prolonged CPR. Epinephrine should be administered following the first cycle of BLS and then following every other cycle.

Adrenergic receptors have been demonstrated to be less responsive in acidotic conditions, such as those found during CPA, making an alternative drug that is not dependent on catecholamine receptors an appealing option. Vasopressin acts on the V1 receptors of vascular smooth muscle cells independent of the alpha-1 receptor. In addition, it maintains its efficacy in the face of acidosis. Due to the lack of adrenergic effects, vasopressin does not cause increases in inotropy or chronotropy, minimizing its impact on myocardial oxygen consumption. The human literature regarding the usefulness of vasopressin in CPR is mixed, with promising results in small trials but failure to demonstrate any clear advantage over epinephrine in larger metaanalyses. The successful use of vasopressin in CPR has been reported in the veterinary literature. Administration of vasopressin (0.8 U/kg IV) in place of or in conjunction with epinephrine may be considered, with subsequent doses administered following every other cycle of BLS.

The use of atropine in ALS is somewhat unique in that atropine is a parasympatholytic drug intended to ameliorate high vagal tone during cardiac arrest rather than directly stimulating catecholamine receptors. The use of atropine should be considered in animals that have asphyxia-induced cardiac arrest or other co-morbid conditions that would be likely to increase vagal tone. A dose of 0.04 mg/kg IV is recommended as higher doses are more likely to result in severe tachycardia and subsequently, increased myocardial oxygen consumption if ROSC is achieved. Repeated dosing of atropine is unlikely to be of benefit (assuming actions directed at the underlying cause have been taken) and should be considered carefully due to the potential for severe tachycardia if resuscitation is successful.

Corticosteroids currently have no place in the CPR algorithm and their use is not recommended. Given the lack of documented improvement in outcome and the known deleterious side-effects, especially in patients with perfusion impairment, this is unlikely to change.

The administration of ALS drugs by intravenous or intraosseous routes (interchangeable in the context of CPR) is always preferred to the intratracheal route. If IV or IO access is not available or not possible then intratracheal administration of drugs can be considered while efforts to attain venous or intraosseous access are continued. If this route is utilized, a long catheter should be advanced through the endotracheal or tracheostomy tube to the level of the carina or beyond. Drugs should be diluted with saline or sterile water. The optimal dosing of drugs for intratracheal administration is not established but doses up to 10 times the normal dose have been recommended. Once established, the IV or IO route should be used for all subsequent drug administrations.

The need for rapid volume expansion with IV crystalloid or colloid solutions during CPR is dependent on the underlying cause of CPA. Animals suffering CPA from severe hemorrhage or hypovolemia should be aggressively resuscitated with IV fluids to reestablish normal circulating volume. Since coronary perfusion pressure is determined by the difference between diastolic aortic blood pressure and right atrial pressure, care should be taken to prevent overresuscitation. IV fluids accumulate in the venous compartment, increasing the central venous and right atrial pressure and consequently reducing coronary perfusion pressure. In general, animals that were euvolemic or hypervolemic (congestive heart failure) do not require volume expansion during CPR and routine use of IV fluids during CPR on these patients is not recommended.

Electrolyte and acid–base disturbances are common during CPA. Severe acidemia occurs frequently during CPA, especially later in the course of resuscitation, and can result in vasodilation, predisposition to arrhythmias, and impaired neurologic function. The administration of 1 mEq/kg sodium bicarbonate can be considered in prolonged instances of CPA lasting 10–15 minutes. The most common electrolyte disturbances during CPA include hyperkalemia and hypocalcemia. Because of the lack of documented improvement in outcomes and the

potential complications associated with over- or under-correction, the management of electrolyte derangements during CPA should be reserved for animals with confirmed rather than assumed disturbances.

Recently, the use of an impedance threshold device (ITD) intended to increase cardiac output during CPR has been described in canine patients and results appear promising. Unfortunately, the use of an ITD is limited to patients greater than 10 kg.

Defibrillation

The purpose of defibrillation is to depolarize as many cardiac myocytes as possible, making them temporarily refractory, allowing the native pace-making cells to resume organized electrical conduction. Electrical defibrillation should only be attempted on rhythms that are potentially responsive to it. Of the four arrest rhythms, only two are responsive to electrical defibrillation: ventricular fibrillation (most significant in veterinary medicine) and pulseless ventricular tachycardia. Any attempts at converting nonresponsive rhythms will not result in return of spontaneous circulation and will only needlessly expose team members to accidental defibrillation and increase time spent without compressions.

There are two types of defibrillators commonly used in veterinary medicine. Monophasic defibrillators function by passing a single electrical current from one electrode through the heart to a receiving electrode. Biphasic defibrillators pass a current from one electrode to the other; the current then reverses direction and is passed back to the original electrode. This technology allows effective defibrillation to be performed using less energy than monophasic defibrillation, resulting in less myocardial injury. If available, biphasic defibrillation is preferred. Being familiar with the type of defibrillator in the practice is important due to the difference in energy selection, with monophasic defibrillator doses beginning at 4–6 J/kg and biphasic defibrillator doses beginning at 2–4 J/kg. If defibrillation is not successful following the first attempt, the dose delivered can be increased by 50% for subsequent defibrillation attempts.

Historically, it was recommended to administer three stacked defibrillation attempts (discharges in rapid succession) prior to resuming chest compressions. The advent of biphasic defibrillators and the recognition that delays in resumption of chest compressions can have a negative effect on outcome have made this recommendation obsolete. It should be remembered that successful defibrillation means that fibrillation has been stopped, not that ROSC has been achieved. Successful defibrillation therefore can result in asystole or an electrocardiographically normal rhythm. However, resumption of normal electrical function does not necessarily correlate with return of normal mechanical function of the heart (i.e., PEA). It is therefore recommended that a single defibrillation attempt be made followed by immediate resumption of chest compressions for a full two-minute cycle prior to ECG evaluation. This improves coronary blood flow to the myocardium, making successful defibrillation with resumption of mechanical activity more likely.

Performing defibrillation begins with selecting appropriately sized paddles. Most defibrillators come equipped with standard-sized adult paddles, which are suitable for most patients larger than 15 kg. Smaller pediatric paddles are usually available as a clip-on attachment and should be used for smaller dogs and cats to ensure focused delivery of the shock through the heart. Defibrillator paste or contact gel is generously applied to the paddles. The animal is typically placed in dorsal recumbency and the defibrillator paddles are placed on either side of the thorax at the level of the costochondral junction with the heart centered between the paddles. The patient is firmly grasped between the paddles and is maintained in dorsal recumbency by the person delivering the defibrillation. Once the patient is positioned, depressing the charge button on the paddles or on the base unit charges the defibrillator. To maintain safety, the patient should be positioned prior to charging the paddles to lessen the likelihood of accidental discharge. Once the defibrillator is charged, the provider should ensure that no one is in contact with the patient or metal tabletop. Verbal commands to "CLEAR" the patient are effective. Once all rescue providers are clear of the patient, the shock is delivered by depressing the shock delivery buttons on the paddles or defibrillator base unit. Animals with thick undercoats that inhibit paddle contact should be rapidly clipped at the intended paddle locations prior to defibrillation attempts. The use of alcohol to improve paddle contact should be strictly avoided due to the risk of fire.

Alternative defibrillation techniques involve the use of defibrillation pads attached directly to the patient and left in place while connected to the defibrillator base unit. The pads are placed on the chest in the same location as the paddles. If pads are used then clipping of the hair is mandatory to ensure good contact between the pads and the patient. The advantage to the use of pads is that no rescue providers have to be in contact with the patient and patient positioning is minimally interrupted. The disadvantage is the necessity of clipping the hair that results in longer time without chest compressions. The use of a posterior paddle assembly, a flat paddle replacement resembling a spatula, may be the best method for delivering defibrillation in veterinary patients. The paddle assembly is coated with paste or gel, as a normal

paddle would be. The assembly is then placed under the patient in lateral recumbency using the normal paddle positioning recommendations. A standard paddle is then used on the upward-facing thoracic wall. This technique allows the patient to remain in lateral recumbency while eliminating the need to clip the area as for defibrillator pads.

Nonelectrical methods of cardiac defibrillation include both chemical and mechanical means. Historically, chemical defibrillation with magnesium or antiarrhythmic drugs has been considered acceptable. Based on the current understanding of CPA in both human and veterinary patients, the use of antiarrhythmic agents is no longer routinely recommended. Among the possible agents available, only amiodarone has been found to be routinely effective. Magnesium salts have only proven to be useful for the treatment of torsades de pointes and electrical defibrillation should always be considered as the best option for ventricular fibrillation or pulseless ventricular tachycardia. The use of a precordial thump has been described as a method for providing mechanical defibrillation. Given the superiority of electrical defibrillation, a precordial thump should only be considered if a defibrillator is not available.

Monitoring During CPR

Monitoring during CPR can be difficult due to lack of normal physiologic responses. The two modalities most useful during CPR are ECG and capnography. Electrocardiography is monitored to determine if an arrest rhythm is amenable to defibrillation while $ETCO_2$ can be utilized as a measure of the effectiveness of chest compressions, as an adjunct to verify placement of the endotracheal tube, and to determine when ROSC occurs.

Traditionally, patients with CPA would be subjected to pulse detection attempts before and during CPR. Unfortunately, pulse detection takes time, is technically difficult in some cases and can lead to increased "hands-off" time, with the patient receiving fewer chest compressions. Capnography has allowed CPR providers a method to monitor not only the effectiveness of chest compressions but also whether or not ROSC has occurred. Following CPA, blood flow through the pulmonary circulation decreases rapidly and $ETCO_2$ levels drop to near 0 since carbon dioxide is not being returned to the alveoli for exhalation. During CPR, pulmonary blood flow is generated by chest compressions. Therefore, any change in $ETCO_2$ levels can be attributed to the cardiac output achieved by the chest compressions, provided the minute ventilation is held constant. $ETCO_2$ is also useful for the detection of ROSC, with a rapid and sustained rise in $ETCO_2$ indicating ROSC due to the much more efficient delivery of blood to the pulmonary circulation by spontaneous cardiac contraction than that achieved during manual chest compressions.

Following the initiation of chest compressions and attainment of an airway, the patient should be instrumented with $ETCO_2$ monitoring if available. Patients with higher $ETCO_2$ levels (15 mmHg dogs, 20 mmHg cats) are more likely to have ROSC than those with lower levels. During CPR, if $ETCO_2$ is less than 15 mmHg, efforts should be made to improve the quality of chest compressions. If compression providers have not been rotated and $ETCO_2$ is found to be low or is decreasing, a rotation should be considered.

Blood gas monitoring during CPR is challenging but is the only way to identify the severe electrolyte and acid–base derangements that are common during CPA. Ideally, a blood sample (venous or arterial) is obtained shortly after the onset of CPA and is evaluated for any abnormalities. Interventions should be directed at severely abnormal results, understanding that complete resolution is not likely and may not be necessary. If sampling is possible, blood gas analysis should be performed every 5–10 minutes during CPR as long as collection of samples does not interfere with the actual provision of rescue efforts. Information regarding acid–base and electrolyte status during CPA and outcome is lacking and should not be used to predict the likelihood of ROSC.

Open Cardiac Massage

Open chest cardiac massage is capable of generating better cardiac output during CPR than closed chest compressions. However, the procedure is invasive and requires significant resources both during and after resuscitation. Therefore, its use is reserved for patients with a clear indication including significant intrathoracic disease (tension pneumothorax, severe pleural effusion), major chest wall defect (flail chest) or pericardial effusion.

To perform open chest CPR, the patient is placed in right lateral recumbency. The fur is rapidly clipped over the 4th–6th intercostal spaces and the skin is quickly wiped with alcohol. The skin is incised at the 5th–6th intercostal space with a scalpel blade. The intercostal muscles are incised with Mayo scissors and the incision is extended from the costochondral junction to the proximal one-third of the rib. Care should be taken to avoid laceration of the lung tissue during this process. Respiration can be temporarily held during this time to further reduce the risk of iatrogenic trauma to the lung. The ribs are then spread with manual retraction or a Finecchetto retractor. The pericardial sac is incised at the

apex of the heart to avoid the phrenic nerve and the sac is then reflected dorsally to the base of the heart. The heart should be compressed from the apex to the base at a rate of 100–120 compressions per minute. This can be done with one or two hands, depending on patient size. In some patients, the descending aorta can be briefly (10–15 minutes) cross-clamped to help direct blood flow to the cerebral and coronary circulation.

If ROSC is achieved, the patient should be maintained in an anesthetized state while a thoracostomy tube is placed and the thoracotomy site is closed. Volatile gas anesthetics have profound vasodilator effects and may be detrimental to a recently resuscitated patient. All efforts should be made to avoid hypotension and total IV anesthesia may be the best option during this time. Prophylactic antibiotics should be considered for patients that have undergone open chest CPR due to the likelihood of contamination.

Postresuscitation Care

Despite initial reported ROSC rates of 35–45% in veterinary medicine, survival to discharge rates range from 2% to 10%. This highlights the need for continued aggressive critical care following ROSC. Initial postcardiac arrest (PCA) care should focus on preventing rearrest, specifically targeting hemodynamic stability and pulmonary/respiratory function. Specific goals of hemodynamic stabilization should include normalization of central venous oxygen saturation, central venous pressure, cardiac output, arterial blood pressure, and arterial oxygen content. IV fluid therapy should be judicious and efforts should be made to prevent overresuscitation. Ventilatory function may be altered in PCA patients with resultant hyper- or hypoventilation. Ventilation should be assessed and positive pressure ventilation should be provided as needed to maintain normocapnia ($PaCO_2$ 35–45 mmHg). Supplemental oxygen or mechanical ventilation is used as needed to maintain normoxemia (PaO_2 90–100 mmHg).

As the PCA period increases, focus should be directed at preventing or minimizing secondary organ damage and neuroprotection. The routine use of corticosteroids, hyperosmotic fluids, and anticonvulsants is not recommended. If evidence of increased intracranial pressure is present then treatment with mannitol or hypertonic saline is warranted. Should generalized seizures develop then appropriate treatment with an anticonvulsant should be started. Prophylactic treatment with anticonvulsant medications may be considered in animals demonstrating global cerebral signs (coma, compulsion) in the postarrest period. The use of corticosteroids has not been documented to improve outcome and their use should be restricted to animals with a clear indication due to the potential for severe adverse effects.

Induction of mild therapeutic hypothermia is rapidly becoming the standard of care in human PCA management. Its use has been described in the veterinary literature but is not widespread at this time. Due to the risks associated and the technical difficulty of safely inducing and maintaining appropriate hypothermia, it is not currently recommended. If, however, mild hypothermia develops spontaneously, the patient should not be aggressively warmed; rather, the return to normothermia should be gradual (0.25–0.5 °C/h).

Discontinuing CPR

The decision to terminate CPR generally lies with the clinician. When making the decision to withhold or terminate CPR, several factors should be considered including the inciting cause of the arrest, interval from onset of arrest to initiation of CPR, duration of CPR, and long-term prognosis associated with the underlying disease process. Although no definitive guidelines exist, continuing efforts for 15–20 minutes is reasonable, after which time the likelihood of a good neurologic outcome is exceedingly small and CPR can be discontinued.

Respiratory Monitoring in Critical Care

Mathew Mellema, DVM, PhD, DACVECC

Applaud Medical, San Francisco, CA, USA

Purpose

The purpose and goals of respiratory monitoring in critical care typically include the following:

- identification of patients in respiratory distress and those experiencing dyspnea
- determination of response to specific or empiric therapies
- assessment of the adequacy of alveolar ventilation
- assessment of the adequacy of oxygenation
- evaluation of gas exchange efficiency
- evaluation of pulmonary mechanics in order to categorize disease states, explain other related clinical findings, or monitor response to therapy.

Identifying Respiratory Distress and Dyspnea

Respiratory distress is a state in which breathing efforts are excessive or inadequate relative to the healthy state or the patient's current requirements. While many definitions rely on inadequate oxygenation or ventilation, such approaches fail to account for patients in whom adequate gas exchange is obtained only with excessive effort. Tachypnea (increased respiratory rate) and hyperpnea (increased respiratory effort and/or chest excursions) are often considered the hallmarks of respiratory distress; however, a smaller subset of patients may present with hyponea (decreased respiratory effort and/or chest excursions), bradypnea (decreased respiratory rate), or both. This second type of patient is also in respiratory distress.

Dyspnea is a term often used synonymously with respiratory distress in veterinary practice, although it has been suggested that this convention is not ideal. In human medicine, dyspnea refers to the unpleasant sensations of feeling unable to catch one's breath or being consciously aware of one's breathing effort. The three subcategories of dyspnea sensations identified in humans are air hunger, increased work/effort, and asthmatic chest tightness. Experimental evidence exists to suggest that vertebrates other than humans are able to experience the first two of these. To date, no experimental approaches have been developed to determine if animals are likely to experience asthmatic chest tightness. Ideally, the term *dyspnea* would be reserved for consideration of the sensory experience (akin to pain) and respiratory distress would be used to describe what clinicians might observe (akin to nociceptive responses). Serial monitoring of patients for signs of respiratory distress or dyspnea is the cornerstone of respiratory monitoring. Respiratory monitoring may include many other tools, but these are always best evaluated in light of current patient status and clinical context.

Clinical Signs of Respiratory Distress

Box 38.1 provides an outline of broad categories of clinical signs that may be present in a patient with respiratory dysfunction or distress. Two categories of sounds may herald respiratory distress: those heard with the ear and those heard with the stethoscope. Stertor and stridor are sounds that typically do not require a stethoscope to be audible. Stertor is the presence of snoring-like noises during respiration. It is the result of abrupt displacement of upper airway soft tissue structures and altered gas flows. It is typically low-pitched, discontinuous, and nonmusical in character. It may be evident on inspiration, exhalation, or both. Stridor is a high-pitched, musical respiratory sound generated by altered gas flows in the large airway. It is more typically heard on inspiration. Either stertor or stridor can indicate an abnormality of the proximal upper airways (i.e., cranial to the thoracic inlet).

Box 38.1 Categories of signs associated with respiratory distress in dogs and cats

- Abnormal sounds
  - Heard without a stethoscope
    - – Stertor
    - – Stridor
  - Heard with a stethoscope
    - – Diminished breath sounds
      - Regional
      - Focal
    - – Adventitious sounds
      - Crackles
      - Wheezes
      - Rhonchi
    - – Borborygmus
- Changes in position/posture/orientation
  - Orthopnea
  - Trepopnea
  - Neck extension
  - Upright stance (flexed pelvic limbs, extended thoracic limbs)
    - – Sternal recumbency (Sphinx pose)
  - Abducted elbows
- Reflex compensatory changes due to hypoxemia and hypercapnia
  - Tachypnea
  - Tachycardia
  - Hyperpnea
- Signs associated with reduced/altered gas flow velocities
  - Phase prolongation
    - – Inspiration
    - – Exhalation
    - – Both
  - Inability to vocalize
- Adaptive responses which reduce respiratory system resistance
  - Open-mouth breathing
    - – Retracted commissures of the lips
  - Nares flaring
  - Neck extension
- Signs secondary to marked hypoxemia
  - Cyanosis
  - Obtundation
- Abnormal or excessive abdominal motion
  - Passive abdominal motion due to hyperpnea
  - Active expiratory abdominal muscle contraction
  - Paradoxical motion
- Signs of the sensation of dyspnea
  - Obtundation
  - "Anxious" expression
  - Dilated pupils
  - Poorly tolerant of restraint/fractious
  - Not eating, drinking, sleeping, and/or grooming

Altered breath sounds can also herald respiratory distress in small animal patients and may also aid in the determination of the underlying cause. Breath sounds may be altered in their distribution, their volume (i.e., loudness), and their character. Diminished breath sounds in the nondependent lung fields may indicate accumulation of gas in the pleural space, whereas the same finding in the dependent lung regions suggests pleural fluid accumulation or nonventilated lung (or both). Focal absence of breath sounds may indicate that one or more lung lobes are obstructed, consolidated, collapsed, torsed, infiltrated, or compressed by an intrathoracic mass lesion. In addition, adventitious sounds (crackles, wheezes, rhonchi) may indicate lower airway and pulmonary parenchymal pathology. Crackles are explosive, discontinuous, nonmusical sounds generated by small airways abruptly opening. They may be fine or harsh in character. While often heard on inspiration (opening during expansion), they may also be present during exhalation in some settings. Wheezes are higher pitched, musical, and of longer duration than crackles. They are often the result of diffuse lower airway narrowing. Rhonchi are similar to wheezes but substantially lower in pitch. Abnormal sounds that might be ausculted over the thorax also include borborygmus, which may indicate a compromise of the diaphragm with displacement of intestinal viscera into the thoracic cavity.

Changes in body position/posture, orientation of the head and limbs, respiratory rate, and the magnitude of inspiratory excursions all may indicate respiratory system compromise. Patients in respiratory distress often assume an upright posture with the pelvic limbs flexed and the thoracic limbs extended. This posture allows the weight of the abdominal contents to rest on the pelvis rather than the diaphragm and reduces the work of breathing. In cats, a more typical posture is to sit propped in sternal recumbency (sphinx pose). Patients that exhibit greater respiratory distress when in recumbency are termed orthopneic and this may manifest as a reluctance to lie down or be restrained. The head is often held in dorsoflexion with the neck extended. This position reduces the work of breathing by straightening the trachea and minimizes narrowing. Moreover, by fixing the head position in this way, accessory respiratory muscles (e.g., serratus ventralis muscle) can be utilized to promote expansion of the cranial thorax. Elbow abduction and fixing the position of the forelimbs allows for the recruitment of other accessory respiratory muscles and reduces the impact of the weight of these limbs on chest expansion. Respiratory compromise that is more severe in one lateral recumbency than the opposite is termed trepopnea and often is due to asymmetric pulmonary parenchymal disease.

Increases in respiratory rate are often the earliest sign of respiratory system compromise. Tachypnea at rest may frequently precede more overt signs in patients with

chronic cardiac or respiratory disease. Tachypnea and hyperpnea with exertion are also considered early signs in this same setting. Both tachypnea and hyperpnea are adaptive responses in most settings, but not all. These responses represent the clinically apparent consequences of attempts to maximize alveolar ventilation. However, they may be triggered by pain, hypotension, and other factors. In patients with upper airway disease, these responses are generally maladaptive as they increase the work of breathing and may promote further airway narrowing via the Venturi effect.

Tachypnea must be distinguished from panting which occurs in hyperthermic (not febrile) animals with the mouth open. Febrile animals have a reset thermoregulatory set-point and thus the elevation in body temperature will only result in occasional panting when body temperature temporarily exceeds this threshold. Tachypnea does not imply open-mouth breathing whereas this is a hallmark of panting. Panting does not alter ventilatory status whereas tachypnea may result in hyperventilation in some settings but not others.

Respiratory monitoring also includes assessing patients for clinical signs relating to reduced respiratory gas flow velocity. Such flow reductions may manifest as prolongations of the inspiratory (upper airway disease) or expiratory (intrathoracic airway disease) phases of respiration. Both phases of respiration may be affected concurrently in some disease states. One example is feline asthma. Bronchoconstriction results in increased resistance to both inspiratory and expiratory flows, although the increase is generally more marked during exhalation. An inability to vocalize indicates a severe reduction in expiratory gas flows and should prompt immediate assessment of upper airway patency.

Several clinical signs that manifest in veterinary patients with respiratory distress represent adaptive responses that serve to reduce airway resistance. Neck extension as discussed above is one example. Flaring of the nares represents recruitment of the dilator naris muscle and is stimulated by hypoxemia and hypercapnia and inhibited by pulmonary stretch receptor activation. Breathing through an open mouth also reduces respiratory system resistance while foregoing the benefits of gas conditioning (humidification, particle trapping) by the nasal passage. Animals in respiratory distress often breathe with their mouths open although other conditions (pain, hyperthermia) can also elicit this same response. Animals in respiratory distress typically do not hang the mouth passively open, but rather actively retract the commissures of the lips and extend the tongue outward. Activity of the genioglossus muscle may be synchronized with the respiratory cycle, resulting in cyclic protrusion of the tongue outwards.

Cyanosis is a severe but unreliable sign of respiratory compromise. When present, it generally indicates severe hypoxemia. However, in anemic patients, the amount of deoxygenated hemoglobin present in the capillary beds may be too low to result in a color change detectable to the clinician.

Abnormal or excessive abdominal motion during respiration may indicate respiratory distress. Passive abdominal motion and increased abdominal effort are not the same thing, although they may look similar from a distance. More pronounced outward motion of the abdomen on inspiration is passive and caused by increased contraction of the diaphragm. Active contraction of the abdominal muscles (e.g., rectus abdominis) represents recruitment of accessory respiratory muscles whereas passive displacement of the abdominal contents during inspiration does not. The clinician may need to palpate the ventral abdominal muscles during exhalation to distinguish between the two conditions. Tensing of the rectus abdominis during exhalation can usually be clearly felt when increased abdominal effort is truly present. Activation of the abdominal muscles during respiration actively aids exhalation and passively assists inspiration. Increasing intraabdominal pressure (and thus passively increasing intrathoracic pressure) raises the pressure driving expiratory gas flows. This increase in abdominal pressure also serves to place the diaphragm in a more cranial position prior to the next inspiratory effort. This diaphragmatic shift places it in a more favorable orientation for contraction and thus abdominal muscle activity can enhance diaphragmatic performance. True increased abdominal effort generally indicates expiratory flow limitation due to intrathoracic airway narrowing or collapse.

Some patients may have atypical abdominal wall motion. Paradoxical motion (abdomen moving inward on inspiration) may be seen with diaphragmatic hernia, fatigue, or paralysis. A more focal inward movement of the abdominal wall adjacent to the costal arch is often seen in patients with pleural effusion. Any significant motion of the soft tissues in the region overlying the thoracic inlet may indicate abnormal or increased respiratory effort.

Clinical Signs of Dyspnea

Small animal patients may also exhibit clinical signs that one might attribute to the unpleasant sensation of dyspnea. Such signs include a blunted response to the environment (obtundation) as the patient focuses solely on the act of breathing. An "anxious" facial expression with dilated pupils bilaterally is common. Such patients are typically not eating, drinking, or sleeping adequately. A patient that has been in respiratory distress and is now devoting energies to these other needs is likely improving. In cats, the absence of grooming behaviors may be associated with sensations of dyspnea. Returning to normal hygiene routines often accompanies a marked

improvement in respiratory status. Patients that are experiencing dyspnea are often excessively fractious and resistant to physical restraint.

Respiratory monitoring in the critically ill veterinary patient should include initial and serial evaluation for the presence of all the above physical exam findings. Serial evaluation often allows the clinician to put quantitative data (see later) into their proper context. The response to specific or empiric therapies is best assessed based on a combination of these physical exam findings, imaging, and quantitative laboratory assay results.

Determination of Response to Specific or Empiric Therapies

Respiratory monitoring plans are frequently designed with the goal of assessing response to therapy. Serial monitoring of respiratory rate is perhaps the most widely used approach in most settings (e.g., monitoring response to diuretics in presumed congestive heart failure patients). Other examples might include the assessment of pulse oximetry, respiratory effort, and breathing pattern in response to oxygen supplementation. Such minimally invasive approaches can be quite useful but in other cases, more invasive procedures such as intubation, positive pressure ventilation, and arterial blood gas sampling are required both to correct the problem and to monitor progression.

Marked improvement in respiratory status following intubation is expected for upper airway obstruction in the absence of other co-morbidities. Likewise, hypoxemia due solely to hypoventilation should resolve with oxygen supplementation in all cases short of apnea or agonal breathing. Failure of hypoxemia to resolve with oxygen supplementation typically indicates significant venous admixture and physiologic or anatomic right-to-left shunting. Hypoxemia that resolves with oxygen supplementation in a patient that simultaneously demonstrates little or no improvement in clinical signs of respiratory distress can be indicative of pulmonary thromboembolism (PTE). Respiratory monitoring plans should be tailored to the individual patient and the pathology believed to be present.

Assessment of the Adequacy of Alveolar Ventilation

The alveolar gas equation or "PCO_2 equation" ($PACO_2 \sim VdotCO_2/V_A$) provides the rationale for all forms of ventilatory status monitoring. The equation states that the partial pressure of carbon dioxide in alveolar gas varies directly with CO_2 production and inversely with alveolar ventilation. The adequacy of alveolar ventilation is defined by the alveolar partial pressure of carbon dioxide. If alveolar ventilation is adequate for the current level of CO_2 production then $PACO_2$ will be within the normal range. If alveolar ventilation is inadequate or excessive, the $PACO_2$ will be increased or decreased, respectively. The rate of production of carbon dioxide ($VdotCO_2$) is largely irrelevant. Ventilatory adequacy is defined relative to current carbon dioxide production *no matter what that current level might be*. In extreme cases such as malignant hyperthermia, carbon dioxide production exceeds the level that *any* healthy respiratory system could remove from the system; however, those patients are still defined as hypoventilating despite having normal (or even exceptional) respiratory function.

Alveolar gas composition is not uniform across all alveoli and is exceedingly difficult to sample. Thus, the partial pressure of carbon dioxide from other sites serves as a surrogate in clinical practice. Clinically useful surrogate samples include arterial blood, venous blood (mixed, central, or peripheral), and end-tidal exhalate. Typical canine blood values for PCO_2 are shown in Table 38.1.

Table 38.1 Blood gas analysis reference intervals

	Arterial (cat)	Arterial (dog)	Mixed venous (dog)	Central venous (dog)	Peripheral venous (dog)
pH	7.39 +/−0.08	7.40 +/−0.03	7.36 +/−0.02	7.35 +/−0.02	7.36 +/−0.02
PCO_2	31 +/−5	37 +/−3	43 +/−4	42 +/−5	43 +/−3
Base deficit	−2 to +8	−4 to 0	−2 to 0	−4 to 0	−2 to 0
Bicarbonate	18 +/−4	21 +/−2	23 +/−2	22 +/−2	23 +/−1
Total CO_2	N.D.	22 +/−2	24 +/−2	23 +/−2	24 +/−2
PO_2	105 +/−10	102 +/−7	53 +/−10	55 +/−10	58 +/−9

Source: Adapted from Ilkiw et al. (1991). Values are presented as mean +/− standard deviation.
N.D., not determined.

The adequacy of each of these sample types is dependent on patient factors as will be discussed later.

Arterial blood is often an ideal surrogate sample for evaluating ventilatory status. Carbon dioxide is highly soluble and diffusible and alveolar partial pressures typically reach equilibrium with those in the bloodstream as venous blood is arterialized. Diseases that result in impaired diffusion of respiratory gases (e.g., emphysema) often result in fatal hypoxemia before becoming sufficiently severe to cause meaningful limitations in carbon dioxide diffusion, although hypercapnia may develop in these patients by other mechanisms. However, extremes of ventilation–perfusion mismatching can result in a dissociation of arterial ($PaCO_2$) and alveolar ($PACO_2$) carbon dioxide tensions. Even with this limitation, $PaCO_2$ remains the preferred surrogate sample for defining the adequacy of alveolar ventilation.

Venous blood PCO_2 can be useful in the assessment of ventilatory status in certain settings. As shown in Table 38.1, the carbon dioxide tensions in venous and arterial blood are not the same; however, in a hemodynamically stable patient the difference between the two is suitably constant (~5–7 mmHg) so as to allow reasonably accurate prediction of what current arterial values are likely to be. Venous values also define the *maximal* value that may be present in arterial samples at that time. For example, if the $PvCO_2$ is 55 mmHg then the $PaCO_2$ is likely to be 49 mmHg and will not be greater than 55 mmHg. Unfortunately, the utility of venous blood samples for defining ventilatory status is strongly dependent on cardiovascular performance. As cardiac output falls, the difference between $PvCO_2$ and $PaCO_2$ becomes progressively larger. In patients in shock or other low-flow states, venous samples are poor surrogate samples for the assessment of the adequacy of alveolar ventilation.

End-tidal CO_2 ($ETCO_2$) is an important means of monitoring ventilation in critically ill animals and encompasses both capnometry (numeric value only) and capnography (waveform representation). Of the various surrogate markers for alveolar CO_2, $ETCO_2$, when it is working well, is the closest to actually measuring $PACO_2$. End-tidal plateau partial pressures of carbon dioxide largely reflect the levels in alveolar gas. End-tidal CO_2 monitoring is the only tool that currently provides continuous, real-time assessment of the adequacy of alveolar ventilation. In addition, respiratory rate can be determined via this methodology as well. Capnography has the added benefit of allowing waveform inspection, which can be used to monitor for rebreathing, airway obstruction/bronchospasm, apnea, dyssynchronous alveolar emptying, valve malfunctions, and many other events.

Capnography and capnometry can also be useful in determining the status of the cardiovascular system. Exhaled carbon dioxide originates in the tissues and requires cardiac pumping activity to generate venous return and CO_2 delivery. Cardiac arrest is associated with an abrupt decline in $ETCO_2$ levels. Conversely, the adequacy of cardiac compressions can be assessed by capnography or capnometry.

Many modern capnography systems (e.g., $NICO_2$®) include a flow disrupter and differential pressure transducers within the same disposable unit that is attached to the patient's breathing circuit. This allows for monitoring of respiratory mechanics as well as single-breath capnography (CO_2 plotted against cumulative exhaled volume instead of over time). Single-breath capnography provides additional data relating to airway dead space, gas distribution, and perfusion that cannot be obtained easily (or at all) with standard time-plotted capnography. The disadvantages of end-tidal capnography are that it can add considerable apparatus dead space volume in small (<2 kg) patients and promote rebreathing and reduced alveolar ventilation. End-tidal capnography also becomes dissociated from arterial carbon dioxide tensions when significant alveolar dead space is present. A larger gap between arterial and end-tidal carbon dioxide tensions develops in the setting of pulmonary thromboembolism or in cardiovascular instability/profound hypotension.

Hypercapnia and hypocapnia represent (and define) inadequate or excessive alveolar ventilation. The absolute values used to define these states will vary with the analyzer used and the species. Typically, normocapnia is defined as PCO_2 of 35–45 mmHg in veterinary species.

Assessment of the Adequacy of Oxygenation

Hypoxemia is the term used to indicate inadequate partial pressure of oxygen in an arterial blood sample (PaO_2). The values at which samples are considered to indicate hypoxemia vary slightly by region/elevation. At sea level, PaO_2 of less than 80 mmHg and 60 mmHg are considered to indicate hypoxemia and severe hypoxemia, respectively. Hypoxemia does not always equate with reduced arterial oxygen content, however. Polycythemic patients may have near-normal arterial oxygen content (~20 mL O_2/dL of blood) despite mild-to-moderate hypoxemia. The increased hemoglobin concentration can allow for the preservation of total content even when partial pressure of oxygen is reduced.

Determination of the adequacy of oxygenation is relatively straightforward. An arterial blood sample is obtained and the determination of whether hypoxemia is present is made. Alternatively, a surrogate can be used in the form of pulse oximetry. With pulse oximetry, the

partial pressure of oxygen can be inferred from the saturation due to the known relationship between the two (the oxyhemoglobin equilibrium curve). If pulse oximetry were to be employed for this purpose then the cutoffs for hypoxemia and severe hypoxemia become 95% and 92%, respectively.

Hypoxemia may be due to hypoventilation, low inspired partial pressure of oxygen (PiO_2), or venous admixture. Hypoventilation typically only results in hypoxemia when the patient is breathing room air. Supplemental oxygen is sufficient to overcome hypoxemia due to increased alveolar carbon dioxide tension in all cases (except apnea). Low inspired partial pressure of oxygen (PiO_2; often incorrectly interpreted as FiO_2) can commonly be due to decreased total inspired gas pressure (low barometric pressure at elevation) or on very rare occasion to a decreased fraction of inspired oxygen (e.g., rebreathing circuit with inadequate oxygen inflow rates; asphyxiation).

Venous admixture is a term to describe all the means by which venous blood may fail to properly equilibrate with alveolar oxygen tensions during pulmonary perfusion. The principal means by which venous admixture occurs are as follows: (1) right-to-left anatomic shunting (congenital defects predominantly, although acquired shunting may occur if pulmonary hypertension develops), (2) ventilation–perfusion mismatch (most common cause), and (3) diffusion impairment (rarely a sole cause, but contributes to a degree any time alveolar surface area is lost due to collapse or flooding). Ventilation–perfusion mismatching may be severe enough to result in physiologic shunting when perfusion is maintained to alveoli that are receiving no fresh gas via ventilation. The other extreme (ventilation of nonperfused alveoli) results in increased dead space ventilation and does not *directly* lead to hypoxemia.

Both PaO_2 and SpO_2 tell one very little by themselves about the adequacy of oxygen delivery. In an anemic patient, the PaO_2 and SpO_2 may be normal while total arterial oxygen content is completely inadequate. It serves little purpose to assess PaO_2 or SpO_2 in isolation from other factors. If one is seeking to determine the adequacy of oxygen delivery to the tissues then venous partial pressures (PvO_2) and saturations (SvO_2) are more informative in this setting. PvO_2 cannot be used to evaluate pulmonary oxygenating performance as the blood has already been modified by cellular oxygen extraction. Properly handled samples can inform the clinician of the lowest value that PaO_2 could be (i.e., if PvO_2 is 64 mmHg then the patient cannot be *severely* hypoxemic as PaO_2 must be at least 64 mmHg).

PvO_2 serves as a reasonable marker of tissue hypoxia. The partial pressure in the venous blood will be a reflection of the partial pressure present in the end-capillary blood. Mixed and central venous samples are preferable as they represent a larger pooled sample than those obtained from a peripheral vein. Values for PvO_2 below 30 mmHg should prompt the clinician to assess global or regional perfusion and oxygen delivery. Values below 20 mmHg should prompt immediate patient assessment and intervention. Recently published work has suggested that central venous hemoglobin saturations greater than 68% are associated with improved outcomes in critically ill small animal patients. This value was obtained on an instrument not validated for canine blood and may only be directly relevant when that instrument is used; however, the value reported is intriguingly similar to that reported for critically ill humans and titrating therapy to maintain $ScvO_2$ in the high 60s is likely to be associated with improved outcomes in populations, if not necessarily in each individual patient.

Analysis of venous blood gases reinforces an important point: adequate partial pressure *and* adequate total oxygen content are *both* required for optimal oxygen delivery. Total content is essential to ensure that sufficient oxygen is available to be extracted due to oxygen's poor solubility in plasma. Partial pressure must also be high enough to drive diffusion from capillary beds to mitochondria. Neither inadequate carrying capacity (hemoglobin concentration) nor inadequate partial pressure (PaO_2) will allow for optimal cellular utilization of oxygen. Adequate partial pressure maintenance is particularly important when the diffusion distance is increased by tissue edema. The combination of hypoxemia and anemia represents a major challenge to homeostasis and oxygen supplementation is advisable while blood products are being obtained.

Evaluation of Gas Exchange Efficiency

As mentioned earlier, PaO_2 and SpO_2 evaluation taken in isolation may tell one very little about the adequacy of oxygen delivery. They also poorly define lung function when the clinical context is not considered. When one evaluates either parameter, the following factors must be considered at the time the reading was obtained: (1) the nature of the gas the patient is currently breathing and (2) the patient's current ventilatory status. A low PaO_2 on room air may be a result of poor lung function and venous admixture or it may be simply due to hypoventilation. An SpO_2 reading of 96% on room air may be acceptable, whereas it is cause for significant concern on 100% oxygen. These other factors cannot be ignored if any PaO_2 and SpO_2 readings are to be correctly interpreted. One approach to incorporating these factors into

a more holistic approach to interpreting oxygenation parameters is to consider *gas exchange efficiency*.

Gas exchange efficiency measures are a means of taking a given PaO_2 and SpO_2 value and asking, "What *alveolar* partial pressure of oxygen was required to achieve that value?" These tools are primarily a means of assessing how efficient the lung is at bringing pulmonary capillary and alveolar partial pressures of oxygen into equilibrium. When patients are breathing room air, the most widely used tool for this purpose is the alveolar-arterial PO_2 gradient (A-a gradient). This approach is based on the ideal alveolar gas equation (equation 1), which provides a means by which alveolar PO_2 may be approximated.

$$[PAO_2 = FiO_2 * (P_B - P_{H2O}) - PaCO_2 / RQ] \quad \text{(Eq. 1)}$$

In order to perform the calculation, one must know the following factors which are assumed or obtained from an arterial blood gas analysis: (1) FiO_2, the fraction of inspired oxygen (0.21 on room air), (2) P_B, barometric pressure (760 mmHg at sea level), (3) P_{H2O}, water vapor pressure (varies with body temperature, but usually taken as 50 mmHg), (4) $PACO_2$, alveolar carbon dioxide tension (arterial value is usually substituted), and (5) RQ, respiratory quotient (which varies with metabolic substrate used as a fuel source, 0.8–0.9 typically used). A simplified version (equation 2) is often used clinically.

$$PAO_2 = FiO_2(P_B - 50) - 1.2(PaCO_2) \quad \text{(Eq. 2)}$$

Once one has calculated PAO_2, the measured value of PaO_2 is subtracted from it to obtain the difference between the two (A-a gradient). Lower values indicate more efficient pulmonary gas exchange, with values less than 15 considered normal and greater than 20 abnormal.

The normal range for the A-a gradient is affected by the inspired oxygen concentration. One rule of thumb is that a normal animal may have a gradient of 1 mmHg for each percent oxygen they are inspiring (e.g., up to a 20 mmHg gradient is normal on room air and up to a 100 mmHg gradient is normal on 100% oxygen). These values are rough approximations only, however, and serial comparisons are best made on room air whenever possible. A-a gradients greater than 20 mmHg indicate that venous admixture is present and contributing to hypoxemia. This does not rule out hypoventilation as a secondary contributor (both may be present). Conversely, hypoxemia with concurrent hypoventilation and a normal (<20 mmHg on room air) A-a gradient suggests that hypoventilation is the sole cause of hypoxemia.

The "Rule of 120" is a nonquantitative shortcut for assessing whether venous admixture is present. If one takes any physiologically plausible value for $PACO_2$ and calculates what the resultant PAO_2 (using equation 1 above) would be on room air then subtracts 20 mmHg from that value, one obtains the lowest value for PaO_2 that could be present with that level of ventilation and no venous admixture. One finds that the $PACO_2$ and PaO_2 obtained this way always add up to greater than 120 mmHg. Thus, for an arterial blood gas result obtained on room air, the finding that the $PaCO_2$ and PaO_2 add up to more than 120 mmHg suggests that venous admixture is unlikely to be the cause of hypoxemia (if present). This is essentially a rapid, nonquantitative means of determining whether the A-a gradient is greater or less than 20–mmHg using an arterial blood gas obtained on room air. It is the author's understanding that this clever shortcut was developed by Dr Steve Haskins at UC Davis. It has proven to be an effective and efficient screening tool for venous admixture in critically ill dogs and cats.

The A-a gradient performs more poorly when patients are receiving supplemental oxygen because of the wide range of gradients that can be obtained from normal, healthy animals under these conditions. In this setting, the ratio of PaO_2 to FiO_2 (or P:F ratio) is more typically employed. Healthy animals have P:F ratios approximating 500 (unitless). For example, a healthy dog with a PaO_2 of 105 mmHg on room air (21% or 0.21 oxygen) would have a P:F ratio of 500 (i.e., 105/0.21 = 500). Humans and animals with acute lung injury (ALI) typically have P:F ratios of less than 300. This equates to a P_aO_2 of less than 63 mmHg on room air. Humans and animals with P/F ratios of less than 200 are considered to have lung function comparable to patients with acute respiratory distress syndrome (ARDS). The P:F ratio is of no use on room air. All that would represent is a transformation (x/0.21) of the PaO_2, which would provide no additional information. Moreover, since the P:F ratio does not take ventilation into account, abnormal values obtained from patients breathing room air could suggest that lung injury/venous admixture is present when in fact hypoventilation is the sole cause of hypoxemia.

The P:F ratio is best used to compare gas exchange efficiency using values obtained from the same patient while receiving supplemental oxygen or on mechanical ventilation (or both). However, the P:F ratio is highly labile and prognostication and lung recovery assessment are best performed with many serial measurements rather than just two.

Recently, it has been suggested that the ratio of SpO_2 to FiO_2 might serve as a noninvasive alternative to the P:F ratio. This approach has been validated in human patients with ARDS, but as of this writing no such validation has been published in the veterinary literature. One small pilot study tends to support the utility of this approach.

Use of Pulmonary Mechanics to Categorize Disease

In the critically ill veterinary patient, the evaluation of pulmonary mechanics is perhaps most often performed via inspection of ventilator waveforms. A discussion of the topic of ventilator waveform analysis herein is prevented by time and space restrictions. Instead, the reader is referred to the recommended readings, which cover the topic in great depth.

Conclusion

The physical exam is arguably the most valuable tool in respiratory monitoring. Blood gas analysis and capnography can provide useful diagnostic and prognostic information that complements exam findings. Ventilation, oxygenation, the adequacy of oxygen delivery, and gas exchange efficiency can all be assessed to a degree with arterial and venous blood samples. Each of these parameters can be assessed separately, but greater diagnostic value is obtained when they are taken as a whole.

Acute Respiratory Failure

Matthew Mellema, DVM, PhD, DACVECC

Applaud Medical, San Francisco, CA, USA

Etiology/Pathophysiology

Acute respiratory failure occurs when an insult to the respiratory system that is sudden in onset or short in duration results in levels of alveolar ventilation or pulmonary oxygen transfer (or both) that are insufficient to maintain vital metabolic processes and homeostasis. This term does not imply that chronic respiratory compromise is not present concurrently. In a subset of cases, the acute exacerbation of a chronic process or the sudden development of a secondary complication (e.g., respiratory tract infection) may lead to signs of acute deterioration in clinical status. Similarly, chronic pulmonary compromise may lead to fairly abrupt fatigue of the muscles of respiration and provoke an acute crisis. The proximate cause of the acute crisis in such a case is the suddenly inadequate ventilatory capacity; however, the ultimate underlying cause may be an unsustainable workload due to a chronic disease process (e.g., progressive dynamic airway collapse, parenchymal fibrosis, etc.).

Categorization schemes for acute respiratory failure are typically multitiered in their organization. The first level of differentiation is often based on the predominant arterial blood gas alteration. With this approach, one often finds acute respiratory failure initially divided into three main subcategories: (1) hypercapneic respiratory failure, (2) hypoxemic respiratory failure, and (3) mixed respiratory failure.

Hypercapneic Respiratory Failure

Hypercapneic respiratory failure includes those conditions that result in a severe, sustained reduction in alveolar ventilation. By definition, a respiratory acidosis is present. Acidemia, or a reduction in blood pH, may or may not be present concurrently, depending on a host of other factors such as the current capacity of the extracellular hydrogen ion buffering systems. Generally, in acute hypercapneic respiratory failure, inadequate time has passed to allow for generation of maximal compensatory responses and acidemia is present more often than not.

The cut-off value for CO_2 at which hypercapneic respiratory failure is deemed to be present varies, but is typically in the 50–60 mmHg range when arterial or end-tidal exhalate sampling is utilized. A $PaCO_2$ of greater than 60 mmHg is often listed among the indications for mechanical ventilation in the veterinary literature, which can thus serve as *de facto* evidence of respiratory failure in many instances.

Hypercapneic respiratory failure (and hypercapnia in general) is the result of one or more of the following circumstances: (1) inadequate or inappropriate ventilatory drive, (2) insufficient ventilatory capacity, or (3) an excessive mechanical or chemical load imposed on the respiratory system. Inadequate or inappropriate ventilatory drive results from intracranial disease, medications/anesthetics/sedatives, or extracranial encephalopathies. The respiratory centers reside in the medulla with inputs from both the pons and cerebrum. Diseases resulting in compromise of these pontine and medullary centers may lead to marked alterations in respiratory pattern (e.g., Cheyne–Stokes breathing, apneusis, etc.) or alternatively a reduction in respiratory rate and/or tidal volume with little alteration in pattern of breathing. In the setting of hypercapneic respiratory failure due to intracranial disease, hypercapnia may be both a result and a cause of elevated intracranial pressure and imminent herniation. Inadequate or inappropriate respiratory drive is typically identified in the laboratory setting by determining the relationship between minute ventilation and $PaCO_2$ or PaO_2. This relationship is rarely defined quantitatively in the clinical setting, however. Qualitatively, a clinician may note that a hypoxemic patient has failed to hyperventilate as would be expected. Such a finding would suggest altered ventilatory drive or inadequate ventilatory capacity.

Insufficient ventilatory capacity is the second general mechanism for hypercapneic respiratory failure and is typically the result of compromise of the respiratory muscles or the neural input to them. Respiratory drive may be sufficient (although it is difficult to assess in this setting), while the transmission or end-effector systems are dysfunctional. The problem may lie anywhere along the myoneural axis. High cervical myelopathies (cranial to the C5 spinal segment) can disrupt transmission at a level cranial to the formation of the phrenic nerve roots. Low cervical myelopathies may impair the intercostal nerves while sparing phrenic nerve transmission (which is usually sufficient on its own to maintain ventilatory status). The nerve roots may be impacted by disease as is seen in polyradiculoneuritis (coon hound paralysis). Similar forms of ascending paralysis (tick paralysis, botulism, some snake envenomations) may result in hypercapneic respiratory failure that appears quite similar in nature although occurring via different mechanisms. The phrenic nerve itself may become compromised (phrenic neuropathy) due to trauma (surgical or external), demyelinating diseases, disruption by tumor growth, or idiopathic causes. Unilateral phrenic neuropathy is often well tolerated, while bilateral dysfunction can require mechanical ventilatory support.

Disorders of the neuromuscular junction can lead to hypercapneic respiratory failure. Junctionopathies may be subclassified as presynaptic, synaptic, or postsynaptic in nature. Presynaptic disorders include those that increase (e.g., low serum magnesium and some envenomations such as black widow spider bites) as well as decrease (e.g., hypocalcemia, botulism, tick paralysis, aminoglycoside antibiotics) acetylcholine release into synaptic clefts. Synaptic cleft disorders include diseases that alter the removal of acetylcholine from this site (e.g., cholinesterase inhibitors, organophosphates). Postsynaptic disorders can include forms of myasthenia gravis as well as administration of depolarizing and nondepolarizing muscle relaxants (e.g., succinylcholine).

Myopathies are a potential cause of reduced ventilatory capacity as well. Specific myopathies of the respiratory muscles are rarely diagnosed in veterinary patients except for traumatic myopathies. Traumatic diaphragmatic herniation or avulsion is perhaps the most frequently recognized myopathic process leading to hypercapnia and respiratory failure. Another uncommon but well-recognized myopathy of small animals that may profoundly reduce ventilatory capacity is potassium depletion polymyopathy of cats. While hypokalemic myopathies are more fully characterized in cats than dogs, it should be noted that profound hypokalemia also may result in hypoventilation in dogs. Other causes of diaphragmatic myopathies reported in humans are rarely reported in veterinary species, seldom associated with respiratory failure, or limited to select lines of highly inbred animals (e.g., Duchenne muscular dystrophy, thyrotoxicosis, myxedema, hyperadrenocorticism, systemic lupus erythematosus). Severe abnormalities of the sternum or chest wall may compromise diaphragmatic function by placing it at an unfavorable orientation or resting length.

An excessive mechanical or chemical load imposed on the respiratory system is the third general mechanism of acute hypercapneic respiratory failure. In this case, the respiratory system may be functioning at a high level but has been required to perform its duties in the face of a mechanical or chemical load that would exceed the capacity of any healthy respiratory system. Mechanical loads that are excessive may be the result of reductions in compliance of the chest wall or pulmonary parenchyma, increases in respiratory system resistance, or both. Reductions in compliance can result from alterations in the biomechanical properties of the structural elements themselves or alterations in surface tension forces. In the former instance, such alterations are typically the result of chronic disease processes and excessive fibrosis. However, acute changes can be superimposed iatrogenically in the form of tight wraps on the trunk at either the thoracic or abdominal level (e.g., spica splints, etc.). Elevated intraabdominal pressure (intraabdominal hypertension, abdominal compartment syndrome) can secondarily result in reduced respiratory system compliance and can develop acutely in the setting of hemoabdomen or other forms of rapid peritoneal fluid accumulation. Likewise, pleural filling disorders can compromise the tidal volume achieved with a given degree of respiratory muscular effort. A given volume of air may reduce tidal volume to a larger degree than an identical volume of fluid in the pleural space. Unlike fluid, air can expand and such expansion during inspiration can compromise tidal volume beyond the effect that results from disruption of pleural contact forces alone.

Acute reductions in the compliance of the pulmonary parenchyma and interstitium are often seen concurrently with disruption of surface tension forces in inflammatory and edematous lung diseases. Pulmonary edema, pulmonary hemorrhage, near-drowning, pneumonitis, and pneumonia all may lead to reduced pulmonary compliance both via tissue edema formation and increased surface tension due to surfactant dilution and alveolar collapse. While these effects are important, each of the diseases mentioned in this context is far more likely to cause hypoxemic respiratory failure than the hypercapneic form. Acute hypoventilation often occurs only when respiratory muscle fatigue develops or the airway becomes occluded with exudate, fluid, or foam.

Increased airway resistance is another important cause of hypercapneic respiratory failure due to an excessive

mechanical load. Many commonly diagnosed diseases in small animal practice can lead to excessive airway resistance, which is the resistance to the flow of gases during inhalation and exhalation. Airway resistance can impact both total gas flow into the system as well as intrapulmonary redistribution of gas after bulk flow has ceased (pendelluft). Many common diseases in small animal practice can cause life-threatening increases in airway resistance at the level of the extrathoracic (e.g., laryngeal paralysis, brachycephalic syndrome) or intrathoracic (e.g., feline asthma, tracheobronchial malacia) airways. These conditions are often chronically active with sudden deterioration resulting from additional factors such as increased environmental temperatures, inhaled particulates and antigens, respiratory tract infections, or atypical activity/exertion. Alternatively, disease progression may lead to a new manifestation that represents an intolerable burden (e.g., the onset of new, or higher grade, laryngeal or pharyngeal collapse).

Focal/localized intrathoracic airway narrowing or collapse typically needs to be quite proximal to significantly impair ventilation (e.g., tracheal or lobar bronchial collapse). Diffuse collapse or narrowing of large intrathoracic airways can severely impair ventilation and limit expiratory flow substantially. Narrowing or collapse of smaller intrathoracic airways generally needs to be diffuse in nature to significantly impair ventilation. Feline asthma and bronchiolitis in dogs (e.g., secondary to canine adenovirus infection) serve as examples of diseases encountered in small animal practice that result in diffuse small airway narrowing.

Increased alveolar dead space ventilation also represents a form of excessive mechanical load. In this setting, an atypically high proportion of respiratory muscular work is being devoted to ventilating alveolar units that are not participating in gas exchange. The effective alveolar ventilation is reduced although total minute ventilation may be normal (or more likely increased). This reduction in alveolar ventilation is identified (and defined) by the accompanying rise in alveolar and arterial carbon dioxide tensions. However, end-tidal concentrations become dissociated and reduced. This increase in the gradient between arterial and alveolar carbon dioxide tensions is due to the simultaneous emptying of those alveolar units that did and those that did not participate in gas exchange. Thus dead space gases dilute the carbon dioxide in the exhalate from perfused alveoli. Increased alveolar dead space may result from pulmonary vascular occlusion (e.g., pulmonary thromboembolism) or from decreased pulmonary capillary hydrostatic pressures in hypovolemia and other forms of severe cardiovascular impairment when intraluminal pressures are below alveolar pressures (i.e., extraluminal pressures exceed intraluminal pressures).

An excessive chemical load on the respiratory system can also manifest as hypercapneic respiratory failure. In this context, the high chemical load is in the form of excessive carbon dioxide and this CO_2 burden exceeds that which any healthy respiratory system might be able to eliminate. An excessive CO_2 load can be the result of an abrupt and marked increase in carbon dioxide production ($VdotCO_2$) as is seen in malignant hyperthermia or status epilepticus. Alternatively, the excessive CO_2 load can be the result of rebreathing exhaled carbon dioxide. Rebreathing may occur in several clinically relevant settings such as a maintaining a patient in a poorly ventilated, confined space (e.g., anesthetic induction box), excessive apparatus dead space (e.g., end-tidal monitoring and other devices attached to orotracheal tubes in very small patients), or exhausted soda lime in a rebreathing anesthetic circuit. The greater density of carbon dioxide relative to oxygen and nitrogen has raised concerns that a gradient may develop over time when animals are delivered supplemental oxygen via an improvised oxygen hood or nonpurpose-built oxygen cage (i.e., Elizabethan collar with plastic wrap cover). Convention is often to place the venting site upwards (12 o'clock) so that heat may readily escape; however, periodic shifting of the vent site to a downward location (6 o'clock) may be useful to reduce carbon dioxide accumulation. Typically, patient movement is sufficient to periodically shift the vent orientation without clinician intervention, but active repositioning may be required in moribund patients.

Hypoxemic Respiratory Failure

Respiratory failure that is categorized as hypoxemic largely results from venous admixture in various forms. Venous admixture is a term for the co-mingling of deoxygenated venous blood with arterialized blood during flow from the right heart to the left heart. Some authors prefer to use the term *true venous admixture* to describe right-to-left shunting through an abnormal anatomic conduit (e.g., right-to-left patent ductus arteriosus). In such frameworks, the mixing of deoxygenated venous blood with arterialized blood that occurs in the pulmonary veins in conditions such as increased ventilation–perfusion mismatching is termed *venous admixture-like* in nature. Such distinctions offer little advantage in the author's opinion. A more clinically relevant approach might be to define venous admixture as those conditions which produce hypoxemia with an accompanying increase in alveolar-to-arterial PO_2 gradient (A-a gradient). The predominant mechanisms resulting in hypoxemia are listed in Box 39.1.

Hypoventilation results in hypoxemia by reducing alveolar oxygen tensions. The retention of carbon dioxide within the alveolar spaces reduces the partial pressure

Box 39.1 Mechanisms of hypoxemia

Associated with a *normal* A-a gradient (no venous admixture)

- Hypoventilation
- Decreased PiO_2

Associated with an *increased* A-a gradient (venous admixture)

- Right-to-left shunting (anatomic shunting)
- Perfusion of nonventilated alveoli (no V–Q; physiologic shunting)
- Ventilation–perfusion mismatching (low V–Q)
- Diffusion impairment

of oxygen via dilution to a degree, but it is ultimately the failure to provide adequate inflow of oxygen to replace what has been taken up that reduces PAO_2. For this reason, hypoxemia due to hypoventilation may be readily corrected by restoring appropriate levels of alveolar ventilation, by increasing the proportion of inspired gas that is oxygen (i.e., FiO_2), or both. Hypoventilation is thus best considered as a form of hypercapneic respiratory failure rather than a truly hypoxemic form. Hypoventilation is an implausible mechanism of hypoxemia in patients receiving supplemental oxygen if one excludes complete apnea from the discussion.

Decreased PiO_2 is an often incorrectly or incompletely categorized cause of hypoxemia. Many authors will list decreased FiO_2 instead of PiO_2 as the mechanism. A truly decreased fraction of inspired oxygen is quite rare as the proximate cause of hypoxemia and would generally only be encountered if a patient were on a rebreathing circuit with inadequate fresh gas inflow. One would hope that this is a rare occurrence. Low PiO_2 in contrast is quite common and occurs any time an animal is taken significantly above sea level unless they are maintained in a suitably pressurized environment such as an aircraft. The hypoxemia that develops at elevation is the result of a decrease in PiO_2 with a normal FiO_2 (i.e., the atmosphere is still 21% oxygen, but total pressures and thus all partial pressures are decreased). For a patient breathing room air at sea level, decreased PiO_2 is not a reasonable differential diagnosis for hypoxemia. In the case of both hypoventilation and decreased PiO_2, the hypoxemia that is observed is due to a decrease in PAO_2. This decrease is accompanied by a proportional decrease in PaO_2 and thus the A-a gradient remains within the normal range.

As mentioned above, causes of hypoxemia that are associated with an increased A-a gradient are those that fall under the overarching category of venous admixture. Venous admixture includes all mechanisms by which blood passing from the right heart to the left heart fails to be properly oxygenated despite an adequate alveolar partial pressure of oxygen (PAO_2). Calculation of the A-a gradient is covered in Chapter 38.

Right-to-left shunting (anatomic shunting) is a relatively uncommon cause of hypoxemia in veterinary practice relative to other forms of venous admixture. Tetralogy of Fallot is perhaps the most common congenital defect in which right-to-left shunting occurs routinely. In many other conditions, a potential shunting conduit may be present but right-to-left shunting does not occur unless cardiac pressures on the right side exceed those on the left (e.g., septal defects). Similarly, pathology involving the great vessels such as patent ductus arteriosus would not be expected to result in right-to-left shunting unless significant pulmonary hypertension, profound systemic hypotension, or both were present. In such cases, differential cyanosis may alert the clinician to the presence of this pathology. When significant anatomic right-to-left shunting is present, hypoxemia may become refractory to correction with supplemental oxygen. When shunt flow reaches 30% of cardiac output, hypoxemia is largely unresponsive to supplemental oxygen, with no improvement expected at all when shunt flow approaches 50% of total blood flow. The shunt equation is slightly cumbersome and a clinically useful shortcut is to estimate 5% extra shunting (5% is normal so this is *additional* shunting added to the 5% baseline value) for every 100 mmHg that the PaO_2 is below the expected value for that FiO2. For example, if a patient has a PaO_2 of 200 mmHg on 100% oxygen then one would estimate the shunt fraction to be 20% (expected PaO_2 is 500 mmHg on 100% oxygen).

Physiologic shunting occurs when perfusion is maintained to nonventilated alveoli. This situation could be considered a failure of hypoxic pulmonary vasoconstriction. Inflammatory mediators and drug agents can compromise the function of both the sensing and effector arms of this response system. As alveolar oxygen tensions drop, the expected response is that the local vascular resistance to those alveoli will increase, thus diverting flow to better-ventilated alveoli. In the case of zero alveolar ventilation, the optimal response would be to reduce perfusion to that region as well. Failure to do so results in physiologic shunting. The effect is the same as if the lung were not there at all and the blood was passing through an anatomic shunt. This mechanism explains why obstruction of ventilation to a lung lobe during lung lobectomy (e.g., during one-lung ventilation for thoracoscopic lung lobectomy) results in hypoxemia, but the subsequent lung lobectomy itself does not. Removal of an excessive amount of lung tissue (e.g., all the lung lobes on the right side) can result in hypoxemia, but this is due to ventilation–perfusion mismatching (excessive perfusion relative to ventilation) in the remaining lung lobes rather than physiologic shunting. Much as is observed

with anatomic shunting, physiologic shunting, when excessive, can result in hypoxemia that is unresponsive to oxygen supplementation. In this setting, the clinical priority is to restore ventilation to the nonventilated alveoli, which often mandates mechanical ventilation with positive end-expiratory pressure (PEEP).

Ventilation–perfusion (V–Q) mismatch is perhaps the most common cause of hypoxemic respiratory failure in small animal practice. Aspiration pneumonia, cardiogenic edema, and noncardiogenic edema are commonly encountered causes of hypoxemia in small animal patients and can each result in respiratory failure. Pleural filling disorders can result in V–Q mismatch as well as hypoventilation. Atelectasis and pulmonary thromboembolism each result in V–Q mismatch as well, albeit by vastly different mechanisms. Pulmonary hypertension is increasingly recognized as a major health concern in veterinary species and can result in substantial V–Q abnormalities. Figure 39.1 illustrates the basic concepts of V–Q matching and mismatching.

In the ideal lung, ventilation and blood flow would be delivered proportionally to alveoli. An increase in ventilation relative to blood flow (high V:Q ratio) is akin to dead space ventilation and does not directly cause hypoxemia since blood flowing to such alveoli encounters alveolar oxygen tensions that are normal or slightly above typical values. Perfect one-to-one matching likewise produces conditions that are favorable for pulmonary capillary and alveolar oxygen tensions to reach equilibrium, assuming blood flow rates are not excessive (and they rarely are except in extreme circumstances). It is in those alveolar units where perfusion is disproportionately high relative to ventilation that hypoxemia develops. In this setting, blood encounters atypically low alveolar oxygen tensions and saturation is submaximal. The mixing of this poorly arterialized blood with the blood draining high and normal V–Q regions results in systemic hypoxemia. The shape of the oxyhemoglobin equilibrium curve precludes the high V–Q regions from "compensating" for the low V–Q regions. The flat portion observed at high PO_2 values prevents an increase comparable to the decrease observed at lower PO_2 values (the steep portion). Moreover, the low V–Q regions may be of that nature because of high flow (not just low ventilation) and are thus contributing a disproportionately high volume to the final mixture. Likewise, the high V–Q regions may represent areas with normal ventilation but lower perfusion and are thus contributing relatively less volume to the final mixture.

As with physiologic shunting, V–Q mismatch may be considered a failure of hypoxic pulmonary vasoconstrictive responses in many settings. Whether the problem arose due to a reduction in ventilation or an increase in perfusion, adaptive compensatory adjustments would be expected in any otherwise healthy animal. In other circumstances, inadequate hypoxic pulmonary vasoconstriction may not be primarily responsible for the V–Q inequality. In massive pulmonary thromboembolism (PTE), the portion of the lung to which blood flow is compromised is now a high V–Q region. It has become physiologic dead space and is not directly responsible for hypoxemia (high V–Q regions provide well-oxygenated blood). In this setting, if cardiac output does not fall substantially then the remaining lung is now overperfused and represents a large region of low V–Q alveolar units. In this way, hypoxemia can result indirectly.

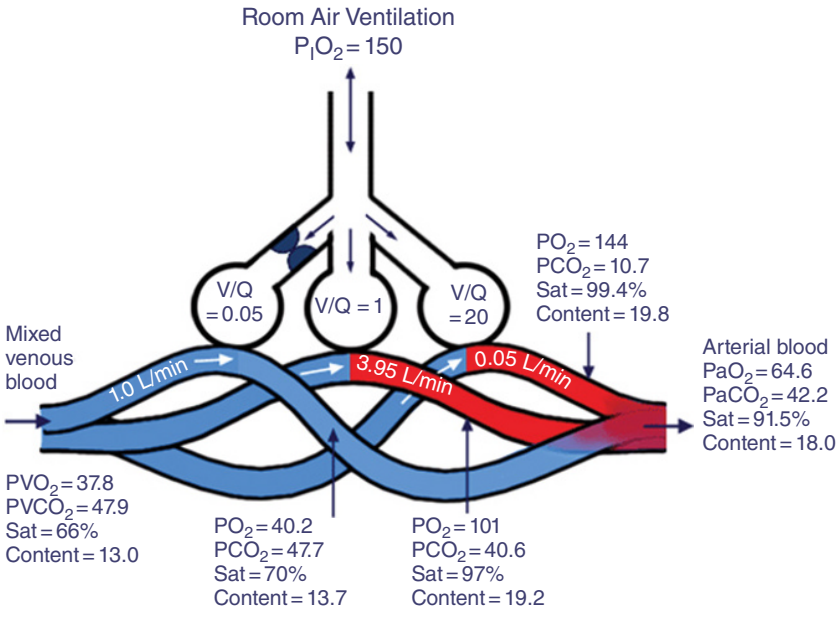

Figure 39.1 Ventilation–perfusion mismatching. Partial pressure values are in units of mmHg. Flow to normal and high V–Q regions produces appropriately arterialized blood. The blood perfusing the region with reduced alveolar ventilation (far left alveolus) produces hypoxemic blood. The final mixture is hypoxemic due to the disproportionate decrease in saturation in the blood (70% vs 97%) from the low V–Q regions and the minimal increase (99.4% vs 97%) in saturation in the blood from the high V–Q regions. Moreover, the low V–Q region has disproportionately high flows relative to the high V–Q regions (1.0 L/min vs 0.05 L/min).

This explanation seems insufficient to explain clinical experiences with this disease process, however. Surgically removing a similarly sized region of lung would presumably produce the same level of overperfusion, but does not typically result in hypoxemia. The missing portion of the mechanism for hypoxemia in this setting is likely to be altered bronchomotor tone. It was first demonstrated in 1942 that pulmonary thromboembolism (or external mechanical occlusion of a pulmonary artery) results in bronchospasm in the dog. The hypoxemia seen in PTE, but not following lung lobectomy, is likely the result of overperfusion combined with regional decreases in ventilation. Relief in sensations of dyspnea in humans is reported following theophylline administration. This may be due to a reduction in bronchospasm or reduced activation of pulmonary C-fibers via adenosine receptor antagonism.

Diffusion impairment is a common contributor to hypoxemia in small animal patients, but rarely a sole or primary cause of such. Fick's law of diffusion details the major contributing factors to gas or solute flux via diffusion: (1) concentration or partial pressure difference, (2) length of the diffusion pathway, and (3) surface area available for diffusion. With these factors in mind, both hypoventilation and low PiO2 represent a reversible form of diffusion impairment. Many of the diseases listed above under V–Q mismatch result in alveolar flooding or collapse which represents a loss of surface area for diffusion. In a similar manner, PTE results in the formation of excessive alveolar dead space, which also represents a loss of surface area for diffusion. Among the diseases common to small animal practice, chronic congestive heart failure likely represents the best example of increased diffusion distance. Remodeling of the alveolar epithelial–capillary endothelial interface in chronic congestive heart failure can result in thickening of this barrier and an increased diffusion distance.

Despite these many examples of means by which common disease processes can compromise the process, diffusion limitation is considered to be a primary cause of hypoxemia on only rare occasion. In human medicine, emphysema can result in a massive sustained loss of surface area and diffusion limitation is considered a more significant cause of hypoxemia in that species. The limited role of diffusion impairment in producing hypoxemia in small animal species is perhaps best illustrated in the setting of chronic congestive heart failure. In this syndrome, some degree of diffusion limitation is likely chronically present yet hypoxemia is rarely noted in the absence of pulmonary edema with alveolar flooding and V–Q mismatch. Pioneering work by Norman Staub has previously demonstrated in acute models of canine congestive heart failure that interstitial pulmonary edema is insufficient to produce hypoxemia in the absence of alveolar flooding in this species. Many clinicians have reported the experience of managing congestive heart failure patients in which clinical signs of respiratory distress have resolved yet thoracic radiographs still demonstrate persistent interstitial edema. Such experiences may reflect resolution of hypoxemia prior to clearance of excessive fluid accumulation in the pulmonary interstitium.

Diffusion impairment may be overcome by increasing the partial pressure gradient by raising PAO_2 or instead by recruiting additional surface area (or both). The recruitment of additional surface area can involve both recruitment maneuvers (breath hold) and the application of PEEP during mechanical ventilation.

Epidemiology

The epidemiology of respiratory failure in small animal patients is largely unknown. The epidemiology of respiratory failure in human medicine is also poorly understood. Most definitions of respiratory failure are based on arterial blood gas values. In human pediatrics, noninvasive tools are widely employed for the assessment of pulmonary function (e.g., pulse oximetry, cutaneous gas monitoring systems, etc.). Conservative estimates suggest that as many as 35% of respiratory failure patients in pediatrics are excluded because noninvasive monitoring methods were employed. Similar concerns are raised in studies of the epidemiology of respiratory failure in adult humans to a lesser degree. Between 2001 and 2009, hospitalizations for acute respiratory failure rose from 1 million cases to 1.9 million cases per year in the United States alone. The associated healthcare costs rose from $30 billion to $54 billion. A decrease in mortality has been observed over this period despite overall rates of mechanical ventilation remaining unchanged.

Attempts could be made to estimate the prevalence or incidence of small animal respiratory failure based on previously published large retrospective studies of mechanical ventilation in small animal patients. However, such data are heavily biased and likely poorly represent small animal patient populations as a whole. Patients in such studies represent only those with the following characteristics: (1) patients that were presented to a secondary or tertiary care center that offers long-term (>24 h) mechanical ventilation, (2) patients in whom respiratory failure was recognized by the attending clinician, (3) cases in which mechanical ventilation was offered, (4) cases in which clients elected to pursue this therapeutic option, and (5) cases which were not excluded from the analysis. Such reports almost certainly document only a small fraction of respiratory failure cases cared for by small animal practitioners.

One recent study examined the distribution of disease type/localization in dogs presenting for respiratory distress (termed *dyspnea* by the authors) [1]. In this study, upper airway disease, lower respiratory tract disease, pleural filling disorders, and cardiac disease represented 32%, 33%, 19%, and 12% of the cases, respectively. If one were to assume that each of these was equally likely to progress to respiratory failure then period prevalence rates might be estimated. However, this is clearly not the case. For example, pleural filling disorders are likely to be managed effectively via drainage methods before overt respiratory failure becomes persistent. Dogs in this study with lower respiratory tract disease were less likely to survive to hospital discharge. It is likely that these patients and patients with upper airway disease are more representative of patients that develop acute respiratory failure. Dogs with upper airway disease and pleural filling disorders were younger on average than dogs with cardiac disease. This finding may impact the epidemiology of respiratory failure if such data were to become available.

While respiratory distress is widely recognized as a common presenting complaint in small animal practice, the epidemiology of respiratory failure in veterinary medicine will remain largely unknown until consensus definitions and routine surveillance measures become commonplace.

Signalment

Acute respiratory failure can result from diverse disease processes and thus the signalment varies widely with the precipitating cause. Certain breeds may be associated with diseases that can predispose them to the development of respiratory failure. Select examples of such diseases for which breed dispositions have been reported include feline asthma, laryngeal paralysis, brachycephalic syndrome, cervical myelopathies, pulmonary fibrosis, tracheal collapse, bronchomalacia, metastatic neoplasia, congenital diaphragmatic hernia, mitral valve insufficiency, dilated cardiomyopathy, and myasthenia gravis. The signalment will thus be heavily dependent on the underlying cause. As mentioned above, dogs with upper airway disease and pleural filling disorders were younger on average than dogs with cardiac disease presenting for respiratory distress. Such associations might also be found in respiratory failure case series, but such has not yet been reported.

History and Clinical Signs

History and clinical signs commonly associated with acute respiratory failure will again vary substantially with the underlying cause. For example, aspiration pneumonia will typically be associated with an historical finding of vomiting, regurgitation, or a recent anesthetic procedure. Alternatively, respiratory failure patients may present with a history of generalized weakness, regurgitation or dysphagia, and megaesophagus if myasthenia gravis is present concurrently. Laryngeal paralysis may be identified more typically in patients with a history of recent voice change, persistent panting, and heat or exercise intolerance. Many other examples could be provided, but space constraints preclude an exhaustive accounting of all the historical and clinical signs that may precede respiratory failure.

What are likely to be uniformly noted among all patients with acute respiratory failure are signs of respiratory distress that precede overt failure. Tachypnea and hyperpnea are commonly, yet not uniformly noted. Patients with hypercapneic ventilatory failure (excluding those with excessive respiratory workload) may present with hypopnea or bradypnea which are often less obvious than other findings in this setting. A more extensive accounting of the signs of respiratory distress and dyspnea may be found in Chapter 38.

Diagnosis

The diagnosis of acute respiratory failure is traditionally based on arterial blood gas analysis. A sustained, repeatable $PaCO_2$ of greater than 60 mmHg is often sufficient to diagnose acute hypercapneic respiratory failure. End-tidal carbon dioxide monitoring may serve as a surrogate for $PaCO_2$ in many patients, but may have reduced sensitivity in patients with cardiovascular compromise and reduced pulmonary blood flows. Venous blood gas measurements serve as poor surrogates for $PaCO_2$ when cardiac output is diminished and should be used cautiously, if at all, to diagnose hypercapneic respiratory failure. Hypoxemic respiratory failure is diagnosed based on PaO_2 levels of less than 60 mmHg in patients breathing room air at sea level. Pulse oximetry may be substituted if arterial blood samples cannot be obtained. Saturation readings obtained by these means of less than 90–92% are consistent with hypoxemic respiratory failure. Venous samples cannot be used to define acute hypoxemic respiratory failure although they may be the more relevant sample for defining alterations in systemic oxygen delivery. Diagnosis of respiratory failure is discussed in more detail in Chapter 38.

Therapy

Therapy will be dependent on the form of acute respiratory failure present. Hypercapneic and hypoxemic respiratory failure will be discussed separately below although the two forms may occur simultaneously.

Hypercapneic Respiratory Failure

In acute hypercapneic respiratory failure, the primary goal is to reestablish adequate levels of alveolar ventilation. If the underlying cause is *reduced respiratory drive*, then therapy should be aimed at increasing central drive by one or more of the following means:

- reversal of agents such as opioids which may be suppressing central drive
- administration of agents that may enhance/increase central drive such as doxapram
- alleviation of elevated intracranial pressure if known or suspected to be present with agents such as mannitol or hypertonic saline
- enhancing elimination of agents suppressing central drive such as toxins or anesthetic agents. This may require fluid diuresis, short-term ventilation, or extracorporeal techniques such as hemodialysis.

If *reduced ventilatory capacity* is the underlying cause of hypercapneic respiratory failure then supportive measures may often play a larger role than specific therapies. Supplemental oxygen and/or mechanical ventilation (see also Chapter 40) may be required until normal ventilatory capacity can be reestablished. In some cases, supportive care may be required for a few days only (e.g., supportive care following removal of the tick in tick paralysis) and in others it may need to be provided for many weeks. Correction of metabolic myopathies and junctionopathies due to hypokalemia or hypomagnesemia should be addressed by rapid correction via parenteral supplementation. Antivenins, when available, may be appropriate for hypercapneic respiratory failure syndromes secondary to envenomations. Reduced ventilatory capacity due to cervical myelopathies may be amenable to surgical treatment in many cases. Stabilization and decompression may speed the restoration of effective transmission of efferent signals to respiratory muscles. Toxic causes of reduced ventilatory capacity may on occasion have specific therapies that may be employed to increase recovery rates. Organophosphate toxicity treated with atropine and pralidoxime (2-PAM) would be just one example. Reducing metabolic rate and carbon dioxide production can help to bring ventilatory capacity and need closer to adequacy. Addressing fever, preventing hyperthermia, and controlling muscle tremors and seizures become even more important goals than usual in this setting.

Lastly, the diaphragm is similar to cardiac muscle in that maximal contractile strength is strongly dependent on adequate perfusion. Typical skeletal muscle is able to maintain contractile strength in the face of reduced perfusion to a larger degree. Diaphragmatic blood flow may be improved by reducing intraabdominal pressures (e.g., removing ascites) or by pharmacologic means (e.g., methylxanthine administration). Maintaining global cardiac output and mean arterial pressures should be a primary goal.

When excessive mechanical loads are the proximate cause of hypercapneic respiratory failure, the primary goal is to restore loads on the respiratory system to more normal values. Intubation and temporary tracheostomy are essential means by which upper airway obstructions can be bypassed and airway patency restored. Having the necessary supplies and personnel immediately on hand is advised in cases where such measures seem likely to be required in the near future. Permanent tracheostomy may be a suitable long-term solution in dogs, but has been associated with poor overall outcomes in cats in one study. Laryngeal paralysis is another example of a cause that may be amenable to surgical therapeutic approaches. While corticosteroids are advocated on occasion for the reduction of upper airway edema, the empirical evidence for beneficial effects of this therapy remains quite limited. Continuous positive airway pressure (CPAP) might be of benefit in many cases of dynamic upper airway narrowing; however, more often than not, this therapy requires general anesthesia in veterinary patients and thus offers less potential benefit over traditional positive pressure ventilation. Heated, humidified, high-flow nasal cannula oxygen therapy (HHHFNC) has comparable effects to nasal mask/pillow CPAP in human pediatrics. The author uses one such device (PrecisionFlow®, Vapotherm) in his practice to provide this form of therapy although direct comparisons have not yet been made to other similar products and no specific recommendations are made here.

Excessive mechanical load due to low tissue compliance may be addressed by reducing parenchymal inflammation and reducing extravascular lung water (edema). Diuretic administration and maintaining a neutral or negative fluid balance are advised in cardiogenic edema states and in some noncardiogenic edema states. However, in patients on mechanical ventilation, the cardiovascular effects of high PEEP may preclude the clinician from keeping the patient as "dry" as one might prefer. Reduced blood volume with high PEEP can often lead to intolerably poor cardiac performance. In some noncardiogenic pulmonary edema states such as the acute respiratory distress syndrome, the use of diuretics remains controversial. In this setting, pulmonary vascular permeability may be increased to the point that diuretic therapy does little to reduce the rate of transcapillary fluid flux and may lead to reductions in cardiac output with no discernible benefit. The pathophysiology of *neurogenic* pulmonary edema is complex

and there is empirical evidence to support both hydrostatic and inflammatory components. Diuretic usage is not considered absolutely contraindicated, but is unlikely to yield the profoundly beneficial responses observed with cardiogenic edema.

Excessive mechanical loads due to chest wall compliance issues (e.g., flail chest, congenital defects, etc.) may be challenging to address unless they are iatrogenic in nature. Iatrogenic alterations in chest wall/diaphragmatic compliance can result from excessively tight thoracic and abdominal wraps, splints, and casts. Incremental loosening of such wraps until chest wall compliance is not excessively low is advised.

Excessive chemical loads are the result of marked increases in carbon dioxide production. Malignant hyperthermia (MH) is perhaps the most common cause and is thankfully a rare occurrence. Active cooling, mechanical ventilation, discontinuance of all volatile inhalational anesthetics (or succinylcholine), and the administration of dantrolene remain the mainstays of MH therapy. In settings other than MH, excessive CO_2 production is addressed by minimizing muscle activity (seizures, tremors) and lowering body temperature when possible. In many instances, active cooling is not required; rather, one needs to only *not* provide active warming therapies. Maintaining adequate hydration to promote effective evaporative heat loss is advised.

Hypoxemic Respiratory Failure

As with hypercapneic respiratory failure, the optimal therapeutic approach to hypoxemic respiratory failure will vary with the underlying cause. In cases of hypoxemic respiratory failure in which a normal A-a gradient is found, therapy should be directed at restoring alveolar ventilation and appropriate inspired gas pressures. This would entail removing the patient from elevations above sea level, providing supplemental oxygen, or the measures described above under hypercapneic respiratory failure.

When venous admixture is the underlying cause of hypoxemic failure, the primary goals are as follows:

- reduce anatomic or physiologic shunting if present
- increase alveolar partial pressure of oxygen
- correct V–Q inequalities
- recruit alveolar surface area available to participate in gas exchange

Achieving a reduction in anatomic shunting often requires an invasive or minimally invasive surgical approach to reducing or ablating flow through the shunt conduit. Reductions in physiologic shunting may be achieved by surgical removal of lung lobes too diseased to be salvaged in some cases. Restoring ventilation to alveolar regions that are atelectatic, obstructed, collapsed, or flooded should improve V:Q ratios. This goal may be achieved by increasing mean airway pressure (mechanical ventilation, typically with PEEP), enhancing alveolar fluid clearance, breath hold recruitment maneuvers, and addressing inflammatory or infectious insults to the lower airways with appropriate drug therapy. Diffuse alveolar hemorrhage syndromes should be addressed with appropriate drug therapies and blood products when they are the result of a coagulopathy. Note that the majority of therapies that aim to reduce physiologic shunting also will generally recruit alveolar surface area and improve overall V–Q matching. The removal of air or fluid accumulations from the pleural space can result in marked improvements in V–Q matching in many cases. Early recognition of pleural filling disorders can lead to improved outcomes.

Ultrasound is the preferred imaging modality if it is available in the emergency room. Many of these patients are not stable enough to tolerate radiographic imaging until after air or fluid has been evacuated from the pleural space. Thoracocentesis should be performed until negative pressure is achieved. If negative pressure cannot be obtained or if pleural filling rapidly recurs then chest tube placement is required.

Increases in the alveolar partial pressure of oxygen may be achieved by several means. First, the restoration of ventilation to alveolar regions with limited fresh gas flows will raise PAO_2 in those areas. More widespread increases in PAO_2 are achieved by providing supplemental oxygen. Mechanical ventilation with PEEP can simultaneously increase alveolar ventilation, recruit underventilated/nonventilated alveolar units, raise mean airway pressures, and provide supplemental oxygen. Intermittent positive pressure ventilation (IPPV) is frequently required in hypoxemic respiratory failure cases and is discussed in Chapter 40. The indication for mechanical ventilation in hypoxemic respiratory failure would be *acute*, persistent severe hypoxemia (PaO_2 <60 mmHg or SpO_2 <90%) that is unresponsive to supplemental oxygen therapy alone. In *chronic* disease states, hypoxemia of this degree of severity may be better tolerated and occasionally requires neither supplemental oxygen nor IPPV.

Supplemental oxygen is generally required in cases of hypoxemic respiratory failure in which the underlying cause cannot be immediately addressed. Supplemental oxygen may be sufficient to address hypoxemia in cases not requiring mechanical ventilation. Delivery may be via nasal or tracheal cannulae, facemask, intubation/tracheostomy with spontaneous respiration, or via an oxygen cage. The lowest FiO_2 required to prevent hypoxemia

Table 39.1 Approximate flow rates of 100% oxygen via nasal cannulae required to achieve an FiO_2 between 30% and 90%. Body weight must be considered and FiO_2 values above 50% may be difficult to achieve in large dogs using this method

	Required flow rate in L/min to achieve an FiO_2 of…		
Body weight (kg)	**0.3–0.5**	**0.5–0.75**	**0.75–0.9**
0–10	0.5–1.0	1.0–3.0	3.0–5.0
10–20	1.0–3.0	3.0–5.0	>5.0
20–40	3.0–5.0	>5.0	ND

ND, not determined.

should be determined on an individual case basis. In many cases, FiO_2 will be known (e.g., 21% or 100%) but at other times it must be estimated. In humans breathing with nasal cannulae in place, the rule of thumb is that one can add 4% for each L/min of oxygen flow. Thus, a person breathing with a 2 L/min flow of oxygen would have an estimated FiO_2 of 28–29% (i.e., 21 + (2 × 4)). This rule works poorly in veterinary patients as their size and tidal volumes vary so much more widely than in humans. Estimates of FiO_2 can be made based on a consideration of both flow rate and patient size (see Table 39.1). Prolonged (>24 h) exposure to greater than 60% oxygen can result in pulmonary oxygen toxicity in most mammals although the toxic range varies with species and age.

However supplemental oxygen is provided, it is important that the gas be properly conditioned. Conditioning in this sense means appropriately warmed and humidified. The inhalation of improperly conditioned gas is associated with several adverse effects in humans, including increased nasal airway resistance, damage to the nasal mucosa (both structural and functional, including epithelial metaplasia and keratinization), increased work of breathing, difficulty in subsequent intubation, patient discomfort, and poor patient compliance. Breathing cold, dry gas from compressed sources can lead to airway dessication (particularly if the nasal passages are bypassed), increases in the tonicity of airway lining fluid, and mast cell degranulation. This airway drying hypothesis is one explanation proposed for exercise-induced asthma.

Prognosis

A specific prognosis for acute respiratory failure cannot be provided in a meaningful way. Clearly, acute respiratory failure is not good news in any context. However, some causes may be easily resolved and carry a good prognosis (fluid overload) whereas others are challenging to address and carry a quite guarded prognosis (ARDS). The prognosis will naturally vary with the underlying cause. Further, prognosis is impacted by whether a specific, effective therapy is available for that disease process or whether one must rely solely on supportive measures. The issue of prognosis is further complicated by the inherent difficulty in reaching a definitive diagnosis in many cases of acute respiratory failure. Patients are often too unstable to undergo the diagnostics required to definitively identify the underlying cause and thus owners are often required to make difficult decisions based on incomplete information.

As mentioned above, retrospective studies of long-term mechanical ventilation in veterinary patients provide some insights into acute respiratory failure, but represent a highly biased sample of such cases. In one such study, veterinary patients with pulmonary parenchymal disease (i.e., hypoxemic respiratory failure) were able to be successfully weaned 36% of the time, with an overall rate of 22% of cases surviving to hospital discharge. Outcomes were better for patients experiencing hypercapneic respiratory failure, with 50% being successfully weaned and 39% surviving to hospital discharge. Patients with mixed respiratory failure (both hypoxemic and hypercapneic) had the poorest outcomes in this study. Overall, cats fared more poorly than canine patients. Whether this is due to the types of diseases that lead to the need for IPPV in cats or whether cats are at greater risk for complications such as ventilator-induced lung injury (VILI) remains undetermined. Cats are a smaller species on average than dogs and smaller species develop VILI more readily than do larger species even when identical inspiratory pressures are applied. No direct comparison of VILI incidence in cats versus 3–7 kg dogs has yet been performed.

Mechanical Ventilation

Kate Hopper, BVSc, DACVESS, PhD[1] *and Mathew Mellema, DVM, PhD, DACVECC*[2]

A respirator or mechanical ventilator is a therapeutic device that performs some or all of the work of breathing. Ventilators are used in clinical practice to provide short- or long-term support of respiratory function in patients with respiratory disease or failure.

Two primary functions of the lung are oxygenation of the arterial blood and the elimination of carbon dioxide from the venous blood in order to provide metabolic substrate, remove metabolic waste, and maintain homeostasis. The ability of the lung to properly oxygenate the pulmonary capillary blood depends largely on several key factors:

- adequate replenishment of alveolar gases with inspired air
- adequate surface area for gas exchange
- proper matching of ventilation and perfusion
- maintenance of the structural integrity of the gas exchange barrier.

In contrast, elimination of carbon dioxide is primarily dependent on the repeated movement of fresh gas into the alveoli and removal of portions of alveolar gas, a process known as alveolar ventilation. Respiratory failure can result from diverse disease processes that interfere with one or more of the lung's primary functions. Patients with respiratory failure can generally be divided into three groups: those with hypoxemic failure, those with hypercapneic failure, and those with mixed respiratory failure, which shares aspects of both of the other two types.

Indications for Mechanical Ventilation

There are three primary indications for mechanical ventilation. The first is persistent severe hypoxemia (PaO_2 <60 mmHg) despite supplemental oxygen therapy. Severe hypoxemia may also be recognized by the presence of cyanosis or SpO_2 <90% when arterial blood gas analysis is impractical or unavailable. Patients with severe hypoxemia will frequently have significant lung disease such as pneumonia, acute respiratory distress syndrome (ARDS), pulmonary edema, diffuse alveolar hemorrhage, or pulmonary contusions. Pulmonary vascular disorders such as pulmonary thromboembolism (PTE) may also cause severe hypoxemia. Other causes such as anatomic right-to-left shunting are far less commonly encountered in veterinary practice.

The second primary indication for mechanical ventilation is persistent severe hypercapnia (hypoventilation) that is refractory to other therapeutic measures. Severe hypoventilation is marked by a $PACO_2$ >60 mmHg. The $PACO_2$ is determined primarily by alveolar minute ventilation and carbon dioxide production (which is often reasonably constant). Alveolar ventilation is dependent on the total amount of fresh gas that reaches the alveoli over time and is equal to the product of the respiratory rate and effective tidal volume. Effective tidal volume is total tidal volume minus dead space volume. Causes of severe hypoventilation are typically diseases that impair the ability of patients to maintain an adequate respiratory rate and/or tidal volume. Examples include intracranial disease, cranial cervical myelopathies, peripheral neuropathies, junctionopathies, and myopathies.

Severe hypoxemia or severe hypoventilation will not always require mechanical ventilation, but the criteria provided above may help to identify potential candidates for ventilator therapy. The necessity of mechanical ventilation should be made on a case-by-case basis and knowledge of the primary disease process and related patient data should factor heavily into the decision. Ventilator therapy is not entirely benign and a careful weighing of the risks and benefits should be made before the provision of this approach.

The third primary indication for mechanical ventilation is persistent, excessive respiratory effort that may

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

potentially lead to respiratory muscle fatigue and exhaustion. Such patients may be able to maintain acceptable blood gas values for a period of time, but uncertainty lies in how long this effort can be sustained. Determination of excessive respiratory effort is largely subjective and based on clinical judgment. Intermittent positive pressure ventilation (IPPV) is indicated in these patients to avoid abrupt exhaustion, asphyxiation, and subsequent arrest. Asphyxiation in experimental canine studies is accompanied by an abrupt drop in heart rate of about 50 beats per minute. Any comparable drop in pulse rate in a dog laboring to breath should prompt immediate patient evaluation and careful consideration of intubation and mechanical ventilation. In these aforementioned canine studies, failure to prevent complete asphyxiation often leads to cardiac arrest in the form of pulseless electrical activity; this is a particularly challenging form of cardiac arrest to reverse and is often refractory to therapy.

Patients with excessive respiratory effort usually have an excessive mechanical or chemical load imposed upon their respiratory system (see also Chapter 39).

Ventilator Settings

Positive pressure ventilators achieve gas flow into the lungs by generating positive airway pressure in a manner similar to that achieved by squeezing the rebreathing bag on an anesthetic machine. Modern therapeutic ventilators have an array of settings that can be altered to change the characteristics of the delivered breath. Despite the complexity of many therapeutic ventilators, there are only a few key settings that are essential to understand in order to provide effective ventilation in most cases. When choosing ventilator settings, the clinician must first select a mode of ventilation and then input initial ventilator settings based on general guidelines (described below) and their own understanding of the nature of the patient's respiratory compromise. Following initiation of mechanical ventilation, the ventilator settings are then adjusted as required to achieve the blood gas, cardiopulmonary performance, and/or oxygen delivery goals desired.

Ventilator Breath Types

There are three main ventilator volume delivery (breath) patterns commonly used in veterinary medicine: assist/control (A/C) ventilation, synchronized intermittent mandatory ventilation (SIMV), and continuous spontaneous ventilation (CSV). Some ventilators only have one breath pattern option, such as a compact volume-control ventilator designed for use in the operating room. Modern therapeutic ventilators typically offer all three formats.

In A/C ventilation, all breaths are completely machine generated. These are termed *mandatory breaths*. In this mode of ventilation, the clinician sets a minimum respiratory rate. If the trigger sensitivity (i.e., pressure or flow alteration required to trigger delivery of a breath that was not prescheduled to be delivered) is set appropriately then the patient can increase the respiratory rate above this minimum value, but all breaths delivered will be full ventilator-delivered (mandatory) breaths. The tidal volume of these ventilator breaths will depend on the machine settings (and any patient–ventilator dyssynchrony if present). Ventilator breaths can either be pressure (PC) or volume controlled (VC). When VC is employed, the clinician presets the desired tidal volume; the resultant peak airway pressure will be dependent on the size of the tidal volume chosen and the compliance of the respiratory system. More compliant lungs will accept a given volume at a lower peak pressure than less compliant lungs. In PC ventilation, the clinician presets the peak airway pressure; in this setting, the tidal volume generated will depend on the level of peak airway pressure chosen and the compliance of the respiratory system. Assist/control ventilation provides maximum support of the respiratory system and is used in patients with severe respiratory disease or those with healthy lungs but reduced respiratory drive or ventilatory capacity.

In SIMV, the operator also sets the number of full ventilator (mandatory) breaths to be delivered. However, between these breaths the patient can breathe spontaneously, depending on their needs. The machine will try to synchronize the ventilator breaths with the patient's own respiratory efforts. This is accomplished by partitioning the periods between mandatory breaths into two periods. The first period immediately follows a mandatory breath. During this period, the patient may breathe spontaneously without triggering a machine-delivered breath. The second period is immediately prior to the next scheduled mandatory breath. Patient effort during this period will trigger early delivery of the next mandatory breath. This latter period is the "synchronized" portion and is what distinguishes SIMV from intermittent mandatory ventilation. As this mode combines full ventilator breaths with spontaneous patient breaths, it is often used for animals that need less than 100% assistance from the ventilator or during the weaning period. Neurologically impaired animals with highly labile respiratory drive or patients with resolving lung dysfunction may not need as much support as A/C provides and SIMV can prove a useful option in these conditions.

There are two widely available options for provision of continuous spontaneous ventilation: continuous positive airway pressure (CPAP) and pressure support ventilation (PSV). In CPAP, the ventilator does not deliver breaths; rather, all breaths are spontaneous breaths and are completely patient generated. The respiratory rate, inspiratory time, and tidal volume are all determined by the patient. CPAP provides a constant level of positive airway pressure (the amount is preset by the operator) throughout the respiratory cycle. Airway pressure is thus maintained at supraatmospheric pressures throughout the respiratory cycle. CPAP has the potential benefits of decreasing respiratory system resistance and increasing pulmonary compliance. These effects as well as the increase in mean airway pressure may serve to improve gas exchange and oxygenation relative to what the patient could achieve without this support. Increased pulmonary compliance effects of CPAP can best be explained by considering the shape of a typical lung pressure–volume relationship (aka compliance curve). Pulmonary compliance curves are typically nonlinear with a flat slope at volumes just above functional residual capacity (FRC). This relatively flat slope indicates that changes in pressure generated by early inspiratory effort are accompanied by only slight changes in lung volume (low compliance). CPAP can reduce the work of breathing by shifting the starting point of breath initiation to a portion of the curve with a steeper slope (higher compliance). Further, maintaining the lung at a higher volume increases mean airway diameter of noncartilaginous airways and reduces airway resistance. With modern ventilator models, the machine will alarm if the animal does not generate adequate breaths or develops apnea. This makes it a useful "monitoring" mode for weaning patients or monitoring intubated patients.

As with CPAP, all PSV breaths are spontaneous breaths; the ventilator does not trigger, deliver, or initiate any breaths. In PSV, the tidal volume is generated by the patient, but also augmented by the machine. The amount of pressure support provided during the inspiratory period depends on what level of PSV support the clinician has prescribed. This mode reduces the effort required to maintain adequate alveolar ventilation and gas exchange in patients with adequate respiratory drive but reduced ventilatory capacity. Pressure support ventilation can be used independently, in conjunction with CPAP, or to augment the spontaneous breaths during SIMV.

Tidal Volume Settings

The normal tidal volume reported for dogs and cats is generally in the range of 10–15 mL/kg although many reports cite a tidal volume for healthy sedated cats of approximately 20 mL/kg. Lower tidal volumes (6–8 mL/kg) may be targeted in animals with severe lung disease to avoid overdistension of the less severely diseased lung tissue. When using volume control ventilation, the clinician presets the desired tidal volume. As overdistension of the lung can lead to significant alveolar injury, it is recommended to start with no more than 10 mL/kg initially. The tidal volume can subsequently be increased if it is determined to be inadequate once an initial steady state is achieved (typically 15 minutes after initiating IPPV or following a settings adjustment). If pressure control ventilation is used then the operator presets a desired peak airway pressure and once the animal is connected to the ventilator, the tidal volume achieved with the preset pressure is evaluated and peak inspiratory pressure adjusted as needed. A tidal volume of around 10 mL/kg would be an acceptable result in most cases.

The clinician must bear in mind that whole-body carbon dioxide stores are enormous relative to the relatively minimal whole-body oxygen stores (excluding pinniped mammals). Step changes in ventilation will result in abrupt, modest changes in $PaCO_2$, but a new steady-state value can take quite a long time to be reached. Only the CO_2 in large, well-perfused organs can truly be considered rapidly exchangeable and this represents a small fraction of whole-body stores. Allowing 15 minutes to pass prior to reassessing steady-state $PaCO_2$ values is a clinically reasonable approach.

Airway Pressure Settings

Patients with healthy lungs such as hypoventilating anesthetized patients, patients with reduced respiratory drive, or those with reduced ventilatory capacity typically only require peak airway pressures in the range of 8–15 cmH_2O. Avoiding peak inspiratory pressures above 20 cmH_2O is preferable whenever feasible. Animals with significant lung disease often have relatively stiff lungs and typically require higher airway pressures to achieve adequate tidal volumes. Peak airway pressures as high as 30–35 cm H_2O may be required in such animals. When using pressure control ventilation, the peak airway pressure target is set by the clinician. Once the animal is connected to the ventilator, the tidal volume achieved with that airway pressure should be determined. Alternatively, in volume control, the tidal volume is preset and the associated airway pressure needs to be monitored. Initially, airway pressures of 10–15 cmH_2O should be targeted; higher airway pressures can be utilized if indicated by unacceptable blood gas values.

Trigger Settings

Most modern ventilators will allow the patient to trigger machine breaths, which allows breath delivery to be

better matched to the patient's intrinsic efforts. The "trigger" or "sensitivity" setting determines what the ventilator will acknowledge as a genuine inspiratory effort by the patient. Appropriate trigger sensitivity is essential to ensure the ventilator recognizes actual respiratory efforts made by the patient while not delivering breaths as a result of minor fluctuations in circuit pressure or flow. Appropriate trigger sensitivity increases patient comfort, reduces dyssynchrony between patient effort and machine delivery, and allows the patient to increase the respiratory rate as required by their needs. The trigger variable can be too sensitive such that nonrespiratory efforts such as patient handling and cardiac contractions may initiate breaths. This situation should be avoided as it leads to patient discomfort, excessive mean airway pressures, breath stacking, auto-PEEP, and greater dyssynchrony. An airway pressure drop of –2 cmH_2O or a gas flow change of 2 L/min are reasonable trigger sensitivity settings to start with. These settings can then be altered as required. Some ventilators (e.g., AutoTrak on the Phillips Esprit line) have proprietary forms of trigger sensing that combine the flow and pressure signals into an integrated variable. Evidence of superiority of this means of sensing patient inspiratory effort is currently lacking in the veterinary literature.

Positive End-Expiratory Pressure Settings

Positive end-expiratory pressure (PEEP) maintains pressure in the breathing circuit above atmospheric pressure during exhalation so that the patient cannot exhale all the way down to functional residual capacity (FRC). This increased expiratory pressure maintains the lung at a higher volume, with less small airway collapse, and improves oxygenating efficiency. PEEP may also help to recruit alveoli collapsed due to atelectasis or increased surface tension forces. Evidence suggests that it may reduce ventilator-induced lung injury by altering cyclic stresses and strains on the alveoli and peripheral airways. Typically, a small amount of PEEP (~2 cmH_2O) is applied in all ventilator modes to reduce atelectasis and to account for the increased work of breathing required simply due to the physical nature of the ventilator circuit (e.g., valves, circuit resistance). In patients with significant lung disease, much higher levels of PEEP may be required to improve oxygenating ability. In continuous spontaneous ventilation, CPAP is functionally equivalent to PEEP although they are often generated by different means (i.e., closure of the expiratory valve at supraatmospheric pressures versus continuous inflow to maintain a given circuit pressure during the expiratory phase).

Inspiratory:Expiratory (I:E) Ratio and Respiratory Rate Settings

An operator-set respiratory rate is available on nearly all ventilators. A respiratory rate of 15–20 breaths per minute with an inspiratory time of approximately one second reflects typical initial ventilator settings in the authors' practice. These settings can then be adjusted as needed to meet the patient's needs. The ratio of the duration of the inspiratory phase relative to the expiratory phase (I:E ratio) may be preset by the clinician or may be a setting that is determined automatically based on rate and inspiratory time settings. Commonly, an I:E ratio of at least 1:2 is utilized to increase the likelihood that patients are able to fully exhale prior to the delivery of the next breath. As respiratory rates are increased, the expiratory time will be reduced in order to accommodate the increased number of breaths. High respiratory rates can lead to a situation known as auto-PEEP or intrinsic PEEP if the patient is not able to fully exhale before the start of the next inspiration. Such an occurrence can easily be detected by inspecting the flow scalar graphic if waveform displays are available. Failure of expiratory flow to return to zero before the next breath is delivered is indicative of the presence of auto-PEEP. To avoid this problem, it is recommended to keep an I:E ratio of 1:1 or higher whenever possible. If a higher respiratory rate is required, a shorter inspiratory time will allow maintenance of an acceptable I:E ratio and is often better tolerated by the patient.

General Guidelines for Initial Ventilator Settings

As discussed above, the optimal ventilator settings for a given patient cannot be predicted reliably. It is likely that animals with hypoxemic respiratory failure will require more aggressive settings than those with hypercapneic respiratory failure. One must choose some initial settings prior to connecting the patient to the ventilator. First the mode of ventilation must be selected; A/C, SIMV or continuous spontaneous ventilation. If A/C or SIMV are selected then it may be necessary to next decide between volume control (VC) or pressure control (PC) ventilation. The more modern and advanced the ventilator, the more options one is likely to have. Ventilator manufacturers are creating new proprietary ventilation modes faster than clinicans can evaluate them. Even the most renowned respiratory therapists in the world admit that they cannot keep up with every mode becoming available. This situation is unlikely to change as equipment manufacturers are often less than forthright about how these novel modes are designed. The settings that need to be selected will vary with the

mode of ventilation chosen. In VC the tidal volume is preset by the operator, once the patient is connected to the machine the operator should note the peak inspiratory pressure associated with this tidal volume and determine whether it is acceptable for this patient. In PC ventilation, the clinician presets the peak airway pressure. Once the patient is connected to the ventilator the operator will need to note the tidal volume and mean airway pressure and determine whether they are acceptable for this patient.

These settings can then be altered as needed once the patient is connected to the ventilator. Whenever possible, it is best to have the ventilator already running and confirmed to be working properly before the patient is connected. When this is not possible, for example initiating mechanical ventilation for patients already on an anesthetic machine, then it is best to start with quite conservative settings and titrate them upwards as required to avoid inadvertent over-distension of the lung. It is imperative to always have a method for performing manual ventilation (e.g. Ambu-bag, Bain's circuit) close at hand during IPPV in case of equipment malfunction, power failure, or operator error.

Mechanical Ventilation for Hypoxemic Respiratory Failure

Patients suffering from hypoxemic respiratory failure often require inspiratory pressure settings that are substantially greater than normal. Pulmonary parenchymal disease often reduces lung compliance and increases airway resistance. The result is that higher pressures will be needed to achieve the same tidal volume. It is now recognized that excessive distension of the lung (or volutrauma) is a major cause of ventilator-induced lung injury. For this reason, it is recommended to deliver smaller tidal volumes when ventilating patients with significant pulmonary parenchymal disease. In very severe lung disease such as ARDS, it may be necessary to deliver tidal volumes as low as 6 mL/kg.

Anesthesia

Unless the patient has significant neuromuscular or intracranial disease, anesthesia will be necessary to allow positive pressure ventilation and maintenance of an airway. Balanced anesthesia incorporating 2–3 drugs is advised to reduce the dose required (and adverse effects) of any single agent. Propofol or alfaxalone infusions are commonly used anesthetic agents in conjunction with a benzodiazepine and/or an opioid and/or a dexmedetomidine infusion. The aim is to keep the patient anesthetized sufficiently such that it will tolerate the endotracheal tube and PPV but to avoid excessive depth of anesthesia in an effort to minimize the adverse effects of the anesthetic drugs. This requires some experience in anesthetic monitoring and constant tinkering with the anesthetic drug infusion rates as drug requirements will change with time.

Typical intravenous anesthetic doses used to maintain patients on mechanical ventilators at the authors' practice include the following.

- Midazolam: loading dose 0.2–0.4 mg/kg IV; constant rate infusion (CRI) 0.1–0.5 mg/kg/h IV.
- Propofol: loading dose 0.5–2.0 mg/kg IV; CRI 0.05–0.4 mg/kg/min IV.
- Fentanyl: loading dose 2–5 µg/kg IV; CRI 1–7 µg/kg/h IV.

The vast majority of patients receiving long-term mechanical ventilatory support in our practice are anesthetized with some combination of these three agents. The occasional patient will also receive a dexmedetomidine infusion (0.1–3.0 µg/kg/h) either as a replacement for one of those three agents or in addition to them. Etomidate is rarely if ever given and has resulted in marked suppression of adrenal function when it was employed. Diazepam may be substituted for midazolam as required. Pentobarbital, once a mainstay in our practice, is rarely used now due to relative expense, reduced availability due to shortages, and prolonged recovery times.

Anesthetic depth should be formally assessed every hour and recorded on the patient's flow sheet/medical record, but caregivers should be continuously assessing anesthetic depth as they work on the patient. It is important to have drug dose charts that correctly convert the mg/kg/h drug doses to mL/h for the drug concentration you are using. In addition, it is recommended to have precalculated some "rescue doses" of drugs in case animals suddenly become light and try to extubate themselves.

Initial Stabilization on the Ventilator

When patients are first connected to the ventilator circuit, an inspired oxygen fraction (FiO_2) of 100% is advised as a safety measure. The FiO_2 can be reduced later once stabilization of the patient has been achieved. When ventilating patients with hypoxemic respiratory failure, it can be beneficial to keep them in sternal recumbency during the initial stabilization period. These animals frequently oxygenate better in sternal recumbency than in other body positions. After connection, the patient's thoracic wall is observed for appropriate movement. When insufficient or excessive thoracic wall motion is observed, the ventilator settings should be adjusted appropriately.

The thorax is next auscultated bilaterally to ensure breath sounds are audible. Next, other monitoring parameters are evaluated (e.g., blood pressure, ECG, pulse oximeter, $ETCO_2$, etc.). Once the patient appears stable, serial arterial blood gas analysis is ideal for accurate titration of ventilator settings. If an arterial blood sample is not available, a venous blood gas can be used to assess PCO_2 if cardiac output is not excessively low. The evaluation of oxygenation by pulse oximetry is the standard of care in some settings (e.g., human neonatology) and may serve as both a noninvasive alternative and a means of reducing iatrogenic blood loss.

Goals of Mechanical Ventilation

The goal of IPPV therapy is to maintain acceptable blood gas values with the lowest level of ventilator support possible. The optimal ventilator settings for each individual patient cannot be predicted and are determined through a careful process of trial and error. The patient should be fully evaluated after every change in ventilator settings, including blood gas analysis whenever possible. It is advisable to make only one change in ventilator settings at a time in order to accurately evaluate what effect each change alone has on gas exchange. Whenever feasible, it is advised to allow 15 minutes to pass before reevaluating $PaCO_2$. Whole-body stores of carbon dioxide are quite large and a quarter of an hour or more may be required for a new steady state to be reached. Common blood gas goals of mechanical ventilation include a PaO_2 of 80–120 mmHg (or SpO_2 >95%) and a $PaCO_2$ of 35–55 mmHg (35–40 mmHg in patients with intracranial hypertension).

In some settings, permissive hypercapnia may be employed. In this approach, $PaCO_2$ is allowed to climb higher to 60–70 mmHg as long as the resultant acidemia does not become too severe (pH <7.1). This approach is often taken when the clinician fears that maintaining carbon dioxide tensions within the normal target range will require injurious ventilator settings. Permissive hypoxemia approaches may also be employed at times. With this approach, the clinician focuses on maintaining central venous hemoglobin saturations ($S_{CV}O_2$) above 65–68%. Hypoxemia (PaO_2 <80 mmHg) is tolerated as long as tissue oxygen delivery appears adequate based on $S_{CV}O_2$ readings. This approach reflects a school of thought in which it is felt that clinicians should focus more on maintaining adequate global oxygen delivery rather than arterial blood gas values.

Adjustments to Improve PaO_2

If the PaO_2 is higher than the desired range (>120–150 mmHg), the first priority should be to decrease the FiO_2 until it is <60%. Once FiO_2 is less than 60%, emphasis shifts to reducing PEEP and peak airway pressure. If the PaO_2 is lower than desired (<80 mmHg), the first option is to increase the FiO_2. If there is an acute and severe drop in PaO_2, placing the animal on 100% oxygen is appropriate until the issue can be resolved and more definitive therapy can be provided. Ultimately, it is hoped that manipulation of ventilator settings will increase the oxygenating efficiency of the lung and allow lowering of the FiO_2 once again. All increases in oxygenation are obtained by raising FiO_2, mean airway pressure, or both. Mean airway pressure may be increased by increasing peak pressure, respiratory rate, PEEP, inspiratory time, or the format of flow delivery (e.g., block versus sine versus descending ramp flow patterns). Acute hypoxemic episodes are life-threatening complications that require immediate intervention.

Adjustments to Improve $PaCO_2$

The $PaCO_2$ is dependent on alveolar minute ventilation, which is the product of the effective tidal volume (excluding dead space volume) and the respiratory rate. If the $PaCO_2$ is higher than the desired range then the respiratory rate, tidal volume, or both should be increased. If the $PaCO_2$ is too low, the respiratory rate and/or tidal volume should be decreased. Excessive gas trapping may lead to carbon dioxide retention. Increasing expiratory time or reducing I:E ratio may increase alveolar ventilation in this circumstance. In patients with lower airway or parenchymal disease, inspiratory times that are too short may lead to minimal ventilation of alveoli with high time constants (product of resistance and compliance). In this instance, prolongation of the inspiratory time may enhance alveolar ventilation.

An abrupt increase in $PaCO_2$ in the ventilator patient may indicate a life-threatening complication. Similarly, an abrupt drop in end-tidal carbon dioxide may reflect a sudden increase in physiologic dead space (e.g., pulmonary thromboembolism) or an abrupt reduction in cardiac output.

Nursing Care for Ventilator Patients

Nursing care of the ventilator patient is one of the most labor-intensive and important aspects of ventilator patient management. Each ventilator patient usually requires a dedicated caregiver and two or more people are needed for many of the patient care procedures. Nursing care includes airway management, oral and eye care, catheter care, and recumbent patient care.

Humidification

Anesthetized patients are not able to cough or clear airway secretions effectively and this can contribute to development of ventilator-associated pneumonia (VAP) and tube occlusion. Airway management is essential in an effort to try to reduce these complications. Gas flow bypasses the nasal passages during mechanical ventilation and is therefore not humidified or filtered. This can lead to a loss of heat and moisture, which can damage the respiratory epithelium. Humidification is also critical in making secretions less viscous and easier to remove.

The breathing circuit should be humidified appropriately without excessive accumulation of liquid in the circuit. There are two basic options for airway humidification: active heated water humidifiers or passive heat moisture exchangers. The heated water humidifiers are very effective, are ideal in patients with substantial airway secretions, and help prevent hypothermia, which can be an issue in small patients. They are expensive and unless they are used in conjunction with heated wire circuits, they are associated with substantial "rain out" in the circuit. This refers to water accumulating in the limbs of the breathing circuit, which in large volumes can interfere with ventilator function. More concerning, it greatly increases the risk of VAP. Heat moisture exchangers (HME) are inexpensive devices that fit on the end of the endotracheal tube and passively take heat and moisture from the exhaled gas and return it to the inhaled gas. They have been found to be equally effective at humidifying the airways as the active humidifiers and may reduce the incidence of VAP by reducing moisture in the circuit. They can occlude and this has the potential to be a life-threatening event. For this reason, the authors advise that they be avoided in patients with excessive airway secretions.

Suctioning

Airway suctioning is another critical aspect of airway management. There are risks associated with this procedure, and proper technique must be followed. The inhaled oxygen concentration should be increased to 100% prior to and during suctioning. The suction catheters should be sterile, soft, and flexible with more than one distal opening and a proximal thumbhole to control the level of suction. Sterile gloves should be worn and sterile technique observed throughout the procedure. Closed suction systems are also available which are helpful in maintaining sterility and preventing issues with disconnection. Suction should be applied while withdrawing the catheter from the airway for no more than five seconds at a time. This procedure can be repeated two or three times as long as the patient's oxygenation remains adequate and the patient does not seem distressed. If suctioning is productive, it can be performed as frequently as every 2–4 hours.

The risks of suction include hypoxemia, patient discomfort, damage to the tracheal mucosa, collapse of small airways and alveoli, and contamination of the lower airways.

If the secretions are too dry to suction well or adequate humidification is not being provided, small aliquots of sterile saline (0.2 mL/kg) may be instilled into the airway prior to suctioning. This practice has been challenged because of the lack of evidence of beneficial effects coupled with the risk of introducing infection.

Tracheal Tube Management

Ventilator patients require an artificial airway, which is most commonly accomplished via endotracheal (ET) intubation and general anesthesia. It is important that ET tubes are sterile and ideally have high-volume/low-pressure cuffs. Tracheal mucosal blood flow can be occluded by pressures over 25–35 mmHg. Ideally, cuff pressure should be maintained between 20 and 25 mmHg and measured regularly with a pressure gauge system. Higher pressures impede mucosal blood flow and may lead to tracheal necrosis. Lower cuff pressures are associated with an increased risk of aspiration. Although frequently used, the pilot balloons do not correlate well with cuff pressure and should not be used as an indicator of appropriate inflation.

Tracheal injury can also be minimized by deflating the cuff and repositioning the ET tube slightly to change the pressure point and then reinflating the cuff every four hours. The mouth and pharynx should be flushed and suctioned prior to deflating the cuff. Endotracheal tubes should be securely tied with IV tubing or another nonporous material, which is less likely than gauze to become saturated with oral secretions and bacteria. The ties should be moved and secured in a different position every four hours to minimize lip trauma.

The endotracheal tube may need to be changed every 24–48 hours, depending on the amount and character of the secretions. It is important to preoxygenate with 100% oxygen prior to changing the tube and to be prepared for a difficult intubation. Tracheostomy tubes should ideally have an inner cannula, which should be cleaned every four hours. If there is no cannula, the tube should be suctioned regularly and changed every 24 hours. The tracheostomy tube should also have a cuff to protect the airway from the migration of oral secretions and to allow PEEP to be used.

Oral Care

Care of the oral cavity is of the utmost importance in these patients. Oral ulceration is a common problem and with poor oral care may occur in 90% or more of patients. Oral ulceration is a primary source of bacterial proliferation and has been reported as a major cause of VAP in human PPV patients. Prevention of oral ulceration with careful positioning of mouth gags, keeping the tongue and mucous membranes moist, and frequent repositioning of the tongue and ET tube are essential. The mouth and oropharynx should be carefully rinsed and suctioned every four hours. A chlorhexidine rinse of the mouth should be performed every eight hours.

Eye Care

Ventilator patients are under anesthesia and require eye care to prevent the development of corneal drying and ulceration. Artificial tear ointment should be applied at least every two hours. If an ulcer is suspected, fluorescein staining should be performed and the patient should be started on an antibiotic ophthalmic ointment. Temporary tarsorrhaphy may be necessary in some cases.

Recumbent Patient Care

Prolonged recumbency can lead to muscle atrophy, pressure sores, peripheral edema, and nerve damage. Patients should be repositioned at least every four hours and should have passive range of motion exercises performed. Ventilator patients should be kept on sufficient padding that is changed immediately if soiled. Frequent changes in body position also help prevent the pooling of secretions in one region of the airways and atelectasis of the dependent lung lobes. Turning may be associated with desaturation in animals with substantial pulmonary pathology; some patients will not tolerate lateral recumbency in which case they may require sternal recumbency with only their hips turned regularly. Oxygenation should be monitored carefully after changes in position. Sternal positioning is generally associated with the best lung function and may be beneficial in hypoxemic patients.

Catheter Care

All indwelling catheters should receive diligent catheter care as ventilator patients are at high risk for secondary infections and catheters provide possible entry sites for microorganisms. Urinary catheters require appropriate cleaning and care every eight hours. Intravascular catheters should be unwrapped and cleaned every 24–48 hours. Other indwelling catheters such as chest tubes should be cared for as appropriate.

Complications of Mechanical Ventilation

Hemodynamic Compromise

Positive pressure ventilation can lead to reductions in cardiac output in some patients. The associated increase in intrathoracic pressure can reduce systemic venous return which in the steady state is equal to cardiac output. Although animals with higher mean airway pressures are at greater risk for developing impaired cardiovascular performance, those with significant pulmonary disease tend to have such poorly compliant lungs that very little of the increased airway pressure is transferred to the cardiovascular system. Hemodynamic compromise secondary to PPV is more of a problem for animals with concurrent hypovolemia or other causes of reduced cardiac filling pressures. Continuous heart rate and blood pressure monitoring is advised for all ventilator patients. Fluid and drug therapy should be given as appropriate if hypovolemia or volume-unresponsive hypotension develops.

Ventilator-Associated Pneumonia

In human medicine, VAP occurs in 10–48% of patients and leads to an increase in mortality. Endotracheal intubation compromises the normal upper airway defenses and bacteria from the oral cavity have greater access to the lower airways. This problem can be compounded by intermittent aspiration of oral secretions or gastroesophageal contents.

Ventilator-associated pneumonia is typically diagnosed when new radiographic evidence of pulmonary infiltrates is detected 48 hours or longer after beginning IPPV. Decreases in oxygenation, a change in the character of airway secretions, new rhonchi or crackles, changes in white blood cell count, and new fevers are also common clinical signs associated with VAP. Prevention of VAP includes maintaining careful oral hygiene standards, including chlorhexidine rinses and the use of sterile technique when handling the circuit or endotracheal or tracheostomy tube. Minimizing circuit disconnections is advised. It is now recommended in some guidelines that ventilator circuits only be replaced every five days (earlier if gross contamination is evident). Many VAP infections have been found to come from the hands of caregivers, so wearing gloves and frequent hand washing are strongly recommended for all those dealing with ventilator patients. Wearing gloves should be considered mandatory when dealing with the oral cavity.

Ventilator-Induced Lung Injury

Ventilator-induced lung injury (VILI) describes pulmonary damage that occurs as a result of stresses and strains placed on lung tissues during PPV. In addition to increasing pulmonary pathology, in human medicine VILI has been found to increase the incidence of multiple organ dysfunction and patient mortality. It is believed that pulmonary inflammation resulting from VILI leads to the elaboration of inflammatory mediators, which amplify the systemic inflammatory response and subsequent organ damage. Indeed, some have suggested that the improved outcomes observed with lung-protective ventilator strategies are not due to improvements in pulmonary performance but rather to reductions in distant organ damage.

There are several mechanisms by which VILI can occur. The two major proposed mechanisms are overdistension of the lung by excessive tidal volumes and repetitive alveolar and peripheral airway collapse. Titration of ventilator settings should always be focused on providing the lowest possible level of ventilator support that still allows the targeted goals to be achieved. When the blood gas value goals cannot be achieved despite the use of high airway pressures and PEEP, a valid alternative approach is to change the blood gas goals for this particular patient. Permissive hypercapnia or permissive hypoxemia-based strategies may be employed in these instances as described previously.

Oxygen Toxicity

Pulmonary oxygen toxicity is discussed elsewhere in this text and the interested reader is referred to the appropriate sections (see also Chapter 39).

Pneumothorax

A pneumothorax can occur in the ventilator patient when alveolar or airway rupture leads to air escaping from the respiratory tract and accumulating in the pleural space. Although pneumothorax is a major concern when high airway pressures are present, studies in human patients have not been able to demonstrate a significant association between airway pressure and the occurrence of pneumothorax. Rather, the incidence of pneumothorax seems to vary with the nature of the lung pathology present. Overdistension of the lung is thought to be the major cause of pneumothorax. Thus, maintaining low tidal volumes, especially in patients with significant lung disease, is currently recommended.

Pneumothorax can be rapidly progressive in patients receiving IPPV and it is imperative that it be recognized early to avoid adverse outcomes. The acute onset of an elevated $PaCO_2$ and a decreased PaO_2 is a common early warning sign. Airway pressure would be expected to be increasing if a pneumothorax occurs in a patient being ventilated with volume control, while tidal volume would decrease if pressure control ventilation is employed. Auscultation may reveal decreased lung sounds, but this finding may be difficult to appreciate in the mechanically ventilated patient. Thoracic radiographs will provide a definitive diagnosis, but are often impractical. Thoracic ultrasound can also be helpful in identifying a pneumothorax if the operator is suitably trained and experienced.

Ultimately, a pneumothorax can be rapidly fatal in the ventilator patient. If there is any doubt that one is present, a diagnostic thoracocentesis should be performed immediately. If a pneumothorax is detected, unilateral or bilateral chest tubes are likely to be required.

Weaning from Mechanical Ventilation

Weaning (or liberation) from the ventilator is generally an ongoing process of gradual reduction in the ventilator settings. Often, as the patient improves, the mode of ventilation may be changed to one that requires the animal to perform an ever-increasing proportion of the work of breathing. SIMV and pressure support modes are often employed for this purpose. If animals have been anesthetized for prolonged periods of time, it may take some time (hours to days) for them to recover adequate ventilatory capacity. Some anesthetic protocols (e.g., barbiturates) employed for IPPV may have very prolonged withdrawal periods. It is important to consider reducing or changing the anesthetic drugs administered when patients begin to improve and weaning becomes a realistic possibility.

Prior to discontinuance of IPPV, the patient should first obtain certain physiologic goals, including the following:

- the original disease process is stable or improving
- a stable and appropriate level of respiratory drive has been demonstrated
- the patient no longer requires significant ventilator support to achieve adequate gas exchange
- adequate gas exchange efficiency has been restored (i.e., PaO_2:FiO_2 ratio consistently above 200; greater than 300 is preferred).

Reasons to suspect that a patient is not ready to be weaned include cardiovascular instability, requirement of high FiO_2 (greater than 60%), high peak inspired airway pressures (>25 cmH_2O), and/or high PEEP levels (>5 cmH_2O).

When a patient has improved sufficiently to consider removing them from the ventilator, it is advised to first determine if they can maintain spontaneous breathing

while still intubated. During such a "spontaneous breathing trial," the patient requires frequent, intensive monitoring. CPAP is often an ideal mode to use during a spontaneous breathing trial as the tidal volume, respiratory rate, and end-tidal carbon dioxide can all still be closely monitored. The development of hypoxemia, hypercapnia, hyperthermia, tachycardia, hypotension, and/or tachypnea are all indications that the trial has failed. Hypertension and the development of a rapid, shallow breathing pattern are common markers used in the authors' practice to identify weaning failure. Positive pressure ventilation should be reinstituted once weaning failure has been identified.

In human medicine, it is frequently recommended to perform spontaneous breathing trials daily once the patient qualifies according to the criteria listed above. When the patient can maintain adequate blood gases without anxiety or fatigue, anesthesia can be discontinued and extubation performed.

Nursing Care

No chapter on mechanical ventilation would be complete without acknowledging the absolute requirement for skilled, highly trained technicians. Patients receiving IPPV require continuous monitoring and care. In the authors' practice, the patient:nurse ratio for ventilator patients is always 1:1. Additional nursing staff needs to be available as required for turning, airway and oral hygiene, circuit changes, and many other nursing procedures. Large numbers of highly skilled veterinary technicians are required to provide mechanical ventilator support and may be the single largest determinant of outcomes in many cases.

Approach to the Patient with Shock

James W. Barr, DVM, DACVECC

Blue Pearl Veterinary Partners, Tampa, FL, USA

Shock is a clinical entity that veterinarians come into contact with regularly and is defined as inadequate delivery or usage of oxygen at the cellular and subcellular level. The result of cellular and tissue hypoxia is the central driver of the pathology of shock. Subsequently, resolving this hypoxia must be the clinician's primary focus to effectively treat a patient in shock. Cellular hypoxia results in the failure of energy-dependent mechanisms. When cells lack the necessary energy, dysfunction of the organelles occurs which ultimately results in the death of the cell. When cells die, organs become dysfunctional and compensatory mechanisms meant to be protective instead exacerbate injury and lead to the death of the organism.

Classically, shock has been defined as lack of organ perfusion resulting from the impaired ability of the cardiovascular system to deliver oxygen to the tissues of the body. This can result from many diseases, but the global effects are similar regardless of cause. There are clinical situations in which the delivery of oxygen to the tissues is normal or increased whilst the tissues are unable to use the oxygen presented to them that can lead to shock. This, fortunately, is not recognized often in veterinary medicine so this chapter will focus on the failure of oxygen delivery rather than failure of oxygen utilization.

It is often helpful to classify shock states according to their underlying etiology. This enables formation of a general treatment plan. In general, shock can be classified as hypovolemic, cardiogenic, distributive, or obstructive. Hypovolemic shock occurs when intravascular volume is reduced, resulting in decreased cardiac output. This can include whole-blood loss (hemorrhagic shock) or loss of plasma volume. Cardiogenic shock is a result of poor cardiac function that reduces cardiac output. Distributive shock develops from inappropriate vasodilation and decreased resistance to blood flow lowering blood pressure despite normal or even increased cardiac output. Obstructive shock is a result of physical impedance of diastolic filling of the heart and subsequent decrease in cardiac output. It is possible for patients to fit more than one category and limiting classification to a single category can lead the clinician astray. For instance, patients that are septic may have shock that has characteristics of hypovolemic, cardiogenic, and distributive etiologies.

In addition to categorizing etiology, shock can be characterized by severity as either compensated or decompensated. The sympathetic nervous system attempts to compensate for perceived decreases in intravascular volume and/or blood pressure, generating some of the clinical signs associated with shock. While the etiologies vary, there are commonalities in the clinical signs of shock. The recognition of shock centers on identifying the compensatory mechanisms the patient displays in response to decreased oxygen delivery. If a patient is in the compensated phase of shock, the sympathetic nervous system has been activated and the subsequent increases in chronotropy, inotropy, and systemic vascular resistance (SVR) will all converge to increase oxygen delivery. Patients in compensated shock will often have a normal blood pressure and mentation on presentation, but will likely have other clinical signs suggestive of shock such as tachycardia and tachypnea. If the initiating cause of shock has been removed then patients in compensated shock may not progress further.

If the underlying etiology of shock is severe or persistent, compensatory mechanisms will be unable to restore oxygen delivery and the patient will progress to decompensated shock. These animals will have profound clinical signs including depressed mentation, cold extremities, thready pulses, and hypotension. If left untreated, patients in decompensated shock will generally progress to an irreversible shock state in which compensatory mechanisms cease to function. This is termed *autoregulatory escape* and results from global vasodilation as oxygen-starved tissues finally demand blood flow. Clinical

signs of autoregulatory escape include venous pooling, bradycardia, and hypotension unresponsive to fluids or vasopressors and eventual death.

There are some specific treatments for each type of shock, but key similarities exist between all categories. The ultimate goal in the treatment of shock is to restore homeostasis by ensuring adequate oxygen delivery to the tissues. For the most part, these treatments do not address the underlying cause of shock; rather, they are nonspecific augmentations of oxygen delivery. The ideal treatment of shock would prevent death, allow the patient time to heal from the initiating insult, and limit ongoing injury as much as possible.

Pathophysiology of Shock and Effect on Organ Systems

Cellular Effects of Hypoxia

Shock occurs due to failure of oxygen delivery to the tissues which results in cellular and mitochondrial hypoxia. The resulting anaerobic metabolism leads to a significant decrease in production of adenosine triphosphate (ATP) with generation of lactate as a byproduct causing acidosis at both local and systemic levels.

The ATP deficiency that occurs during shock has numerous detrimental effects on the cell. ATP-dependent transport proteins cease to function and membrane gradients of electrolytes are lost. This results in cellular swelling, cellular death, and ultimately organ dysfunction if enough cellular death occurs. Cell death resulting from hypoxia is usually necrotic and not apoptotic, and can therefore induce an inflammatory response. This organ failure, if not corrected in time, results in the death of the organism.

Sensors of Cardiovascular Homeostasis

In order to maintain homeostasis, volume, pressure (baroreceptors), and chemical status (chemoreceptors) of the blood must be monitored at all times. This is the job of afferent sensors in various parts of the body capable of sensing a change in one or more of these variables. These sensors send signals primarily to the autonomic nervous system and if an abnormality is detected, cause physiologic responses intended to reestablish homeostasis.

Baroreceptors are mechanoreceptors located within the walls of vessels that are excited with stretch of the vessel wall (pressure) and are important for the beat-to-beat regulation of blood pressure. The information collected by baroreceptors is used to regulate the function of the heart, vascular smooth muscle tone, and endocrine responses aimed at managing intravascular volume.

Chemoreceptors are sensory organs responsible for monitoring the blood for appropriate concentrations of key chemicals, primarily oxygen and carbon dioxide. The carotid bodies, which are located near the carotid bifurcation, sense oxygen tension and the partial pressure of carbon dioxide (CO_2) in arterial blood. The aortic body, located in the aortic root, senses pressure in addition to oxygen and carbon dioxide tension and pH of arterial blood. These chemoreceptors send signals to the medulla oblongata to regulate breathing and blood pressure and are a potent mechanism by which respiratory rate and heart rate are controlled.

Compensatory Mechanisms

During shock, hypoxia is sensed centrally which prompts the firing of the respiratory center efferent nerves, increasing the respiratory rate in an effort to raise the amount of fresh gas presented to the alveoli to ensure oxygen extraction from the atmosphere is maximized.

Control of cardiac output is regulated by the autonomic nervous system. The sympathetic branch of the autonomic nervous system acts on the areas of the heart that have pacemaking capability (i.e., sinoatrial node, atria, atrioventricular node ventricles). Sympathetic stimulation results in an increase in sinoatrial node rate of firing, decrease in atrioventricular node delay, and increase in speed of the spread of an action potential through the specialized myocardial conduction system. Sympathetic stimulation directly increases the strength of contractility through the action of epinephrine stimulating beta-1-adrenergic receptors. Indirectly, sympathetic stimulation increases inotropy by increasing vascular tone through arteriolar vasoconstriction, increasing resistance to blood flow (systemic vascular resistance) and blood pressure. Preferential vasoconstriction shunts blood flow away from peripheral sites and to the brain and heart, increasing preload and causing a reflex increase in inotropy.

The parasympathetic branch of the autonomic nervous system regulates chronotropy (heart rate). Parasympathetic stimulation slows the heartbeat with little effect on the strength of ventricular contractions. In shock, parasympathetic tone is reduced to increase the heart rate. The net result of the increase in sympathetic tone and decrease in parasympathetic tone is increased inotropy and chronotropy. As a consequence, most patients in shock exhibit tachycardia. Patients with hyperkalemia or in the decompensatory phase of shock may demonstrate bradycardia, however.

Other less immediate compensatory mechanisms are also activated during shock. The renin-angiotensin-aldosterone system (RAAS) is activated and a nonosmotic release of antidiuretic hormone in response to hypotension occurs. Both of these responses attempt to

expand intravascular volume by inducing retention of water. This process takes hours to days to occur and is therefore of little use in the immediate compensatory attempt to return homeostasis.

Macro- and Microcirculation

Clinicians often consider shock to be a macrocirculatory phenomenon (i.e., an absolute decrease in blood flow and perfusion in large arteries). It must be remembered, however, that the purpose of the entire circulatory system is to deliver blood through the capillaries (microcirculation) to exchange oxygen and nutrients and remove waste products from individual tissue beds. While arteriolar constriction will increase global pressures and improve macrocirculatory parameters, it can reduce blood flow to the capillary or downstream side of the arterioles.

Under normal conditions, arteriolar tone changes from minute to minute depending on the metabolic demand of the particular tissue bed in which it is located. If a tissue demands more or less oxygen, concentrations of metabolites including adenosine, oxygen, and carbon dioxide will cause vasoconstriction or vasodilation. This is termed *chemical autoregulation* and is key in coupling blood flow to the metabolic needs of the tissue. In shock states, however, sympathetic stimulation causes vasoconstriction and overrides local tissue autoregulatory mechanisms. This often reduces perfusion of the tissues supplied by the constricted arterioles and, if oxygen consumption is higher than oxygen delivery, will result in the onset of anaerobic metabolism.

It is possible, if not common, for a patient in shock to have normal or even increased cardiac output and blood flow to the level of the arterioles yet have poor flow through the capillaries. This alteration in microcirculation is especially significant in septic shock and ischemia/reperfusion injury.

Diagnosis

A key feature of shock is that all organ systems are affected due to a global decrease in oxygen delivery, differentiating shock from local perfusion derangements. Due to the systemic nature of shock, the compensatory mechanisms in place are meant to preferentially perfuse the organ systems most important for immediate survival. This means that the brain and heart are perfused at the expense of the abdominal viscera such as the kidneys, gastrointestinal (GI) tract, and liver. Therefore, the clinical signs of shock represent the compensatory changes that occur in response to, rather than directly from, the cause of shock, meaning the underlying etiology of shock may not be evident on initial physical exam since similar clinical signs are present in all types of shock.

Tachycardia is one of the most consistent clinical signs of shock and although it is a frequent finding, the etiology is often multifactorial. The origin of tachycardia typically belongs in one of three categories: related to pain or anxiety, related to an appropriate physiologic compensatory mechanism, or due to primary cardiac disease. As usual, cats provide a notable exception to this generalization and frequently present bradycardic, as do dogs in the decompensatory or terminal stage of shock. In general, bradycardia in the context of shock should be considered a negative clinical sign and if recognized, should elicit a rapid and diligent search for the underlying reason for shock.

Pale mucous membranes can represent either anemia or vasoconstriction and mucous membrane evaluation provides a very crude assessment of hemoglobin concentration and microcirculation. While it is possible that a patient in shock is anemic, more commonly mucous membrane pallor is due to vasoconstriction. Capillary refill time (CRT) reflects the amount of time it takes for blood to fill the capillaries after they have been forcibly evacuated and provides an estimate of the efficiency of microcirculation. Normal CRT ranges from one to two seconds and prolongation of the CRT would reflect microcirculatory disturbance. Patients with pallor typically have a slow or difficult to evaluate CRT due to anemia preventing appreciable blanching of the mucous membranes. Occasionally, patients will have bright red mucous membranes and faster than normal CRT. This finding suggests the patient has vasodilation in conjunction with normal or high cardiac output and this occurs most frequently in septic shock or in shock associated with heat stroke. It does not imply that these patients have better than normal perfusion. Similarly, patients can have dark or dusky mucous membranes and a prolonged CRT indicating the presence of vasodilation and decreased cardiac output, as is seen in cardiogenic shock. Patients with these findings can have significant perfusion deficiencies and the clinician should seek to treat these patients aggressively.

Weak pulses are inconsistently present in shock. If the animal is in the compensated stage of shock, there is likely sufficient blood pressure to generate a detectable pulse. Some clinicians use the presence of a pulse in different areas of the vascular tree to give an estimate of blood pressure and argue that detection of pulses in the dorsal pedal artery and in the femoral artery represent systolic pressures of 80 mmHg and 60 mmHg respectively. There is limited evidence to support this finding in veterinary medicine and quantitative measurement of

blood pressure should always be used when available. A systolic blood pressure of less than 90 mmHg or a mean arterial pressure (MAP) of less than 60 mmHg should be aggressively pursued.

Numerous factors can confound the interpretation of pulses in clinical cases. Since the pulse that is palpated is the difference between the systolic and diastolic pressures, a small difference will cause the pulse to be weak or thready and a large difference will cause the pulse to be strong or bounding. None of these descriptions reflect the actual pressure within the vessel, and all of these pulse qualities can represent a patient in shock. An obstruction to blood flow can also inhibit the detection of pulses, as is the case in aortic thromboembolism by causing an absolute reduction in blood flow through the artery.

Patients in shock also frequently demonstrate tachypnea as the body attempts to maximize oxygen delivery to the alveoli and subsequently to the arterial blood. Respiratory rates in excess of 40 breaths per minute for a dog and 60 breaths per minute for a cat are consistent with shock. In this instance, tachypnea must be differentiated from true dyspnea or respiratory distress, the presence of which may indicate an underlying etiology but does not lead to a diagnosis of shock. Tachypnea is also a common response to pain, which may confound the use of respiratory rates for evaluation of possible shock. Often, evaluating the respiratory rate after administration of analgesia provides a better representation of the patient's ventilatory status.

Altered mentation is seen in patients in decompensated shock as blood flow and oxygen delivery to the brain are reduced. Since the brain has high demands for energy and little reserve for energy production, cerebral function and consciousness are affected early after decompensation begins. The typical patient in compensated shock will appear bright and alert while the patient in early decompensated shock will be mildly to moderately obtunded. As shock progresses so will mentation change and patients that find themselves in late decompensated shock will appear severely obtunded to stuporous. Pain can also affect a patient's response to its environment and care should be taken to ensure that changes in behavior are in fact due to altered mentation rather than pain. Evaluation of mentation is especially relevant in cases with head trauma when the level of consciousness can be used as a prognostic sign or metric of the severity of injury. In these cases, shock and pain should be addressed before those assessments are made or at the very least, they should be interpreted with these facts in mind.

The GI tract is affected in almost all cases of shock as evidenced by the ubiquity of the term "shock gut." Recall that the GI tract is one of the organ systems that is sacrificed in order to divert the scarce blood flow toward the heart and brain. This decrease in splanchnic blood flow has a significant impact on the mucosal integrity of the GI tract, leading to the vomiting and hemorrhagic diarrhea often seen in shock. As with most of the exam findings associated with shock, GI signs are usually mild to absent in animals in the compensatory stages of shock and can be moderate to severe in animals that have progressed to the later stages of decompensated shock.

The use of biomarkers for detection of shock and comorbidities has become widely accepted as standard of care in human medicine. These measurements (i.e., electrolytes, blood glucose, creatinine) can provide important information regarding the underlying cause of shock in addition to aiding in its recognition and diagnosis. Biochemical abnormalities can be prognostic or diagnostic and can direct the clinician to appropriate therapeutic interventions. All patients in shock should have a blood gas profile with lactate as a part of the initial and ongoing evaluation of the patient whenever possible.

Lactate is an important marker of tissue perfusion and has been the most widely used biomarker of shock in veterinary patients. Lactate is easily measured in clinical practice with a range of options from bench-top blood gas analyzers to handheld monitors that have been validated in veterinary patients. Blood lactate concentrations greater than 2.5 mmol/L are indicative of significant anaerobic metabolism and, in a patient with other signs consistent with shock, should be considered to be diagnostic for failure of oxygen delivery.

The availability and use of ultrasound in veterinary medicine has become very common. While not particularly useful for the diagnosis of shock itself, ultrasound has become especially useful because it allows identification of the etiology faster. The use of focused assessment with sonography for trauma (FAST) protocols for the abdomen (AFAST) and thorax (TFAST) have been very well described in veterinary medicine. These techniques can be performed with minimal training and are quite effective at the identification of fluid in cavities as well as the presence of a poorly contracting heart or pneumothorax. If available, and as long as positioning and restraint will not be detrimental to the patient, ultrasound should be used to evaluate patients in shock to attempt to determine the underlying cause. A description of the FAST procedures is provided in Chapter 46.

Classification of Shock

The following provides a guide to the classification of shock. The categorization of shock can be beneficial for formulating a diagnostic and therapeutic approach to a patient. While clinically useful, it should be reiterated that a patient in shock might often have disease processes

occurring that overlap categories, and it is possible that categorization may change as the underlying pathology progresses. Therefore, a singular approach to each specific shock category is not possible.

Hypovolemic Shock

Hypovolemic shock occurs when there is an absolute or perceived decrease in the intravascular volume. This is the classic example of shock and is arguably the most common cause of shock in veterinary patients. Hypovolemic shock can result from a loss of whole blood, loss of sodium-rich fluid (plasma) or in severe cases lack of adequate water intake. Chronic endocrine diseases can occasionally present as a unique subset of hypovolemic shock. As an example, a patient in a hypoadrenicortical (Addisonian) crisis may be hypovolemic but may not exhibit the typical clinical signs of shock.

Hemorrhagic shock is the classic example of hypovolemic shock. A distinguishing characteristic that sets hemorrhagic shock apart from other causes of hypovolemic shock is the absolute loss of whole blood, which can occur as overt blood loss from the laceration of a vessel or covert blood loss resulting from cavitary bleeding. A complicating component of hemorrhagic shock is the necessary loss of red blood cell mass concurrent with the loss of intravascular fluid. Patients suffering from hemorrhagic shock may only have shock completely ameliorated by the administration of both IV fluids and hemoglobin-containing products.

Cardiogenic Shock

Cardiogenic shock results from an inability of the heart to move blood into the pulmonary or systemic circulation. This is classically imagined to be a result of "forward failure" of the heart due to the heart being unable to maintain forward blood flow. As in the case of congestive heart failure, this may occur in the face of normal or increased preload. Due to the unique etiology and treatment approach to cardiogenic shock, a closer examination will be made in Chapter 42.

Distributive Shock

Distributive shock describes shock that occurs primarily due to loss of systemic vascular resistance (i.e., blood pressure). This is most often a result of inappropriate vasodilation resulting in decreased venous flow and thus decreased preload. Recall that in the absence of significant heart disease, preload is positively correlated with cardiac output. Besides the decrease in cardiac output that occurs in distributive shock, regional perfusion is disrupted with loss of blood pressure.

The classic example of distributive or vasodilatory shock is anaphylaxis whereby massive vasodilation lowers blood pressure to such a degree that capillary blood flow decreases. This reduction in capillary blood flow limits oxygen delivery to the tissues and results in tissue oxygen debt. In addition to vasodilation, an increase in the permeability of the capillaries results in a higher than normal net movement of water from the intravascular space to the interstitial space, further decreasing intravascular volume and worsening hypotension.

Neurogenic shock is an uncommon manifestation of CNS injury specifically in the brain, cervical or thoracic spinal cord and results from a decrease in sympathetic tone leading to significant loss of systemic vascular resistance. The presumed mechanism behind this rapid vasodilation is disruption of the autonomic paths in the spinal cord and is different from "spinal shock," which refers to the temporary loss of function of the spinal cord after spinal cord trauma.

Obstructive Shock

Obstructive shock results from impairment of blood return to the heart. It is typically associated with intraabdominal disease that sequesters blood within the abdomen and decreases preload (e.g., gastric dilation and volvulus [GDV]). Some argue that pericardial effusion with cardiac tamponade is a form of obstructive shock. Similar to GDV, during pericardial tamponade the intrapericardial pressure is higher than the venous pressure and results in decreased preload of the right atrium.

Septic Shock

Septic shock can be considered a form of distributive shock but has enough unique characteristics that it is often classified as a separate entity. As a result of infection and systemic inflammation, fluid is lost to the interstitium, water intake is decreased, systemic vascular resistance decreases, and myocardial performance is impaired. The therapy for septic shock must address each of these in turn as well as the underlying cause of sepsis. Septic shock will be investigated in detail in Chapter 43.

Oxygen Delivery

At its most basic, there are two primary components of oxygen delivery: cardiac output (CO) and arterial oxygen content (CaO_2). Therefore, a useful way to approach the treatment of shock is to separate the components of the cardiovascular system into the individual determinants

of oxygen delivery (DO_2). In fact, only seven parameters can be manipulated to augment oxygen delivery: those associated with cardiac output (heart rate, preload [end-diastolic volume], afterload [MAP], systemic vascular resistance, and ejection fraction), and those associated with arterial oxygen content (hemoglobin concentration and partial pressure of inspired oxygen).

Cardiac Output

Cardiac output is determined by the amount of the blood ejected from the heart with each beat (stroke volume) and the rate at which the heart is beating (heart rate). Stroke volume, in turn, is determined by the amount of blood that returns to the heart (preload), the force that must be overcome to eject blood out of the heart (afterload/systemic vascular resistance), and the physical force that the heart must generate to move blood (contractility or inotropy). Cardiac output is arguably the easiest component of DO_2 to manipulate. Accordingly, increasing preload is the most common initial treatment of shock and is accomplished with the administration of IV fluids and vasoactive medications to augment preload by increasing venous pressure and consequently right ventricular volume.

The heart has the ability to increase or decrease the force of contraction (inotropy) exerted during systole. Intrinsically, the heart pumps more powerfully when there is a larger amount of blood present in the ventricle at the end of diastole (Starling law of the heart). Sympathetic stimulation can also increase the force of contraction and is in fact the primary mechanism by which inotropy can be altered by the clinician through administration of beta-1-adrenergic agonists.

The impediment of flow that must be overcome to eject blood out of the heart is the systemic vascular resistance (afterload). This is the force that the cardiac wall is placed under when it contracts in systole and is usually considered as the mean arterial blood pressure (MAP). Although convenient, this is not always accurate. As an example, MAP and afterload are uncoupled when an anatomic obstruction to flow exists, such as subaortic stenosis. Manipulation of afterload (SVR and MAP) is possible through the administration of agents acting on specific vasoactive receptors (alpha, dopamine, and vasopressin). Most frequently, the goal is to increase both SVR and MAP. Afterload reduction is infrequently a concern in veterinary patients although it is common in humans due to that species' propensity for developing primary hypertension.

Heart rate changes are important for the second-to-second adjustment of cardiac output. During shock, increases in heart rate typically parallel increases in inotropy. Clinically, heart rate measurement is a useful tool for diagnosing a patient in shock. Heart rate can be manipulated pharmacologically with beta-2-adrenergic agonists and anticholinergic drugs. However, the ability of changes in heat rate to improve cardiac output is limited. Diastolic filling time is essential for preload and tachycardia shortens the amount of time spent in diastole during the cardiac cycle. At very high heart rates, this shortened diastolic time can significantly decrease preload and cardiac output. Patients in the decompensatory stage of shock can become absolutely or relatively bradycardic as the heart begins to fail due to poor oxygen delivery to the heart itself.

Arterial Oxygen Content

Oxygen content of the blood is the sum of the oxygen dissolved in the blood (PaO_2) and the amount of oxygen that is bound to hemoglobin. The amount of oxygen bound to hemoglobin is a much more important contributor to total blood oxygen content while PaO_2 is a more important indicator of the lungs' ability to oxygenate the blood.

Interventions directed at improving arterial oxygen content include provision of supplemental oxygen (increasing PaO_2) and transfusion of hemoglobin in the form of red blood cells or hemoglobin-based oxygen carriers (increasing oxygen-carrying capacity). The importance of hemoglobin concentration in oxygen delivery cannot be overstated. Hemoglobin makes the transport of oxygen in the blood and subsequent offloading at the tissue bed much more efficient. Consequently, raising hemoglobin is the best way to improve arterial oxygen content if lung function and ventilation are normal. Supplementation of oxygen to those patients who are normoxic (have a normal PaO_2) will do little to increase the amount of oxygen presented to the tissues (assuming the supplementation is at normal atmospheric pressure) when compared to supplementation of hemoglobin. Consider a dog breathing room air; assuming a hemoglobin concentration of 6 g/dL (HCT 18%), PaO_2 of 90 mmHg, and arterial hemoglobin saturation (SaO_2) of 95%, the calculated CaO_2 would be 8.0 mL O_2/dL. By increasing the fraction of inspired oxygen to 40%, the resultant CaO_2 would increase to 8.55 mL O_2/dL for an 8% increase. Now assume raising the hemoglobin with no oxygen supplementation. By increasing the hemoglobin concentration to 9 g/dL (HCT 28%), a CaO_2 of 12 mL O_2/dL can be achieved for a 54% increase. In order to extract the most benefit from an increase in hemoglobin concentration, it must be maximally saturated with oxygen so oxygen supplementation is always warranted during shock to ensure the highest possible PaO_2 is achieved.

Treatment

If possible, the treatment of shock should be directed at the underlying cause and should be aggressive and comprehensive. Most patients in shock can be initially resuscitated in a similar or identical manner with a few notable exceptions. If the patient has an obvious cause of shock with tachycardia without significant heart disease present or suspected, then fluid therapy is almost always beneficial. In cases of hypovolemic, distributive, or obstructive shock, increasing intravascular volume often results in significant improvement. The exception to fluid administration for shock is cardiogenic etiology.

The type and dose of fluid administered for shock are among the most controversial topics in medicine. In most circumstances, isotonic crystalloids are as effective or better, as safe or safer, and less expensive than any of the other choices for the initial resuscitation of shock. There are subtle nuances, with different resuscitative fluid strategies for specific disease states, but in general replacement crystalloid fluids are suitable choices.

The traditional dose of fluids for patients in shock for dogs and cats respectively is 90 mL/kg and 60 mL/kg of crystalloid fluids. This represents approximately one blood volume that is intended to be administered over a short period of time. Many patients do not require an entire shock dose of fluids to be effectively resuscitated so the most utilized clinical approach is to divide the dose into four equal parts and administer the aliquots until endpoints of resuscitation are reached. Although effective at restoring circulating volume, the duration of effect of replacement crystalloids is short due to rapid redistribution of bolus fluids into the interstitial space. For this reason, it may be necessary to administer subsequent boluses to maintain the desired volume expansion. Unfortunately, overaggressive resuscitation can lead to interstitial edema formation and dilutional coagulopathy. Because of this risk, it is necessary to keep track of the total volume of replacement crystalloid administered to a patient and to consider alternative methods of resuscitation if initial crystalloid boluses do not result in lasting resolution of shock.

Alternatives to replacement crystalloid fluids include hypertonic saline, blood products (i.e., fresh frozen plasma, fresh whole blood or packed red blood cells), synthetic colloid solutions (i.e., hydroxyethyl starches), albumin-based colloid solutions (human serum albumin or lyophilized canine albumin), hemoglobin-based oxygen carriers (HBOC), or combination of any of the above. Of these, hypertonic saline and synthetic colloids are used the most frequently.

Hypertonic saline has the advantage of being relatively inexpensive and having a long shelf-life. Doses of 4–6 mL/kg of 7.5% NaCl can be used in nondehydrated traumatized or hemorrhaging patients and may be particularly useful for resuscitation of animals with head trauma. Hypertonic saline recruits fluid from the intracellular space to rapidly increase the intravascular volume, providing much needed volume expansion while minimizing the risk of overresuscitation and edema formation. Boluses of hypertonic saline can be administered over a shorter period of time than boluses of isotonic crystalloid fluids due to the smaller volume required. Unfortunately, hypertonic saline behaves in a similar manner to replacement crystalloids, with rapid redistribution of fluid into the interstitial space, and because of the high osmolarity of hypertonic saline and the absolute solute load, repeated dosing is not recommended due to the risk of hypernatremia. Relative or absolute contraindications to hypertonic saline include preexisting dehydration, hypernatremia or hyperosmolar conditions (ex. hyperosmolar-hyperglycemic diabetes mellitus). To maintain the volume expansion derived from administration of hypertonic saline, it is often combined with a synthetic colloid such as hetastarch (10–20 mL/kg) and administered together.

Colloids have been used successfully in the resuscitation of patients in shock for years. However, controlled studies have not consistently shown that colloidal solutions are more effective at achieving resuscitation than isotonic crystalloids. Theoretically, the use of a colloid for resuscitation in patients with low serum protein or those with edematous diseases may be preferred. Incremental doses of 5 mL/kg of hydroxyethyl starch is a reasonable starting point, with a total shock dose equaling 10 mL/kg and 20 mL/kg for cats and dogs respectively. Clinically, the primary utility of synthetic colloids for resuscitation is to maintain the duration of volume expansion achieved with isotonic crystalloids. Synthetic colloids are almost never used alone for resuscitation of a patient. Rather, they are co-administered with either isotonic or hypertonic crystalloids. An effective resuscitation plan would include alternating administration of isotonic crystalloid and colloid solutions (1/4 volume aliquots of each) until resuscitation has been achieved. Significant debate exists regarding the impact of synthetic colloids on coagulation and platelet function. There is little debate that synthetic colloids can impair platelet function *in vitro*, but the clinical implications are less clear. Perhaps of more clinical import is the potential for synthetic colloids to induce dilutional coagulopathy. For these reasons, synthetic colloids should be used thoughtfully in patients with thrombocytopenia/thrombocytopathia or documented coagulopathy. Ultimately, the clinician should attempt resuscitation with the method they are most comfortable with rather than attempting to use a resuscitation strategy that is unfamiliar.

The use of blood products in shock resuscitation is not routine since most patients have adequate oxygen-carrying capacity. If a patient has been administered an adequate volume of fluid for resuscitation, has persistent clinical signs of shock and requires oxygen-carrying capacity, then the administration of blood is indicated. This can be in the form of packed red blood cells, whole blood or hemoglobin-based oxygen carriers. No agreed-upon transfusion trigger exists and the decision to administer blood depends on the chronicity of the anemia and the patient's clinical signs. For patients with an acute drop of 30–50% in packed cell volume (PCV), the administration of blood should be strongly considered. In these cases, a reasonable goal is to raise the PCV by 15–20% with a minimum PCV target of 20%. Typical doses of 10 mL/kg of packed red blood cells or 20 mL/kg of whole blood should be effective.

The actual rate of administration of blood products for resuscitation will depend on the patient's condition. Under ideal circumstances, blood products are administered slowly with careful monitoring for transfusion reactions. Patients in shock, however, do not often have the benefit of time and bolus administration may be needed. In this case, care has to be taken as techniques that apply pressure to the red blood cells or increase shear stress, such as administration with an infusion bag through a small-bore catheter, can result in significant lysis of transfused cells. When bolusing blood products, it is best to allow blood to flow by gravity as quickly as possible. Administration of blood should be through a dedicated IV catheter, meaning that other resuscitative fluids should be held during transfusion unless provided through a different catheter or lumen (in the case of multilumen catheters). It is safe to administer normal saline with blood products and co-administration may improve the fluid dynamics of the blood product and speed the delivery rate.

The treatment of pain may be needed in many patients with shock, and is mandatory if they have been traumatized. In unstable painful patients, pain control should be achieved with short-acting pure mu opioid agonists (ex. fentanyl, hydromorphone, oxymorphone or morphine) administered via the intravenous or intramuscular route. The dose should be adequate to effectively treat pain but not depress respiration. This will help the clinician evaluate the patient, as it will mitigate the contribution of pain to tachycardia. With pain controlled, the presence of tachycardia likely indicates shock or hypoxia in the traumatized patient. Typical doses of common analgesics are provided in Table 41.1.

Vasopressors and positive inotropes are rarely used during the initial resuscitation of shock but can be invaluable for the treatment or management of vasodilatory or septic shock that is refractory to resuscitation.

Table 41.1 Dosages of commonly used opioid analgesics in the patient with shock

Drug	Dosage	Frequency
Fentanyl (bolus)	2–5 µg/kg	PRN, q15 min
Fentanyl (CRI)	5–20 µg/kg/h	CRI
Hydromorphone/ oxymorphone	0.05–0.2 mg/kg	q4-6h
Morphine	0.5–2 mg/kg	q4h
Buprenorphine	0.01–0.02 mg/kg	q6-12h
Methadone	0.2–0.5 mg/kg	q4-6h

CRI, constant rate infusion; PRN, as needed (*pro re nata*).

Administration of vasopressors or positive inotropes should not be performed prior to adequate volume expansion, with the possible exception of treating cardiogenic shock due to systolic failure with a positive inotrope. Clinically, the most frequently used vasopressor during shock is epinephrine administered for the acute treatment of anaphylaxis. A more detailed discussion of vasopressors can be found in Chapter 43.

Some patients in shock will not be stabilized until the underlying disease process has been corrected, as is often the case with obstructive shock. Patients with significant amounts of pericardial effusion causing cardiac tamponade improve dramatically when even a small amount of fluid is removed, as do patients with GDV following decompression of the abdomen. Patients in obstructive shock often do not have an absolute volume deficiency, but increasing preload can transiently improve the diastolic filling of the heart while preparations for definitive treatment are under way.

Reevaluation and Endpoints of Resuscitation

The importance of reevaluating the patient during and after resuscitation cannot be overstated. When evaluating the efficacy of treatment, the clinician expects physiologic signs of shock to resolve. If resolution is not achieved, further resuscitation is needed or reconsideration of the diagnosis is necessary. As with all medical treatments, it is necessary to have predetermined endpoints in mind to decide when treatment is no longer needed. The optimal endpoints of resuscitation have been debated for a number of years and although recommendations and general agreement exist, no consensus has been reached. The ultimate endpoints of resuscitation should tell the clinician when the patient is out of shock, meaning adequate oxygen delivery to all tissues has been reestablished. Possible endpoints

Box 41.1 Endpoints of resuscitation. Each of these values must be interpreted within the clinical context as improvement in an isolated variable may not indicate complete resolution of shock

- Normalization of heart rate
- Normalization of respiratory rate
- Improvement of pulse quality
- Normalization of capillary refill time
- Blood pressure
- Improvement of blood lactate concentration
- $ScvO_2$

include physical exam findings or biochemical variables (Box 41.1). These should be evaluated before, during, and after therapy has been instituted.

Normalization of heart rate, respiratory rate, and CRT as well as improvement of pulse quality have been traditionally used by clinicians to judge if resuscitation is complete. These endpoints are intuitive because they coincide with the findings that are initially used to determine if a patient is in shock. It follows that when those findings normalize, resolution of shock has been achieved. The reality is more complex as physical exam endpoints can normalize while inadequate oxygen delivery is ongoing at the cellular and subcellular level. Therefore, the use of endpoints that include evaluation of cellular oxygen usage such as lactate, base excess, and hemoglobin saturation should be incorporated into all shock treatment plans. In practice, resuscitation should continue until there is resolution of the physical exam endpoints, at which time analysis of the biochemical endpoints should be performed. If those endpoints have been reached then resuscitation is complete; if biochemical derangements persist then resuscitation efforts should continue until resolution is achieved.

Blood Pressure

Blood pressure can be measured in a variety of ways but is most commonly performed using a Doppler with sphygmomanometer or a digital monitor with oscilllometric capability. Unfortunately, blood pressure is an unreliable predictor of perfusion as it is influenced by the compensatory mechanisms previously discussed. In fact, a patient can have significant microcirculatory hypoperfusion while maintaining normal blood pressure. However, hypotension does occur as shock progresses and when present should be aggressively treated with a target of returning the systolic blood pressure to at least 90 mmHg and MAP to 60 mmHg.

Lactate

Because lactate is a byproduct of anaerobic metabolism, has a relatively short half-life and can be measured readily, it is a very useful biomarker for shock. Lactate measurement is an inexpensive adjunct to traditional physical exam endpoints and its use has become standard of care in human medicine.

In most cases, elevations in lactate occur secondary to anaerobic metabolism, so by measuring the concentration of lactate in a blood sample, the clinician can form an idea of whether or not anaerobic metabolism is occurring. Occasionally, neoplastic or endocrine diseases can cause the production of lactate to be higher than the body's ability to metabolize it, leading to elevation of blood lactate concentration. Similarly, significant liver disease or liver failure can reduce lactate clearance and lead to hyperlactatemia. When lactate is elevated due to causes other than anaerobic metabolism, it is termed type B hyperlactatemia. Occasionally, strenuous exercise can cause hyperlactatemia. This appears clinically in patients with prolonged seizures or patients that require aggressive restraint during examination or blood collection. These possibilities should be considered when a patient has a high blood lactate concentration but no other clinical signs that would indicate the presence of shock. This is an uncommon occurrence in veterinary medicine and an animal presented in shock with blood lactate elevation should be assumed to have inadequate oxygen delivery until proven otherwise.

The finding of elevated lactate alone does not necessarily mean that global oxygen delivery is inadequate as local perfusion abnormalities can have significant impact on lactate concentration. Although absolute lactate concentration can be correlated with patient outcomes, lactate clearance following resuscitative efforts is probably a better prognostic indicator and patients with persistently elevated lactate concentrations despite aggressive treatment should be considered to have a worse prognosis. As with all resuscitation endpoints, the results of lactate measurement must be interpreted in light of the patient's clinical condition.

Mixed Venous or Central Venous Oxygen Saturation

Measurement of venous hemoglobin saturation can provide meaningful insight into the consumption of oxygen within the body. The hemoglobin saturation of venous blood is expected to be lower than that of arterial blood. If this difference is greater than expected, it may indicate that oxygen-starved tissues are removing more oxygen than usual from each hemoglobin molecule. This is best explained by the oxygen extraction ratio (OER), which is simply the mathematical ratio of the amount of oxygen

that is delivered to the capillaries via the arteries and the amount found in the venous blood draining the capillaries. This ratio indicates the proportion of oxygen that the mitochondria are using versus the amount supplied. If venous blood has high hemoglobin saturation, then the mitochondria did not consume as much oxygen as expected. This may indicate low metabolic rate or mitochondrial dysfunction, as seen in sepsis. However, if venous oxygen saturation is low, it suggests that the mitochondria are extracting more oxygen than expected and that an oxygen debt may be present.

Importantly, venous hemoglobin saturation only reflects the oxygen consumption that is occurring in the tissue bed that the blood is draining. As an example, if you were to draw blood from a cephalic vein, you will only be gaining knowledge about oxygen usage in the distal limb. Blood drawn from the jugular vein will provide information about oxygen consumption in the head, including the brain. Under most circumstances, samples drawn from the jugular vein are approximately reflective of oxygen consumption throughout the body, but a better representation of the global oxygen usage would be venous blood that has been mixed from all parts of the body. This ideal sample is retrieved from the pulmonary artery and is termed the mixed venous oxygen saturation (SvO_2). The pulmonary artery is not routinely catheterized in people and even less frequently in veterinary patients, but there is a strong correlation between mixed venous samples and central venous samples ($ScvO_2$) obtained from the cranial vena cava or right atrium. Obtaining an $ScvO_2$ sample is much more feasible in clinical practice and can prove very useful for guiding resuscitation efforts.

The most significant advantage of venous hemoglobin saturation monitoring is that increases in OER (i.e., lower than expected venous hemoglobin saturation) may be evident before the onset of anaerobic metabolism, giving the clinician an essential head start in the treatment of shock. An $ScvO_2$ of <70% indicates that a patient is experiencing tissue oxygen debt. When performing resuscitation, therefore, the goal is to maintain an $ScvO_2$ of >70%. If this is not possible with the administration of vascular expansion and vasopressor support alone then treatment with red blood cells may be indicated. Venous hemoglobin saturation may be low for several reasons, including slow capillary transit time (poor microperfusion), increased tissue demand for oxygen, low arterial hemoglobin saturation or anemia. Once again, venous hemoglobin saturation should be interpreted with the patient's overall condition in mind.

Conclusion

A simplified and systematic approach to the patient in shock is necessary for successful management. It is easy to become overwhelmed with the totality of clinical implications and lose sight of the ultimate goal. Approaching shock from the standpoint of oxygen delivery makes the interventions that need to be considered finite and easier to implement. Frequent reevaluation of the patient through the endpoints of resuscitation will allow determination of the efficacy of therapy.

Pathophysiology

Cardiogenic shock occurs when oxygen delivery is insufficient to maintain normal aerobic cellular metabolism as a result of cardiac dysfunction in the presence of adequate intravascular volume. In other words, cardiogenic shock occurs when cardiac output is decreased despite adequate blood volume. Importantly, cardiogenic shock does not imply congestive heart failure (CHF) although CHF can be present in cardiogenic shock patients.

Cardiogenic shock occurs in two settings. Forward failure results from the heart's inability to adequately pump blood forward from either the left or right ventricle into either the aorta or main pulmonary artery respectively. Backward failure, on the other hand, results from inadequate ventricular filling of the heart during diastole with a subsequent reduction in stroke volume and cardiac output. Common conditions resulting in forward failure of the heart include rupture of one or more chordae tendinae or acute-onset severe pulmonary hypertension. Causes of backward failure include paroxysmal ventricular tachycardia or pericardial tamponade.

Cardiogenic shock is somewhat different from other forms of shock due to the greater potential impact on the myocardium. When cardiac dysfunction underlies the development of shock, coronary perfusion is often impaired as a result of increased right-sided pressures or decreased aortic root pressure. Because of the potential for decreased coronary perfusion and subsequent ischemic myocardial injury, it is imperative that cardiogenic shock is recognized early and treated aggressively.

When ventricular function or efficiency is acutely diminished, cardiac output declines rapidly. If ventricular dysfunction is a result of systolic myocardial failure (as seen with dilated cardiomyopathy), the force of ventricular contractions (inotropy) is not sufficient to eject a normal volume of blood from the ventricles. Since stroke volume is one of two determinants of cardiac output (cardiac output = heart rate × stroke volume), a decrease in inotropy will reduce cardiac output in a direct fashion unless compensation occurs by increasing heart rate. Perceived ventricular dysfunction also occurs when there is a sudden change in valvular integrity resulting in an acute increase in regurgitant fraction and decrease in cardiac output. If this occurs, a large portion of the ventricular load is directed backwards through the atrioventricular valve rather than the semilunar valves of the aorta or main pulmonary artery. Although this occurrence is uncommon in the general population, animals that have existing degenerative valvular disease are at an increased risk of suffering rupture of one or more of the chordae tendinae.

Bradycardia is an uncommon cause of forward failure and cardiogenic shock but can occur with third-degree atrioventricular block. This condition results in diminished cardiac output as a result of drastic reduction in heart rate (the other main determinant of cardiac output). Regardless of the inciting cause of forward failure, the end-result is an increase in the end-diastolic ventricular volume with subsequent increases in atrial volumes and pressures. Cardiogenic shock from forward failure states is often exacerbated by development of pulmonary edema and hypoxemia.

Backward failure results from diseases that cause decreased ventricular volume at end-diastole. Since the volume of blood pumped out of the heart is dependent on the volume of blood present at the beginning of the cardiac cycle, it follows that any decrease in this volume will result in diminished cardiac output. The Frank Starling law of the heart states that the greater the volume of the ventricle at end-diastole, the more forceful the corresponding contraction has to be to meet the demand for greater output, effectively tying preload (end-diastolic volume) to cardiac output.

While it is convenient to consider the heart as consisting of two separate pumps (the left and right), it must be remembered that the two operate in a dependent manner. The right heart is obligated to pump the same volume of blood that is returned to it from the venous circulation in the same fashion that the left heart is obligated to pump the volume of blood that is returned from the pulmonary circulation. This interdependence means that dysfunction of either the left or right heart results in a decrease in total cardiac output. Therefore, sudden failure of one side of the heart will result in dysfunction of the entire heart and can lead to cardiogenic shock.

Once global oxygen delivery is insufficient to maintain aerobic metabolism, the pathophysiology of shock at the cellular level is identical regardless of the underlying etiology.

Epidemiology

Many of the conditions that cause cardiogenic shock in dogs are chronic, progressive diseases that have an acute worsening. Myxomatous mitral valve disease can predispose dogs to rupturing one or more chordae tendinae, leading to cardiogenic shock. Unfortunately, the severity of valvular lesions is not predictive of risk of chordae tendinae rupture in dogs so little can be done to predict which patients will suffer from this condition. When rupture of a first-order chorda occurs, patients will often exhibit acute, severe clinical signs. Rupture of second or third-order chordae may result in minimal to no clinical signs and may only be detected during routine echocardiography or necropsy.

Pericardial effusion is arguably the most common cause of cardiogenic shock in dogs and can occur more or less acutely. Chronic pericardial effusion is less likely to result in cardiogenic shock while acute pericardial effusion almost uniformly causes tamponade and subsequent cardiogenic shock. Acute pericardial effusion can occur secondary to a rapid bleeding event from a neoplastic lesion associated with the heart (hemangiosarcoma of the right atrium), or from rupture of one of the vascular structures within the pericardial sac (atrial rupture in dogs or cats with severe left atrial enlargement secondary to chronic cardiac disease). Idiopathic pericarditis is an uncommon cause of acute pericardial effusion but is a frequent cause of cardiac tamponade in dogs. Pericardial effusion in cats is rare and infrequently results in tamponade.

Canine heartworm disease can occur anywhere in the continental United States, but the incidence reaches 45% along the Atlantic and Gulf Coast regions and the Mississippi River region. Caval syndrome can manifest as cardiogenic shock when dogs have large heartworm burdens that mature rapidly. The severity of disease is directly related to worm burden and patient size and caval syndrome occurs most often when worm burdens approach 60–100 although it has been reported with worm burdens as small as 12.

Tachyarrhythmias can result from primary conductional abnormalities such as arrythmogenic right ventricular cardiomyopathy (ARVC) or may be secondary to structural changes within the heart, as is the case with dilated cardiomyopathy (DCM). In fact, sudden death due to ventricular tachycardia occurs in up to 50% of Doberman pinschers affected with DCM. A rare but severe form of ventricular tachycardia called Wolff–Parkinson–White syndrome can be seen in dogs or cats with ventricular preexcitation. These patients are at risk for development of paroxysmal ventricular tachycardia due to the establishment of a reentry circuit that allows for the establishment of a reciprocating tachycardia and are at increased risk of developing cardiogenic shock.

Third-degree atrioventricular (AV) block can result from progression of a chronic infiltrative cardiac disease, infectious disease (e.g., Chagas disease), myocarditis or ingestion of cardiotoxins, including prescription medications (e.g., beta blockers, calcium channel blockers) or plant alkaloids (e.g., digitalis glycosides). If acute in onset (not preceded by second-degree AV block), third-degree AV block can result in development of cardiogenic shock although this is uncommon and usually coincident with significant structural cardiac disease. Sick sinus syndrome is a disease that occurs primarily in miniature schnauzers and infrequently in other breeds. It is characterized by periods of severe bradycardia or sinus arrest with occasional paroxysmal tachycardia resulting in potentially significant perfusion abnormalities.

Myocarditis is an extremely rare cause of cardiogenic shock that can be caused by infectious organisms, trauma, immune-mediated diseases, and toxins. Infectious causes of myocarditis include viral (parvo, distemper), bacterial (various), rickettsial (*Bartonella*), and protozoal organisms (*Trypanosoma*, *Toxoplasma*), among others. Myocarditis can induce myocardial failure through a cycle of inflammation, myofiber dropout and fibrosis, the cumulative effect of which is a clinical syndrome that mimics dilated cardiomyopathy. In general, myocarditis results in a subacute to chronically progressive form of cardiac dysfunction, but patients with undiagnosed myocarditis can present with end-stage disease in cardiogenic shock.

Rarely, intracardiac neoplasia can result in development of cardiogenic shock by directly affecting blood flow within the heart itself. Neoplasia associated with the atrioventricular valves, semilunar valves, right ventricular outflow tract, and right and left atria has been described. Tumor types that have been reported include

ectopic thyroid carcinoma, hemangiosarcoma, and osteosarcoma, among others.

Cardiogenic shock in cats occurs infrequently. When it does occur, it is usually due to cardiomyopathy (dilated [DCM], restrictive [RCM) or hypertrophic [HCM] with or without left ventricular outflow tract obstruction [LVOT]). The clinical importance of LVOT obstruction in cats with HCM is not fully understood but in cats with severe LVOT secondary to HCM, the dynamic obstruction of the left ventricular outflow tract can result in significant decreases in cardiac output. A more common cause of cardiogenic shock in cats is a form of "low-output" heart failure, usually characterized by hypothermia, bradycardia, and severe hypotension. This form of heart failure appears to be more common in cats with RCM and may be the result of ischemic heart injury.

Signalment

Cardiogenic shock can occur in a patient of any age or breed, making it difficult to describe a typical signalment, but because myocardial failure or neoplasia is often the inciting cause of cardiac dysfunction, these patients tend to be older middle-aged to geriatric animals. Pericardial effusion occurs most commonly in large- and giant-breed dogs, although endocardial ruptures resulting in acute pericardial effusion appear to be more common in older male small-breed dogs, with dachshunds and cocker spaniels being overrepresented.

Young dogs and cats with congenital cardiac abnormalities can develop cardiogenic shock. These patients are often identified as having a cardiac abnormality during an early veterinary visit and have frequently exhausted most if not all management options by the time cardiogenic shock develops. Therefore, when it occurs in these patients, it is usually a terminal, irreversible event.

Canine heartworm disease occurs in middle-aged dogs of both sexes. Smaller dogs appear to be at greater risk of developing caval syndrome and subsequently would be at greater risk for development of cardiogenic shock, likely due to the smaller worm burdens required to cause significant clinical disease in these smaller patients.

Certain breed predispositions for cardiac disease exist and by extension, these breeds may be at increased risk for development of cardiogenic shock. Boxer dogs are much more likely than other breeds to develop arrythmogenic right ventricular cardiomyopathy while Doberman Pinschers are considered most at risk for development of dilated cardiomyopathy. Both of these conditions can lead to ventricular tachycardia with cardiogenic shock. Besides the potential for tachyarrhythmias, dogs with DCM are at risk for systolic failure. Large- to giant-breed dogs are at increased risk for development of atrial fibrillation. Cats are rarely able to propagate atrial fibrillation due to their relatively small atrial mass but cats with severe atrial enlargement due to cardiomyopathy (Maine Coon, Himalayans) should be considered to be at risk.

History and Clinical Signs

A common historical complaint for animals presenting with cardiogenic shock is collapse or syncope. Owners commonly describe "seizures" rather than syncope so a careful history must be taken to determine if intracranial disease or seizures are in fact a contributing factor. A thorough history includes the patient's activity and behavior immediately preceding and following the event, state of consciousness during the event, and frequency of events. Syncope can result from many different cardiac conditions but brady- or tachyarrhythmias and pulmonary hypertension are the most common. Often syncope in these animals is exercise induced and the occurrence of syncope at rest should be considered evidence of advanced disease. If a patient presenting in shock has a history of syncope or collapse or if the owner describes exercise-induced "seizures," the clinician should be alert to the potential for a cardiogenic cause of shock. Most, if not all, patients in cardiogenic shock will present with acute exercise intolerance or weakness.

Regardless of the underlying cause of cardiogenic shock, all of these patients will present with perceptible derangements in perfusion parameters. The mucous membranes may be pale (evidence of poor perfusion) or cyanotic (evidence of hypoxemia). Delayed capillary refill time is an indicator of poor peripheral perfusion. In cases of severe shock, the mucous membranes may fail to blanch altogether. Often, the distal extremities will be cooler to the touch than the trunk. As shock progresses from compensated to the early, then late decompensatory stages, the mental status will change and the patient will become obtunded. Patients presenting obtunded to stuporous are in the late stages of shock and without timely intervention are likely to die.

As a general rule, patients in cardiogenic shock will have one or more abnormal findings during cardiac auscultation. Animals with pericardial disease will often have decreased heart sounds. Auscultation of animals with myocardial dysfunction may reveal either brady- or tachyarrhythmias. When present, arrhythmias can either be regular (e.g., sustained ventricular tachycardia) or irregular (e.g., atrial fibrillation). Cats often have gallop rhythms although extra heart sounds can be present in the dog also and usually indicate structural cardiac disease. Increases in adventitial lung sounds (crackles) may be present in cases with forward failure that results in the

development of pulmonary edema. Occasionally, acute worsening of a previously detected murmur with or without development of a precordial thrill is present and may be indicative of rupture of a first-order chorda tendina.

In some instances, as in the case of cardiac tamponade, the history may be one of subacute progression. Physical exam findings suggestive of pericardial effusion include muffled heart sounds, decreased precordial impulse, detection of pulsus paradoxus (although weak pulses are also common), and presence of jugular pulses. The finding of ascites and a positive hepatojugular reflex is more likely to occur in cases of chronic pericardial effusion and may be absent in the patient presenting with cardiogenic shock.

Respiratory distress may or may not occur as a result of cardiogenic shock but respiratory failure is rare. Tachypnea is likely to be present as a result of normal compensatory mechanisms to improve oxygen delivery. Significant hypoxia or hypoxemia can occur in situations such as pulmonary hypertension or pulmonary edema due to chordae tendinae rupture. For a more in-depth discussion on respiratory failure, the reader is referred to Chapter 39.

Diagnosis

Unique clinical characteristics of cardiogenic shock include concurrent hypotension (systolic blood pressure <90 mmHg or mean arterial pressure <60 mmHg), decreased cardiac output, and elevated central venous or left atrial pressures. There is no single diagnostic test that will confirm the presence of cardiogenic shock. Rather, the clinician will be forced to reconcile available diagnostic results (limited by patient stability, availability within the clinic, and finances) with the patient's historical findings, presenting complaint, and physical exam findings to achieve a diagnosis.

When presented with a patient in cardiogenic shock, the clinician will be faced with the decision about whether or not the restraint required to perform a diagnostic test is going to be tolerated by the patient. Unfortunately, it may be necessary to delay or forego some diagnostic tests that require restraint due to the tenuous nature of the patient's condition and every effort should be made to limit stress to the patient. Staging of testing can be helpful, focusing efforts on performing tests in the order most likely to yield meaningful results. As an example, it would be best to delay collection of blood in order to obtain even a single thoracic radiograph or an electrocardiograph (ECG). Occasionally, it is necessary to accept less than ideal results for testing such as obtaining a single radiographic view rather than orthogonal views or performing a limited echocardiogram or thoracic ultrasound rather than a complete exam to preserve patient safety. In fact, thoracic ultrasound can often be performed in the ER with minimal restrain and can produce repeatable results with a small amount of training. It is extremely disappointing when patients die during diagnostic procedures so the patient's condition, stability, and the value of the potential information obtained should be taken into consideration prior to ordering or performing a test.

The use of ECG provides real-time evaluation of the electrical conductance of the heart and enables the clinician to determine the source of cardiac depolarization and if a conduction abnormality exists. When evaluating a patient with suspected cardiogenic shock, an ECG should always be obtained. Patients are usually tolerant of ECG leads placed with either alligator clips or pads. The goal of ECG evaluation in this setting is to determine which cardiac cells are acting as pacemaker cells and if electrical conduction is occurring in an organized fashion. Therefore, patients can often be allowed to remain in sternal recumbency with minimal restraint. Evaluation of a lead II ECG should enable the clinician to answer pertinent urgent questions. A more thorough six-lead ECG can be performed if the patient's condition is considered stable enough to allow for restraint in lateral recumbency. While the presence of sinus tachycardia will not enable diagnosis of cardiogenic shock (sinus tachycardia is expected to occur in most shock states regardless of etiology), the presence of paroxysmal ventricular tachycardia supports the diagnosis. Additionally, the finding of multiform ventricular ectopy or electrical alternans may increase the clinician's suspicion of a cardiac origin of shock.

Radiography is a useful diagnostic tool and is readily available in most veterinary facilities. When using radiography in the emergency setting, it is important to keep patient safety in mind, realizing that the quality and completeness of the study may have to be compromised to ensure patient safety. Diagnostic radiographs can often be obtained with minimal restraint. In fact, patients can often be allowed to remain in sternal recumbency while a dorsoventral (DV) projection is obtained. A single lateral or DV projection may provide clues regarding the cause of shock (e.g., a globoid cardiac silhouette) but orthogonal views are always preferred if possible. Animals with rupture of a first-order chorda may manifest fulminant pulmonary edema characterized by the presence of an alveolar lung pattern while animals with cardiogenic shock secondary to ventricular tachycardia may have no radiographic abnormalities.

Echocardiography can be used to diagnose many of the causes of cardiogenic shock. The minimally experienced ultrasonographer will be able to recognize the presence of

pericardial effusion and will likely correctly identify tamponade if present. Additionally, with a small amount of focused training, the emergency clinician can recognize acute systolic failure (e.g., dilated cardiomyopathy). Evaluation of ventricular function and filling pressures in patients with chronic valvular disease requires more training and is complicated by the fact that ventricular systolic and diastolic function changes with age and disease severity in dogs. The recognition of chordae tendinae rupture, mild to moderate valvular insufficiency, caval syndrome or pulmonary hypertension will likely require evaluation by a veterinary cardiologist. Echocardiography can also be used to identify rare causes of cardiogenic shock such as intracardiac tumors.

The use of biomarkers in veterinary medicine is an area of active investigation. While many biomarkers have been studied and show promise for distinguishing cardiac disease from respiratory disease or for stratifying severity of cardiac disease (NT-proBNP, troponin-I), most are not available as point-of-care (POC) tests, limiting the clinical usefulness of these assays for evaluation of the patient in cardiogenic shock. The exception to this is troponin-I, which is available as a POC test (iStat by IDEXX) and has been shown in several veterinary studies to correlate with myocardial injury. A high troponin-I level in a patient presenting for shock should prompt the clinician to further explore the possibility of an underlying cardiac cause. It should be noted, however, that troponin-I levels have been shown to increase in dogs with gastric dilation and volvulus and may be elevated in any patient that has cardiovascular instability. The degree of troponin-I elevation is likely greater in dogs with myocardial injury than in those with shock of noncardiac origin. Therefore, the true utility of troponin-I may be in its ability to rule out myocardial injury in the acute setting.

Determination of cardiac output would provide strong support for a diagnosis of cardiogenic shock, especially in the absence of other possible causes of shock. While cardiac output monitoring technology exists in veterinary medicine, its clinical use remains limited at this time.

Therapy

Cardiogenic shock is a unique form of shock that is not generally responsive to traditional treatments for other types of shock, (i.e., volume expansion and vasopressor support). In fact, intravascular volume expansion and vasopressor therapy can be detrimental or even fatal when administered to a patient with cardiogenic shock. Rather, cardiogenic shock must be treated primarily by improving cardiac performance and secondarily by altering vasomotor tone (usually reduction of vasomotor tone).

As with all forms of shock, oxygen administration should be started immediately upon recognition of the shock state in an effort to maximize arterial oxygen content as far as possible. Oxygen can be provided by a variety of methods. The use of flow-by oxygen with a mask is easy to perform but requires constant restraint of the patient. This method of oxygen supplementation is relatively inefficient unless a tight-fitting mask is used. Unfortunately, animals in shock are often intolerant of having a mask held over their muzzles and they may struggle or resist. Holding a tube attached to an oxygen source in front of an animal's face is an extremely inefficient method of providing oxygen but, recalling that perfect is the enemy of good, is probably better than not providing any supplemental oxygen. Occasionally, animals will tolerate placement of nasal prongs similar to those used in human medicine. Due to the large size of the prongs, this is most feasible in large-breed, no-brachycephalic dogs.

A less labor-intensive way of providing oxygen is through the use of an oxygen chamber or cage. Purpose-built oxygen cages are available but require a significant financial investment and utilize large amounts of oxygen. A less expensive alternative is a plexiglass door with a gasket attached to a standard cage that allows introduction of oxygen through a port. While this method is less expensive than installing purpose-made cages, the clinician has little control of the oxygen content and limited ability to reduce carbon dioxide accumulation within the cage. The amount of oxygen used in these cages is usually higher than in purpose-made oxygen cages due to leakage through imperfect seals.

When providing supplemental oxygen in the acute setting, the highest achievable F_iO_2 should be used. Once the patient begins to stabilize, the F_iO_2 can be reduced to below 60% to decrease the likelihood of oxygen toxicity developing.

Animals with confirmed or suspected pulmonary edema and cardiogenic shock should be given loop diuretics upon presentation. Loop diuretics are rapidly acting, effective diuretics that can quickly improve the clinical condition of patients with pulmonary edema. Furosemide (2 mg/kg) should be administered intramuscularly and repeated every 30–60 minutes as needed until clinical signs improve. Attempts at IV catheter placement or IV administration of diuretics can be considered but patient safety must always be kept in mind.

Sometimes it becomes apparent that without more aggressive intervention (i.e., IV administration of medications), the patient's condition will continue to deteriorate. If, in the clinician's mind, the patient is progressing irreversibly toward cardiopulmonary arrest unless such intervention is undertaken, all attempts should be made to minimize the stress and duration of restraint by carefully

choreographing the steps to be taken. The use of mild sedatives can facilitate catheter placement in this situation. Administration of butorphanol (0.1–0.3 mg/kg) is generally safe and is unlikely to have an untoward effect on cardiac performance. The use of diuretics is not expected to improve clinical signs in animals with pulmonary hypertension, tamponade, or tachycardia-induced cardiogenic shock but is also not likely to result in acute decompensation.

Medications that increase cardiac contractility (positive inotropes) should be considered in animals that have documented systolic dysfunction. It must be remembered that positive inotropes not only increase cardiac contractility but also increase myocardial oxygen consumption. Dobutamine, an injectable beta-adrenergic agonist, can be administered as a constant rate infusion to treat systolic failure. For dogs with strongly suspected or confirmed systolic dysfunction, dobutamine can be started at a rate of 2.5 µg/kg/min. The dose is uptitrated every five minutes until systolic function improves or to a maximum rate of 20 µg/kg/min. In certain clinical situations, systolic dysfunction cannot be confirmed due to the patient's condition or unavailability of echocardiography. In this situation, the clinician will rely on signalment and results of other diagnostic tests to determine if systolic dysfunction is likely.

Systolic dysfunction in cats can be difficult to confirm due to their rather tenuous condition when in cardiogenic shock, therefore inotropic support should be considered in any cat presenting with heart failure and bradycardia. The dose of dobutamine for cats ranges from 1 to 5 µg/kg/min and should again be uptitrated to effect. In some instances, it may be possible to use pimobendan to improve cardiac contractility. Pimobendan is a phosphodiesterase III inhibitor and a calcium sensitizer that increases inotropy while reducing vascular tone, making it an attractive treatment option for many causes of cardiogenic shock. Unfortunately, pimobendan is only available as an oral medication in the United States, limiting its use in emergency situations. Administering oral medications to patients in shock should be avoided due to the stress associated with pilling and concerns about absorption of the drug from the underperfused gastrointestinal tract. An injectable form of pimobendan has recently been approved for use in Europe with a labeled dose of 0.15 mg/kg.

As mentioned earlier, the use of vasoactive medications in cardiogenic shock is rare. Almost never,will a patient with cardiogenic shock benefit from an increase in vascular tone alone. The same cannot be said for decreasing vascular tone, however. Patients that are likely to benefit from afterload reduction include those with rupture of a first-order chorda tendina or dilated cardiomyopathy – in other words, patients with forward heart failure.

The most effective medication to achieve consistent, rapid vasodilation is nitroprusside, which acts by increasing nitric oxide (a powerful arterial dilator) primarily at the level of the arterioles. Due to the potential for profound hypotension, the use of nitroprusside should be reserved for patients with confirmed congestive heart failure and systolic or valvular dysfunction. When used, nitroprusside is most effective as a constant rate infusion (CRI) with doses starting at 1 µg/kg/min. As with dobutamine, nitroprusside dose should be uptitrated until the desired effect is achieved or a maximum dose of 10 µg/kg/min is reached. Patients being treated with nitroprusside should have their blood pressure monitored very closely. Ideally, blood pressure is checked every 10–15 minutes until the target pressure (mean arterial pressure [MAP] 70 mmHg, systemic arterial pressure [SAP] 90 mmHg) is achieved. Mean arterial pressures less than 60 mmHg or systolic pressures less than 90 mmHg should be avoided due to the potential for additional organ injury. An early sign of hypotension in patients on nitroprusside is vomiting and if this occurs the patient should have blood pressure checked immediately and the CRI rate adjusted accordingly. Fortunately, nitroprusside has a very short half-life so discontinuation of a CRI should result in rapid recovery of blood pressure. Inadvertent, abrupt cessation of nitroprusside should be avoided due to the risk of rebound hypertension.

The use of nitroglycerine paste has been advocated in the past. There is not good evidence to support its routine use and dosing of transdermal medications can be notoriously difficult, especially in low cardiac output states where absorption and perfusion are likely to be impaired.

Sildenafil citrate is a phosphodiesterase V inhibitor that has been shown to be useful for the treatment of pulmonary hypertension in dogs. While the use of sildenafil is well documented for management of chronic pulmonary hypertension, the benefits in the acute setting are less clear. Sildenafil has a rapid onset of action so administration in a crisis would be expected to result in at least some improvement in pulmonary pressure. Clinically, this appears to be the case. As with pimobendan, however, sildenafil is currently most widely available as an oral medication and its administration needs to be carefully considered prior to dosing. An injectable form of sildenafil is approved for use in human patients with pulmonary hypertension but there are no descriptions of clinical use in veterinary medicine. When given, the recommended dose of sildenafil for management of pulmonary hypertension is 1–2 mg/kg PO TID.

Treatment of acute pericardial tamponade involves immediate pericardiocentesis. Although the possibility of continued, uncontrolled hemorrhage exists, the morbidity and possible mortality associated with tamponade

cannot be tolerated. If complete drainage is not achieved, serial attempts can be made but may not be necessary. Because the pericardial sac is essentially an enclosed sphere, the removal of even a small amount of fluid will exponentially decrease the pressure within the sac. Observation of the pericardial space with ultrasound (if available) following every attempt at pericardiocentesis should be made. Often, the pericardium is lacerated during the attempt and although only a small amount of fluid is retrieved, tamponade has been relieved and pericardial fluid has been drained into the thoracic cavity where it is better tolerated. In cases where hemorrhage cannot be controlled or multiple attempts at percutaneous pericardiocentesis are unsuccessful, emergency thoracotomy may be required although this should only be attempted as a last resort when death is believed to be imminent or cardiac arrest has already occurred.

Treatment of tachyarrhythmias can be achieved through one of two mechanisms: conversion of the rhythm to a normal sinus rhythm or control of the rate of ventricular contractions. Administration of antiarrhythmic medications can be used in an emergency setting to treat patients with cardiogenic shock from tachyarrhythmias in an attempt to achieve either of these endpoints. Due to the urgency inherent in this condition, injectable antiarrhythmics are always preferred to oral formulations. Lidocaine or procainamide are considered first-line therapies for the treatment of ventricular tachycardia. Control of ventricular tachycardia begins with a 2 mg/kg slow bolus of lidocaine. If no response is seen, a second dose of lidocaine can be administered. Occasionally, rhythms that are refractory to lidocaine will respond to procainamide so if the rhythm has not improved with lidocaine, a dose of procainamide 5–15 mg/kg slow IV can be attempted.

Amiodarone has recently been incorporated into the human CPR guidelines developed by the American Heart Association for use during cardiopulmonary arrest as a treatment for pulseless ventricular tachycardia and ventricular fibrillation refractory to electrical defibrillation. Amiodarone has been used as an oral medication in veterinary medicine to treat many different arrhythmias, including atrial fibrillation and ventricular tachycardia. The use of injectable amiodarone is reported in veterinary patients but has been associated with development of anaphylactic or anaphylactoid reactions. Due to these potential adverse effects, it should be considered as a second-choice option for management of acute, life-threatening tachyarrhythmias. If amiodarone is going to be used, the recommended starting dose is 5–10 mg/kg as a slow IV bolus to effect and the amiodarone should be diluted prior to administration.

Occasionally, dogs will present with supraventricular tachycardia (SVT) or sinus tachycardia causing cardiogenic shock as a result of toxin ingestion. For dogs with ECG-confirmed sinus tachycardia (with a rate >180 bpm), the administration of beta-blockers should be considered once other causes of shock have been ruled out and the absence of congestive heart failure has been confirmed. Due to the need to urgently address cardiogenic shock, injectable, ultra-short-acting beta-blockers should be used as first-line treatment with oral formulations reserved for patients that have stabilized. Esmolol administered as a bolus of 0.2–0.5 mg/kg followed by a CRI of 50–200 µg/kg/min is preferred. If bradycardia develops, the CRI rate should be slowed or discontinued. Diltiazem (5–20 µg/kg/min) can also be used and may be more effective at managing nonsinus SVT. Because of their negative inotropic effects, the use of beta-blockers and calcium channel blockers should be avoided in patients with congestive heart failure.

Some cardiac rhythms are amenable to electrical cardioversion using a debrillator (atrial fibrillation, paroxysmal ventricular tachycardia). When used to perform cardioversion, the energy delivered is generally much lower (0.5–1 J/kg) than for defibrillation and the timing of energy delivery must be synchronized with the R-wave of the ECG. The synchronization function on the defibrillator should be activated and the energy dosage should be selected. Once the synchronization function has correctly identified the R-waves, defibrillation can be performed as usual. If the defibrillator is not equipped with a synchronization feature then electrical cardioversion should not be attempted as inappropriately timed delivery of the shock can result in ventricular fibrillation. Heavy opioid sedation or anesthesia should be used if electrical cardioversion is going to be attempted on a conscious patient to minimize discomfort associated with the procedure (see description for transcutaneous pacing).

Treatment of cardiogenic shock due to complete (third degree) AV block consists of temporary or permanent placement of a pacemaker. Temporary transcutaneous pacing can be used in emergency situations and requires little advanced training to be effective. Most modern defibrillators are capable of performing temporary transcutaneous pacing while temporary transvenous pacing may require the use of a pacemaker programmer or purpose-made generator. Transcutaneous pacing is an uncomfortable experience at best and requires general anesthesia. To perform transcutaneous pacing, the patient is prepared while awake. The fur is clipped over the heart on both sides of the chest at the level of the costochondral junction. The temporary pacing pads are placed and plugged into the defibrillator base unit. Once the patient is instrumented, a rapid-sequence anesthetic induction (IV bolus premed followed immediately by IV bolus of induction agent) is performed and temporary

pacing is begun. Once pacing has begun, the voltage of the pacing leads is gradually increased until they are "captured" by the heart. Evaluation of ECG, pulse oximetry or digital palpation of the pulses can be used to verify capture. Transcutaneous pacing is always a stopgap measure to allow time for the placement of either a temporary transvenous pacing mechanism or a permanent pacemaker and should not be considered if these options are not available.

Management of caval syndrome secondary to heartworm infection often requires direct removal of the worms from the right heart. The use of a transvenous approach has been well described and, provided the dog survives the perioperative period, appears to be very effective for management of acute caval syndrome. Surgical management is also the best treatment for well-defined intracardiac tumors. Unfortunately, open-heart surgery requires total venous inflow occlusion or cardiac bypass, significantly limiting its availability in veterinary medicine at this time.

Prognosis

Published mortality rates for cardiogenic shock in veterinary patients are lacking, but many human studies report mortality rates of 50–80%. In most instances, the development of cardiogenic shock is a sequela to a severe underlying structural or progressive conductive disease. Therefore, both the short- and long-term prognosis should be considered guarded to poor. Patients that recover from cardiogenic shock are usually left with residual cardiac dysfunction that is irreversible in nature. The exception to this may be dogs that are treated for caval syndrome secondary to canine heartworm disease and animals receiving a pacemaker for bradyarrhythmias.

Septic Shock

James W. Barr, DVM, DACVECC

BluePearl Veterinary Partners, Tampa, FL, USA

Etiology/Pathophysiology

The ability of an organism to mount an inflammatory response is necessary for the survival of nearly all life forms. Through the simple interaction of the body with its internal and external environments, a constant bombardment with infectious agents and minor injuries occurs that is prevented from progressing to systemic disease by the innate immune system. This process is performed successfully on a continuous basis without any conscious effort on the part of the organism or need for prior exposure to offending antigens.

Unfortunately, these same mechanisms, which are protective when functioning normally, can become unregulated or overactive, resulting in added pathology, perhaps even worse than the original insult would have caused. This idea is reinforced by the fact that patients often die of sequelae to infections or systemic inflammation rather than directly from the primary insult.

The systemic inflammatory response syndrome (SIRS) is the systemic manifestation of a response to an insult and may result from anything creating inflammation. Importantly, this can be the result of a systemic condition (e.g., heat stroke) or a severe local insult (e.g., pancreatitis). While systemic inflammation may be necessary to combat the initial insult, when left unregulated it can lead to severe consequences. The presence of certain clinical findings is used to define SIRS and sepsis in both veterinary and human medicine. Definitions for SIRS have been proposed and are currently being used clinically (Table 43.1).

Since there is little difference between the clinical appearance of SIRS and uncomplicated sepsis, the two terms are often used interchangeably. When SIRS occurs due to an infectious cause, the term used to describe it is sepsis. As a result of these definitions, it means that sepsis always occurs in conjunction with SIRS while SIRS can exist without the presence of sepsis. As is the case with most aspects of veterinary medicine, sepsis/SIRS is not an all-or-nothing condition but rather occurs along a spectrum, the least severe form of which is a hemodynamically stable patient that fulfills the clinical criteria. Severe sepsis is defined as sepsis with acute dysfunction of one or more organs. Common examples of secondary organ dysfunction include the development of a coagulopathy or acute kidney injury. The worst permutation of the septic spectrum is septic shock in which a patient not only fulfills criteria for severe sepsis but also has hypotension and signs of shock that are not reversed with fluid therapy and is consequently vasopressor dependent.

Response to Infection or Injury

Innate Immunity

The immune system has evolved into two complementary systems that work together to fight infection and mitigate the damage that occurs in the host: the innate immune system and the adaptive immune system. For convenience, they are often discussed separately, but it should be remembered that neither branch works in isolation from the other and that cross-talk and feedback are constantly occurring between the two branches.

The innate immune system is the portion of the immune system that is nonspecific and responds to any insult that may be present without need for preexposure while the adaptive arm of immunity is a more specialized system that requires preexposure to an organism or antigen. The adaptive response can have infinite, very specific targets but unfortunately, the delay necessary to recognize an antigen and synthesize antibodies in order to mount a response makes adaptive immunity unsuitable as a primary means of defending the host from an acute injury or novel infection.

As a consequence, most of the clinical manifestations associated with sepsis and SIRS, with few exceptions, are associated with the response of the innate immune system. It is important to note that the body makes no distinction between these two systems and they function synergistically. For instance, proinflammatory cytokines elicited as a result of an innate immune response help to augment the subsequent or concurrent adaptive response.

Innate immunity relies on recognition by the host of some very specific, evolutionarily conserved molecular patterns that are found in association with infection, inflammation, cell death or all of the above. Pattern recognition receptors (PRRs) are a relatively small set of receptors that are able to recognize a wide range of pathogens, including viruses, bacteria, and fungi. Many cell types that participate in immune function, including macrophages, monocytes, dendritic cells, neutrophils, and epithelial cells, express PRRs that allow the rapid recognition of pathogens at the site of infection. Numerous PRRs have been identified (Nod-like receptors, C-type lectin receptors, RIG receptors, and RAGE receptors) with remarkable homology across species in all parts of the phylogenetic tree. The fact that these PRRs are found in such diverse species highlights their importance for survival.

The most studied and best-known PRRs are the toll-like receptors (TLRs), which are expressed by many cell types including macrophages, dendritic, endothelial, and epithelial cells. TLR activation is generally considered to be proinflammatory and results in the production of antimicrobial peptides, inflammatory cytokines and chemokines, and adhesion molecules, all of which work together to coordinate the innate response.

As a result of PRR activation, there is a coordinated response by the immune system to recruit other cells into the fight against infection. This recruitment, the actions of the recruited cells, their associated killing mechanisms, and soluble factors have led some authors to compare the TLRs and other PRRs to keys on a piano. When one key is struck alone, the resultant note does not make a song, but when several keys are played at the same time and in different combinations, a piece of music emerges. The appropriateness or lack thereof of this process is the central driver in the pathology associated with sepsis and septic shock.

Dysregulated Immunity

Once a pathogen has been recognized and the immune response initiated, there are numerous opportunities for dysregulation to occur, adding to morbidity and possibly mortality of the patient. This dysregulated immunity was considered to be exclusively an overexuberant inflammatory response and in fact, the "inflammation only" theory explains most of the clinical signs observed in septic patients. It does not, however, explain all the clinical signs and it has subsequently become clear that hyperinflammation alone does not fully account for the morbidity and mortality experienced by septic patients.

A compensatory anti-inflammatory response syndrome (CARS) was proposed as an alternative that may occur in some patients as a result of systemic inflammation. The CARS theory states that in some patients, overcompensation by the anti-inflammatory arm of the immune system results from a combination of excessive anti-inflammatory cytokine production and, possibly more importantly, from the death and dysfunction of immune cells. This theory helps to explain some of the clinical manifestations of sepsis/SIRS. It is convenient to consider these conditions in the extreme as distinct identities but clinically most patients will lie somewhere in the middle.

Physiologic Consequences

Patients with sepsis can develop shock that often shares characteristics of hypovolemic, vasodilatory, and cardiogenic etiology due to the actions of inflammatory mediators and their cumulative effect on the circulatory system. In addition to tissue perfusion derangements, patients with sepsis or septic shock can suffer from cytopathic hypoxia or an inability to utilize oxygen at the mitochondrial level. This further complicates understanding the pathophysiology of sepsis and septic shock.

Hypovolemia often develops from vomiting, diarrhea or bleeding but can also occur due to accumulation of cavitary effusion or peripheral edema reducing effective circulating volume. Changes in vascular permeability, vascular hydrostatic pressure, decreased colloid osmotic pressure or lymphatic occlusion all occur in septic patients and result in a tendency for fluid to move out of the vascular space. As a result, significant "third spacing" of fluid can occur in the thoracic or abdominal cavities or interstitium of patients with sepsis or SIRS. The net effect of this fluid movement is decreased intravascular volume that contributes to lower cardiac output and impaired oxygen delivery.

Besides loss of effective circulating volume, sepsis can induce significant alterations in vascular tone. Because

these patients may have low intravascular volume, compensatory mechanisms are activated in an effort to maintain blood pressure. To minimize the effect of hypovolemia on organ systems in nonseptic patients, systemic vascular resistance generally increases to compensate for the lower cardiac output and maintain organ perfusion. In sepsis, however, numerous factors counteract these compensatory mechanisms to the detriment of the patient. This can result in decreased effectiveness of vasoconstriction or, worse, to pathologic dilation of the vessels.

The most well-understood vasodilatory agent in sepsis is nitric oxide (NO). In sepsis and septic shock, inducible nitric oxide synthase (iNOS) produces supraphysiologic levels of nitric oxide that interfere with myocyte calcium metabolism and impair the ability of vascular smooth muscle cells to contract. The end-result is vasodilation with a characteristically poor response to vasoconstrictive stimuli, including reduced vascular response to catecholamines. Additionally, the surplus of nitric oxide leads to production of reactive oxygen species, including peroxynitrite, which are directly toxic in the local environment and act to cause further damage to endothelium and smooth muscle myocytes. Nitric oxide is also responsible to some degree for the cardiac depression found in patients with sepsis or septic shock.

Endocrine abnormalities occur in sepsis and can also adversely affect the ability of the vascular tree to respond to stimuli. With the additional demand for vasoconstriction, the neurohypophysis (posterior pituitary) depletes its stores of vasopressin and is unable to meet the demand, leading to a well-documented deficiency in some septic patients.

A distinct cardiac failure component is present in some human patients with septic shock but is of unknown clinical relevance in veterinary medicine. It was believed that a circulating myocardial depressant factor was present in the blood of septic patients that decreased cardiac function. This myocardial depressant factor was subsequently identified as tumor necrosis factor (TNF)-alpha which, together with interleukin (IL)-1, has been associated with cardiac myocyte dysfunction. TNF-alpha and IL-1, both potent inducers of iNOS, are now known to be the offending molecules that lead to sepsis-induced cardiac dysfunction. If decreased systolic function is coupled with decreased systemic vascular resistance, as seen in septic shock, the cardiac output often stays the same or even increases although tissue perfusion is severely compromised. However, if vasoconstriction persists, as seen in uncomplicated or severe sepsis, decreased systolic function can lead to a significant reduction in cardiac output.

Sepsis-induced endothelial injury affects the lungs by allowing neutrophil migration into the lung parenchyma and increased vascular permeability that impairs gas exchange. This disease has been termed acute lung injury (ALI) or acute respiratory distress syndrome (ARDS), depending on severity, with ALI describing a less severe manifestation than ARDS. Both are characterized by acute-onset bilateral pulmonary infiltrates with no evidence of left-sided heart failure. Classification is further determined by the degree of hypoxemia. For more information on ALI/ARDS the reader is referred to Chapter 38.

Significant alterations in normal gastrointestinal function, motility, and vascular permeability result from inflammatory mediators, altered blood flow, and oxidative stress. This may allow exposure of the bloodstream to the luminal contents of the gastrointestinal (GI) tract and allow bacteria access to the bloodstream or lymph, although the clinical significance and actual incidence of bacterial translocation are unknown.

Hepatic dysfunction in sepsis is manifested as hypoalbuminemia, icterus, hypoglycemia, and coagulation abnormalities and decreased detoxifying ability. The underlying cause of hepatic dysfunction is unknown but may result from hypoperfusion of the liver, or may be directly due to the systemic inflammatory process (i.e., inflammatory mediators) as many of the constitutive functions of the liver are downregulated as part of the acute phase response.

Coagulation abnormalities can be significant and can lead directly to the death of the patient. Sepsis-induced coagulopathy is a manifestation of the procoagulant nature of almost all proinflammatory mediators. In general terms, the procoagulant state in sepsis causes generation of microthrombi that result in inflammation within the vascular beds in which they lodge. This systemic activation of the coagulation system finally results in the consumption of coagulation factors and in the later stages ultimately induces a hypocoagulable state. This scenario has been termed disseminated intravascular coagulation (DIC) and continues to be a significant clinical complication in the management of sepsis. Unfortunately, due to clinical limitations in identifying patients in the procoagulant phase of DIC, this complication is often found in the last stages when profound bleeding tendencies predominate and it is extremely difficult to manage or reverse.

The discovery of renal dysfunction or acute kidney injury is an easily identified marker of multiple organ dysfunction syndrome. Acute kidney injury results from decreased renal blood flow secondary to systemic hypotension; alterations in renal blood flow from vasoactive substances, microthromboembolism, and poorly understood renal cellular apoptosis are also believed to contribute. Patients may exhibit a progressive increase in creatinine and decreased urine production despite normal intravascular fluid volume. Even small changes in

serum creatinine (within the reference range) can indicate renal impairment and emerging multiorgan failure.

The central nervous system manifestations of sepsis and septic shock may be due to the effects of systemic hypotension and decreased cerebral perfusion or may be related to the direct effects of sepsis-induced cytokines. Alterations in cerebral blood flow, increased capillary leakage, and disruption of the blood–brain barrier are thought to be mechanisms contributing to brain dysfunction in sepsis. In addition to primary intracranial causes, sepsis-induced hypoglycemia can cause neurologic dysfunction. The clinical signs seen with sepsis and septic shock are predominantly alterations in mentation (i.e., obtundation, stupor, coma) and seizures.

Epidemiology

The exact incidence of sepsis in veterinary medicine is unknown. However, sepsis is likely a common occurrence in clinical practice and remains among the most difficult to treat conditions. According to the NIH, about 750 000 people become septic in the United States each year with a mortality rate of 28–50%. In fact, the rates of hospitalization for human sepsis have become higher than those of myocardial infarctions. The death rate from sepsis eclipses that of prostate cancer, breast cancer, and AIDS combined.

Despite the difficulty in diagnosing sepsis, there are common veterinary diseases that can cause a patient to develop sepsis. Parvoviral enteritis, pyometra, pneumonia, and septic peritonitis are just a few of the diseases responsible for sepsis and septic shock in dogs and cats.

Septic peritonitis occurs in both cats and dogs and most commonly results from perforation of the GI tract. Because of the propensity of dogs to ingest foreign objects, septic peritonitis occurs more commonly in that species. Most frequently, perforation of the GI tract occurs from ingestion of foreign material that physically obstructs aboral flow or damages the walls of the GI tract to the point of rupture. Perforation of the stomach and duodenum can occur secondary to nonsteroidal antiinflammatory drug (NSAID) administration. Neoplasia can cause perforation in any part of the bowel.

Disease of organ systems other than the GI tract can cause septic peritonitis. This occurs most frequently when a normally sterile organ becomes infected and the infection extends into the abdomen via perforation or through translocation of bacteria to the blood or lymph. Extension of infection from the urogenital tract can occur because of prostatitis, prostatic abscess, pyometra, pyelonephritis or rupture of the urinary bladder containing infected urine or calculi. Septic bile peritonitis results from perforation of an infected biliary tree, most frequently the gallbladder. Less frequently, infection or abscessation of organs such as the liver or spleen, or necrotic tissue secondary to strangulation or torsion is the source. Spontaneous septic peritonitis can occur in cats with no evidence of gastrointestinal compromise or other identifiable source.

Numerous other diseases are capable of causing sepsis in dogs and cats. Penetrating trauma from animal bites is a common occurrence and contamination from bite wounds can result in sepsis. Blunt trauma without penetrating injury (e.g., being struck by a vehicle or falling from a height) frequently results in significant soft tissue injury that can result in sepsis if infection of the damaged tissue occurs.

Signalment

All species, breeds, sexes, and ages can develop sepsis. Consequently, there is no signalment specific to sepsis but there are populations that are susceptible to diseases that can be the underlying cause of sepsis. For example, young, unvaccinated puppies are at risk of contracting Parvoenteritis while intact female dogs and cats may develop pyometra. Dogs that develop septic peritonitis tend to be younger with indiscriminate eating habits that ingest foreign material, resulting in perforation of the GI tract. A report including nearly 75 000 dogs identified some distinct breed- and age-related differences in all-cause mortality, with younger patients having a significantly higher likelihood of dying of infectious disease or trauma. Geriatric dogs with chronic, progressive diseases necessitating treatment with NSAIDs, corticosteroids, or other immunosuppressive medications are also at higher risk than the general population for developing GI tract perforation. Ruptured neoplasia of the GI tract occurs in both geriatric dogs and cats.

Lifestyle of the pet can significantly affect the likelihood of developing sepsis. Pets that are primarily outdoors or that spend a significant amount of time outdoors and unsupervised are more likely to be exposed to injuries that can result in sepsis.

History and Clinical Signs

Patient historical information often relates to the underlying cause of sepsis. For example, animals with septic peritonitis may have historical complaints such as vomiting, abdominal pain or hemorrhagic diarrhea while patients with sepsis secondary to pyometra often

have polyuria, polydipsia, and vulvar discharge as part of their history. Many dogs with septic peritonitis secondary to gastrointestinal perforation will have a history of NSAID or corticosteroid administration. Some of the etiologies of sepsis are subacute to chronic in nature and subsequently the historical complaints may be somewhat vague. Regardless of the underlying cause of sepsis, it is common for owners to report decreased activity levels and loss of appetite for varying amounts of time prior to presentation. Travel history, exposure to any and all medications (including common over-the-counter drugs), housing (indoor vs outdoor), and exposure to other animals are all important historical facts to elucidate.

Just as sepsis/SIRS occurs on a spectrum, the clinical signs associated with sepsis/SIRS vary depending on the severity of the condition. By definition, all animals with sepsis have clinical signs consistent with SIRS. Additional clinical signs that may be present include lethargy, recumbency, vocalization, or seizures, with some patients even presenting moribund.

Once septic shock develops, clinical signs vary but are generally related to deficits in oxygen delivery. Patients with septic shock can have two different presentations: they can be in hyperdynamic (compensated) or hypodynamic (decompensated) shock. Hyperdynamic shock implies that there is greater than normal cardiac output with vasodilation and these patients will be tachycardic, have red mucous membranes, bounding femoral pulses, and warm extremities. Patients in the hypodynamic phase of shock can be tachycardic or bradycardic, have weak pulses, pale to gray mucous membranes, and cold extremities.

Diagnosis

The diagnosis of septic shock is made by fulfilling the SIRS criteria and key hemodynamic parameters in conjunction with identification of an underlying infection. Patients in septic shock will show similar physical exam findings to patients in shock for other reasons, but there will generally be additional abnormalities related to the underlying cause of sepsis. For instance, a patient with septic peritonitis will have traditional signs of shock (tachycardia, weak pulses, and pale mucous membranes) but will also often have abdominal pain and peritoneal effusion as evidenced by abdominal distension with the possibility of a palpable fluid wave.

When presented a patient with suspected sepsis or septic shock, it is important to first gather as much data as you can. The minimum database consists of a complete blood count, biochemistry profile, and urinalysis. Abnormalities in the minimum database generally reflect the underlying disease although specific sepsis-related changes could be present.

An inflammatory response is expected on the hemogram, although individual patients may demonstrate high, normal, or low leukocyte counts with or without toxic change or presence of band neutrophils. Patients may have a regenerative or nonregenerative anemia and may be thrombocytopenic.

The biochemistry profile can often be quite abnormal. Septic patients have a significant inflammatory component to their disease that can affect blood protein levels dramatically. Hypoalbuminemia is found frequently in septic patients as albumin loss into exudates occurs concurrently with downregulation of albumin production during the acute phase response. Other abnormalities identified on the biochemistry profile may include hypoglycemia, hyperbilirubinemia, hypocalcemia, and elevated creatinine and blood urea nitrogen. Of these, hypoglycemia is of particular concern since it contributes to morbidity or mortality if not identified and corrected rapidly.

Imaging studies are often key to the identification of the source of sepsis. Plain radiographs of the chest and abdomen are useful for identifying possible sources of sepsis and the finding of unstructured interstitial to alveolar pulmonary infiltrates, pleural effusion, obstructive intestinal pattern, free abdominal air, or loss of abdominal detail indicating free fluid should be considered significant and additional confirmatory diagnostic tests should be pursued.

Collection of free abdominal fluid, if present, is often the first step in diagnosing septic peritonitis and can be accomplished via blind four-quadrant paracentesis or ultrasound-guided needle aspiration. Ultrasound allows the clinician to bring imaging to the bedside and perform a rapid evaluation of the thoracic and abdominal cavities. This can help with the initial identification of disease, and can provide a method to monitor progression. Ultrasound is particularly useful for identifying pockets of fluid within the chest and abdominal cavities that can then be sampled. In clinical practice, ultrasound is more effective at identifying free fluid than is blind four-quadrant paracentesis, making it an objective and effective tool in the ER and ICU.

Once fluid is obtained, cytologic evaluation can confirm the diagnosis of septic peritonitis or prompt the clinician to investigate further. Identification of intracellular bacteria signifies that bacteria present in the peritoneal cavity are being phagocytized by inflammatory cells and indicates infection rather than sample contamination. The finding of even one intracellular bacterium is significant and is an indication for immediate

surgical exploration. While identification of even one intracellular bacterium confirms the diagnosis of septic peritonitis, the absence of this finding does not rule out sepsis. If the fluid obtained is highly cellular (composed of mixed inflammatory cells) or is turbid, flocculent or malodorous then further investigation may be needed.

Comparison of the biochemical values, specifically lactate and glucose, of abdominal fluid with blood can be invaluable for aiding in the diagnosis of septic peritonitis. The comparison of glucose and lactate concentrations of abdominal fluid and blood is both sensitive and specific for differentiating septic peritonitis from other causes of peritoneal effusion. Under normal conditions, the concentration of glucose and lactate in peritoneal fluid is essentially the same as that of blood. As infection progresses within the peritoneal cavity, bacteria and white blood cells utilize glucose for energy and produce lactate as a by-product. If the lactate concentration of abdominal fluid is 2.0 mmol/L higher than that of the blood or if glucose is 20 mg/dL lower in the effusion than in the blood, a presumptive diagnosis of septic peritonitis can be made and surgical exploration should be recommended.

Monitoring coagulation assists with identification of needed therapies rather than identification of sepsis or septic shock and coagulation assays may be normal or abnormal in these patients. A prothrombin time (PT) or partial thromboplastin time (aPTT) that is >50% prolonged indicates coagulopathy. Fibrinogen levels may be normal, low or high, depending on the chronicity of the disease. Patients that have a prolonged disease course tend to have higher fibrinogen levels, but it is not uncommon to find low fibrinogen due to active consumption. D-dimers are often elevated as a result of the underlying condition or inappropriate coagulation (i.e., DIC). Identification of three of the following in a patient identifies DIC: prolongation of PT or aPTT, hypofibrinogenemia, thrombocytopenia, elevation of fibrin degradation products (FDPs) or D-dimers, or documented antithrombin deficiency.

Treatment

Treatment of sepsis and septic shock must be aggressive and aimed at eliminating the underlying cause. In broad terms, treatment of sepsis and septic shock can be divided into several distinct components: resuscitation, source control (eliminating the cause of sepsis), antimicrobial therapy, and supportive care. The resuscitation of a patient with severe sepsis or septic shock is different from that of patients with other forms of shock. This is due to the multifactorial nature of the development of shock in the septic patient, meaning that in any one patient, low systemic vascular resistance, cardiac dysfunction, and hypovolemia may all be coexistent and may all contribute to failure of oxygen delivery (i.e., shock).

Resuscitation

Complicating septic shock resuscitation is the fact that vascular permeability may be increased, which can decrease the efficacy of crystalloid resuscitation or lead to overresuscitation and subsequent edema formation. The use of goal-directed therapy, consideration of other fluids options, and use of vasoactive agents as well as fastidious reevaluation can improve the efficacy of resuscitation.

The most important initial therapy in the resuscitation of a patient with septic shock is the administration of appropriate doses of IV fluids to restore effective circulatory volume and improve global perfusion. The appropriate amount and character of the fluids that should be administered are a matter of debate. The author prefers to give an initial bolus of 20–30 mL/kg of crystalloid fluids such as lactated Ringer's solution or 0.9% sodium chloride. This initial dose serves to act as a fluid challenge and will help the clinician determine if continued fluid resuscitation may be beneficial. If a positive response is seen, this dose can be repeated 2–3 more times until one of three endpoints occurs: signs of shock resolve, there is no further improvement in perfusion parameters or volume overload becomes evident. Signs of volume overload include development of peripheral or pulmonary edema or measurement of central venous pressures greater than 10 cmH_2O.

Colloidal solutions are commonly used as a primary or secondary resuscitative fluid in veterinary patients in shock. Colloids have several theoretical benefits, but one of the most important is that they discourage formation of tissue edema since they do not move out of the vascular compartment as quickly as crystalloid fluids. If colloids are used, total doses of 20 mL/kg are typically broken into aliquots similar to the technique used with crystalloids and are administered in incremental 5–10 mL/kg boluses until endpoints are achieved. Hetastarch (Hespan®, Hextend™) is the most commonly used colloid in veterinary patients and has replaced the dextran solutions that were in use previously. A newer generation of hydroxyethylstarchs, generally classified as tetrastarchs, is also available with a similar dosing schedule.

Patients in septic shock, by definition, have hypotension that is not responsive to fluid loading alone, meaning that vascular expansion has been completed without resulting in resolution of shock. Determining when patients are adequately volume expanded is difficult.

One method for determining if volume loading has been adequate is measurement of central venous pressure, with a target of 8–12 cmH_2O. Many of these patients will not have a central line in place, in which case lack of improvement in blood pressure following IV fluid boluses can be interpreted as evidence that volume expansion is complete. When this happens, vasopressors are needed to increase systemic vascular resistance in an effort to increase blood pressure and maintain vital organ perfusion. There is no consensus on which vasopressor is most effective and selection is largely based on clinician preference. The most commonly used first-line vasopressors are dopamine (5–20 µg/kg/ min) and norepinephrine (0.05–0.3 µg/kg/min). If normotension is not achieved at the upper end of the dose range for a single vasopressor then the addition of a second agent is needed. Typical secondary vasopressors include vasopressin (0.01–0.04 U/kg/h) or norepinephrine if not already used as a first-line agent.

While vasopressors function to increase systemic vascular resistance and improve perfusion of tissue beds, patients with sepsis or septic shock often have concurrent systolic dysfunction. Positive inotropes are drugs that increase inotropy (contraction strength) and chronotropy (contraction rate), resulting in an increased stroke volume and heart rate, and consequently cardiac output. The most commonly used inotropic medication is dobutamine. If evidence of systolic failure is present then dobutamine should be started (5–15 µg/kg/min) and the dose titrated up every 15 minutes until endpoints are reached or the top of the dose range is reached. If dobutamine fails to result in resolution or improvement in shock then the addition of a vasopressor should be considered. It should be remembered that many adrenergic drugs are positive inotropes in addition to being vasopressors (ex. dopamine and norepinephrine) and the primary effect is often dependent on the dose administered. For more information about resuscitation endpoints, the reader is directed to Chapter 41.

Source Control

Source control is important for the resolution of sepsis and septic shock and should be performed as soon as possible after the source is identified to improve the likelihood of recovery. Source control almost always requires some degree of surgical intervention, ranging from lancing of an abscess to resection of perforated bowel. Good source control for wounds includes early and aggressive debridement of devitalized or infected tissue. Dogs with necrotizing fasciitis may require radical resection of affected tissue and the use of vacuum bandaging or application of wet to dry bandages for continued debridement following the initial surgical intervention.

If the septic source is an abdominal viscus such as the uterus or bowel then laparotomy should be performed as soon as the patient is stable enough for anesthesia with the goal of eliminating ongoing bacterial contamination with dilution or removal of already affected tissue. Similarly, if the septic source is in the thorax (ex. pyothorax or lung abscess) then thoracotomy should be recommended. Pyothorax can be managed conservatively with placement of thoracostomy tubes acting as source control mechanisms and is reported to be effective 71% of the time. The decision to manage cases with thoracostomy tubes versus surgical intervention depends on geography, as well as clinician preference or training. In areas of the country where inhaled grass awns from foxtails are common, the frequency of surgery is expected to be higher than that of an area in which those plants are not found. Lung abscesses must be managed with lung lobectomy. For cases with severe sepsis or septic shock secondary to pyelonephritis, source control interventions to consider include percutaneous renal pelvis centesis or nephrectomy.

Antimicrobial Therapy

The early administration of appropriate antibiotics is key for successful treatment of patients with sepsis and septic shock. Every effort should be made to collect culture samples before antibiotics are administered; however, one cannot wait indefinitely to initiate treatment and the goal should be to begin antibiotics within one hour of recognition of septic shock. In patients with sepsis without shock, it is often much more feasible to withhold antibiotic therapy until appropriate cultures have been obtained.

Ideally, the antibiotic administered would be effective against the offending organism in question. Unfortunately, in most cases the antibiotic sensitivities or the identity of the organism are unknown prior to initiation of antimicrobial therapy. Even when appropriate culture samples are collected, the results are delayed by 48–72 hours or longer. Therefore, the initial antimicrobial selection should be effective against bacteria in all four quadrants (gram positive, gram negative, aerobic, and anaerobic). This usually requires the co-administration of two or more antibiotics. Unless a clear contraindication exists, the dose of all antibiotics should be at the high end of the dose range, they should be given IV, and penetrate the desired tissue bed. Examples of effective antibiotic combinations include combining potentiated penicillins (ex. ampicillin/sulbactam 30–50 mg/kg q8h or ticarcillin/clavulanate 40–50 mg/kg q8h) with fluorquinolones

(ex. enrofloxacin 10–mg/kg q24h) or aminoglycosides (ex. gentamicin 6–8 mg/kg q24h).

Once culture results are returned, the antibiotic spectrum can be narrowed based on the microbial sensitivity pattern. The duration of therapy required by septic patients is unknown and difficult to determine. A useful guide is to continue antibiotics therapy until one week after clinical resolution of infection.

Supportive Care

There are numerous additional components that are integral to the recovery of any critically ill animal. In septic patients, nutrition, monitoring, and high-quality nursing care cannot be emphasized enough. Diligent monitoring is necessary for these animals as their status can change quickly and with little notice. Heart rate, respiratory rate, respiratory effort, blood pressure, hemoglobin saturation, urine production, and blood glucose should be checked at regular intervals.

Due to the catabolic state that occurs during sepsis, nutritional support is a very important component of treatment for these patients. In addition to helping prevent hypoglycemia, nutrition allows for some anabolic activity to occur and enables synthesis of components of the immune system. In patients with severe sepsis or septic shock, dextrose supplementation is often necessary to treat hypoglycemia. When possible, it is always preferable to provide these patients with enteral rather than parenteral nutrition. Early enteral nutrition (defined as consistent caloric intake within the first 24 hours) has been shown to decrease length of hospitalization in dogs with septic peritonitis. This can be accomplished through voluntary alimentation by the patient or through the use of feeding tubes. The use of feeding tubes is becoming more common in the management of critically ill patients as more diets specifically formulated to be used in small-caliber tubes are developed. While most feeding tube options require heavy sedation or general anesthesia for placement, nasoesophagal tubes are small-caliber tubes that can be placed with little to no sedation and are therefore very useful for providing enteral nutrition to those patients that are unwilling to eat voluntarily. Although patients with sepsis as a rule have a negative energy balance, the goal with nutritional support should be to meet the resting energy requirement. There is little to no evidence that hyperalimentation improves clinical outcomes and it has been associated with development of complications including feeding intolerance and hyperglycemia.

Critical illness-related corticosteroid deficiency (CIRCI) is a multifactorial deficiency in circulating cortisol in critically ill patients. This condition was first described when it was found that a subset of patients with refractory hypotension improved following administration of physiologic doses of corticosteroids. Initially CIRCI was diagnosed by determining if patients responded appropriately to an adrenocorticotropic hormone (ACTH) stimulation test. It was found, however, that even some patients with normal response to ACTH stimulation benefited from corticosteroid supplementation. This led to the recommendation for supplementation of hydrocortisone in critically ill human patients with unresponsive hypotension regardless of ACTH stimulation results and in fact, ACTH stimulation tests are no longer considered necessary for the diagnosis of CIRCI.

Corticosteroid administration should be considered only if fluids and vasopressors do not correct hypotension. If used, the author prefers hydrocortisone 1–4 mg/kg/day divided q12h or once every 24 hours. Corticosteroids should be discontinued when the patient is no longer vasopressor dependent.

Prognosis

The prognosis for septic shock is tremendously variable in both veterinary and human patients. Severity and reversibility of the underlying disease process as well as the presence of comorbid conditions affect prognosis of sepsis and septic shock. However, it must be recognized that the farther along the septic spectrum (toward development of septic shock) that a patient goes, the worse the prognosis will be. Veterinary survival data are difficult to interpret as the practice of euthanasia complicates the evaluation of outcome, but survival rates of 50–60% are commonly reported. This correlates with studies showing mortality rates of nearly 50% in humans with septic shock.

Patients with sepsis or septic shock have significant disease and regardless of the cause, this condition is considered serious. Every effort should be made to set realistic owner expectations with the understanding that the prognosis is guarded to poor (especially in the case of septic shock). The financial and emotional cost of treating a dog with sepsis can be very high. The long-term prognosis for patients that survive sepsis and septic shock is unknown although good long-term outcomes appear to be common.

Disorders of Heat and Cold

Sarah Allen, DVM, DACVECC

Massachusetts Veterinary Referral Hospital, Woburn, MA, USA

Normal Thermoregulation

Body temperature is closely maintained in mammals around an optimal set point at which ideal cellular function can occur. This is a complex process that ultimately results in a balance between heat production and heat loss. The hypothalamus acts as the main regulator of this process with multiple sensors throughout the body in the skin, thoracic and abdominal viscera, and spinal cord. The body can be viewed as two thermal divisions: the core and peripheral compartments. The core compartment is well perfused with a mostly constant temperature. The peripheral compartment is composed of the extremities and peripheral temperature is dependent on heat transmission from the core via blood flow, heat conduction from adjacent tissues, and heat loss to the environment.

Heat is generated by muscle activity and metabolism, with the brain, heart, and abdominal organs being the main generators of metabolic heat. Changing blood levels of thyroxine, epinephrine, and norepinephrine can change the basal metabolic rate, and subsequently body heat. Increased muscular activity (i.e., shivering) is also used as a means of generating heat. Heat retention occurs by physiologic responses including piloerection and peripheral vasoconstriction, as well as behaviors such as seeking shelter and warmth and curling up.

In order to prevent hyperthermia, methods of heat dissipation are necessary to maintain an ideal body temperature. The four main mechanisms of heat loss from the body are evaporation, conduction, convection, and radiation. *Evaporation* is loss of heat from moisture on the body surface. In canine and feline patients, the main source of heat loss by the evaporative route is from the respiratory tract, with panting providing a means of increasing heat loss from the body. *Conduction* is the transfer of heat from body surfaces to objects contacting the body, such as exam tables or cage floors. *Convection* occurs when body heat is transferred to the air surrounding the body and *radiation* is the transfer of heat from the body to distant surfaces without direct bodily contact. In small animals, conduction and convection are the primary means of heat dissipation. Individual patient factors that contribute to increased heat loss may include increased relative surface area in a neonate, decreased fat insulation in a thin patient, inability to prevent excessive heat loss to a conductive surface or decreased heat seeking due to weakness or altered mentation.

Hypothermia

Hypothermia is defined as body temperature of less than 38 °C (100.4 °F) and is classified by severity as mild (32–37 °C/89.6–98.6 °F), moderate (28–32 °C/82.4–89.6 °F), or severe (<28 °C/82.4 °F). With the onset of hypothermia, compensatory responses including peripheral vasoconstriction and shivering are stimulated. Once body temperature reaches <34 °C (93.2 °F), vasodilation occurs and metabolic rate is decreased. Below 31 °C (87.8 °F), thermoregulation ceases completely and if hypothermia is allowed to continue unabated, death shortly follows.

Primary hypothermia is the result of prolonged exposure to low environmental temperatures, where the processes of heat production and retention are insufficient to maintain normal body temperature. Some patients may be more vulnerable to developing primary hypothermia due to decreased body condition, increased relative body surface area or a decreased ability to generate heat. Neonates, geriatrics, and patients suffering from chronic illnesses that result in decreased body fat and lean mass may be more susceptible to primary hypothermia.

Secondary hypothermia is a result of disease, anesthesia, and/or surgery, or other processes that cause alterations

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.
© 2020 John Wiley & Sons, Inc. Published 2020 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/bruyette/clinical

in heat production, heat retention or thermoregulation. A common cause of secondary hypothermia in small animal patients is general anesthesia. Perioperative hypothermia consists of three phases, starting with an initial rapid decrease in the core temperature of 1–1.5 °C during the first hour. Most anesthetics cause vasodilation, which results in venous pooling and redistribution of heat from the core to the periphery. This is accompanied by a decrease in the temperature threshold needed to cause reflex vasoconstriction. This phase is followed by a slower decrease in temperature over the next 2–3 hours as heat loss exceeds the rate of metabolic heat production that is decreased 20–30% by anesthetics. Heat loss during this period is more profound in patients undergoing open cavitary surgical procedures due to increased heat loss by all means of heat transfer as a result of the increased surface area available for heat exchange. The plateau phase is the final phase where metabolic heat production is equivalent to continued heat loss. At this point, the core temperature has decreased to a point where vasoconstriction occurs and heat loss is decreased.

The consequences of primary and secondary hypothermia are similar, although patients with secondary hypothermia are generally more symptomatic at higher temperatures. In the anesthetic setting, postoperative hypothermia has been associated with increased mortality in humans.

Hypothermia has many physiologic effects and consequences. One major effect of hypothermia is a decrease in the overall metabolic rate. This includes decreased hepatic metabolism, which may prolong the effects of anesthetic medications and consequently anesthesia-associated hypothermia. In the kidneys, hypothermia initiates cold diuresis due to increased glomerular filtration rate (GFR) and decreased sensitivity to antidiuretic hormone (ADH). During severe hypothermia, renal effects can progress to decreased renal blood flow, decreased GFR and ischemic renal tubular damage, which can lead to acute renal tubular necrosis.

Besides the effects on abdominal viscera, hypothermia can lead to a hypocoagulable state due to thrombocytopenia, thrombocytopathia, alteration in coagulation factor function and disruption of fibrinolysis. Hypothermia has also been documented to cause suppression of the immune system, resulting in increased surgical site infections and altered wound healing in human and veterinary patients.

Cardiovascular consequences of hypothermia include an initial catecholamine-stimulated increase in heart rate and blood pressure that increases myocardial oxygen demand and consumption. Hypothermia induces a left shift in the oxygen–hemoglobin dissociation curve resulting in decreased oxygen release to the tissues. Combined with reflex vasoconstriction, this results in significant tissue hypoxia, especially to the skin and extremities. During more severe hypothermia, there is decreased catecholamine responsiveness resulting in bradycardia and hypotension. Arrhythmias can occur due to myocardial ischemia as well as myocardial irritation, with ventricular fibrillation as a commonly documented rhythm.

Hypoxia is propagated by a decrease in respiratory rate and tidal volume. While mild hypothermia may protect the brain from ischemia in cases of cardiopulmonary resuscitation and traumatic brain injury, in normal patients the negative consequences of hypothermia are likely greater than the benefits. Even mild hypothermia can result in altered mentation due to decreased cerebral blood flow. Prolonged recovery from anesthesia due to hypothermia and decreased drug metabolism can potentiate altered mentation.

Therapy

The primary treatment goal of hypothermia, regardless of cause, is the restoration of normal body temperature. The main difference between the treatment of primary and secondary hypothermia is that since it can be anticipated, the best treatment for secondary hypothermia is prevention. Prevention of perianesthetic hypothermia requires close patient monitoring with rectal or esophageal thermometers. Indwelling probes allow for continuous temperature monitoring.

Prevention of hypothermia utilizes the same therapies and techniques as treatment of hypothermia. Heat loss can be prevented with passive surface rewarming in the form of a blanket covering the patient and placed between the patient and conducting surface. Extremities can be wrapped in insulating material. Active surface rewarming increases the temperature of the air and surfaces surrounding the patient to minimize heat loss. Forced warm air blankets and circulating water blankets significantly decrease heat loss from anesthetized patients and should be used on all patients undergoing general anesthesia of any significant duration (i.e., greater than 30 minutes).

Active core rewarming increases the temperature of the core by introducing heat centrally and can be performed by administration of warmed IV fluids, warm pleural or peritoneal lavage, warm water enemas, warm saline urinary bladder lavage, and inhalation of warm, humidified air. Warmed IV fluids are helpful in preventing hypothermia but are of minimal assistance in rewarming hypothermic patients. IV fluids can be warmed to 40 °C (104 °F) in a microwave for 2.5 minutes (microwave variation exists and each clinic should verify individual microwave time) or stored in an incubator for immediate use. In-line fluid warmers help to maintain the temperature as the fluid is being administered. Peritoneal and

pleural lavage fluids should be warmed to 40–43 °C and are invaluable in rewarming and preventing further heat loss in surgical patients.

When rewarming hypothermic patients, all these measures can be employed based on the severity of the hypothermia. When hypothermia is mild (>32 °C/89.6 °F), passive surface rewarming may be sufficient. With moderate hypothermia (>28 °C/82.4 °F), active external rewarming is required with the main efforts aimed toward the core region rather than the extremities. Once hypothermia becomes severe (<28 °C/82.4 °F), active core rewarming is mandatory. Warm lavage allows heat transfer from the fluids to the bowel and heart and can help prevent further decrease in temperature. Heat transfer is able to occur as long as the lavage fluid temperature exceeds the core temperature, ideally 40–43 °C (104–109 °F). Warm peritoneal or pleural lavage can be performed in nonsurgical patients but is technically more difficult than in animals with an open body cavity in the operating room. If necessary, a peritoneal catheter or thoracostomy tube is placed using sterile technique and 10–20 mL/kg of warmed lavage fluid (0.9% NaCl) is infused. The amount of time that fluid is allowed to remain within the body cavity (dwell time) will determine how much heat is transferred. Dwell times should be of sufficient duration to allow for maximum heat transfer, with typical dwell times lasting 2–5 minutes. Transfers can be repeated as needed until the target body temperature is reached.

Similar to peritoneal or pleural lavage, warm lavage of the urinary bladder and colon is an option but is of unknown benefit due to limited surface area available for heat exchange. However, urinary bladder lavage and warm water enema administration is less invasive and does not require placement of catheters within the peritoneal or thoracic cavities. If used, the dwell times, exchange volumes, and temperature of the infusate are the same as for the cavitary lavage techniques.

Hypothermic patients require cautious IV fluid resuscitation to assist in restoring blood pressure and effective circulating volume. As hypothermia progresses, the decreased affinity of catecholamines for receptors leads to reduction of cardiac contractility and vasodilation. This may manifest as a minimal response to IV fluid therapy and does not automatically indicate the need to continue volume expansion with fluids in the absence of ongoing hypovolemia. As the body temperature returns to normal, rebound vasoconstriction and increased contractility may result in fluid overload as the intravascular fluid volume is centralized. When IV fluid therapy is needed, warm IV fluids are recommended so fluid resuscitation does not potentiate hypothermia. The ideal rate at which to rewarm a hypothermic patient is unknown but a general recommendation is 1–2 °C per hour. Active rewarming efforts are stopped once the patient has reached 37 °C (98.6 °F) to prevent hyperthermia.

Primary hypothermia is less common than secondary hypothermia. When it does occur, the decrease in body temperature is generally more severe; however, the recovery may be less complicated due to the absence of concurrent diseases, surgery or anesthetic drugs.

With rewarming, there is an increase in the metabolic rate and oxygen consumption that may not be appropriately compensated for in patients that are hypotensive or hypoventilating. Supplemental oxygen may be beneficial in preventing hypoxia from this increase in oxygen demand. When utilizing external warming techniques, a condition known as afterdrop can occur in which the core temperature actually continues to decrease as peripheral vasodilation allows movement of warm core blood to the periphery and return of cold peripheral blood to the core. Afterdrop may be prevented by instituting core rewarming techniques concurrent with external rewarming, and by directing rewarming techniques at the trunk rather than the limbs. At the far end of the afterdrop spectrum lies rewarming shock, which occurs when rapid vasodilation from external warming results in significant venous blood pooling and circulatory collapse. Thermal burns due to active rewarming efforts can occur if excessive heat is used (>42 °C/107.6 °F), prolonged contact time between patient and heat source is allowed, or there is a lack of insulation between the heat source and patient.

Prognosis

Rewarming complications can affect the prognosis of hypothermic patients.

Hyperthermia

Hyperthermia is defined as an increase in body temperature greater than 38 °C (100.4 °F) and can be due to an alteration of the set point of the hypothalamus to a higher temperature with deliberate efforts of the body to raise itself to that temperature (true fever) or can result from loss of the thermoregulatory balance of the body in which heat production is increased or heat loss is inhibited but the set point remains the same. Hyperthermia can be induced by extreme muscular activity. Sustained exercise, especially in an underconditioned or overweight patient, sustained seizure activity or frequent cluster seizures can induce severe hyperthermia if not controlled.

An uncommon cause of hyperthermia in dogs and cats is malignant hyperthermia. This is a condition of disturbed calcium metabolism that is initiated by drugs, most commonly volatile anesthetic gases, that results in

a myopathy with increased metabolic heat production. Clinical signs include elevated body temperature and often muscle rigidity. In patients under anesthesia, an increase in end-tidal CO_2 may be noted due to the increased metabolic rate associated with this condition. Various pathologic conditions, including endocrine disorders (hyperthyroidism, pheochromocytoma), can induce an increase in metabolic rate and heat production, as well as decrease heat loss due to peripheral vasoconstriction. Hypothalamic lesions that result in an increase in the temperature set point will create hyperthermia.

Prolonged extreme elevations in body temperature can increase the metabolic rate and demand for oxygen, water, and calories that may exceed the body's ability to supply them. When this occurs, protein denaturation occurs and resulting cellular dysfunction is manifested as cardiac arrhythmias, liver dysfunction, kidney failure, and damage to the gastrointestinal barrier with secondary bacterial translocation. Acid–base and electrolyte derangements occur due to dysfunction at the cellular and organ level. Muscle damage from high temperatures and hypoxia causes rhabdomyolysis, hyperkalemia, and myoglobinuria, leading to further renal injury. Significant alterations in systemic coagulation manifest as disseminated intravascular coagulation (DIC) with thrombosis adding to organ dysfunction. Consumption of clotting factors results in inappropriate bleeding that may produce clinically significant anemia.

Treatment

Treatment of hyperthermia should be directed at correcting the underlying cause and returning the body temperature to normal through the use of active cooling. Active cooling techniques include placing the patient in front of a fan to improve convective heat transfer, removing bedding to allow contact with cool cage or floor surfaces to maximize conductive heat loss, and application of alcohol to the foot pads to enhance evaporative heat dissipation. These techniques are generally sufficient for treatment of hyperthermia of less than 41 °C (106 °F) and should be started on animals with hyperthermia greater than 40 °C (104 °F). If these mechanisms are ineffective or if hyperthermia is more severe, then dousing the patient (wet to the skin, not just the hair coat) in cool water and placing them in front of a fan is the best way to transfer heat from the core to the skin and subsequently to the environment. Ice water should be avoided as it will induce peripheral vasoconstriction and inhibit heat transfer from the skin and delay core cooling. Application of ice water may also induce shivering which can result in heat generation. Cooling should be closely monitored and active cooling stopped when the core body temperature is still above 39 °C (102.2 °F)

Hyperthermia secondary to seizure activity requires aggressive medical management of the seizure activity with antiepileptic drugs (diazepam 0.5 mg/kg IV) and active cooling. Treatment of malignant hyperthermia includes stopping the causative medication, active cooling, and administration of dantrolene (2.5–5.0 mg/kg IV).

Fever

Hyperthermia in the form of fever is part of the systemic acute phase response to a pathogen or tissue injury and is aimed at decreasing the ability of infectious agents to replicate and survive. The response may be triggered by a variety of infectious agents including bacteria, fungi, and viruses, as well as tissue injury from trauma or surgery. Neoplastic cells are also capable of inducing fever. A substance that is created by the body and induces fever is an endogenous pyrogen, the most significant of which are the cytokines interleukin (IL)-1, Il-6, and tumor necrosis factor (TNF)-alpha. A substance released by an infectious agent that induces fever is known as an exogenous pyrogen and includes lipopolysaccharide (LPS) of gram-negative bacterial cell walls. LPS and other exogenous pyrogens bind to immune cells and result in cytokine release and initiate the acute phase response. Infectious agents also create tissue damage that leads to the release of cytokines. Once released, cytokines stimulate the arachidonic acid pathway and result in the production of prostaglandin-E_2 (PGE_2). PGE_2 is the main mediator of the fever response through its action on the hypothalamus that results in vasoconstriction to prevent heat loss and catecholamine release (among other mechanisms) to increase thermogenesis.

The cause of fever may be obvious based on history and physical exam, as in the case of an infected wound or surgical site, or an abscess from a bite wound. If not readily apparent, an extensive work-up may be required to identify the underlying cause. A tiered approach to working up a fever is often proposed, starting with a minimum database including complete blood count, chemistry profile, and urinalysis. Thoracic and abdominal radiographs with ultrasound are also often included in the initial work-up. If these tests do not provide a diagnosis, further diagnostics including relevant infectious disease titers (based on geographic area), urine culture, blood cultures, echocardiogram, joint taps, and cerebrospinal fluid analysis may be required.

Treatment

Identifying and eliminating the cause of true fever is the mainstay of treatment. Therapeutic treatment with IV fluids to maintain hydration and electrolyte balance may

be necessary. Broad-spectrum antibiotics are recommended if a bacterial infection is suspected and when possible, antibiotic therapy should be deescalated based on culture results. Prolonged fever with no response to antimicrobials and a thorough, inconclusive work-up may indicate an immune-mediated process that requires immunosuppression, a viral process that requires continued monitoring and supportive care, or a neoplastic process that has yet to be identified. Treatment with antipyretics that inhibit prostaglandin synthesis, such as nonsteroidal antiinflammatory drugs (NSAIDs), is controversial as inhibiting the fever may allow continued propagation of an infectious agent. Possible side-effects of these medications in each individual patient should also be considered carefully prior to their administration. Although uncommon, true fevers exceeding 41 °C (106 °F) require more aggressive intervention with active cooling to prevent organ damage and other systemic effects.

Heat Stroke

Heat stroke is probably the most common cause of life-threatening hyperthermia (>40 °C/104 °F) encountered in veterinary medicine and results from inadequate heat dissipation from the body. Classic heat stroke is caused by exposure to high environmental temperatures, which overwhelm the body's ability to offload heat by means of convection and radiation. The most common situation causing classic heat stroke occurs when an animal is locked in an enclosed vehicle where the temperature can rapidly increase past the outside ambient temperature due to solar heat and poor interior ventilation. This situation develops more rapidly in larger dogs that produce greater body heat and have less relative surface area for heat dissipation than smaller dogs.

Exertional heat stroke is the result of physical activity in a hot and/or humid environment and is often seen in working dogs. Increased environmental humidity decreases respiratory evaporative heat loss while increased work of breathing promotes heat production and further exacerbates this condition. Many cases of exertional heat stroke occur early in the warm weather season due to lack of acclimatization to the change of temperature. Dogs with altered means of respiratory evaporative heat loss, such as brachycephalic dogs and dogs suffering from laryngeal paralysis, may be more vulnerable to exertional and classic heat stroke. Obesity and a thick hair coat can further decrease the ability to dissipate heat from the body in both forms of heat stroke.

Some dogs may have a genetic resistance to heat stroke due to increased levels of heat shock proteins (HSP), which protect and repair essential cellular proteins from heat damage. NSAIDs upregulate HSPs and may confer protection against heat stroke in patients that are on NSAIDs at the time of the heat stroke incident. In fact, in humans, NSAIDs may be indicated for heat stroke prevention during heat waves although there is no published research on this in dogs. Importantly, NSAIDs are contraindicated after a heat stroke event has occurred due to the risk of negative effects on the kidneys, coagulation system, and gastrointestinal tract.

The clinical signs of heat stroke depend on the degree and duration of temperature elevation, as well as a significant contribution by individual patient factors. Diagnosing heat stroke is often based on a history of confinement or exertion on a hot, humid day. Most animals will present with an elevated body temperature although it may be normal or low, especially if external cooling has been initiated prior to presentation or the patient is in the advanced stages of shock. On initial physical exam, tachycardia, panting, and injected mucous membranes may be noted. Cardiac arrhythmias may be ausculted or suspected due to the presence of pulse deficits. Neurologic deficits ranging from obtundation to coma and seizure may occur. Skin and mucous membranes should be examined for evidence of petechiae and ecchymosis and venipuncture sites should be monitored for appropriate hemostasis.

Initial work-up includes an electrolyte panel (including blood glucose), packed cell volume (PCV) with total solids (TS), complete blood count, chemistry profile, and coagulation assays. Common abnormalities include hemoconcentration with elevations in PCV and TS, elevations in liver enzymes (ALT, AST, alkaline phosphatase, bilirubin), renal and prerenal azotemia, elevated creatine kinase, prolonged clotting times, and hypoglycemia.

Treatment

The initial therapy for heat stroke should be aimed at rapidly returning body temperature to normal and correcting hypovolemia and acid–base and electrolyte derangements. Immediately upon recognition of a heat stroke crisis, owners should be instructed to thoroughly wet a patient with tepid water. Support staff should be trained to instruct owners in this crucial step provided it will not unnecessarily delay transport to a veterinary hospital. Upon presentation, the previously described active cooling techniques should be initiated. At least one peripheral IV catheter should be placed and room-temperature fluids administered to increase effective circulating volume and improve perfusion, enhancing peripheral heat loss.

During fluid resuscitation, heart rate, blood pressure, lactate, PCV/TS, and urine production should be monitored to guide therapy. A description of goal-directed resuscitation targets is found in Chapter 41. If hypoproteinemia

is present (albumin <2.0 g/dL, TP <5.0 g/dL), colloid therapy with natural colloids may be needed to support intravascular volume and prevent third spacing of fluids. If hypoglycemia is present (blood glucose <70 g/dL), an initial bolus of 50% dextrose (0.5–1.0 mL/kg, diluted to 25% with crystalloids) should be administered, then a constant rate IV infusion of a crystalloid solution with 2.5–5% dextrose initiated for continued glucose support. Blood glucose should be monitored and dextrose supplementation titrated to prevent hyperglycemia. If coagulation parameters indicate a hypocoagulable condition (prolonged prothrombin time [PT] or partial thromboplastin time [PTT]), appropriate blood products (ideally fresh frozen plasma 10–20 mL/kg) may be indicated. If bleeding is evident or the degree of derangement is great enough to raise concern for spontaneous hemorrhage then plasma is administered as needed until coagulation times rechecked 1–2 hours after transfusion are normal.

Continuous ECG monitoring is recommended to allow rapid identification of the development of cardiac arrhythmias. In patients with severe neurologic deficits or seizure activity, diazepam (0.5 mg/kg IV), phenobarbital (12–16 mg/kg), or levetiracetam (60 mg/kg) should be administered to achieve seizure control. If neurologic evaluation suggests increased intracranial pressure then mannitol (0.5–1.0 g/kg IV over 15 min) may be considered for possible treatment of cerebral edema although hyperosmolar agents should be used with care in animals that have acute hypernatremia, as often happens with heat stroke. Coverage with broad-spectrum antibiotics is advised due to the concern for bacterial translocation from a disrupted gastrointestinal (GI) barrier. If evidence of GI injury is present in the form of hematemesis or hematochezia then GI protectants, including histamine-2 blockers (famotidine 0.5 mg/kg IV BID) or proton pump inhibitors (omeprazole 1 mg/kg PO BID, pantoprazole 1 mg/kg IV BID) are indicated.

Nonsteroidal antiinflammatories have been associated with preventing or decreasing the severity of a heat stroke episode when given prior to the incident. There is no evidence of any benefit to administering NSAIDs in the face of an active heat stroke episode and there is warranted concern for adverse effects on the already compromised renal, gastrointestinal, and coagulation systems. Similarly, there is no supporting evidence for the administration of corticosteroids during or after a heat stroke episode.

Additional treatments are indicated based on diagnostic test results and individual patient needs. For more information on general critical care considerations, see Chapter 35.

Prognosis

Heat stroke is a serious condition and the prognosis is dependent on many factors, including duration of temperature elevation, extent of temperature elevation, rapidity of initiation of treatment, and development of complications. Poor prognostic indicators include coma or hypothermia at the time of presentation, progressive decline in neurologic status, worsening azotemia, hyperbilirubinemia, persistent hypoglycemia, DIC, cardiac arrhythmias, and pulmonary edema. Hypoglycemia has been found to be more profound in nonsurvivors and persistent hypoglycemia despite treatment with dextrose has been associated with increased mortality. Increasing creatinine level despite IV fluid therapy has also been associated with increased mortality. The presence of nucleated red blood cells at the time of presentation may indicate more severe heat stroke and correlates with outcome.

In general, animals with moderate to severe heat stroke should be given a guarded to poor prognosis. Animals that survive an episode of heat stroke are expected to make a full recovery although lasting neurologic deficits or renal dysfunction may occur. Survival of heat stroke does not confer protection from future events and owners should continue to be aware of environmental conditions to minimize the chances of occurrence.

Acute Poisoning

Ben O'Kelley, DVM, DACVECC

BluePearl Veterinary Partners, Tampa, FL, USA

Veterinarians are frequently presented with patients who may have been exposed to a toxin. Often the suspected toxicity is based on known exposure to a toxin. In other situations, patients exhibit symptoms (such as muscle tremors, central nervous system [CNS] dysfunction, spontaneous intracavitary hemorrhage, acute liver failure in the absence of an obvious cause, etc.) that lead the clinician to suspect toxicity. A basic understanding of common toxins, diagnostic testing for toxic compounds, general decontamination procedures, and available antidotes is important for the practicing small animal clinician. Prompt diagnosis and treatment of the intoxicated patient can lead to good clinical outcomes while failure to recognize toxicity may lead to death.

History

Obtaining a detailed history is extremely important whenever a patient may have been poisoned. Owners often fail to recognize a substance as possibly toxic, especially when the onset of clinical signs is delayed or the intoxicants are common items. Asking general questions such as "Has your pet been exposed to any toxins?" may lead to a quick response of "No" if clients do not identify medications (e.g., ibuprofen, phenazopyridine ["AZO standard"], etc.) or plants (lilies in cats, sago palms in dogs, etc.) as toxicants. Asking specific questions may help to identify a possible exposure. It is often useful to ask if the patient has been given *any* medications or ingested *any* plants. It is necessary to ask clients about toxic exposure *over the past few weeks*, as they may not recognize the delay between ingestion and symptoms that can be seen with toxins such as vitamin K antagonist rodenticides.

Physical Examination

A thorough physical examination of any patient suspected to have been poisoned is important. Ensuring a patent airway, verifying respirations, and assessing circulation (the basic "ABCs" of examination) should always be the first part of the physical exam. Many toxins target the CNS or the gastrointestinal (GI) tract, and symptoms such as mental obtundation or severe vomiting and diarrhea may be obvious. Stimulants and cardiotoxins may cause tachyarrhythmias, bradyarrhythmias, or signs of poor perfusion, including pale or gray mucous membranes, cool extremities, and poor pulse quality. Careful physical examination may uncover subtle symptoms such as pain on palpation of the kidneys of a patient who has ingested a nephrotoxin. Cats who exhibit acute, severe muscle tremors often have recent exposure to topical parasiticides such as pyrethrins or permethrins. Veterinary patients poisoned by a vitamin K1 antagonist frequently exhibit signs of hemorrhagic shock, including tachycardia, pale gums, and tachypnea. Signs of hemorrhage may include muffled ventral lung sounds, a palpable abdominal fluid wave, hematemesis, hemoptysis, hyphema, hematuria or ecchymoses of the skin. If history or physical exam suggests poisoning as a possibility, treatment should proceed according to a plan designed around the suspected toxin.

Clinical Approach

Diagnostic Testing

Every patient who is known or suspected of having been exposed to a poison should have a minimum database of complete blood count (CBC), blood chemistry profile,

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

and urinalysis. The urinalysis is often incorrectly omitted in clinical practice. Failure to perform a urinalysis may prevent the clinician from uncovering evidence of renal injury (casturia, crystalluria, etc.) prior to the onset of azotemia. Once azotemia develops, the window of opportunity for successful therapeutic intervention may have closed for some patients. More specific diagnostic testing may be recommended on a case-by-case basis, depending on the specific toxin suspected. For instance, blood ethylene glycol testing and determination of anion gap and measurement of blood osmolality (if possible) are recommended if ethylene glycol ingestion is suspected. Coagulation testing, such as prothrombin time (PT) and activated partial thromboplastin time (aPTT), is recommended for suspected cases of rodenticide ingestion.

The use of urine testing kits for illicit drug intoxication in veterinary patients has been described. One study comparing urine test screen results with the gold standard of urine toxin detection (gas chromatography/mass spectrometry) found that an on-site urine toxin screen (QuickScreen Pro Multi-Drug Screening Test) accurately detected the presence of amphetamines, barbiturates, benzodiazepines, and opiates in canine urine but did not reliably detect THC (the main psychoactive substance in marijuana) or methadone.

Certain Exposure to a Known Toxin

When a patient is known to have ingested a specific substance, the clinician has a unique opportunity to intervene. Contacting an animal poison control service (such as the Animal Poison Control Center Hotline [888-426-4435] or Pet Poison Helpline [855-764-7661]) provides access to a database containing all known pharmacokinetics of the toxin, including toxic dose, routes of metabolism, and excretion. Expected symptoms and recommended therapies to offset the toxicity are also provided by these hotlines. A one-time fee is charged by the providers of these services.

If contacting a poison control center is not an option, an internet-based search utilizing a veterinary-specific network (such as the Veterinary Information Network [VIN.com]) often provides much of the same information. Even a search of free, nonveterinary websites such as www.pubmed.gov can help locate useful information or publications regarding treatment of a known toxin. If the toxin is a manufactured product (i.e., not a naturally occurring toxin such as a plant), the manufacturer of the product can be contacted. The manufacturer will have information regarding the toxic potential of the substance and may be able to provide treatment recommendations based on the type of exposure.

When considering the approach to a patient known to have ingested a toxin, many factors must be considered. If a patient is asymptomatic, the clinician must consider the likelihood of toxic symptoms developing. Although the exact dosage of toxin exposure is not always known, treatment should proceed according to the maximum possible dose. Let us consider, for example, an 80-pound Labrador retriever with exposure to a bottle of 200 mg ibuprofen tablets. The bottle initially contained 100 tablets, but it had been opened prior to this exposure. Twenty tablets were counted following the ingestion but the owner is unsure how many tablets are missing. In this scenario, the clinician should approach the treatment of the dog as if 80 of the tablets were ingested, constituting a toxic exposure dose of 220 mg/kg, even though the actual exposure was likely less than this amount. Ibuprofen dosages above 125 mg/kg have been reported to cause acute kidney injury in dogs, so the clinician in this case should warn the client of this risk and treat accordingly.

Every attempt should be made to establish a likely timeline of exposure. When the development of significant symptomatic toxicity is a possibility, decontamination should be considered. Ingestion is the most common route of toxin exposure so GI decontamination is often needed. GI decontamination is no longer recommended for every case of ingestion of a known toxin, but decontamination should be considered if there is a likelihood of toxic symptoms developing (see "GI decontamination" later in this chapter).

When the specific toxin and dosage are known and symptoms are expected or present, available antidotes should be administered as soon as possible. Timely administration of an antidote following toxin exposure is of utmost importance. Examples of common toxins for which antidotes exist include ethylene glycol, anticoagulant rodenticides, organophosphates, acetaminophen, and opioids.

Two Common Examples: Timing is Everything

An in-depth discussion of all known toxins is beyond the scope of this chapter, but vitamin K antagonist anticoagulant rodenticides and ethylene glycol are two of the most common toxins encountered in small animal practice. The importance of establishing a timeline of exposure whenever possible is highlighted by these two poisons, because a successful outcome following intoxication depends on timely diagnosis and intervention.

Vitamin K1 antagonists inhibit activation of the vitamin K-dependent clotting factors II, VII, IX, X, protein C and S. These toxins typically take up to 48 hours to cause prolongation in clotting times; clinical symptoms of bleeding may take 4–5 days or longer to develop. Factor VII has a significantly shorter half-life than factors II, IX,

and X, so factor VII depletion results in the initial clotting test abnormalities detected in animals with anticoagulant rodenticide ingestion. However, significant hemorrhage does not begin until factor II depletion occurs 3–4 days after toxin ingestion. Diagnosing anticoagulant rodenticide toxicity in the initial 3–4 days following exposure allows for successful treatment prior to major bleeding.

Many patients present for veterinary care very shortly (e.g., one hour) after ingestion of anticoagulant rodenticide. Unless a concurrent disorder of hemostasis is suspected or clinical bleeding is present, coagulation testing is unnecessary in these patients as long as the client is absolutely certain that exposure occurred recently (e.g., within the past few hours). If exposure has occurred more than 24 hours prior to presentation, or if timing of exposure is unknown, diagnostic testing is indicated. Common testing recommended for anticoagulant rodenticide toxicity includes packed cell volume (PCV), total solids (TS), and clotting times (PT and aPTT). Activated clotting time (ACT) can be tested if PT and aPTT are unavailable. PT prolongation, which usually occurs 48 hours after ingestion, occurs prior to aPTT prolongation due to the short half-life of factor VII (6.2 hours) compared with factor II, IX, and X. aPTT prolongation is typically seen after depletion of factor IX, whose half-life is 13.9 hours. Prolongation of both PT and aPTT is expected prior to significant clinical bleeding following anticoagulant rodenticide exposure. These different test results at various time points after ingestion of anticoagulant rodenticide highlight the critical importance of establishing a timeline of exposure whenever possible.

The "proteins induced by vitamin K antagonism" (PIVKA) test and specific blood tests for anticoagulant rodenticide levels are typically not useful in the acute diagnosis and treatment of the routine small animal patient with anticoagulant rodenticide ingestion because plasma samples must be sent to a diagnostic lab and there is delay in test results. These tests may be indicated when anticoagulant rodenticide toxicity is suspected but the patient has no known exposure; however, samples must be collected prior to treatment, and the clinician must proceed with treatment before test results are available.

Treatment for a patient exposed to anticoagulant rodenticide invariably involves enteral or parenteral vitamin K1 therapy, but the timeline of exposure and symptoms dictates the specific therapeutic plan for each patient. Vitamin K1 (2.5–5 mg/kg/day IM, SC, or PO for up to six weeks) can be started orally in the asymptomatic patient with recent exposure (<48 hours ago). If more than 48 hours have passed since exposure and coagulation tests are prolonged, but clinical bleeding is not observed, a single dose of parenteral vitamin K1 can be given prior to starting oral vitamin K1 therapy. Patients experiencing clinical bleeding secondary to vitamin K antagonists should be treated with fresh frozen plasma (FFP) transfusion in addition to parenteral vitamin K1 administration.

Patients who may have ingested ethylene glycol (EG) present a unique clinical challenge due to the extremely time-sensitive and dangerous nature of this toxicity. Cats exposed to EG less than three hours prior to presentation (and dogs exposed less than eight hours prior to presentation) must be aggressively tested and/or treated. The presence of EG can be proven by blood tests, but available tests are imperfect. Bedside tests include the Kacey Ethylene Glycol Test Strips (Kacey Inc., Asheville, NC) and the Catachem VetSpec Ethylene Glycol Qualitative Test Kit (Catachem Inc., Oxford, CT). These tests are subjective and based on visual determination of color change, and the presence of other substances such as proplylene glycol or ethanol may cause false-positive test results. The results of two small studies led to some concern regarding the sensitivity and specificity of these tests. One study evaluating the Kacey Ethylene Glycol Test Strips published in 2008 reported a sensitivity of only 56–67% for detection of 20 mg/dL EG (a potentially lethal dose for cats) in blood. This study also reported a specificity of 25–50% for detection of 80 mg/dL EG in blood. The authors of the study concluded that the test should not be used as a sole determinant of intoxication due to the risk of both false-positive and false-negative results.

The results of a second study were published in 2014 in the Journal of Veterinary Emergency and Critical Care. This study compared the Kacey Ethylene Glycol Test to the Catachem VetSpec Etylene Glycol Qualitative Test Kit. EG was added to canine blood at concentrations ranging from 0 to 100 mg/dL, and 30 samples were evaluated separately by two individuals. The tests were assigned a score of less than 20 mg/dL, 20–50 mg/dL, or greater than 50 mg/dL. Sensitivity and specificity were 100% for the Kacey test, with good agreement between two readers. In this study the VetSpec test performed less well. Sensitivity and specificity were only 65% and 70% respectively for one reader and 95% and 40% for the other.

A separate publication evaluated an EG test kit designed for use on a chemistry analyzer found in major clinical pathology laboratories (the Hitachi P-modular 800 chemistry analyzer). This test was found to accurately measure blood EG, and results were not significantly altered by the presence of propylene glycol.

Although the development and assessment of new tests continue, most veterinary hospitals do not, at this time, have a reliably sensitive and specific way to measure blood EG levels. Woods' lamp evaluation of the oral cavity, face, vomitus, and urine can provide evidence of

exposure to EG since many formulations contain a fluorescent dye. Unfortunately, since some formulations do not contain added dye, Woods' lamp evaluation cannot be used as a sole diagnostic test. Diagnosis of EG toxicity must therefore be made based on clinical suspicion and the presence of certain findings on any of the following tests: osmole gap, anion gap, urinalysis (calcium oxalate crystalluria), blood chemistry, or abdominal ultrasonography. Ethylene glycol is an effective osmole, and the presence of significant ethylene glycol levels in the blood can result in neurologic symptoms (e.g., ataxia and stupor) due to hyperosmolality.

The presence of significant amounts of EG in the blood leads to an increase in the "osmole gap," which is the difference between measured blood osmolality and calculated blood osmolality (equation 1).

$$\text{Osmole gap} = \text{Measured osmolality} - \text{Calculated osmolality} \quad \text{(Eq. 1)}$$

Osmolality can be estimated using equation 2.

$$\left[\left(1.86\times\left(\text{Na}+\text{K}\right)\right)+\left(\text{BUN}/2.8\right)+\left(\text{Glu}/18\right)\right]/0.93 \quad \text{(Eq. 2)}$$

The normal whole-blood osmole gap has been reported as 3.49 mOsm and the normal plasma osmole gap as −2.01 mOsm. A significant increase in the osmole gap in a patient who may have been exposed to EG or who is showing symptoms should raise clinical suspicion for EG poisoning.

Fatalities due to EG toxicity are caused by acute renal failure as EG metabolism leads to accumulation of metabolic acids such as glycolic and oxalic acid. This accumulation leads to a metabolic acidosis and an elevated anion gap (AG) seen at approximately three hours after ingestion, peaking at six hours, and lasting up to 48 hours. AG can be determined using equation 3.

$$\text{Anion gap} = \left(\text{Na}^{+} + \text{K}^{+}\right) - \left(\text{Cl}^{-} + \text{HCO3}^{-}\right) \quad \text{(Eq. 3)}$$

Normal AG is 12–24 mEq/L in dogs and 13–27 mEq/L in cats. An elevated AG indicates accumulation of unmeasured anions. An elevated AG is not specific to EG intoxication, but an elevated AG 3–6 hours or more after possible exposure to EG may be considered a sign of EG exposure. The oxalic acid formed during metabolism of EG binds calcium, resulting in calcium oxalate monohydrate crystalluria as early as three hours after ingestion in cats (six hours in dogs).

In some cases, EG toxicity may not be diagnosed prior to the development of oligoanuric renal failure. Progressive azotemia may help establish a diagnosis of EG poisoning, but this finding almost always indicates a grave prognosis. Diagnosis of EG toxicity must be made prior to the development of azotemia to allow the best chance at survival. The different clinicopathologic findings at different time points following EG ingestion again demonstrate how important it is to establish a timeline of possible exposure.

The treatment of EG toxicity is similarly dependent on timing of exposure. Definitive treatment of EG ingestion revolves around preventing accumulation of toxic metabolites. Metabolism of EG to glycolic acid by the enzyme alcohol dehydrogenase (ADH) is the most important step in the development of EG toxicity. Veterinary patients have traditionally been treated with IV ethanol administration. Ethanol is metabolized by ADH, and ADH has a higher affinity for ethanol than EG. Administration of ethanol, therefore, can limit glycolic acid accumulation. At the same time, high rates of IV fluids can be given to drive urinary excretion of unmetabolized EG molecules. Ethanol administration can be an effective treatment for EG ingestion, but long courses of treatment are needed and side-effects (including hyperosmolality, CNS signs such as sedation, and GI signs such as vomiting) are frequently observed. ADH inhibitors such as 4-methylpyrazole (4-MP, also known as fomepazole) prevent metabolism of EG to toxic metabolites while offering less risk of side-effects than ethanol. The primary drawbacks to 4-MP are limited availability and relatively high cost compared with ethanol. Cats require very high doses of 4-MP compared with dogs, making cats more likely to develop side-effects such as CNS depression and ataxia following treatment with 4-MP. Treatment of cats with ADH inhibition using ethanol or 4-MP is typically ineffective if not begun within three hours of ingestion, whereas treatment of dogs is typically successfully if started within eight hours of ingestion.

Hemodialysis is a very effective treatment for removal of EG and glycolic acid; 90–95% of circulating EG can be removed in a single hemodialysis session. Intermittent hemodialysis may also effectively treat azotemia and hyperkalemia in patients with acute kidney injury from EG toxicity, allowing time to determine if recovery of kidney function occurs over the span of several weeks.

Regardless of the mode of treatment, prompt intervention is of utmost importance due to the time-dependent nature of this lethal toxin.

Uncertain Exposure to a Known Toxin

When treating a patient who may or may not have been exposed to a known toxic substance, the clinician must formulate a diagnostic testing and treatment plan based on the presence or absence of clinical symptoms, the likelihood of clinical symptoms developing if toxic exposure did in fact occur, and the danger of the toxin involved. The clinician should consider contacting an animal poison control center to obtain the most extensive and up-to-date information regarding the probability of toxicity from any possible exposure to the substance in

question. Patients exhibiting symptoms consistent with toxicity from the substance should be treated as if they have been poisoned, even if exposure cannot be completely confirmed. If symptoms of toxicity are not present and the possible toxicity is not life-threatening, then a "wait and see" approach of close monitoring may be all that is needed. If signs of toxicity are not present, but the toxin to which the patient was possibly exposed carries some risk of significant morbidity, then decontamination (see "Decontamination" later in this chapter) should be considered if appropriate, and close monitoring should be recommended. If the possible exposure involves a toxin conferring serious risk of organ failure and/or death, then aggressive testing to confirm or rule out exposure is recommended. Decontamination and treatment should also be instituted, even if toxic exposure cannot be definitively confirmed.

Certain Exposure to an Unknown Substance

Frequently, small animal veterinarians are presented with a patient who was observed to lick, ingest or otherwise contact an unknown substance. This situation typically involves ingestion of a plant while outdoors. A good familiarity with the local flora will prove useful to the clinician in this instance. Even if the client has obtained a sample of the ingested plant, it may be difficult or impossible for the clinician to identify whether or not the plant is dangerous. If clinical symptoms are present and consistent with a poison known to be present in the local environment, then treatment should proceed as if the poisonous compound in question caused the symptoms.

One commonly encountered situation utilizing this approach is the young, otherwise healthy dog presented for muscle tremors after being exposed to rotten food or compost. In this situation, the clinician cannot be completely certain that there has been toxin ingestion, and even if ingestion is strongly suspected, the exact toxic compound is unclear. The patient in this scenario is typically assumed to have ingested a tremorgenic mycotoxin. Diagnostic testing of the patient should aim to rule out other causes of muscle tremors (hypocalcemia, hypoglycemia, etc.). Once these other common causes have been ruled out, treatment of this patient should involve centrally acting muscle relaxants such as methocarbamol and supportive measures such as IV fluids to prevent dehydration resulting from increased muscle activity in a patient who is unable to drink properly. The client should be informed that tremorgenic mycotoxin toxicity is suspected but cannot be confirmed. If initial diagnostic testing reveals no obvious cause of the symptoms, and if symptoms do not improve over 24–48 hours despite appropriate treatment for tremorgenic mycotoxin toxicity, then further diagnostic testing is recommended to search for a separate cause of the muscle tremors.

Decontamination

Topical Decontamination

Topical exposure to a toxin most often involves parasiticides such as permethrins or pyrethrins. Patients with topical poison exposure should be bathed thoroughly in a mild soap (such as Dawn® liquid dishsoap) as soon as safely possible. Minimum protective equipment for veterinary personnel should include rubber gloves. Eye protection and a rubber apron may be needed, depending on the nature of the toxin involved.

Ocular Decontamination

Eye injury may occur when ocular surfaces contact a caustic irritant. The resultant corneal damage can be minor (only resulting in discomfort) or severe enough to cause melting corneal ulceration. The pH of the ocular irritant strongly influences the severity of corneal injury. Acid compounds injure the corneal epithelium, but alkaline compounds are associated with more severe damage and a higher likelihood of anterior chamber changes and permanent vision impairment. The pH of an ocular irritant can be checked by applying litmus paper to the conjunctival fornix. This may help the clinician prepare the client for the likelihood of severe damage.

Regardless of the specific chemical toxin, the degree of damage is also related to the duration of exposure, so the eye must be flushed as soon as possible. Continuous flushing of the cornea should continue for at least 15 minutes following ocular surface exposure to a toxin; many resources recommend a full 20–30 minutes of flushing. The eye can be flushed using a balanced fluid such as 0.9% NaCl or lactated Ringer's solution (LRS). Tap water is an acceptable flushing solution, but the hypoosmolality of tap water may contribute to corneal edema formation following toxic injury. Bottles of eye wash solution are typically too small (i.e., contain too little volume) to effectively flush the surface of the eye for 15 minutes or longer. The damage caused by severe chemical burns of the cornea can be reduced by using buffered eye wash solutions such as Diphoterine®, but these solutions are not available in most veterinary hospitals.

Gastrointestinal Decontamination

Emesis

Induction of emesis may be indicated whenever a toxin has been ingested and may still be in the stomach. If ingestion has occurred within the previous 4–6 hours, it is reasonable to consider inducing emesis. While usually a safe procedure, there are potential risks associated with inducing emesis, including aspiration pneumonia and esophageal or oropharyngeal injury. In general,

only asymptomatic patients should be made to vomit, as the risk for aspiration pneumonia is greatly increased by CNS dysfunction or neuromuscular weakness. The risk of esophageal or oropharyngeal injury is increased if large or sharp objects have been ingested along with the toxin. Though uncommon, these possible complications must be considered and discussed with the client when deciding whether or not to induce emesis in a patient that has ingested a toxin. Patients that have ingested caustic substances (e.g., bleach) or hydrocarbons (e.g., gasoline) should never be made to vomit. Ingestion of zinc phosphide rodenticide leads to liberation of phosphine gas in the acidic environment of the stomach; induction of emesis following zinc phosphide rodenticide must be done carefully in a well-ventilated area (ideally, outdoors) to reduce the risk of dangerous phosphine gas inhalation by veterinary staff.

Hydrogen peroxide and apomorphine are the two most common agents used to induce emesis in dogs. Due to an increased risk of side-effects, the use of syrup of ipecac, sodium chloride salt, dishwashing liquid or mustard powder is not recommended. Inducing emesis is typically easy in canine patients. Hydrogen peroxide (3%) can be given PO at a dose of 2.2 mL/kg (up to a maximum of 45 mL) and repeated if vomiting has not occurred within 10–15 minutes of administration. Hydrogen peroxide causes vomiting by acting as a local irritant in the oropharynx and stomach. Rarely, protracted vomiting can occur after administration. Occasionally, mild side-effects such as lethargy and diarrhea can occur. Very rare instances of symptomatic gastric ulceration or even gastric dilation and volvulus (GDV) have been anecdotally reported following administration of hydrogen peroxide. A prospective observational study reported a relatively low incidence of mild side-effects (14%) in 70 clinical canine patients following induction of emesis using hydrogen peroxide; no serious or life-threatening side-effects were reported in this study.

Apomorphine is a centrally acting emetic agent that reliably induces emesis in dogs by stimulation of the chemoreceptor trigger zone. It can be given as a 0.03–0.04 mg/kg intramuscular (IM) or IV injection. Vomiting typically occurs soon after apomorphine injection. If vomiting does not occur, dosing can be repeated once or twice more, but the drug may depress the vomiting center in the medulla, so repeat administration may be unlikely to induce vomiting if the first dose was unsuccessful. Conjunctival application of apomorphine is also a very effective way of inducing emesis in dogs. The conjunctiva should be thoroughly flushed after emesis to limit further absorption of apomorphine and decrease the risk of CNS depression or protracted vomiting. PO administration of apomorphine to induce emesis is not recommended due to slow absorption and high first-pass clearance by the liver. If prolonged vomiting occurs after apomorphine treatment, administration of an injectable antiemetic (e.g. maropitant, metoclopramide, or ondansetron) is indicated. Rarely, significant sedation will occur after apomorphine administration. The sedative effects of apomorphine can be reversed using naloxone.

Induction of emesis in cats is more challenging than in dogs. Injectable administration of an alpha-2-adrenergic agonist is currently the method of choice. Xylazine is commonly given at a dose of 0.44 mg/kg IM for this purpose; as much as 1.1 mg/kg can be given. Dexmedetomidine (20–40 µg/kg IM) can also be used. One major drawback to the use of alpha-2-adrenergic agonists for this purpose is that profound sedation may occur. Reversal of the alpha-2-adrenergic agonist using yohimbine (0.1 mg/kg IM or IV) or atipamezole (50 µg/kg IM) is recommended following emesis to prevent sedation from interfering with interpretation of symptoms of poisoning.

Gastric Lavage

When induction of emesis is unsuccessful or contraindicated and an ingested toxicant is likely to cause significant morbidity or mortality, gastric lavage may be considered. Gastric lavage should always be done under general anesthesia (unless the patient is already unconscious), and a cuffed endotracheal tube should always be placed to guard the airway against aspiration of gastric contents. Lavage is performed using warm (body temperature) water given through a large orogastric tube, keeping the head below the level of the chest throughout the procedure to discourage aspiration of gastric contents (which can occur even in the presence of a cuffed endotracheal tube). Initial lavage volumes are typically 5–10 ml/kg, and lavage is repeated until the fluid obtained from the stomach is completely clear. If indicated, a dose of activated charcoal can then be given through the orogastric tube prior to its removal. The tube should be kinked in more than one place during removal from the stomach to prevent fluid within the tube from spilling into the airway. Gastric lavage carries risks, including anesthesia and aspiration pneumonia; careful consideration of the risk:benefit ratio must precede this intervention.

GI Adsorption

Activated charcoal (AC) has been, and will likely continue to be, one of the most common treatments administered to veterinary patients who have ingested a toxin. The use of AC in human medicine has recently been critically reevaluated, and routine use has been discouraged due to a lack of evidence that its administration affects outcome. There have been no published veterinary studies comparing conventional therapy with AC versus conventional therapy alone. Inherent differences

between veterinary small animal patients and human patients make the veterinary application of human guidelines questionable. Veterinary patients may be more likely than human patients to ingest large quantities of toxins, and paradoxically veterinary patients may present for medical care sooner after ingestion than human patients due to the intentional nature of many human intoxications. Furthermore, advanced treatments such as hemofiltration for toxin removal or prolonged, aggressive hospital-based care for treatment of organ dysfunction are more readily available and more often pursued in human medicine than in veterinary patients, making it that much more important to limit toxin adsorption in veterinary patients as much as possible prior to signs of intoxication.

Products containing AC are administered at a dose of 1–5 g/kg body weight PO or via orogastric intubation to bind any remaining toxin within the GI tract and prevent further absorption of the toxin. AC administration is indicated when the ingested poison binds to AC, is likely to cause significant toxicity, and has been recently ingested (within the past 4–6 hours) and/or undergoes enterohepatic recirculation. Repeated dosing (every 4–6 hours for four total doses) is recommended for dangerous toxins for which enterohepatic recirculation is known to occur and no antidote is available. The use of AC-containing products may lead to vomiting, and aspiration of gastric contents or charcoal creates a risk of pneumonia. Injection of an antiemetic prior to AC administration may help decrease the incidence of emesis. AC may bind water within the GI tract, and repeated doses have been associated with dehydration and hypernatremia in rare cases. When repeated doses of AC are needed, many sources recommend the repeat doses be given at a lower dose (for instance, half the initial administered dose), and IV fluid administration is recommended to help prevent significant dehydration. It is also important that veterinarians and clients know which patients have received AC so that the resultant black stools are not misinterpreted as melena.

Activated charcoal binds to most but not all toxins; it does not bind alcohols, heavy metals, or small organic molecules. Use of AC is therefore not indicated for toxic ingestions of xylitol, ethylene glycol, zinc, nitrates, or sodium chlorate, among others. It is important to confirm that the suspected toxin binds to AC prior to administration of AC. If the binding affinity of a poison to AC is unknown by the clinician, a poison control hotline should be contacted prior to administration. Studies have shown that the timing of AC administration in relation to toxin ingestion directly influences the percentage of ingested toxin that is bound within the GI tract. If AC use is indicated, it is important that the treatment be administered as soon as possible.

Few dogs (and almost no cats) willingly ingest AC solutions. One commonly utilized clinical method of administration involves combining the charcoal with a small amount of highly palatable food. While the food binds to the charcoal and reduces binding capacity, a published veterinary study suggests the reduction in toxin-binding capacity is clinically insignificant.

Cathartics

Cathartics are given to speed GI transit times in an effort to decrease the time a toxin is available for absorption within the GI tract. The two types of cathartics used in veterinary medicine are saccharides (e.g., sorbitol) and saline (e.g., magnesium sulfate); sorbitol is the most commonly used cathartic, and it is most commonly stocked in veterinary hospitals as an AC-sorbitol combination product. Because cathartics such as sorbitol act by drawing water into the GI lumen, significant risk of dehydration and hypernatremia exists with repeated use of these products. When a cathartic is used, it is typically only administered as a one-time dose. The most common clinical practice is to give only the first dose of AC with sorbitol, utilizing AC products *without* a cathartic for repeated doses.

Decontamination of Blood

Extracorporeal Therapies

One of the most effective methods to treat certain poisonings is removal using extracorporeal therapies such as hemodialysis and hemoperfusion. Hemodialysis involves circulating blood through an extracorporeal circuit and allowing for transfer of solutes and water across a semipermeable membrane. Toxins are good candidates for removal via hemodialysis if they are relatively small (<1500 daltons), poorly protein bound and with a low volume of distribution. Ethylene glycol and aspirin are examples of compounds that are readily cleared by hemodialysis. Hemoperfusion refers to the direct exposure of blood in an extracorporeal circuit to an adsorbent column of charcoal or (less commonly) a different adsorbent specially designed to bind a specific toxin. Hemoperfusion greatly increases the number of poisons that can be removed using extracorporeal therapy. Hemodialysis and hemoperfusion require specialized, often expensive, equipment and highly trained personnel. The availability of hemoperfusion is currently limited in veterinary medicine, but the number of facilities offering this potentially life-saving intervention will likely increase in the future.

Intravenous Lipid Therapy

Administration of intravenous lipid emulsions (IVLE) is a common therapy for the treatment of poisoning with lipophilic toxins. IVLE therapy was first used to treat

cardiotoxicity secondary to local anesthetic administration in humans. The proposed mechanism of action involved overriding the local anesthetic-induced inhibition of myocardial carnitine acylcarnitine translocase, potentially by mass effect or competitive inhibition, allowing fatty acids to reach the mitochondria and be used for energy production.

Since its initial introduction into the arsenal of available medical treatments, IVLE therapy has proven beneficial in the treatment of lipophilic toxins other than local anesthetics. Many of these lipophilic toxins cause dysfunction to organs other than the heart, yet their effects may still be reversed by IVLE administration, suggesting that IVLE treatment has a different or additional mechanism of action beyond improved free fatty acid availability or intracellular calcium accumulation. The most widely proposed mechanism of action for the beneficial effects of IVLE treatment of patients poisoned by liphophilic substances is the "lipid sink" theory. This theory states that increasing the plasma lipid content "sequesters" lipophilic toxins within the plasma, decreasing movement out of the bloodstream and into target organs such as the brain.

Anecdotal and published reports describe successful IVLE use in the treatment of a wide variety of toxins ranging from local anesthetics (bupivacaine) and vasoactive drugs (amlodipine, propranolol) to antiparasitic drugs (ivermectin, moxidectin) and antidepressant medications (bupropion, etc.). IV lipid emulsions are available as 20% formulations. The optimal dose is unclear at this time, but recommendations have been extrapolated from available human literature, animal research, and veterinary case reports. Current guidelines suggest 1.5–4 mL/kg IV bolus be given over one minute and followed by a constant rate infusion (CRI) of 0.25 mL/kg/min over 30–60 minutes. Patients who fail to respond to this protocol may require additional boluses of 1.5 mL/kg every 4–6 hours for 24 hours. Continued CRI doses of up to 0.05 mL/kg/h for up to 24 hours can be considered for patients who remain severely symptomatic. Utilizing a "lowest effective dose" approach is recommended due to the general lack of information regarding adverse effects of IVLE therapy in veterinary patients.

Reported side-effects in human medicine include infection due to contamination of the lipid product, anaphylactoid reactions, and allergic reaction to the egg or soybean component of the IVLE. A syndrome known as "fat overload syndrome" (FOS) has been observed in humans. FOS is associated with fat embolism, liver dysfunction, or coagulation system dysfunction (thrombocytopenia and prolonged clotting times). These side-effects have not yet been reported in clinical veterinary patients, but the use of IVLE as a treatment for lipophilic toxins is still somewhat new in veterinary medicine. When considering IVLE administration, the clinician must carefully weigh the severity and duration of toxic symptoms against the cost and potential complications associated with this intervention.

Conclusion

Small animal veterinarians commonly encounter acute poisoning. A sound, comprehensive approach to patient care (building on the fundamentals of a good history, physical exam, and diagnostic work-up) is important for diagnosing toxic exposure. A solid understanding of common toxins and appropriate utilization of available resources such as poison control hotlines help the clinician to establish the treatment plan most likely to result in a successful outcome. Exciting new therapies such as hemoperfusion and IVLE administration continue to evolve, making it important for the practicing small animal clinician to remain up to date on the most current available treatments.

Medical Management of Trauma and Burns

Nathan Peterson, DVM, DACVECC

VCA West Los Angeles Animal Hospital, Los Angeles, CA, USA

Etiology/Pathophysiology

The pathophysiology of trauma and burns is complex and explains why trauma and burn wounds are capable of affecting organs distant from the original insult and why the clinical course of disease can be so variable. Our current understanding of the pathophysiology of trauma is based on the theory that both primary and secondary insults contribute to morbidity and mortality. This is termed the *two-hit theory*. Primary insults (first hits) result in direct tissue injury from the trauma or burn (fractures, soft tissue destruction, organ rupture or vascular disruption). These factors are not under the control of the veterinarian. Secondary insults can be further divided into endogenous or exogenous causes. Typical endogenous second hits include shock, hypoxia, ischemia/reperfusion injuries, and infection. Exogenous (interventional) second hits include surgical trauma, anesthetic complications, and transfusion of blood products.

Systemic Inflammatory Response

The magnitude of the primary and secondary insults determines the systemic inflammatory response of the host. Immediately following a trauma load, the patient begins mounting a systemic response composed of both pro-inflammatory and anti-inflammatory components intended to limit entry of microorganisms, on the one hand, and limit secondary tissue damage, on the other. The balance, or lack thereof, determines if the patient will mount an appropriate response, or whether a pro-inflammatory or anti-inflammatory state will predominate.

Plasma levels of primary pro-inflammatory cytokines rise within 1–2 hours following trauma. Secondary pro-inflammatory cytokines begin to rise several hours following trauma and contribute to the systemic inflammation and activation of immune cells associated with severe trauma. The culmination of this activation is an increased number of circulating polymorphic nucleic cells (PMNs) and additional tissue injury.

Concurrent with the systemic inflammatory response (SIRS), an anti-inflammatory response called the compensatory anti-inflammatory response syndrome (CARS) is taking place. The purpose of this response is to minimize the tissue damage induced by the pro-inflammatory response and is achieved through release of anti-inflammatory mediators that reduce the synthesis of pro-inflammatory cytokines by their action on transcription factors necessary for their production.

Coagulation and Inflammation

Activation of the inflammatory system is closely tied to activation of the coagulation and complement cascades. Complement activation occurs through both the contact phase pathway and the classic pathway and results in recruitment and activation of phagocytic cells, induction of the hepatic acute phase response, and degranulation of mast cells. Mast cell degranulation releases vasoactive mediators including histamine, leading to leukocyte adhesion and increased vascular permeability (edema). Activation of the complement system also results in activation of the coagulation cascade although the most important inciting cause of activation of the coagulation cascade in the context of trauma is through the tissue factor pathway. Direct and secondary tissue injury exposes tissue factor (TF) on the endothelial cell surface which then complexes with factor VII (FVII) and activates the coagulation cascade. In severely traumatized patients, activation of the coagulation cascade can result in development of disseminated intravascular coagulation (DIC).

Acute Phase Response

The release of pro-inflammatory cytokines tumor necrosis factor (TNF)-alpha, interleukin (IL)-1-beta, and IL-6 following trauma induces the acute phase response in the liver which results in up-regulation of positive acute phase proteins, including fibrinogen and prothrombin. At the same time positive acute phase proteins are being up-regulated, the production of negative acute phase proteins albumin, protein-C, protein-S, and antithrombin (AT) is reduced. The net effect of the acute phase response is generally in the direction of enhanced coagulation through the increased production of prothrombin, fibrinogen and the decreased production of endogenous anticoagulants protein-C, protein-S, and AT. The resultant hypercoagulable state can contribute to the development of DIC in patients following severe trauma or burns.

Ischemia and Reperfusion

Systemic ischemia can occur following trauma and is attributed to hypoxemia and hypotension immediately following trauma and during the early resuscitative period (<24 hrs). Local ischemia can occur due to blunt trauma, disruption of local blood supply or compartment syndrome. During periods of ischemia, several important intracellular changes occur. As energy stores are depleted, adenosine triphosphate (ATP) levels decrease and ATP is degraded to adenosine diphosphate (ADP) and hypoxanthine. As ischemia continues, intracellular pH decreases and lactate, hypoxanthine and sodium and calcium ion concentrations increase, leading to cellular swelling. Upon reperfusion, oxygen interacts with hypoxanthine, resulting in the formation of reactive oxygen species (ROS). This occurs within seconds of reintroduction of oxygen to ischemic tissues. Reactive oxygen species are capable of causing lipid peroxidation and cell death. The release of ROS into the systemic circulation and their subsequent delivery to the lungs following reperfusion may form the basis for the development of acute lung injury associated with trauma.

The liver and gut may be particularly sensitive to ischemia/reperfusion injury. In fact, ischemia and reperfusion of the gut following shock and subsequent resuscitation result in the gut becoming a source of proinflammatory mediators capable of inducing SIRS.

Traumatic Brain Injury/Spinal Cord Injury

The response of the brain and spinal cord to trauma is unique. Similar to general trauma, brain injury consists of primary (direct result of trauma) and secondary injury (subsequent to primary injury). Secondary brain and spinal cord injury is composed of hemorrhage, edema, vasospasm or enzymatically induced neurotoxicity. As an organ, the brain is particularly sensitive to injury by ROS due to high levels of unsaturated fatty acids and low antioxidant capacity. Periods of hypoxia and hypotension lead to the accumulation of the excitatory neurotransmitter glutamate in the interstitial compartment. High extracellular levels of glutamate in addition to intracellular depletion of ATP lead to accumulation of calcium and sodium ions within the neuronal cell and culminate in cellular dysfunction and death. Because of this, several autoregulatory countermeasures have been developed, including the brain's ability to regulate blood flow across a wide range of blood pressures. However, if hypoxia or shock is severe enough in magnitude or duration, these defense mechanisms are overcome and secondary neuronal injury occurs.

It is important to remember that primary brain injury can impair the autoregulatory functions of the brain, making it susceptible to secondary injury that would otherwise not occur. For this reason, initial resuscitative measures should be focused on improving oxygen delivery to the vital organs, especially the brain.

Burns

Local burns covering less than 30% of total body surface area (TBSA) rarely cause severe systemic effects while severe burns (those covering more than 30% of TBSA) are capable of inducing a syndrome called "burn shock" that is characterized by decreased intravascular volume, reduced cardiac output (CO), and increased systemic vascular resistance.

The physiologic response to burns is generally divided into two distinct phases. The resuscitation phase begins immediately following burn injury and is characterized by depleted circulating volume with increased vascular permeability and protein-rich fluid loss into the interstitial space, resulting in edema formation of both burned and unburned tissue. This phase coincides with a systemic response similar to that observed in severe trauma patients as described above. Hypoproteinemia in burn patients occurs secondary to protein loss in the form of edema fluid and fluid loss from the affected skin surface and can develop during the resuscitative phase of burn management.

Following the resuscitation phase of burn injury (3–5 days), a hyperdynamic/hypermetabolic phase, primarily mediated by counter-regulatory hormones including cortisol, glucagon, and catecholamines, begins. During the hyperdynamic phase, cardiac output is increased and vascular permeability begins to return to normal. In addition to the circulatory changes, an increase in metabolic rate occurs that results in negative

energy balance with protein catabolism, gluconeogenesis, glycogenolysis, hepatic insulin resistance, lipolysis, decreased lean body mass, and fever. Ultimately, energy requirements during this period can be increased threefold above basal metabolic rate.

Patients that suffered burn injuries in an enclosed structure fire are also at risk for developing inhalation injury. The inhalation of hot gas and particulate debris results in direct thermal injury to the airway mucosa and chemical irritation. Patients are at risk for developing upper airway obstruction, bronchospasm, small airway occlusion, pulmonary infection, and respiratory failure. The effect of direct thermal injury and chemical irritation is development of an inflammatory response resulting in interstitial edema formation. The damaged mucosal surface generates large amounts of cellular and necrotic debris, leading to further inflammation and distal migration within the bronchial tree with resultant lower airway plugging. This typically occurs 3–5 days post inhalation injury and, in conjunction with mucociliary dysfunction, can lead to development of bronchopneumonia.

Epidemiology

The incidence of trauma in veterinary medicine is relatively unknown with one large retrospective study finding that trauma accounted for 13% of admissions to an urban referral hospital. When it does occur, trauma in veterinary patients appears to be more likely to affect dogs than cats, with dogs comprising approximately 80–90% of trauma patients. In dogs, the mechanism of trauma is most likely to be blunt trauma associated with vehicular injury followed by sharp trauma and animal attacks. In the feline population, the mechanism of trauma is often unknown. In cases where the mechanism behind the trauma is known, cats are essentially equally as likely to suffer from blunt vehicular trauma, falls from height, crush injury or weapon-related trauma. The prehospital mortality rate of veterinary patients suffering trauma is unknown; in hospital, mortality ranges from approximately 10% to 20%.

Blunt trauma in the canine patient is more thoroughly described. The thorax and extremities are the most likely sites of injury from blunt trauma in dogs, with pelvic fracture, head trauma, and abdominal trauma occurring less frequently. The most common thoracic injuries incurred are pulmonary contusions, pneumothorax, and chest wall trauma/rib fractures. In blunt abdominal trauma, the most commonly encountered injuries are hemoperitoneum (25%), body wall hernia (5%), and rupture of the urinary system (3%). The two most commonly encountered orthopedic injuries are pelvic fractures and long bone fractures. Axial orthopedic injuries are relatively uncommon. Head trauma is more likely to be encountered in animals with a higher total trauma load and is associated with a worse outcome

Little is known about the incidence of penetrating ballistic injuries in dogs and cats although a recent study of military working dogs sheds some light on the topic. Obviously, military and law enforcement working dogs are at a higher risk than the general pet population of ballistic trauma and that trauma is more likely to be due to high-velocity/high-energy projectiles (rifle bullets). A higher incidence of penetrating ballistic injury is also likely in young, male dogs of the working breeds with lower velocity/energy ballistics (shotgun pellets) more likely.

Signalment

Young (1–3 years) large-breed dogs of both sexes are more likely to suffer blunt trauma (hit by car) than small-breed dogs. Conversely, small-breed dogs are more likely than large-breed dogs to be victims of animal attacks, with males being more commonly affected than females. Male cats are more likely to suffer trauma associated with vehicles or animal interaction than female cats while female cats appear more likely to fall from heights. Burn injuries most often occur in the veterinary hospital setting (heating pads) or structure fires; there is no species, breed or sex predilection.

History and Clinical Signs

The diagnosis of trauma is generally made based on history and physical exam findings rather than diagnostic test results. Often, the medical history is incomplete and it is not uncommon for the animal to be presented by a Good Samaritan rather than the owner. Cats frequently present with no history but with physical exam findings that are consistent with trauma.

Clinical signs associated with trauma will be dependent on the mechanism behind the trauma and the location on the body at which that trauma was inflicted. Typical injuries following trauma include fractures, contusions and abrasions, bruising or bleeding. Any animal presenting with one or more of these findings should be considered to have suffered trauma until proven otherwise. Blunt trauma patients are frequently presented with few outward signs of trauma but often have difficulty breathing, reluctance or inability to ambulate or decreased mentation. Initially, clinical signs may be mild and the animal may appear stable due to the catecholamine surge associated with the fight or flight response. Animals suspected of

suffering blunt trauma should be reevaluated frequently for new clinical signs or progression of existing clinical signs.

Penetrating trauma is much less difficult to diagnose, as these patients will have visible external wounds consistent with sharp or ballistic injuries. Very often in penetrating trauma, the amount of apparent external blood loss is small and animals with thick coats should be closely inspected for small penetrating wounds.

Diagnosis

Trauma is not often a diagnostic challenge. However, elucidating the extent of injuries can be. In all cases of suspected trauma, a complete medical history and a detailed description of the traumatic event, if possible, are essential. Owners should be asked about the patient's behavior immediately following the traumatic event. Specifically, the owner should be questioned about loss of consciousness, ambulation status, and whether the pet has urinated since the event. The owner should be asked to estimate the speed of the vehicle, height of the fall, and size of attacking animal, as applicable. Additionally, the owner should be asked to describe where on the pet they believe most of the trauma occurred. If a car hit the pet, the owner should be asked if the pet was seen traveling under the car or tire. If the pet was attacked by an animal, it should be determined if the pet was bitten and released or clenched and shaken. Finally, if a patient fell from height, the type of substrate upon which they landed should be ascertained.

A complete physical examination should be performed, with special attention paid to the neurologic system and thoracic and abdominal cavities. When evaluating the neurologic system in a trauma patient, a stepwise approach targeting life-threatening injuries first is utilized. The patient's mentation and level of consciousness (LOC) should be evaluated and their motor activity should be noted. Decerebrate rigidity (extension of all four limbs and opisthotonus) is associated with brainstem compression and altered LOC. Decerebellate rigidity (extension of forelimbs with hindlimb flexion) indicates cerebellar herniation and may be associated with normal or altered LOC. Motor function should be noted, taking care to discriminate between spinal reflexes and voluntary movement. Finally, brainstem reflexes are assessed. Pupil size, symmetry, and responsiveness are evaluated. Attempts should be made to elicit an occulocephalic reflex, taking care to avoid exacerbating possible cervical injuries.

Following evaluation of the neurologic system, the thorax should be evaluated for evidence of trauma. A visual inspection of the thorax should be performed and any lacerations, puncture wounds, abrasions or bruising should be noted. The patient should be observed while breathing prior to auscultation. Careful attention should be paid to the rate, depth, and pattern of breathing. Paradoxical movement of the thoracic wall inward during inspiration (flail chest) is indicative of segmental fracture of contiguous ribs. Thoracic auscultation should be performed in a quiet environment. The presence of breath sounds should be evaluated. Decreased breath sounds ventrally may indicate the presence of pleural fluid whereas decreased or absent breath sounds dorsally may indicate the presence of pneumothorax. In addition to ventral and dorsal differences, the breath sounds in each hemithorax should be compared to determine if unilateral pleural space disease (e.g., tension pneumothorax) is present.

Once the presence of breath sounds is confirmed, the quality of the sounds should be evaluated. Increases in bronchovesicular sounds or the presence of focal or diffuse crackles may indicate pulmonary contusion or hemorrhage. Detection of borborygmi within the thoracic cavity indicates herniation of abdominal contents through the diaphragm. Auscultation of the trachea should also be performed. Tracheal injury may result in loud guttural sounds while laryngeal injury may result in higher pitched wheezes (stridor).

The oral mucous membranes should be evaluated for color and capillary refill time (CRT). Pale mucous membranes can be present from anemia or peripheral vasoconstriction and decreased cardiac output, as seen with shock. Cyanosis may be observed if severe pulmonary or pleural space disease is present. Normal CRT is 1–2 seconds. Prolongation of CRT is consistent with decreased cardiac output and early to late decompensated shock. Patients in compensated shock may have a brisker than normal CRT and mucous membrane color may be bright pink to red.

The presence of cardiac sounds should be confirmed and the rate and regularity of the rhythm should be noted. Tachycardia can occur secondary to shock, pain or anxiety. Bradycardia may occur during shock in cats, but its presence in dogs is a harbinger of circulatory collapse and cardiopulmonary arrest. The absence of heart sounds may indicate pleural space disease (hemothorax), pericardial effusion or cardiac arrest. Pulses should be palpated during cardiac auscultation and should be evaluated for strength and synchrony with the heart. Heart sounds that do not generate a palpable pulse or pulses of varying strength are abnormal and electrocardiography should be considered. Severe peripheral vasoconstriction as seen in shock states results in the distal limbs being cooler to the touch than the trunk. A rectal temperature below normal is consistent with decompensated shock and should be considered a negative prognostic indicator.

Evaluation of the abdomen consists of visual inspection and palpation. Small puncture wounds over the abdomen, especially puncture wounds associated with animal bites, may belie severe trauma to the abdominal wall or abdominal viscera. Abdominal distension with or without a palpable fluid wave may occur with traumatic hemoabdomen. Palpation of the urinary bladder should be attempted although the presence of a palpable urinary bladder does not exclude the possibility of uroabdomen. A rectal exam should be performed in any animal that suffered blunt trauma to the caudal half of the body. Palpation of the pelvic ring for fractures and evaluation of anal tone are important components of a complete physical exam.

Assessment of the abdomen with ultrasound is becoming commonplace and has been shown to be a more sensitive indicator of free abdominal fluid than blind four-quadrant abdominocentesis or diagnostic peritoneal lavage. To perform an abdominal focused assessment with sonography for trauma (FAST) exam, the patient is placed in either left or right lateral recumbency. The ultrasound probe is placed at the first location on midline just caudal to the xyphoid process (diaphragmatico-hepatic position). The probe is then rotated cranially, caudally, and laterally in both directions. If no free fluid is observed then the probe is moved to the second site. The process is repeated, targeting the four points of investigation: diaphragmatico-hepatic, spleno-renal (left body wall over the left kidney), cysto-colic (midline over the urinary bladder), and hepato-renal (right body wall over the right kidney). If free fluid is found, the test is considered positive and an attempt should be made to obtain a sample for evaluation.

In most cases, orthopedic and cutaneous wounds are not immediately life threatening and their evaluation should complete the physical examination when the patient is deemed stable. The patient should be fully evaluated for the presence of lacerations, puncture wounds, abrasions or bruising. Gross deformity of limbs is assessed followed by a detailed orthopedic exam targeting long bones and joints of the appendicular skeleton. If not already done, the animal should be observed ambulating, if able. Radiographs of any areas of pain or instability should be obtained to determine the extent of the injuries. Wounds should be gently clipped to facilitate assessment.

Burn-Specific Considerations

When evaluating patients that have been burned, it is important to assess both the depth of the burn and the TBSA affected. Burn depth is classified as follows: superficial burns, superficial partial thickness, deep partial thickness, and full thickness. This terminology has supplanted the older classification scheme of grading burns by degree and provides a better description of burn severity. It is important to remember that the depth of the burn may vary across the affected area. Superficial wounds are erythematous and may have a dry, flaky appearance. Superficial partial-thickness burns are erythematous and moist. They blanch and blisters may be present. Deep partial-thickness burns are characterized by an absence of blisters and they appear waxy with reduced pain sensation. Full-thickness burns are white and may have eschar formation. Hair is easily plucked from the burn site.

Special attention should be paid to the airways of patients that have suffered burns in fires. The oropharynx should be evaluated for the presence of soot and the thorax should be carefully auscultated for evidence of airway or pulmonary parenchymal injury. If the animal smells of smoke then there is a high likelihood that some degree of inhalation injury is present. Notation of respiratory rate and effort should be made immediately and respiratory patterns and oxygenation status should be reevaluated regularly.

Therapy

The treatment of trauma patients can be divided into two distinct phases. The primary or acute phase of trauma management is focused on restoration of systemic and local oxygen delivery to preinjury levels to minimize secondary ischemic injury. The second phase of trauma management lasts until the patient is discharged and centers on maintaining oxygen delivery, definitive treatment of wounds or fractures, provision of nutritional support, and pain management.

Primary Phase

Successful resuscitation begins with recognition of its need. Resuscitation should be directed at reexpansion of effective circulating volume and re-establishment of systemic and local blood flow. The exact method of resuscitation is less important than the goals that are targeted. Classic resuscitation endpoints have focused on macrocirculatory findings such as heart rate, pulse quality, and blood pressure. Recent developments in shock treatment have identified microcirculatory markers that may be better for determining when resuscitation is complete (i.e., adequate oxygen delivery and usage has been restored).

Beyond the traditional resuscitation endpoints, the evaluation of biochemical markers such as base deficit, lactate, and central venous oxygen saturation has been advocated for use in veterinary medicine. The rationale

for using biochemical markers depends on the fact that cellular hypoxia may continue despite normalization of traditional resuscitation endpoints and the selected markers can detect this ongoing oxygen debt. If undetected, occult shock can be prolonged and can lead to further secondary injury. The best approach for determining when resuscitation is complete is one that incorporates both traditional and goal-directed endpoints.

Volume expansion should be achieved using replacement crystalloid fluids, hypertonic crystalloid fluids, synthetic colloids or blood products (packed red blood cells, fresh frozen plasma, fresh whole blood) as needed, although low-volume resuscitation (hypertonic saline and synthetic colloid) should be considered as the best choice for patients suffering head trauma or pulmonary contusions to minimize the likelihood of overresuscitation and exacerbation of vascular leak. There is no evidence that achieving supraphysiologic values for any of the macrocirculatory variables confers a benefit; on the contrary, overresuscitation may lead to increased morbidity (wound edema, fluid overload, dilutional coagulopathy) and should be avoided. Once normalization of macrocirculatory variables occurs then biochemical analysis should be performed to determine if oxygen debt is ongoing.

The provision of supplemental oxygen should be considered in any patient that has suffered trauma to the thorax or head, any patient in shock, or any patient that may have suffered inhalation injury. The ideal method to provide supplemental oxygen would allow the animal to move freely without restraint and would not contribute to stress. Oxygen cages or chambers approach this ideal. Flow-by oxygen or oxygen provided by facemask may prove useful during the initial evaluation period when it is imperative that the animal be handled. Nasal cannulation using purposemade nasal oxygen prongs is well tolerated by some patients and may allow for provision of supplemental oxygen without significant restraint. In rare circumstances, it may be necessary to secure an airway via orotracheal intubation or tracheostomy. In these cases, 100% oxygen is provided via an anesthetic circuit or self-inflating rescue bag.

Early analgesic management is an important part of the resuscitation phase of trauma management. Once it is determined that the patient's life is not in immediate danger, analgesia should be administered. In general, veterinary patients are less sensitive to the respiratory depressant effects of opioid medications and due to the minimal impact on cardiac indices and their reversibility, pure opioid agonists (morphine, hydromorphone, oxymorphone or fentanyl) should be considered the analgesic of choice in the acute setting. Head trauma patients should be treated for pain once it is determined that their neurologic status is stable. Completely withholding analgesia from head trauma patients is no longer advocated. Adequate analgesia improves patient comfort, facilitates examination, and improves healing.

Primary Wound Management

The goal of wound management during the primary phase of treatment is to prevent further contamination of the wounds and prevent additional tissue injury from occurring. Wounds should be clipped, cleaned with an antiseptic solution (chlorhexidine or betadine) and lavaged with saline. Following lavage, the wounds should be gently probed for depth and extent and then covered with a nonadherent sterile dressing until the patient has been stabilized and definitive treatment is possible. Very recent thermal burn wounds should be lavaged with cool saline to arrest ongoing thermal injury and should then be covered with silver sulfadiazine and a nonadherent bandage. Most chemical burns can be immediately lavaged with tap water for 30 minutes although some alkaline agents may take longer to remove. Elemental metals, including solid sodium, can ignite when they come in contact with water and should instead be covered with mineral oil. Wounds should never be allowed to go unaddressed for longer than 2–4 hours.

Any gross deformities suggesting luxation or fracture should be identified. If fractures are present distal to the stifle or elbow, the limb should be immobilized with a soft bandage, ensuring that the joints above and below the affected area are incorporated. Attempts to reduce fractures are not necessary in the acute phase of management. Fractures of the humerus, femur, pelvis or scapula are not bandaged due to muscular coverage and inability to achieve adequate immobilization. Patients with suspected cervical or spinal fracture or luxation should be sedated, treated for pain, and immobilized using a backboard to prevent further injury to the spinal cord. If sedation or analgesia is inadequate, these patients often struggle and can exacerbate their injuries. Luxations are treated in a similar fashion to fractures and attempts at reduction should be delayed until the patient's condition has stabilized.

Secondary Phase

The secondary phase of treatment begins when the endpoints of resuscitation have been met and the patient is either admitted to the hospital or moved to surgery. As stated previously, the focus of the secondary treatment phase is ensuring adequate oxygen delivery is maintained and establishing definitive treatment for surgical wounds. Additionally, at this stage supportive care including nutritional support, analgesia, and preventive nursing care is considered.

Fluid Therapy

Arguably the most important part of medical management of trauma patients is fluid therapy. Trauma and burn patients have unique fluid needs that require special consideration. Judicious use of crystalloid fluids in patients that suffer thoracic trauma and, in particular, those that develop pulmonary contusions is needed. It should be remembered that endothelial cell dysfunction and perturbations in vascular integrity might contribute to fluid loss from the intravascular space. Excessively high volumes of crystalloid fluid may exacerbate pulmonary contusions due to their rapid redistribution into the interstitial space following administration. Patients with head trauma should be treated in a similar fashion. If brain edema develops secondary to exuberant fluid resuscitation, cerebral blood flow may be impaired. This concern must be balanced by the need to maintain adequate blood pressure for brain perfusion.

Hypoproteinemia is common in trauma patients, especially following burn injury, animal bites, or crush injury. The routine use of synthetic colloids in veterinary medicine is somewhat controversial due to concerns associated with development of coagulopathy and possibly renal failure. However, no clinical veterinary trials to date have demonstrated a negative association and their use should be considered to maintain colloid osmotic pressure and reduce edema formation in nonaffected tissue. In addition to its importance for maintaining colloid osmotic pressure (COP), albumin is an important carrier molecule and facilitates healing. Therefore, canine patients may benefit from receiving human serum albumin or canine-specific lyophilized albumin rather than synthetic starches for colloidal support.

Pain Management

The importance of effective pain management goes beyond the ethical consideration of ameliorating pain. The presence of pain causes increases in sympathetic tone and catecholamine secretion, leading to increased cardiac output, peripheral vascular resistance, and myocardial oxygen consumption. While important for the fight or flight response, these changes, if chronic, further impair oxygen delivery to tissues. In addition to the cardiovascular effects of pain, a neuroendocrine response occurs, resulting in elevated levels of catabolic hormones including cortisol while a concurrent decrease in the anabolic hormones insulin and testosterone is present. The net result of the neuroendocrine response is the development of a catabolic state characterized by hyperglycemia, type B hyperlactatemia, and ketogenesis. Treatment of pain reduces or eliminates these responses, facilitates patient evaluation, improves patient quality of life, and leads to more rapid healing and reduced morbidity.

Patients that suffer severe trauma or burns should be considered to be very painful and analgesia should be provided liberally. The best method of pain management in traumatized or burned patients utilizes a multimodal approach. Pure opioid agonists are the mainstay of pain management and should be provided early in the course of treatment. Opioid medications have no ceiling effect, meaning that there is no maximum dose at which further administration would not be expected to affect a result. In most cases, administration should be continued throughout the duration of hospitalization. While opioids are capable of depressing respiratory drive in veterinary patients, this is rarely clinically relevant. If there is concern over a patient's ventilatory drive then the dose of opioid can be reduced or broken into aliquots and administered to effect.

The dissociative agent ketamine has some analgesic properties, particularly for superficial pain. More importantly, perhaps, are the n-methyl D-aspartate (NMDA) antagonistic properties of ketamine that may alter spinal modulation and prevent or ameliorate central sensitization (wind-up). In order to derive the full benefit of ketamine with regard to sensitization prevention, it should be administered for at least 24 hours as a constant rate infusion (CRI) (5–15 μg/kg/min). The use of ketamine alone is not effective for deep or visceral pain and can result in behavioral changes, therefore ketamine should almost always be administered in conjunction with an opioid. When discontinuing ketamine for patients that have been on a CRI for longer than 24 hours, a gradual reduction of the infusion rate over several hours is used to prevent behavioral changes associated with abrupt discontinuation.

Clinically, the alpha-2-agonists are most commonly used for sedation although their use for pain management is becoming more common. Their short half-lives and reversibility make them theoretically attractive options in many trauma patients but careful consideration should be taken prior to their use since clinically relevant cardiovascular side-effects are possible. Animals in shock or with significant heart disease (especially diseases causing decreased systolic function) should not be administered alpha-2-agonists. A CRI is often employed to most effectively use this class of drugs as a component of the pain management protocol. When used at rates of 0.5–2 μg/kg/h, dexmedetomidine can result in anxiolysis and analgesia without significant cardiovascular side-effects.

Regional or local anesthesia should be considered as an adjunct to traditional, systemic analgesic methods. The use of regional or local anesthesia often requires coordination with the surgical team since these interventions often require general anesthesia or sedation to be performed. Placement of diffusion catheters for repeated administration of local anesthetic medication should be

considered at the time of surgery, if applicable; their use in contaminated wounds (bite wounds) should be avoided, however. Epidural administration or placement of an epidural catheter can provide excellent pain management for animals with pelvic limb or pelvic ring trauma. If sacral fracture or sacroiliac luxation is present or the landmarks used for epidural administration are disrupted then epidural administration should not be performed. Local anesthetic drugs can also be used systemically, with IV infusion of lidocaine being useful as both an analgesic adjunct and a promotility agent for management of ileus.

Both blunt trauma and burn injury are capable of inducing a very pronounced inflammatory state. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) can be very beneficial in these patients. However, animals that are severely traumatized or are in shock should not be administered NSAIDs until all tissue perfusion has normalized and is not anticipated to change abruptly. Patients with severe soft tissue injury or crush injury are at risk for development of myoglobinuria and renal failure. Any animal that has pigmenturia or evidence of renal insufficiency should not receive NSAIDs. The decision to use NSAID medications should be deliberate and if case selection is appropriate then NSAIDs may prove to be a very useful analgesic adjunct. Due to the risk of systemic side-effects, including further impairment of the already compromised immune system in these patients, animals that have suffered severe trauma or burn injury should not receive corticosteroid medications unless specifically indicated.

Many animals that suffer severe soft tissue injury require repeated sedation events on concurrent days or even multiple sedation events within the same 24-hour period. Patients that are going to require repeated sedation should be identified early in the course of hospitalization and measures should be taken to coordinate their care. Following repeated sedation with the same anesthetic medications it is common to see recovery times become more prolonged and patients require larger doses of drugs to achieve the same level of sedation due to the development of tolerance. It is good practice to alter the sedation protocol every few days to prevent development of tolerance or toxicity with repeated dosing such as reported with propofol administration in cats. Additionally, animals that are sedated serially are at risk for nutritional deficiency due to repeated fasting. Efforts should be made to sedate the animal at the same time every day to allow for the most opportunities to provide nutrition.

Nutrition

The benefits of enteral nutrition (EN) for critically ill patients are well documented and include stimulating production of local antibody, prevention of villous atrophy and prevention of gut-derived inflammatory complications. There are many ways of providing EN, including voluntary ingestion, force feeding or syringe feeding, nasogastric, nasoesophageal or nasojejunal tube feeding or surgically placed feeding tube (esophagostomy tube, percutaneous gastrostomy tube, surgically placed gastrostomy tube, jejunostomy tube or gastrojejunostomy tube). The best way to provide EN will likely vary on an individual case basis and consideration should be given to several factors when deciding the best method for each patient.

Nasoesophageal or nasogastric feeding tubes are useful for animals that are not stable enough for an anesthetic event or for those that need a temporary bridge to voluntary eating or placement of a longer term feeding tube option. Nasogastric tubes can be useful for gastric decompression in animals with severe ileus and delayed gastric emptying. One major limitation to the use of nasoenteral feeding tubes is the limited number of diets that can be administered through the small diameter of the tube. Although generally well tolerated in the hospital setting, these tubes are not particularly useful to send home with patients. Nasoenteral feeding tubes can be used in most veterinary patients but some small dogs and cats may not be able to accommodate the tubes comfortably within the nasal cavity.

Animals that require a definitive surgical treatment may benefit from placement of a longer term feeding tube option at the time of surgery. Esophagostomy tubes or PEG tubes can be placed quickly in patients under general anesthesia. Esophagostomy tubes can be used for provision of nutritional support immediately following placement but are often limited in the types of food that they can accommodate. Tube clogging is a common problem and may necessitate altering the food formula to a more watery consistency. Percutaneously placed gastrostomy tubes cannot be used for nutritional support for the first 24 hours to prevent leakage of gastric contents until a fibrous adhesion forms at the stoma. Surgically placed gastrostomy or gastrojejunostomy tubes can be utilized immediately.

The optimal timing of implementing nutritional support is not known but evidence suggests that earlier is better. The clinician should strive to provide nutritional support within the first 24–48 hours following severe trauma or burns. Patients that are hemodynamically compromised should not have nutritional support begun until they are fully resuscitated and stable.

When starting nutritional support, it is important to have a plan in place for meeting nutritional requirements. There is no evidence that provision of calories in excess of basal energy requirement (BER) is beneficial; in fact, it may be detrimental. Many formulas are available for calculating caloric requirements but the basal energy

formula 30(BW in kg) +70 = kcal/day is both easy to use and remember. When instituting a feeding plan, begin by feeding a fraction (1/3 to 1/2) of the calculated resting energy requirement (RER) for the first 24 hours with the goal of achieving full RER over the next 48–72 hours. It is common for the actual delivered kcal to be less than the calculated requirement due to the fact that animals may be intolerant of the volume or rate required to meet the RER, the need to water food down (reducing the caloric density) to prevent tube clogging, or the necessity to fast animals for sedation or anesthetic events. Selection of a calorically dense formula (≥1 kcal/mL) is best in most settings to ensure that the caloric target is being reached. If available, the use of immune-modulating formulas enriched with omega-3 fatty acids and antioxidants may be a good choice.

Parenteral nutrition (PN) has been associated with a variety of complications such as hyperglycemia, hyperlipidemia, electrolyte disturbance (hypophosphatemia, hypokalemia), and septicemia. Although enteral nutrition is always preferable to parenteral nutrition, sometimes it is not feasible due to intolerance of EN or nonfunctional GI tract (severe ileus, preexisting disease). For patients that were healthy prior to trauma, PN is not considered necessary for the first 5–7 days of hospitalization while the patient's progress is monitored. If anorexia persists or GI dysfunction becomes evident then PN should be instituted.

Trauma patients are at high risk for development of ileus due to voluntary or involuntary immobilization, opioid administration, pain, and general anesthesia. Aggressive management of ileus should be attempted with metoclopramide, cisapride, lidocaine, erythromycin or ranitidine. Consideration should be given prior to routine treatment with H2 blockers due to the potential for bacterial overgrowth in the proximal GI tract and subsequent complications. Ideally, the use of gastric alkalinizing medications would be based on evidence of gastric ulceration or esophagitis or the probability of either of these complications developing.

Transfusion

Severely traumatized patients may require red blood cell or plasma component therapy due to hemorrhage or development of complications such as DIC. Red blood cell transfusion increases the oxygen-carrying capacity of the blood and helps to reestablish the oxygen reserve normally present in health. Determining a transfusion trigger is clinician dependent and no clear guidelines have been established. The decision is made on a case-by-case basis, carefully weighing the pros and cons of each transfusion. As a general rule, the more acute the drop in hemoglobin, the higher the transfusion trigger since the necessary time to adapt to the decrease in blood oxygen content has not passed. If a patient is exhibiting clinical signs associated with anemia, is in hemorrhagic shock refractory to crystalloid or colloid resuscitation, or is undergoing a planned surgical procedure with anticipated blood loss then transfusion of red blood cells should be considered. The target packed red blood cell volume (PCV) for blood transfusion is also unknown but achieving a PCV of 25–30% is reasonable, with little evidence that higher values are beneficial. Improving blood oxygen content can subsequently improve wound healing and prevent or ameliorate secondary injury associated with ischemia or inadequate oxygen delivery.

Since blood transfusion is becoming more common in veterinary medicine, it is important to obtain a full transfusion history from the owner prior to administration of any blood product. Pretransfusion testing will vary by case according to how urgently the product is needed. If time allows then complete pretransfusion testing, including blood typing and major cross-match, should be performed. Blood typing of cats is mandatory in all cases regardless of time sensitivity due to the potential for fatal reactions to first-time transfusions. Cross-matching of cats should be considered in all transfusions if time permits due to the prevalence of preformed antibodies in this species. It is not necessary to cross-match dogs receiving their first blood transfusion, as the existence of preformed antibodies is very uncommon, and in the emergency setting a universal donor or DEA 1.1-negative donor unit can be given with little to no pretransfusion testing. Animals that require multiple transfusions during a hospitalization should have a major cross-match performed for all transfusions occurring 72 hours after the first due to the risk of severe hemolytic transfusion reaction.

The rate at which blood is administered is determined by the patient's volume status and cardiovascular stability. In patients that are in hypovolemic shock secondary to massive hemorrhage, blood can be administered as fast as it will flow into the patient. Under more controlled circumstances, most blood transfusions are started at reduced rates that are gradually increased with the goal of completing the transfusion over several hours. Close attention should be paid to vital signs in an effort to detect transfusion reactions early.

Fluid overload is an uncommon complication in dogs receiving packed red blood cells but may be a concern in cats (especially if underlying heart disease is present). In addition to volume concerns, each red blood cell transfusion will expose the patient to foreign antigen and will stimulate an immune response to a greater or lesser degree. In patients that are already experiencing systemic inflammation, this second hit may precipitate further injury, as in the case of transfusion-related acute lung injury.

Sepsis Prevention

While animals with penetrating injuries or with grossly contaminated wounds should be started on antibiotics, the use of prophylactic antibiotics in animals that have suffered blunt trauma without disruption of the integument is controversial. When necessary, first-generation cephalosporins are generally adequate for wounds not related to animal bites. Patients that suffer animal bites should be treated with potentiated penicillins or fluoroquinolones to cover common oral pathogens. Available evidence suggests that burn patients should not routinely be administered prophylactic antibiotics. If signs of infection develop, such as redness, new or worsening pain, or malodorous or purulent discharge, then antibiotic therapy should be instituted at that time. As always, antibiotic therapy guided by culture results is the best practice and when possible, cultures should be obtained prior to administration of antibiotics.

Strict adherence to catheter hygiene should always be followed (gloves worn, IV lines kept off the floor), and IV catheters should be monitored daily for signs of phlebitis or infection and should be replaced or removed if present. Any patient that develops a fever while in hospital should have all catheter and tube sites inspected for signs of infection. In addition to daily visual inspection, catheter wraps should be changed daily. Urinary catheters should be connected to a closed collection system upon placement and the collection system should be changed daily. IV fluid lines should be changed on a routine basis and disconnections of the IV fluid line from the patient should be avoided as much as possible. Any gross contamination of the IV line should be immediately cleaned and the line should be changed.

Severely traumatized or burned patients should always be handled with gloves to prevent colonization with bacteria from caregivers. Colonization with methicillin-resistant *Staphylococcus* species is common in healthcare professionals and can put patients at risk if normal barrier prophylaxis and hand hygiene are not followed.

Monitoring

Critically ill trauma and burn patients are at risk for decompensating acutely due to myriad causes including multiorgan failure, acute lung injury or acute respiratory distress syndrome (ARDS), pulmonary thromboembolism, pneumonia, DIC or sepsis. Diligent monitoring of these patients will allow the clinician to identify possible complications early and increase the likelihood of successful intervention.

Severe trauma patients, especially those that have suffered traumatic brain injury or thoracic trauma, should be placed on a respiratory watch and have both respiratory rate and effort evaluated at least hourly. Continuous electrocardiographic monitoring should be strongly considered in all trauma patients, especially those with thoracic trauma. If continuous ECG monitoring is not feasible then heart rate and pulse synchrony should be checked frequently. Blood pressure monitoring should be performed regularly. Monitoring mentation, central venous pressure, direct arterial pressure, pulse oximetry, urine output, and body weight can provide invaluable information on progression of the patient's condition. Laboratory monitoring should include serial blood gas analysis (venous or arterial), blood lactate and blood glucose measurement. Serum biochemistry analysis, complete blood count, and urinalysis should be performed at admission and then every 2–3 days as the patient's condition dictates. Coagulation assays should be considered if DIC is suspected or if the patient has had substantial blood loss or blood component therapy. Serial radiographs are useful for monitoring progression of pulmonary injury and serial ultrasound can aid in monitoring progression of abdominal disease.

The nursing staff is often the first to be aware of a patient's changing condition and the longer they work with a patient, the more attuned they become to subtle changes in status. Therefore, a good working relationship with the nurses providing treatments is imperative for successful monitoring of severely injured patients.

Preventive Nursing Care

It is important to prevent trauma patients from remaining recumbent for long periods of time. Nonambulatory patients should be repositioned several times a day to prevent pressure sores from developing. Mobility facilitates mucus clearance from the lower airways and supervised walks should be encouraged as soon as possible. If walks are not possible, patients should have passive range of motion performed several times a day. In addition to encouraging mobility, recumbent patients should be provided with soft bedding to distribute weight over pressure points and further decrease the likelihood of pressure ulcer formation.

A concerted effort should be made to keep the patient clean and free from fecal or urine contamination. Prompt removal of waste and bathing when necessary will aid in prevention of fecal or urinary scalding that can lead to compromise of the integumentary barrier. If urine or fecal scalding is present then the fur from the area should be clipped, the area should be cleaned with dilute antiseptic solution and a barrier ointment such as zinc oxide should be applied several times a day. Many of these patients may require urinary management such as intermittent bladder catheterization, indwelling urinary catheter placement or intermittent urinary bladder expression. The presence of an indwelling urinary catheter is a risk factor for development of urinary tract infection and can be an important contributor to patient morbidity. If a urinary catheter is present then

the collection system should be maintained closed to reduce the chances of ascending contamination and urinary tract infection.

Patients with bandages covering wounds should have the bandages changed immediately if strikethrough is present or if the bandage becomes contaminated with feces or urine to prevent bacterial contamination of the wound bed. Regardless of contamination, bandages should be changed at least daily initially.

Burn-Specific Therapy

In the early postresuscitation phase of burn management (2–24 hours), patient fluid needs are likely to be much greater than would normally be expected. With this in mind, care should be taken to avoid excessive fluid administration and the goals of fluid administration should focus on maintaining blood pressure and urine production within normal limits.

Due to decreased local perfusion, burn wounds should be treated with topical antimicrobial agents and covered with nonadherent dressings after initial decontamination to prevent bacterial colonization rather than relying on systemic antimicrobial therapy. The topical antimicrobial of choice is silver sulfadiazine (SSD), which has a broad antimicrobial spectrum and few side-effects. Manuka honey can be used as an alternative to SSD.

Rehabilitation

Comprehensive management of trauma and burn patients does not end with hospital discharge. These patients often require weeks to months of physical rehabilitation, which should begin in hospital, to regain lost mobility and to complete the healing process. Often patients are discharged earlier than planned due to financial limitations of the owner. In these instances, it is imperative that in-depth discharge instructions be provided to the owner on how to perform nursing care, including passive range of motion, tube feedings, bladder expression, medication administration, etc. Consideration should be given to referring the client to a certified veterinary rehabilitation specialist, especially if spinal trauma, long bone fractures or severe soft tissue injuries were present. Burn patients are at risk for development of contracture as burns heal and physical therapy can help to prevent severe contracture deformity and maintain functional mobility.

Prognosis

Euthanasia is always a confounding factor when determining prognostic factors in veterinary patients. However, factors that appear to be correlated with an increased mortality include higher injury severity score, presence of head trauma, requirement of mechanical ventilation, hemoperitoneum, and vertebral fractures. Many scoring systems have been recommended for both human and veterinary patients to help predict patient outcomes. While care should be taken when using scoring systems to predict likely outcomes for individual patients, they may be useful to assess risk of death.

The Animal Trauma Triage (ATT) Score (Box 46.1) was developed to estimate risk of death following trauma. The ATT is easy to use and has been validated in several patient populations. The score uses a numerical value from 0 to 3 in six categories with a total possible score of 18. For every one-point increase in ATT, the patient's risk of death increases by 2.3–2.6 times. While the ATT has proven useful in trauma patients, it fails to take into account the presence of preexisting disease or nontarget organ system evaluation.

The use of a Modified Glasgow Coma Score (MGCS) for prognostication following head trauma has been reported in the veterinary literature (Box 46.2). The MGCS assigns a conglomerate score from 3 to 18 based on scores ranging from 1 to 6 in three categories: motor activity, brainstem reflexes, and level of consciousness. The lower the score, the worse the patient's performance is within each category, and a total score of less than 8 correlates with 50% survival at 48 hours. While the utility of a one-time MCGS performed at presentation is open for debate, serial evaluation can be used and may help the clinician to make a more objective assessment of the progression of traumatic brain injury. A worsening MGCS during the first 24–48 hours should be considered a negative prognostic indicator. The short-term prognosis for dogs with traumatic brain injury is similar to mortality rates for blunt trauma in general (12–15%). The long-term neurologic outcome of dogs surviving after head trauma is generally considered to be good to excellent. However, it is reported that 7% of dogs suffering head trauma develop a seizure disorder.

The prognosis for animals suffering blunt trauma is generally good with aggressive supportive care. Animals that suffer blunt trauma secondary to vehicular injury have a reported mortality rate of approximately 15–25%. Negative prognostic indicators include cranium fractures, recumbency at admission, development of DIC, multiple organ dysfunction syndrome, the need for ventilation or vasopressor therapy and cardiopulmonary arrest.

Animals that suffer bite wounds from larger animals should be considered critically ill until proven otherwise. The amount of trauma to the underlying tissue is disproportionate to the amount of external injury visible during examination and all of these wounds should be considered contaminated with bacteria. Small dogs and cats that have been bitten by larger canids also are likely to have a component of crush injury associated with the wound. For these reasons, animals with severe bite injury

Box 46.1 Animal Trauma Triage Score (ATT)

Perfusion

MM pink/moist CRT 2 s, T ≥100F, strong or bounding femoral pulse quality	0
MM hyperemic OR pale pink, tacky, T ≥100F, CRT 0–2 s, fair femoral pulses	1
MM very pale pink and tacky, CRT 2–3 s, T <100F, detectable but poor pulses	2
MM gray/blue/white, CRT >3 s, T <100F, no palpable femoral pulses	3

Cardiac

HR canine 60–140 bpm, feline 120–200 bpm, normal sinus rhythm	0
HR canine 140–180 bpm, feline 200–260 bpm, NSR or VPC <20/min	1
HR canine >180 bpm, feline >260 bpm, consistent arrhythmia	2
HR canine <60 bpm, feline ≤120 bpm, erratic arrhythmia	3

Respiratory

Regular resp rate with no stridor, no abdominal component to resp	0
Mild incr resp rate and effort, +/- abd comp, mild upper airway sounds	1
Mod incr resp rate and effort, some abd comp, elbow abduct, mod incr upper airway	2
Marked resp effort OR gasping/agonal resp, little/no air passage	3

Eye/muscle/integument

Abrasion/laceration – none or partial thickness. Eye: no fluorescein uptake	0
Abrasion/laceration – full thickness. NO deep tissue involved. Eye: corneal lac, not perf	1
Abrasion/laceration – full thickness, deep tissue involved. Artery/nerve/muscle intact. Eye: corneal perforation, punctured globe or proptosis	2
Penetration of abdomen/thorax. Abrasion/laceration full thickness, deep tissue involved. Artery/nerve/muscle compromised	3

Skeletal

Wt bearing 3 or 4 limbs. No palpable fx/jt laxity	0
Closed limb fx/rib fx or any mandibular fx. Single jt laxity/lux (including SI), pelvic fx with unilateral intact SI-ilium-acetabulum. Single limb open/closed fx at or below carpus/tarsus	1
Multiple grade 1 conditions, single long bone open fx above carpus/tarsus with cortical bone preserved. Nonmandibular skull fx	2
Vertebral body fx/luxation except coccygeal, multiple long bone open fx above tarsus/carpus, single long bone open fx above tarsus/carpus with loss of cortical bone	3

Neurologic

Central: consciousness: alert to sl dull. Periph: normal spinal reflexes; purposeful movement and nociception in all limbs	0
Central: dull/depressed/withdrawn. Periph: abn. spinal reflexes with purposeful movement and nociception intact in all 4 limbs	1
Central: unconscious. Responds to noxious stimuli. Periph: absent purposeful movement with intact nociception in 2 or more limbs OR nociception absent in 1 limb. Decr anal or tail tone	2
Central: nonresponsive to all stimuli, refractory seizures. Periph: absent nociception in 2 or more limbs; absent tail or perianal nociception	3

have a worse prognosis than animals with a comparable blunt trauma load. For small to medium-sized dogs with severe bite wounds, a mortality rate of approximately 20% has been reported although a subset of patients (those with crush injury and development of pigmenturia) appear to have a much worse prognosis.

The prognosis for veterinary burn patients is unknown. The overall mortality rate in human burn victims without inhalation injury is approximately 14%. This increases to 20% in humans with inhalation injury and burns. Factors that affect prognosis in humans include TBSA affected and concurrent inhalation injury. The mortality rate for dogs and cats with smoke inhalation alone is approximately 10%. Animals that have suffered burns in addition to inhalation injury should be expected to have a higher mortality rate.

Venomous Snake Bites

Nathan Peterson, DVM, DACVECC

VCA West Los Angeles Animal Hospital, Los Angeles, CA, USA

Etiology/Pathophysiology

The degree of pathology related to snakebites is determined by two main factors: the composition of the venom and the amount of venom injected into the victim. In veterinary medicine, there are two families of venomous snakes that are responsible for the vast majority of envenomations: the Viperidae and Elapidae. In general, vipers are capable of injecting venom through hollow fangs and once they (vipers) are mature, they have the ability to control the volume of venom injected with each bite. The Elapidae do not have such an advanced venom delivery system and rely on introduction of venom secreted from a venom gland through a wound created by biting. These snakes use their teeth and underdeveloped fangs in a chewing motion to create the wound. Therefore, elapid envenomation usually requires a snake to "adhere" or "chew" on a victim for some amount of time to allow adequate envenomation and consequently, these snakes strike and hold to allow for venom introduction whereas vipers strike and retreat, allowing the venom injected during the bite to immobilize the patient.

The composition of snake venom is extremely complex and it varies between species and within species based on geographic range. Venom composition also varies with age of the snake and the time of year. There are many potential effects of snake envenomation including flaccid paralysis, systemic myolysis, coagulopathy and hemorrhage, renal damage/failure, cardiotoxicity, and local tissue injury at the bite site. While the traditional view of venomous snakes was that vipers caused local and hemorrhagic effects (hemotoxic venom) and elapids caused systemic and nonhemorrhagic effects (neurotoxic venom), the reality is that any species of snake is capable of producing venom that can affect one or more of the body systems. Some Asian and African cobras (vipers) produce profound tissue injury while some South and Central American rattlesnakes (also vipers) produce primarily paralytic or neurotoxic venoms.

The venom of the North American pit vipers (Crotalidae) is typically classified as necrogenic/hemorrhagic and is capable of causing massive tissue damage and inducing life-threatening inflammation or hemorrhage. The venom is primarily composed of water, with proteins and peptides making up approximately 10% of the total volume. It is this portion of the venom that is responsible for most of the direct tissue injury and hemostatic perturbation seen with envenomation. It is also this portion that is responsible for inducing endothelial cell damage leading to endothelial dysfunction, cell lysis, and ultimately circulatory collapse. So far, over 60 purified polypeptides and approximately 50 enzymatic fractions have been identified with at least 10 enzymes and 3–12 nonenzymatic proteins and peptides present in any individual snake's venom.

Hyaluronidase and collagenase act to break down connective tissue, facilitating the spread of venom and beginning the digestive process. Together, these enzymes are capable of causing massive tissue damage and necrosis and are responsible for many of the outward sings of envenomation. The impact of envenomation on hemostasis is profound and can be considered in light of the areas of hemostasis that are affected.

Venom proteins acting directly on coagulation factors include procoagulant proteins such as factor V (FV) activators, FX activators, prothrombin activators, and thrombin-like enzymes. Anticoagulant venom factors also exist and include FIX/X binding proteins, protein C activators, thrombin inhibitors, and phospholipase A_2. Finally, factors acting on fibrinolysis include fibrinolytic enzymes (metalloproteinases and serine proteases) and plasminogen activator.

Many of the components of snake venom exert an effect on platelet function. The C-type lectins, disintegrins, and proteinases inhibit platelets by a variety of

Clinical Small Animal Internal Medicine Volume I, First Edition. Edited by David S. Bruyette.

Companion website: www.wiley.com/go/bruyette/clinical

mechanisms, including interactions with von Willebrand factor (vWF) receptors and fibrinogen receptors. Platelet activation occurs through a thrombin-like effect of proteinases and phospholipase A_2, among other mediators.

Besides the effect of venom on primary and secondary hemostasis, proteins in the venom can affect the endothelium. Metalloproteinases, disintegrins, and C-type lectins degrade the blood vessel extracellular matrix, induce endothelial cell apoptosis, and inhibit platelet binding through interference with vWF. The net result of this combined action is consumption of fibrin and development of bleeding diathesis that is not generally characterized by thrombosis or intravascular coagulation.

Neurotoxins contained in snake venom exhibit a predilection for peripheral nervous tissue and relatively few are capable of crossing the blood–brain barrier. Venoms that exert a primarily neurotoxic effect act as either presynaptic (beta-neurotoxins) or postsynaptic (alpha-neurotoxins) neuromuscular blocking agents; most neurotoxic venoms contain toxins that affect both the pre- and postsynaptic neuron. Presynaptic or beta-neurotoxins have been isolated from members of the Elapidae and Viperidae (including Crotalidae) families. Most of these toxins inhibit neurotransmitter (acetylcholine) release although a small number have been identified that actually enhance neurotransmitter release. Postsynaptic or alpha-neurotoxins result in a curare-like syndrome by binding acetylcholine receptors on the postsynaptic membrane or interfering with acetylcholine interaction with its postsynaptic receptors. The degree of inhibition is related to the number of receptors occupied by toxin molecules. Most of these toxins bind irreversibly to the acetylcholine (ACh) receptor although treatment with antivenin seems to accelerate toxin–receptor dissociation.

A unique syndrome resulting in myokymia (spontaneous undulating fine contractions of multiple individual motor units) has been identified with venom from timber rattlesnakes (*Crotalus horridus*). Primarily neurotoxic snake bites result in much less local tissue inflammation and pain than their necrogenic counterparts. Large necrosing wounds are uncommon in these cases.

Epidemiology

Of the approximately 2300 species of snakes worldwide, about 420 are venomous. Venomous species can be found on every continent except Antarctica, with members of the Viperidae family found throughout the world. In North, Central, and South America, the Viperidae family is represented primarily by the pit vipers (Crotalidae) and is responsible for the majority of veterinary envenomations. The true incidence of veterinary patients bitten by snakes every year is unknown but it is estimated to be between 150 000 and 300 000. Animals that are most at risk are those that live in a rural or semi-rural environment although dogs that are taken on walks in wilderness areas are also at high risk, especially if allowed off leash. There is a strong seasonal influence on the incidence of snake bites, with the majority of bites occurring in the spring and summer months.

The severity of a bite depends on several variables, including the time that has elapsed since the snake's last meal (it takes approximately 20 days for pit vipers to replenish venom stores), the motivation of the snake (defensive or offensive), and its age. Bites from immature snakes in the spring months are often more severe than bites that occur later in the season since juvenile pit vipers have not developed the ability to control the amount of venom that is injected with each strike but rather deliver an "all or nothing" bite. Therefore, somewhat counterintuitively, it is arguably better for an animal to be bitten by a large adult pit viper than a juvenile. The metabolic demands required to synthesize venom are quite high so adult snakes will often deliver an initial "dry bite" (a bite containing no venom) as an attempt to deter a pet from further harassing them. Subsequent defensive strikes, however, are often very severe as the snake continues to feel threatened and is committed to finally deterring its assailant.

The most common location of bite wounds is the head (79%) followed by extremities (16%) while bites to the torso account for less than 2% of confirmed snake bites. Additionally, single bites are much more common than multiple bites, with multiple bites occurring approximately 15–30% of the time. The small puncture wounds typical of snake bites are often difficult to locate and can be easily overlooked, especially if no surrounding local tissue reaction is present. Only 20–25% of known rattlesnake bites are actually envenomating.

Cats appear to be inherently more resistant to pit viper venom than dogs. However, when cats do present for veterinary care, their clinical condition is generally more advanced. This may be due to cats' habit of hiding and avoiding human contact following a snake bite compared to dogs who are more likely to seek human interaction. Cats' smaller body size and inclination to "toy" with possible prey may also be contributing factors to explain these findings.

The species of snake is known in less than 50% of cases although this can often be inferred based on the known ranges of different species. Owners should be discouraged from attempting to identify the snake due to the danger that is posed with handling a live or very recently dead snake. Envenomating bites can occur from recently dead or decapitated snakes. These agonal bites typically inject the entire volume of the venom gland, making them very severe.

Coral snake envenomations are relatively uncommon in the United States and are most likely to occur in the southeastern US and Gulf Coast region. The infrequency of bites is due to the reclusive nature and physical limitations of the snake. North American coral snakes are small in size and have small fixed fangs that are incapable of penetrating thick undercoats. Coral snakes depend on venom being introduced through a chewing motion rather than being injected. This requires the snake to be attached to the victim for some time to allow sufficient venom delivery. Dogs may even present to a veterinarian with the snake still maintaining its grip on the victim.

Due to the rural location in which bites often occur and the relative proximity or distance to veterinary care, the time from bite to veterinary care is highly variable but is usually within the first 2–3 hours.

Signalment

Young dogs of both sexes are equally at risk of being bitten by a snake. Although a clear breed predilection has not been identified, the sporting and working breeds appear to be overrepresented. Any dog or cat that spends time outdoors, especially if off leash or unsupervised in a rural or semirural environment, is at risk for being bitten by a snake.

History and Clinical Signs

Pets that have been bitten by snakes will have a very short pertinent history that may include known exposure to snakes. Owners will often report the presence of a swelling on the face or limbs that seems to be getting worse rapidly. The pet will be exhibiting signs of pain and may be either seeking or eschewing attention. Snakes are reclusive animals and owners frequently do not see them interact with their pet, making observation of a strike uncommon. When presented with a patient that has clinical signs consistent with snake bite, the veterinarian should question the owner about observed snake activity and possible exposure. Signs of snake envenomation almost always occur within the first four hours but may be delayed up to 24 hours, making the possibility of determining when snake bite could have occurred relatively easy.

Patients with necrogenic snakebites will exhibit swelling or erythema around the puncture wounds. Localized swelling is present in approximately 90–95% of cases at the time of initial examination. If the patient is presented very early following the bite then outward clinical signs can be initially very mild and may easily be overlooked but signs reliably appear within 30 minutes from the time of bite. When evaluated early, these patients can be mistaken as having a hypersensitivity reaction as is commonly seen with Hymenoptera stings. If the owner cannot provide a history that supports a diagnosis of snake bite, these patients may initially be incorrectly treated for hypersensitivity reactions. A distinguishing feature of snake bite is significant pain associated with the swelling whereas severe pain is generally absent in hypersensitivity reactions. Petechiae may be seen at presentation about 20% of the time.

Diagnosis

The diagnosis of snake bite is usually suspected based on a history of snake interaction observed or suspected by the owner. Confirmation of the diagnosis is achieved through examination of the patient with the presence of characteristic puncture wounds and local, progressive lymphedema.

Initial biochemical laboratory evaluation is usually normal although creatine kinase (CK) and aspartate aminotransferase(AST) may be elevated secondary to muscular injury. Complete blood count may reveal thrombocytopenia. When present, thrombocytopenia is generally moderate (135 000–160 000 platelets/μL). Mild to moderate leukocytosis may also be present during the initial evaluation. Pit viper envenomation has been shown to cause echinocytosis and a blood film revealing significant echinocytosis is supportive of a diagnosis of envenomation. Coagulation assays performed at the time of hospitalization may reveal prolongation of prothrombin time (PT), partial thromboplastin time (PTT) or activated clotting time (ACT). When present, the prototypical venom-induced coagulopathy is defined by low fibrinogen and platelet counts, increased fibrin split products (FSP), normal D-dimer concentration, and prolonged PT and PTT. This characteristic coagulation profile is due to the defibrination of plasma without overt coagulation resulting in failure of D-dimer concentration to become elevated. Clinically, D-dimer levels are often mildly elevated, most likely reflecting systemic inflammation and clot formation at the site of the bite wound. Recently, thromboelastography has been used to evaluate dogs with snake bite and may prove a useful adjunct for both diagnosis and prognosis.

Although uncommon, snake venom is capable of causing cardiac arrhythmias. Routine monitoring of electrocardiographs (ECGs) is probably not necessary but any animal that has tachycardia and/or an audible irregularity should have an ECG performed to evaluate for the presence of potentially malignant arrhythmias. While not specific, the presence of an arrhythmia in a patient exhibiting signs of snake bite may support the diagnosis.

Diagnosing coral snake envenomation is complicated by the lack of local tissue reaction and the fact that signs may not develop for up to 12 hours following envenomation. Any patient exhibiting signs of a rapidly progressive ascending paralysis in coral snake endemic areas should be considered at risk and be treated appropriately. Owners may not be as aware of coral snake exposure due to the smaller size of the snakes and the lack of a warning system such as a rattle.

Therapy

First Aid

Appropriate veterinary care should not be delayed to allow first aid measures to be performed. First aid for snake bites has a long and storied past, including lancing and suctioning the wound, placing tourniquets, ice packing, warm packing, and administering electroshock, among other techniques. To date, none of these measures has demonstrated any improvement in outcome; in fact, some can significantly worsen the clinical course of disease. Placement of tourniquets may exacerbate the amount of tissue injury by preventing dilution of the venom as it is distributed throughout the body and prolonging the duration of time that venom is present in the affected tissue bed. Envenomation that would not otherwise induce tissue necrosis might therefore result in massive tissue loss if a tourniquet is placed inappropriately in the field. Cold packing can induce local vasoconstriction and exacerbate tissue injury through a similar mechanism. Incision and suction should never be performed. It is not likely to result in any improvement in outcome and may put the care provider at risk. The best first aid measure available is to immobilize the affected area if possible and to transport the patient to the nearest veterinary facility capable of treating snake bite. Due to the preponderance of snake bites being located on the head and muzzle of dogs and cats, immobilization is not often feasible and rapid transport is the best option.

While first aid measures in necrogenic snake bites do not include application of a tourniquet or compression bandage, coral snake envenomations do benefit from constriction. There is very little local tissue injury associated with coral snake envenomations, meaning the application of a tight compression bandage on the affected area should be performed if possible.

Antivenin Therapy

Regardless of the primary effect of the venom, the mainstay of treatment for snake bite is the administration of venom antibodies (antivenin) specific to the envenoming species if possible. Because the effectiveness of antivenin is dependent on binding circulating venom molecules, a molar dosing regimen is followed, meaning that the dose of antivenin is dependent on the volume of venom injected rather than the patient's body size. In fact, smaller animals often require higher doses of antivenin due to differences in the volume of distribution of venom in a small versus large dog. Antivenin therapy is most effective when instituted early in the disease course although it is effective as long as circulating venom is present and should be considered even many hours after an envenomation if clinical signs are severe or progressive or if a coagulopathy develops.

Unfortunately, the cost of antivenin therapy can be quite high and often results in patients receiving less antivenin than ideal circumstances would dictate. When faced with the predicament of whether or not to administer a dose of antivenin with the belief that it will not be a completely effective dose, the clinician should err on the side of treatment since binding even a portion of the free venom may improve the clinical course.

There are currently two major types of antivenin commercially available. Polyvalent whole molecule antivenin is derived from the serum of horses sensitized to several North, Central, and South American pit viper species and contains the entire IgG antibody and may contain equine albumin, depending on manufacturer. The second type of antivenin is composed of the F_{ab} portion only of an ovine- or equine-derived antibody rather than the complete immunoglobulin molecule. Whole immunoglobulin antivenin is generally less expensive and more readily available than F_{ab}-based antivenins but due to the presence of the entire IgG molecule and possibly additional foreign proteins (equine or ovine albumin), the possibility of hypersensitivity reaction is increased. Antivenins containing the smaller F_{ab} portion of the immunoglobulin molecule are less immunogenic and may be better able to diffuse into damaged tissue due to their smaller size. However, this smaller size results in a shorter elimination half-life than the larger complete molecule antivenins. This can lead to a situation in which the antivenin is eliminated more rapidly than it is capable of binding circulating venom molecules, resulting in recurrence of clinical signs. If using an F_{ab}-based antivenin, the clinician should be aware of this possibility and recognize the fact that repeated dosing may be needed every six hours to most effectively treat the patient.

While the F_{ab}-based antivenins are less immunogenic than the whole molecule formulations, both types of antivenin are capable of causing immediate and delayed immune reactions, with a reported incidence of 5–13%. Anaphylactic (type I) or anaphylactoid hypersensitivity reactions occur immediately upon administration of antivenin, are dose related and are due to either an

IgE-mediated response (type I) or direct activation of the complement cascade (anaphylactoid). Signs of anaphylactoid reactions are identical to signs of true anaphylaxis and can range from mild facial edema and pruritus to complete circulatory collapse. Premedication with antihistamines has been reported but has not been proven to be beneficial in reducing the incidence of reactions. Delayed (type III) hypersensitivity reactions have been reported up to several weeks after administration and are the result of immune complex formation and complement activation. Clinical signs associated with delayed type III hypersensitivity reactions include fever, lethargy, vasculitis, peripheral edema, and glomerulonephritis. Type III hypersensitivity reactions are generally self-limiting but can rarely be life threatening. The risk of hypersensitivity reactions, including acute anaphylactic reactions, increases in animals that have been previously treated with antivenin products.

When edema formation is severe or when the location of the bite wound is likely to result in life-threatening complications (airway obstruction), early and aggressive antivenin therapy should be instituted. Antivenin should be administered to effect until the progression of the signs abates (i.e., there is no further evidence of new edema formation, bruising has stopped spreading, and coagulopathy is controlled). Median doses of antivenin for dogs have been reported as one vial (range 1–10), and beginning with one vial given over 30 minutes is reasonable. Additional doses can be administered every 30–60 minutes as needed. It should be remembered that antivenin products have colloidal properties that can significantly expand the vascular space. Volume overload is a concern in small patients, especially those that require higher doses of antivenin.

Serial measurement of muzzle or limb circumference can help the clinician decide whether progression has in fact stopped. It is important to remember that as edema matures, it becomes gravity dependent. Recognition of edema migration rather than progression is difficult and is best achieved through good-quality serial evaluations. Cage-side rounds provide an opportunity for all staff to observe the site, decreasing interobserver variation in assessment. Similarly, maturation of bruising should not be confused with ongoing bruising. Clipping the fur from affected areas and marking the leading edge of bruising can help the clinician differentiate the two. The use of digital photography may aid the clinician in monitoring progression and can facilitate communication between team members if questions arise.

It should be emphasized that snake bite-induced coagulopathy is not identical to other types of consumptive coagulopathy, so treatments used for common coagulopathies are often ineffective if applied to snake bite coagulopathy. Because the coagulopathy observed in snake envenomation is the result of defibrination rather than disseminated coagulation, the treatment of choice is not factor replacement, at least not initially. The underlying cause of defibrination is the presence or persistence of venom components in the blood. As long as venom components are circulating, fibrin and fibrinogen will continue to be degraded and treatment with factor replacement therapy in the form of fresh frozen or frozen plasma is not expected to be beneficial. In fact, administration of plasma products in the presence of circulating venom may exacerbate coagulopathy by providing more substrate for degradation, leading to higher levels of FSP, which further inhibit coagulation. Consequently, the most vital treatment is inactivation of circulating venom components by administration of antivenin.

Even with early and aggressive antivenin therapy, bite wounds to the head can result in severe, progressive edema and swelling and may pose a threat to airways. Often, early placement of a temporary tracheostomy is beneficial. Once edema has stopped forming, it will become gravity dependent and can result in severe swelling of the ventral muzzle and neck. If the decision to perform a tracheostomy is made too late, the dissection through edematous tissue is significantly more difficult.

If open wounds develop, they should be treated like any other contaminated, large, soft tissue wound. Any areas of necrosis should be surgically debrided; the wound should be cleaned daily and protected with a sterile bandage. Consultation with a surgeon should be considered for large wounds or wounds involving the joints. Primary closure of these wounds is rarely feasible due to the large amount of tissue loss that occurs. When wounds are present on limbs, the affected limb should be immobilized in a functional position to reduce the likelihood of wound contracture resulting in decreased range of motion. Most snake bites result in venom deposition within subcutaneous tissue rather than muscle bellies, so fasciotomy is rarely needed in dogs and cats.

Antibiotic therapy for snake bite is controversial in both human and veterinary medicine. There is little evidence that prophylactic antibiotic therapy improves the clinical course or prevents wound infection. The rationale for antibiotic use is grounded in the fact that bacterial cultures of snakes' mouths document heavy pathogenic bacterial loads; however, the actual incidence of documented infection is small. Therefore, the routine use of prophylactic antibiotics is likely not necessary and the decision to treat with antibiotics is clinician dependent. If used, broad-spectrum antibiotics should be selected. Antibiotic therapy is less controversial once a necrotic wound is present. As always, antibiotic therapy should be guided by culture and sensitivity results when possible to allow for deescalation and more responsible antibiotic usage.

Analgesia is an important component of snake bite treatment and should be considered early in the treatment

course. Administration of antivenin can reduce the acute pain associated with the snake bite although antivenin alone is insufficient to provide adequate analgesia. The use of opioid analgesics has been discouraged due to the possible respiratory depressant effects of this class of drugs. However, clinically significant respiratory depression in veterinary patients is uncommon with opioid medications and should not be considered a reason for withholding their administration. Administration of bolus opioids may be insufficient to manage the severe pain associated with snake bite. Constant rate infusion (CRI) of fentanyl (3–5 µg/kg/h) or morphine (0.1–0.3 mg/kg/h) should be considered in cases of severe envenomation. As always, a multimodal approach to pain management may be more effective than reliance on a single analgesic protocol. Ketamine has good somatic analgesic properties and a CRI (5–15 µg/kg/min) can be a nice addition to the analgesic protocol for snake bite victims. Lidocaine (50 µg/kg/min) and dexmedetomidine CRI (0.7–1.5 µg/kg/h) have both been demonstrated to provide analgesia, especially when used in conjunction with opioids. The ultimate pain management strategy implemented should take patient factors such as age, conformation, location and severity of envenomation, and cardiovascular status into consideration.

Edema formation of the face can impair the pet's ability to prehend food and move the lips and tongue. Accumulation of mucus in the buccal pouch can lead to bacterial overgrowth and development of oral ulcerations. Good oral care, including rinses with water and/or antiseptic solution, should be instituted if muzzle swelling is severe.

Some components of snake venom have been demonstrated to result in mast cell degranulation. While theoretical benefits of antihistamine administration exist, the routine use of H1 and H2 blocking drugs is not currently recommended for human snake bite victims and their use in veterinary patients is up for debate.

As is often the case with corticosteroids, their use is controversial. There is little conclusive veterinary or human literature to either support or refute their use for snake bite. Due to the lack of evidence of a clear advantage to patients receiving corticosteroids and their well-documented side-effects, the routine use of corticosteroids in snake bite cannot be advocated. Administration of corticosteroids may be indicated if a patient develops signs of an acute or delayed hypersensitivity reaction to antivenin administration. Similarly, nonsteroidal antiinflammatory drugs (NSAIDs) should not be administered to snake bite victims until any venom-induced coagulopathy has been effectively managed due to the potential for NSAID-induced thrombocytopathia. Following appropriate management of coagulopathy and hemodynamic stabilization, NSAIDs may prove useful in the analgesic management of snake bite victims. Nonsteroidal antiinflammatory medications should not be administered if myoglobinuria is present.

A rattlesnake vaccine (Red Rock Biologics, Woodland, CA) is commercially available in the United States for use against western diamondback rattlesnakes (*C. atrox*). There are currently no peer-reviewed studies evaluating the clinical efficacy of vaccination in mitigating signs and none are likely to be performed due to the high incidence of dry bites and variability in venom dose between patients. In fact, owners who have had their pets vaccinated may have a false sense of security when it comes to snake bite and may be slower to seek veterinary care. For this reason, it is not recommended to vaccinate for snake bite. Aversion training is available but is also considered unreliable as this too may result in a false sense of security when in snake habitats.

Prognosis

Fatality associated with snake bite injury is generally uncommon although these patients experience significant morbidity. Reported mortality rates range from 4% to 20% and are correlated with antivenin treatment. Despite the overall favorable prognosis for survival from snake bite, many pets are euthanized due to the financial burden associated with hospitalization and antivenin therapy, which can easily reach several thousand dollars.

The prognosis is directly dependent on the severity of the envenomation and the treatment received. Progression of envenomation is subjective and can be difficult to assess. One tool that can be utilized is the assignment of a snake bite severity score (SSS) at the time of admission and then every 4–6 hours for the first 24 hours (Box 47.1). The SSS assigns a numerical value ranging from 0 to 4 in six categories, with a total possible score ranging from 0 to 20, with more severe bites having higher scores. While the SSS has not been validated in dogs and cannot be used to assess a particular patient's risk for death, it aids the clinician in evaluating progression by assigning value to objective findings.

The prognosis for patients exhibiting signs of neurotoxicity secondary to envenomation is less clear. The severity of signs depends on the volume of venom introduced through the bite. Because of the limited local tissue reaction associated with coral snake bites, the severity of envenomation may not be readily apparent at the time of presentation. If patients develop severe clinical signs then the prognosis is guarded to poor if mechanical ventilation is not available. Commercially available coral snake antivenin is difficult to obtain but has proven useful for treatment of elapid envenomation in the US. Fortunately the majority of coral snake bites are nonenvenomating (a consequence of the snake's primitive venom delivery system).

Box 47.1 Snake bite severity score

Pulmonary system

Signs within normal limits	0
Minimal – slight tachypnea	1
Moderate – respiratory compromise, tachypnea, use of accessory muscles	2
Severe – cyanosis, dyspnea, extreme tachypnea, respiratory insufficiency or respiratory arrest from any cause	3

Cardiovascular system

Signs within normal limits	0
Minimal – tachycardia, general weakness, benign dysrhythmia, hypertension	1
Moderate – tachycardia, hypotension	2
Severe – marked tachycardia, hypotension (systolic <80 mmHg), malignant dysrhythmia or cardiac arrest	3

Local wound

Signs within normal limits	0
Minimal – pain, swelling, ecchymosis, erythema limited to bite site	1
Moderate – pain, swelling, ecchymosis, erythema less than half of extremity	2
Severe – pain, swelling, ecchymosis, erythema more than half of extremity, rapid spread	3
Very severe – pain, swelling, ecchymosis, erythema beyond affected extremity, significant tissue slough	4

Gastrointestinal system

Signs within normal limits	0
Minimal – abdominal pain, tenesmus	1
Moderate – vomiting, diarrhea	2
Severe – repetitive vomiting, diarrhea, or hematemesis	3

Hematologic system

Within normal limits	0
Minimal – coagulation parameters slightly abnormal, platelets 100 000–150 000/mm^3	1
Moderate – coagulation parameters abnormal, platelets 50 000–100 000/mm^3	2
Severe – coagulation parameters markedly abnormal, platelets 20 000–50 000/mm^3	3
Very severe – coagulation parameters markedly abnormal with bleeding present or threat of spontaneous bleeding, platelets <20 000/mm^3	4

Central nervous system

Signs within normal limits	0
Minimal – apprehension	1
Moderate – chills, weakness, faintness, ataxia	2
Severe – lethargy, seizures, coma	3

Conclusion

The only proven effective treatment for snake bites is the early administration of antivenin therapy. When patients are presented very early following a bite, the clinical signs may be very mild. The astute clinician will recognize the risk of rapid progression of signs and will be prepared to intervene early and appropriately. Ultimately, the best treatment for snake bite is prevention. Veterinarians should have frank discussions with owners of at-risk pets about the need for leashing at all times when in snake habitat.

Gastrointestinal Imaging

Susanne M. Stieger-Vanegas, DVM, PhD, DECVDI

Carlson College of Veterinary Medicine, Oregon State University, Corvallis, OR, USA

General Imaging Principles

Medical imaging is an important element of the clinical work-up of a patient with gastrointestinal disease. Plain radiography is commonly used to evaluate patients with suspected gastrointestinal disease, but plain radiography can often be unremarkable and abdominal ultrasonography or cross-sectional imaging techniques such as contrast-enhanced abdominal computed tomography might be required to further evaluate the etiology of the disease.

Plain Radiography

Plain radiography is a widely available imaging technique and in many cases, it is the principal method used to evaluate the abdomen. Numerous studies have evaluated the usefulness of this technique in cats and dogs with suspected lesions of the oral cavity, esophagus, and gastrointestinal tract, in patients with acute abdominal signs, gastrointestinal foreign bodies, and small intestinal obstructive disease. However, in the past decade, abdominal ultrasound and more recently contrast-enhanced computed tomography have become major imaging modalities in patients with acute or chronic gastrointestinal signs. When abdominal radiographs are obtained, they often are used as a screening test. Abdominal radiographs have demonstrated the greatest value in patients in whom intestinal obstruction and/or perforation and urinary calculi are suspected. Therefore, the major value of abdominal radiographs is to exclude intestinal obstruction or free air in the peritoneal cavity secondary to perforation of a hollow organ such as the gastrointestinal tract. Despite advances in other imaging modalities, plain radiography remains the first modality of choice in patients with suspected gastrointestinal perforation. Additionally, abdominal radiographs are often used to evaluate tube or drain placement.

The most commonly used views are ventrodorsal (VD) and right and/or left lateral recumbent views. The VD view is usually preferred over the dorsoventral (DV) view as it is easier to position the abdomen close to and aligned with the cassette than in a DV view. There are slight differences in the radiographic appearance between right and left lateral recumbent views, which mainly include the change of position of mobile viscera and of the gas and fluid in the gastrointestinal tract due to the effect of gravity. Additional views, dependent on the clinical question asked, may include DV for evaluation of gas, contrast agent or foreign material in the stomach. Lateral or VD views with a horizontal beam are occasionally used to evaluate for the presence of gas/air in the peritoneal cavity.

Imaging Contrast Agents and Pharmacoradiology

Contrast radiography or computed tomography are both valuable imaging techniques, often providing additional information in the management of patients with gastrointestinal signs. Typically, the greatest value is in patients where radiographic and clinical signs suggesting gastrointestinal obstruction are equivocal. Contrast imaging may help to identify the extent and cause of gastrointestinal obstruction. Contrast agents currently used for gastrointestinal imaging can be classified into three groups: (1) intraluminal contrast agents for gastrointestinal tract studies; (2) intravascular contrast agents for computed tomography (CT) and angiography; (3) contrast agents for magnetic resonance tomography (MRI). These various types of contrast agents are discussed separately in the following sections.

Intraluminal Contrast Agents

Barium Sulfate

Barium sulfate suspension is the most commonly used contrast agent for gastrointestinal radiographic studies in veterinary medicine. Barium sulfate is a white crystalline powder, which is inert and does not support bacterial growth. Coating of the mucosa of the gastrointestinal tract or opacification of the lumen of the gastrointestinal tract can require different barium formulations. Throughout the gastrointestinal tract, the pH, type, and amount of mucus and type of mucosa vary and therefore optimal coating in one segment does not necessarily result in optimal coating in another segment.

Aspiration of small amounts of barium formulations is of very little clinical significance. Barium within the trachea and main bronchi is usually cleared within 30 minutes. If barium aspiration is more extensive, it is retained within the interstitium of the lungs and a very slow decrease of barium in the lungs might be noted over several months to years (Figure 48.1). If diffuse extensive alveolar infiltration of barium occurs throughout the lungs, though, this can lead to death of the patient. Therefore, if major concerns for aspiration exist before the study, nonionic iodinated contrast agents should be considered.

Hypersensitivity reactions to barium have not been reported in veterinary medicine, but have been reported rarely in human medicine.

Barium leakage into the peritoneal cavity can occur due to a preexisting perforation of the gastrointestinal tract or secondary to a procedure such as a barium enema. In veterinary medicine, it is commonly accepted that the suspicion of gastrointestinal perforation is a contraindication for barium studies in patients. Most of our knowledge regarding barium peritonitis is from human medicine but the small number of reported reactions in small animals seem to be similar. If large amounts of barium are spilled into the peritoneal cavity, profound hypovolemia can develop secondary to exudation of large quantities of fluid associated with the chemical peritonitis. Furthermore, bacterial contamination may lead to sepsis and shock within hours. If a barium leakage occurs, immediate treatment should be started, including intravenous fluid therapy and antibiotic administration due to the commonly associated bacterial contamination. Once the patient is stabilized, abdominal surgery is commonly performed. However, barium can be difficult to remove surgically as new barium formulations can adhere strongly to the peritoneum.

Negative Contrast Agents

Air is one of the cheapest contrast agents for gastrointestinal studies. In veterinary patients, it is most commonly used to outline the colon, especially in patients where a small intestinal foreign body is suspected. Another application is in double contrast studies of the gastrointestinal tract; the most common application of this technique is in evaluating the stomach for the presence of a foreign body or to identify the location of the colon and differentiate the colon from small intestine in cases of intestinal obstruction.

Iodinated Contrast Agents

Water-soluble, iodine-containing contrast agents are most commonly used for gastrointestinal imaging when esophageal or gastrointestinal perforations are suspected. However, the role of water-soluble iodinated contrast agents and the merit of these compounds for

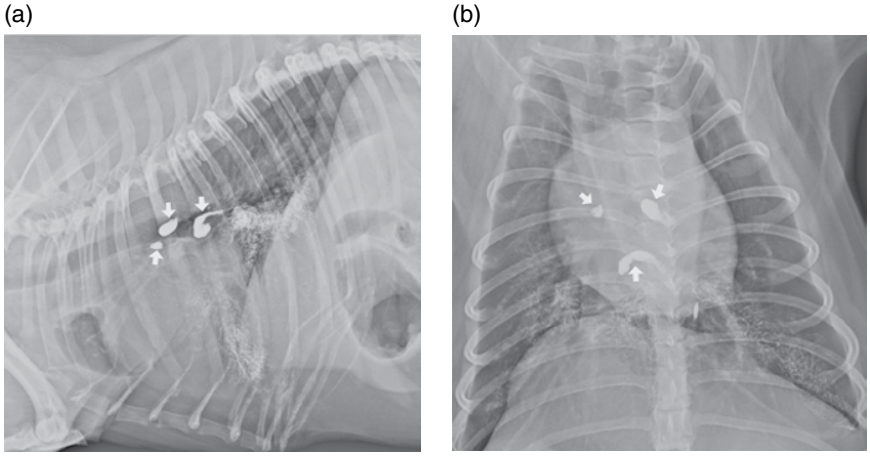

Figure 48.1 Left lateral (a) and ventrodorsal (b) radiographs of the thorax of a dog illustrating a previous aspiration of barium contrast agent, which occurred during a contrast radiographic study performed six years before. The barium is persistently present in the parenchyma of the right and left caudal as well as accessory lung lobes. Barium has localized to the tracheobronchial lymph nodes (*arrows*), which has no clinical significance.

general imaging of the gastrointestinal tract are areas of controversy. Water-soluble iodinated contrast agents do not coat the gastrointestinal mucosa. The most commonly used iodinated contrast agents formulated for the gastrointestinal tract are hypertonic and therefore pull fluids into the intestinal tract, resulting in distension of the intestinal lumen and better definition of the intestinal walls. The hypertonicity and fluid pull into the gastrointestinal tract can result in diarrhea and dehydration. If the contrast agent is aspirated or enters the lungs through a fistulous tract from the esophagus, severe pulmonary edema can result. If a perforation into the pleura or lungs is suspected, nonionic iodinated contrast agents can be used and are reported to be safer than ionic iodinated contrast agents.

Intravascular Contrast Agents

All currently used contrast agents used for vascular enhancement (except agents used for MRI) utilize iodine for X-ray absorption. Currently, the dominant areas for use of intravascular contrast agents are CT and MRI. No routine techniques have been described for evaluation of the gastrointestinal tract using radiography and intravascular contrast agents. Significant improvements in the composition of intravascular contrast agents have been made in the past decades, making them safer to use and better tolerated. As sodium iodide is toxic, it must be delivered in a molecule structure that is safe to use. The closer the osmolarity of the contrast agent is to water, the lower the toxicity of the contrast agent. When iodinated contrast agents are used, the patient should always be well hydrated as iodinated contrast agents can cause renal toxicity. Adverse reactions to intravenous iodinated contrast agents are rare in veterinary patients, but can range from anaphylactic shock to local reactions.

Ultrasonography

Ultrasonographic examination is one of the most useful techniques for evaluating the gastrointestinal tract in most veterinary patients. Ultrasound of the gastrointestinal tract is not only used to make an initial diagnosis, but also to monitor response to treatment or disease progression. Ultrasound can be used to evaluate superficial aspects of the esophagus in the cervical area and in the abdomen to evaluate the stomach to descending colon. Superficial structures are better evaluated with a high-frequency ultrasound probe, whereas deeper structures may require the use of low-frequency probes. Higher-frequency ultrasound probes have less tissue penetration but provide a better resolution of intestinal structures, including wall layering, compared to low-frequency ultrasound probes.

Ultrasound of the gastrointestinal tract provides information about the gastrointestinal wall and peristalsis of the gastrointestinal tract, which is information currently not provided by any other diagnostic technique, including radiography (plain and using oral or gastric contrast agents), CT, and endoscopy. One of the biggest limitations of the use of ultrasound when evaluating the gastrointestinal tract is its inability to penetrate air-filled structures, which can include air in the peritoneal cavity secondary to a perforation or recent surgical procedure or luminal air in the gastrointestinal tract. However, this limitation can often be overcome by repositioning the patient or ultrasound probe relative to the air-filled viscera or peritoneal air.

The ultrasound examination of the abdomen in the dog and cat is commonly performed in lateral or dorsal recumbency. Usually, the ultrasound exam is started cranial in the abdomen for evaluation of the gastrointestinal tract or other abdominal disease and then progresses caudally, usually in the anatomic order of the gastrointestinal tract.

Computed Tomography of the Gastrointestinal Tract

In small animals and humans, CT is used extensively to evaluate the abdomen, but veterinary reports of its use to evaluate the intestines, especially the intestinal wall, are rare. Gastrointestinal CT has been used in veterinary patients to diagnose intraluminal gastrointestinal foreign bodies. However, no significant improvement in sensitivity and specificity was reported in comparison to plain film radiography. Future veterinary applications using gastrointestinal CT are likely to develop, particularly with the advent of new multidetector row helical CT (MDCT) scanners. Faster scan times and greater spatial resolution are achievable with these new scanners, allowing for high-resolution multiphasic and multiplanar evaluation of the gastrointestinal tract, gastrointestinal wall, and lumen.

In human medicine, CT enterography and enteroclysis, in which oral contrast is used to distend and illuminate the gastrointestinal wall, are extensively used to evaluate the gastrointestinal tract as they allow evaluation of extraluminal pathology in addition to luminal disease. They are regularly used in the diagnosis and treatment of inflammatory bowel disease, to assess the severity and extent of disease, as well as inflammatory activity. CT without luminal contrast has successfully been used in dogs and cats to evaluate the anatomy of the gastrointestinal tract, to assess segments of the gastrointestinal tract for the presence of intraluminal or wall lesions, and to measure the intestinal width. The use of gastrointestinal CT examination to evaluate for foreign

bodies and obstructive intestinal disease in small animals has not been shown to have statistically significant increased sensitivity or specificity compared to plain radiography. In gastrointestinal CT without the use of intraluminal contrast agents, the lack of distension of the small intestine hinders evaluation of the intestinal wall throughout the entire gastrointestinal tract.

In human medicine, it has been well demonstrated that a critical technical requirement for CT of the bowel is full distension of a clear lumen with complete separation of the intestinal walls. In CT enterography, combinations of positive and neutral attenuation oral contrast agents are used, which allow distension of the intestinal tract and outlining of the wall. Conventional positive attenuation oral contrast media such as barium- or iodine-based agents are used for evaluation of the gastrointestinal tract similarly to their use in radiography or fluoroscopy (Figure 48.2). Conventional positive attenuation oral contrast agents allow visualization of the mucosal detail and assessment of mucosal enhancement. Neutral oral contrast agents, which are more commonly used in human medicine, have an attenuation close to water and are mainly used to distend the small intestinal tract and therefore better outline the intestinal walls, allowing for better evaluation for mural lesions. Commonly used neutral attenuation luminal contrast agents include water, milk, polyethylene glycol, 12.5% corn-oil emulsion, and methylcellulose.

Magnetic Resonance Imaging of the Gastrointestinal Tract

Magnetic resonance imaging is rarely used for evaluation of the gastrointestinal tract in human and veterinary patients. In human patients, new MRI applications for imaging of the colon are being developed. The most common use of MRI related to digestive disease in veterinary patients involves imaging of the oral cavity or cranial neck in patients where abscesses secondary to perforating injuries or foreign bodies are suspected.

Gastrointestinal Scintigraphy

Ultrasound and contrast radiography continue to be the most common imaging techniques used for the gastrointestinal tract. However, contrast radiography, similarly to contrast-enhanced CT, provides only very limited or no information about esophageal or gastrointestinal motility. It has been suggested that esophageal scintigraphy might provide valuable information in gastroesophageal

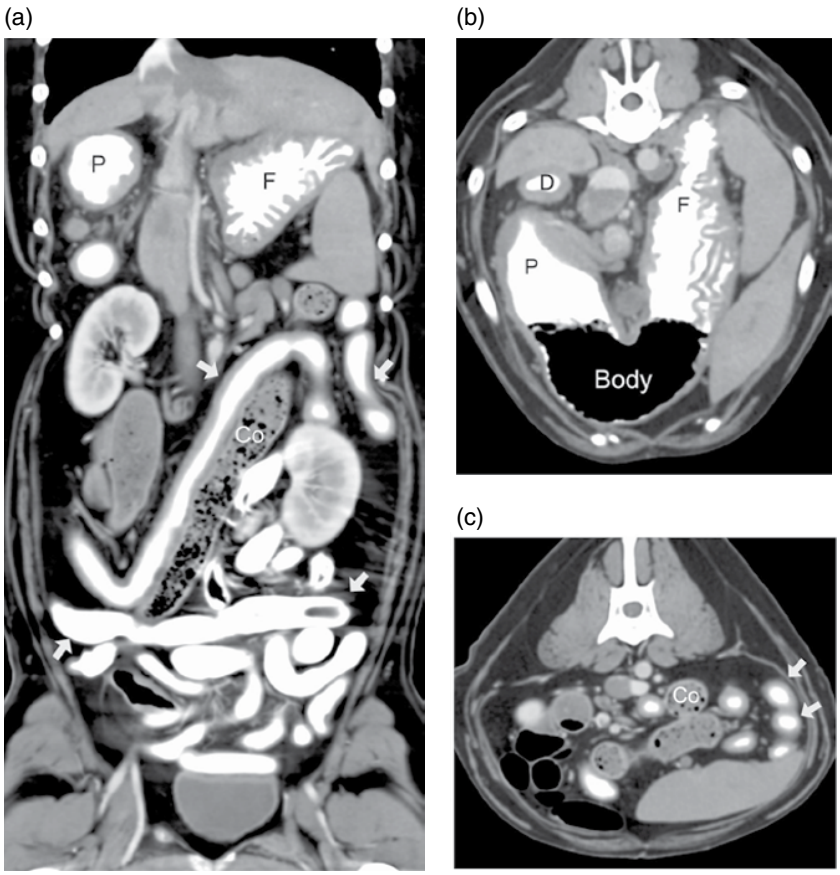

Figure 48.2 Dorsally reconstructed CT enterography image (a) and corresponding transverse CT images at the level of the stomach (b) and midabdomen (c). Iodinated contrast agent is noted in the stomach and small intestinal tract (*arrows*). The pylorus (P) and fundus (F) of the stomach are fluid filled and the gastric body is gas filled as the patient was scanned in dorsal recumbency. No contrast agent filling is noted in the colon (Co).

reflux patients. Scintigraphy is considered to be the gold standard for noninvasive evaluation of gastric emptying and intestinal transit times. Gastric emptying is evaluated by providing the animal with a standardized radiolabeled food and carrying out repeated nuclear imaging of the patient at defined intervals and in various positions for 4–6 hours. The variability of gastrointestinal transit times in dogs is very high, however, which limits the application of scintigraphy for clinical use.

Scintigraphy may have a use in clinical patients, if serial studies are done so that progression or response to treatment can be followed. However, in addition to the high variability of the gastrointestinal transit times, the lack of access to scintigraphy equipment and the need for the use of radiopharmaceuticals, which requires radiation safety precautions, limit the use of this technique in the daily clinical work-up of gastrointestinal disease.

The Pharynx

Normal Anatomy and Examination Technique

The pharynx is at a three-way crossroads of respiration, swallowing, and vocalization. The pharynx is located caudal to the oral and nasal cavities and cranial to the esophagus; this region allows transport of food from the mouth to the esophagus. During respiration, the pharynx allows the passage of air from the nasopharynx to the larynx. During vocalization, the pharynx functions as a resonating chamber and can alter sounds. Disorders of the pharynx may therefore result in dysfunction of swallowing, respiration or vocalization. Patients may therefore present with signs of dysphagia, choking, gagging and retching, or voice changes and the generation of unusual sounds.

Structural abnormalities of the pharynx are rare. The most commonly reported congenital abnormality of the pharynx is an elongated soft palate. Rarely, unilateral or bilateral hypoplasia or aplasia of the soft palate or midline clefts have been reported. Even less commonly, nasopharyngeal or intrapharyngeal stenosis has been described.

Head and neck survey radiographs are often a first step to evaluate for problems in the oropharyngeal phase of digestion. The most common radiographic views include a lateral and DV or VD view of the head and neck. In the VD and DV view, the pharyngeal and cricopharyngeal structures can be difficult to evaluate due to the complexity of the anatomy and the summation with adjacent skeletal and soft tissue structures. Survey radiographs are evaluated for the presence of anatomic abnormalities, including clefts, fractures of the adjacent osseous structures including the hyoid apparatus and abnormalities or fractures of the temporomandibular joints. With a cleft palate, an abnormal connection between the oral and nasal cavity exists, allowing food to enter the nasal cavity from the oral cavity. Radiographically, lack of air filling of the nasal cavity and abnormal content within the nasal cavity may be noted. Neuropathies are less commonly encountered reasons for oropharyngeal dysphagia. Survey radiographs mainly provide morphometric information in neuropathy patients, as there is often no anatomic abnormality present. Although survey radiographs followed by contrast radiographs with barium administration can provide valuable information, fluoroscopy is often needed to identify functional abnormalities.

Commonly, contrast imaging for pharyngeal motility studies is performed by administering liquid barium sulfate contrast agent; this should always be followed by administration of a mixture of solid food coated with barium sulfate. Patients may exhibit more signs when swallowing liquid or solid material and therefore both aspects should be evaluated. Additionally, thoracic radiographs should be considered, as secondary lung disease might be present.

Ultrasound Examination of the Pharynx

Ultrasound is infrequently used to evaluate the pharyngeal area as the summation with surrounding air-filled and osseous structures limits the evaluation of this region. Ultrasound has shown value if perforating injuries by plant material are present and can help to identify penetrating foreign bodies and assist in surgical interventions.

Assessment of Pharyngeal Function

Dysphagia is a nonspecific term and mainly describes abnormal swallowing. Common clinical signs include regurgitation, recurrent respiratory disease or weight loss. Dysphagia can result from functional or anatomic lesions, which can be intrinsic to the alimentary tract or extrinsic from adjacent structures causing compression of the alimentary tract. Dysphagia can involve any or all of the structures involved in swallowing, including the tongue, hyoid apparatus, soft palate, pharyngeal muscle, cranial esophageal sphincter, esophagus, and caudal esophageal sphincter. Various classifications of dysphagia have been made. Typically, dysphagia will be classified based on the location of the swallowing impairment as oropharyngeal, esophageal, or gastroesophageal.

Oropharyngeal dysphagia can occur in any of three different phases of swallowing: oral, pharyngeal, or cricopharyngeal. Dogs with disturbances in the oral phase of swallowing usually have difficulty with prehension of food and moving the bolus to the caudal aspect of the tongue. The main indications for radiography in cases of

suspected oropharyngeal dysfunction include screening for anatomic, mechanically obstructive lesions, particularly if there is a history of trauma or concern for a neoplastic lesion. In the early stages of the disease, oral neoplasms rarely cause swallowing disorders. When swallowing disorders are noted secondary to neoplasia, the disease process is typically very advanced.

In routine barium swallow studies, contrast medium may be noted in the dependent buccal fold, oral cavity, and valleculae. No contrast should be noted in the pharynx, cranial esophageal sphincter, and esophagus.

Pharyngeal phase dysphagia is associated with inadequate peristalsis, leading to retention of the contrast agent bolus in the oral cavity and reflux into the nasopharynx, oral cavity, and potentially the larynx.

With cricopharyngeal dysphagia, discoordination of the motor activity of the pharynx, cricopharyngeus muscle, and upper esophageal sphincter occurs. Cricopharyngeal achalasia refers to a lack of opening of the cricopharyngeal sphincter; radiographically, the passage of contrast agent is impeded and contrast agent can reflux into the nasopharynx, larynx, oropharynx, and piriform recesses.

Cricopharyngeal chalasia is a failure to close the cricopharyngeal sphincter. Radiographically, this is seen as a persistent passage of contrast agent between the pharynx and cranial esophageal sphincter. Additional reflux of contrast agent is typically noted, including into the piriform recesses. Pharyngeal and cricopharyngeal dysphagia show similar patterns of retention of contrast agent. If pharyngeal dysfunction is suspected, it is important to evaluate the swallowing of liquid and solid material.

Esophageal dysphagia causes a problem in transport of food through the body of the esophagus. Gastroesophageal dysphagia occurs secondary to a functional abnormality, which includes a motility disturbance or an obstructive process.

The Esophagus

The esophagus is a muscular tube that extends from the cricopharyngeus muscle at the level of the cricoid cartilage to the stomach. The largest aspect of the esophagus is located within the middle mediastinum. The normal esophagus is usually not visualized radiographically; occasionally a normal esophagus can be visualized due to small quantities of air present in the esophageal lumen secondary to swallowing of air. A normal esophagus might also be visualized if air is present in the mediastinum (pneumomediastinum). The normal esophagus may also be dilated during or immediately following general anesthesia; repeat radiographs can be necessary, with the patient awake, to exclude esophageal disease. The normal esophageal wall consists of four layers: mucosa, submucosa, muscularis, and serosa. In the dog, the entire musculature of the esophagus is striated. In the cat, the caudal third of the esophagus, caudal to the heart base, is smooth muscle. This causes obliquely directed folding of the overlying mucosa of the esophagus, resulting in a characteristic herringbone pattern noted during contrast imaging studies of the esophagus in cats.

The most common indications for radiography of the esophagus include a history of regurgitation and dysphagia, recurrent unexplained respiratory illness, ptyalism, gagging, change in attitude often associated with feeding, or cervical pain and swelling. The most common reasons for further imaging of the esophagus after survey radiographs include generalized dilation (megaesophagus), localized dilation, suspected esophagitis, esophageal foreign body or masses, and esophageal perforation. It is important to remember that failure to visualize the esophagus on plain radiographs does not exclude the presence of esophageal disease. An early sign of esophageal disease might include the retention of air in the esophagus noted on survey radiographs. This might warrant further evaluation of the esophagus, which can include an upper gastrointestinal tract radiography or endoscopy.

Upper Gastrointestinal Tract Radiography (Esophagram)

An exhaustive examination of the esophagus includes contrast radiographic examination as well as fluoroscopic evaluation of the motility of the esophagus. Contrast radiography of the esophagus requires no special preparation; however, plain radiographs should always be obtained prior to administration of contrast agent to outline abnormalities of the esophagus. It is important to include the entire esophagus in the study, from the pharyngeal area to the stomach.

The normal esophagus is collapsed after a primary peristaltic wave and contrast studies should therefore be performed with a reasonable amount of oral contrast agent to ensure adequate coating and distension of the esophagus for evaluation. Barium sulfate suspensions or paste are usually administered at a dosage of 2–6 mL/kg bodyweight. It is important to give a large enough bolus (usually 5–20 mL of contrast agent) to ensure complete swallowing. Smaller sized boluses may not stimulate a strong primary esophageal peristalsis sufficient to clear the contrast agent from the esophagus. Therefore, at least medium-sized fluid or solid boluses are recommended for evaluation of swallowing and the esophagus. The high-density, low-viscosity barium formulations designed for the stomach and small intestinal tract also coat the esophagus well. If, however, inadequate coating

of the esophagus results, barium paste should be used to enhance coating of the mucosa.

Double contrast esophagus studies are commonly performed in human patients but are rarely used in veterinary medicine. In some patients, where air is present in the dilated esophagus, it functions as an endogenous negative contrast agent and no additional contrast medium may be needed. If barium sulfate suspension is used for the esophagram, no contrast should be remaining in the esophagus in approximately 5 minutes; if barium paste is used, all contrast agent should be cleared from the esophagus by approximately 30 minutes. In general, in the normal esophagus, no contrast agent should be stored or remain after a contrast agent study has been performed.

In patients with suspected esophageal perforation, water-soluble contrast solutions should be used for evaluation of potential leakage from the esophagus. However, water-soluble iodine solution contrast agents should be used with great care for an esophagram, as ionic iodinated contrast agents are hypertonic and, when aspirated, will most likely cause severe pulmonary edema. If a bronchoesophageal fistula is suspected, nonionic iodinated contrast solutions should be used to reduce the risk of iatrogenic pulmonary edema. Water-soluble contrast agents for outlining the esophagus are usually administered at a dosage of 2–3 mL/kg bodyweight to achieve approximately 700 mg iodine per kg bodyweight and adequate distension of the esophagus. However, if no contrast leakage is identified, a repeat study with a higher density barium suspension can be performed to allow visualization of a smaller sized lesion that was potentially missed using a water-soluble contrast agent. It has been noted in studies in humans as well as experimentally in rats that no significant mediastinitis was identified post barium leakage through a very small esophageal defect, nor was a significant interference with subsequent radiographic evaluations noted. It has been recommended to warm up the barium solution to 40 °C when a perforation is suspected, as this decreases the viscosity of the barium sulfate solution without decreasing the radiopacity and increases the sensitivity of detecting smaller sites of leakage in the esophagus.

Generalized Esophageal Dilation (Megaesophagus)

Megaesophagus is a disorder caused by diminished esophageal tone and hypomotility, causing generalized dilation of the esophagus. Congenital and acquired forms of megaesophagus are recognized in the dog and cat. The underlying cause of congenital megaesophagus remains unknown, but inadequate development of the esophageal innervation or altered biochemical properties of the esophagus have been discussed.

Survey radiographs are often diagnostic for a dilated esophagus, when the esophagus contains food, water or air (Figure 48.3).

On lateral radiographs, the dilated esophagus is usually well demarcated dorsally by the longus colli muscle or summating within the thoracic vertebrae and ventrally summating with the dorsal aspect of the trachea, leaving the impression of a dorsally thickened trachea wall (the tracheal stripe sign; Figure 48.4). It is important not to confuse the tracheal stripe sign with pneumomediastinum, where the esophagus is circumferentially surrounded by air. In severe esophageal dilation, a ventral

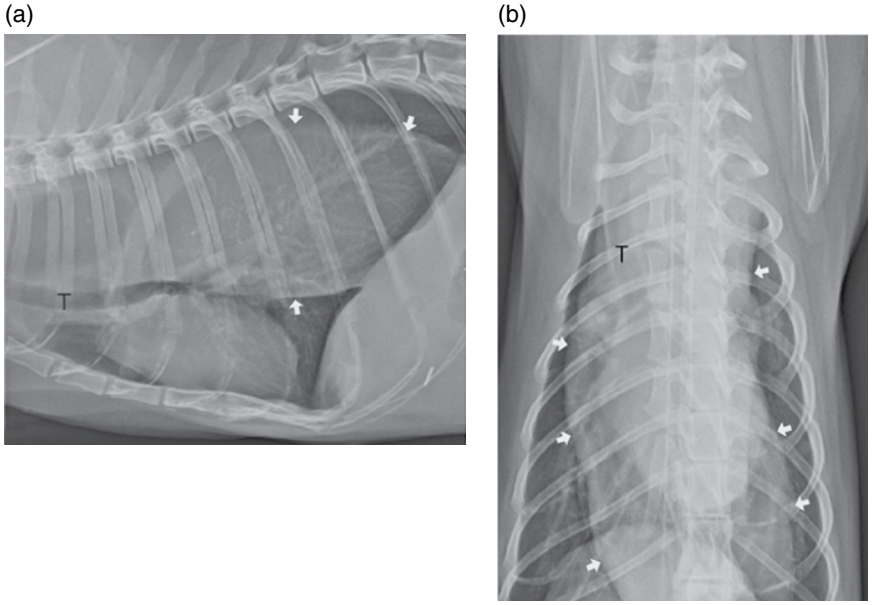

Figure 48.3 Severe generalized dilation of the esophagus with fluid and gas (megaesophagus) in a cat. Right lateral (a) and ventrodorsal (b) radiographs of the thorax demonstrating severe dilation of the esophagus (megaesophagus) resulting in ventral and right lateral displacement of the trachea (T) and ventral deviation of the cardiac silhouette.

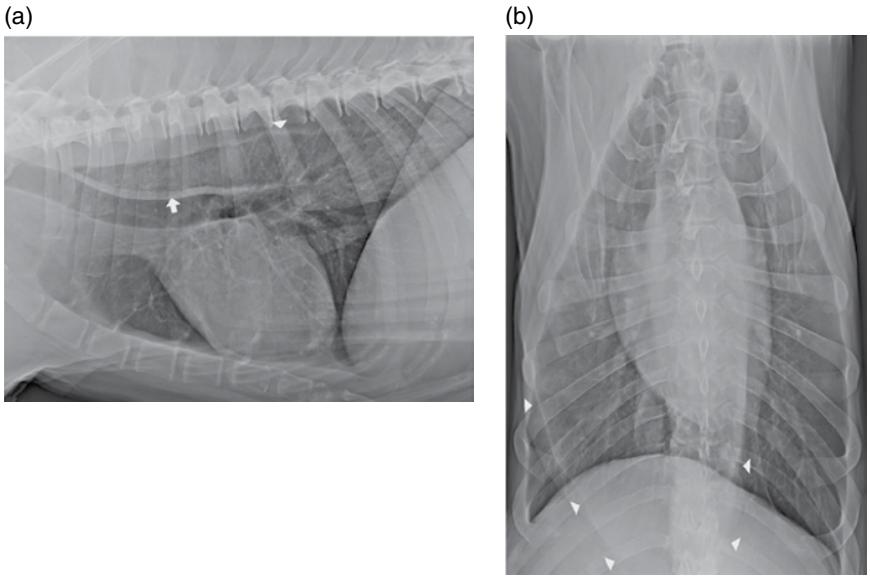

Figure 48.4 Moderate generalized dilation of the esophagus with gas in a dog. Left lateral (a) and dorsoventral (b) radiographs of the thorax. The ventral wall of the dilated esophagus is summating with the dorsal wall of the trachea resulting in a "tracheal stripe sign" (*arrow*) in the lateral radiograph. The borders of the dilated esophagus (*arrowheads*) show in the dorsoventral view a characteristic V-shape.

deviation of the trachea and cardiac silhouette may be noted. When the esophagus is fluid filled, a wide soft tissue attenuating area can be seen in the dorsal aspect of the thorax. In the VD or DV view of megaesophagus, the esophagus is usually located on or to the right of midline. A fluid- or gas-filled, dilated esophagus typically shows a V-shape narrowing from cranially to caudally on a VD or DV radiograph, with the narrowest area at the level of the esophageal hiatus at the diaphragm. A contrast esophagram is recommended if it is not possible to differentiate between generalized and focal esophageal dilation.

Vascular Ring Anomalies

Vascular ring anomalies are the most common reason for focal dilation of the esophagus in the cranial mediastinum. Other, less common causes for focal esophageal dilation include bronchoesophageal fistulae, neoplasia or strictures secondary to trauma of the esophagus. In addition to regurgitation, patients with vascular ring anomalies are often smaller than their littermates, have an overall low body condition and can have a history of regurgitation of solid food when weaning.

Vascular ring anomalies are developmental abnormalities of the primordial aortic arches resulting in a complete or partial circle of tissue around the trachea and the esophagus, causing compression of the encircled structures. Most commonly, a focal dilation of the esophagus cranial to the base of the heart is noted on imaging studies. Additionally, a marked focal leftward shift of the trachea is noted on DV or VD radiographs. A ventral deviation of the esophagus can be noted on lateral radiographs (Figure 48.5). In the dog, the persistent right aortic arch is the most commonly encountered vascular anomaly, reported in 95% of dogs with vascular ring anomaly. In patients with persistent right aortic arch, the aorta is formed by the right instead of the left fourth aortic arch. The left ligamentum arteriosum, connecting between the abnormally positioned aorta and the pulmonary artery, creates a vascular ring anomaly around the trachea and esophagus. Approximately one-third of these dogs also have an aberrant left subclavian artery, which, in combination with the persistent right aortic arch, can contribute to an additional partial ring formation, resulting in focal dilation of the esophagus.

In the cat, vascular ring anomalies occur less frequently than in the dog and reported vascular anomalies include a persistent right aortic arch with right or left ligamentum arteriosum, double aortic arch or aortic coarctation. If, in addition to the aforementioned imaging changes, a tracheal stenosis and/or malformation of the tracheal rings is present, a double aortic arch should be considered. Contrast-enhanced CT angiography will help to more accurately define and outline the vascular anomaly responsible for the focal dilation of the esophagus and can therefore help to improve surgical planning.

Esophageal Foreign Bodies

Esophageal foreign bodies occur commonly in dogs, but are less commonly noted in cats. Esophageal foreign bodies are most commonly found in the caudal esophagus and are often located between the heart base and the diaphragm. However, esophageal foreign bodies in the mid-mediastinum dorsal to the heart, in the cranial mediastinum cranial to the heart as well as just caudal of the pharynx have also been reported. Esophageal obstruction secondary to foreign bodies can lead to perforation (Figure 48.6).

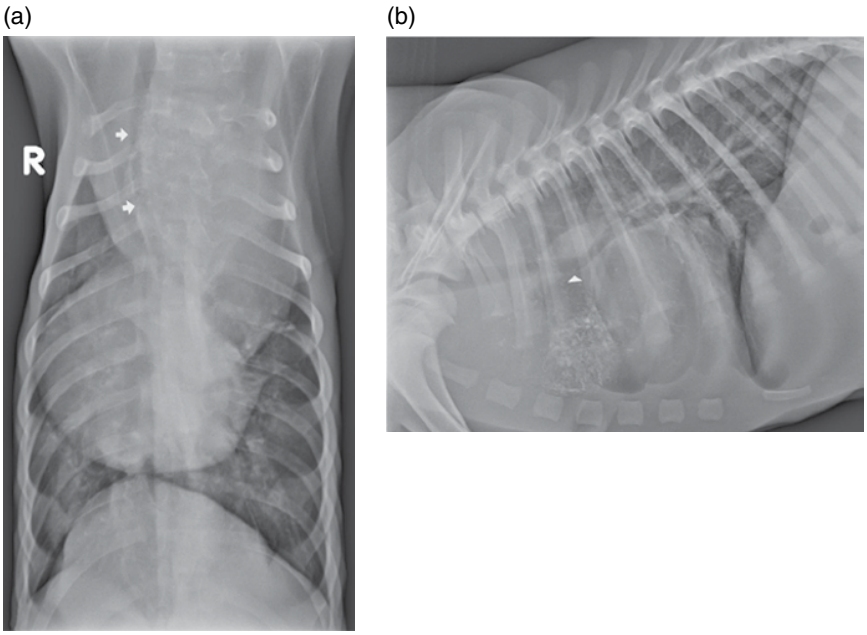

Figure 48.5 Dorsoventral (a) and right lateral (b) radiographs of the thorax of a young dog with a persistent right aortic arch and left ligamentum arteriosum confirmed at surgery. The esophagus cranial to the base of the heart is dilated (esophageal diverticulum), which is noticeable as a soft tissue attenuating structure within the cranial mediastinum, displacing the trachea (*arrows*) to the right and mildly ventrally (*arrowhead*). A small amount of mineral attenuating material is noted in the dilated aspect of the esophagus. Mild narrowing of the trachea is noted in the deviated segment.

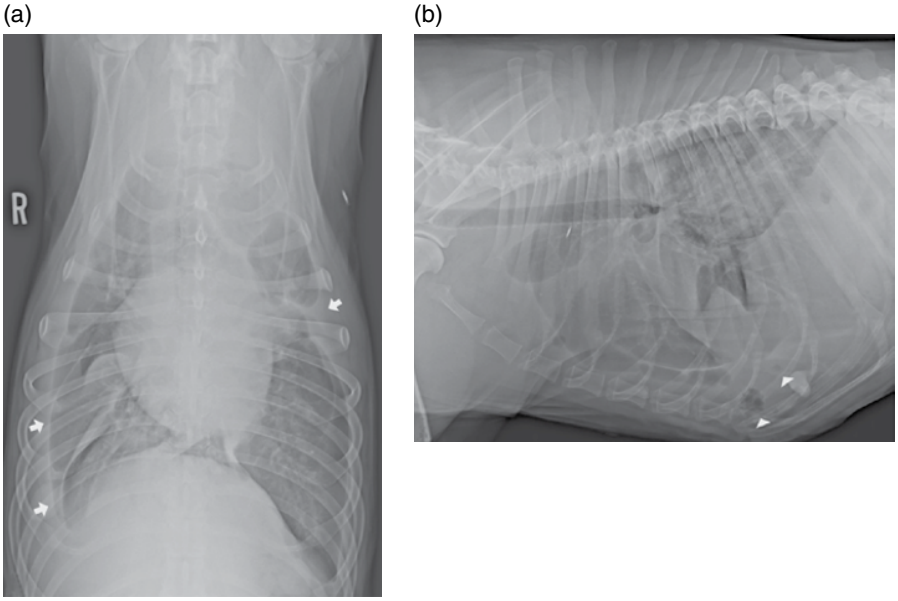

Figure 48.6 Esophageal perforation with secondary mediastinitis and pleuritis in a dog secondary to esophageal foreign body caused by swallowing a hoof dog treat. Dorsoventral (a) and right lateral (b) thoracic radiographs. Pleural fluid (*arrow*) and mediastinal fluid and gas (*arrowheads*) is present. The borders of the esophagus are indistinct.

Esophageal foreign bodies may be radiopaque and easily visualized (Figure 48.7) or soft tissue opacity and difficult to identify. Sometimes gas within the esophageal lumen might help in outlining the foreign body. A negative or positive contrast agent study of the esophagus might provide additional information. If perforation of the esophagus is suspected, small quantities of water-soluble contrast agent should be used to demonstrate the esophageal wall defect instead of barium sulfate suspension.

Figure 48.7 Esophageal foreign body. In the cranial cervical esophagus on a lateral radiograph of the neck of a dog a bone surrounded by gas is noted.

Esophagitis, Gastroesophageal Reflux

Common causes for esophagitis include gastroesophageal reflux, structural abnormalities of the hiatus of the esophagus (hiatal hernia), neoplasia, trauma, medication, and chronic vomiting. Esophagitis is difficult to diagnose on survey radiographs. On an esophagram, a caudally thickened and irregular esophagus might be noted. Radiographically, reflux esophagitis can be confirmed by filling the stomach with barium and pressing on the stomach. If reflux esophagitis is present, reflux of contrast agent into the esophagus is likely to be noted.

Esophageal Strictures

Esophageal strictures can occur secondary to severe erosive esophagitis, and are often associated with perianesthetic esophageal reflux or secondary to foreign body impaction, trauma or a surgery, where the esophagus was displaced and/or manipulated, such as during ventral cervical slot surgery. Plain contrast esophagram is usually diagnostic, revealing a segment of esophagus that persistently fails to dilate.

Esophageal Fistula

An esophageal fistula is an abnormal connection between the esophagus and trachea, bronchus, lung parenchyma or skin. Veterinary reports of esophageal fistulae are rare. Esophageal fistulae are very rarely reported in dogs and cats. The disease is occasionally reported in humans, especially children. The most commonly reported clinical signs include spontaneous coughing, coughing after drinking water, and recurrent chronic respiratory disease. The most commonly reported fistulae are congenital, but acquired fistulae secondary to injury of the esophagus, such as secondary to a foreign body, have been observed. The most commonly reported acquired fistulae are esophagobronchial, with less common reports of esophagotracheal and rarely esophagoaortic fistulae. As the clinical presentation of esophageal fistulae is similar to patients with aspiration pneumonia, it is crucially important to differentiate between the two conditions.

It is possible that the fistula opening can be identified during bronchoscopy or endoscopy of the esophagus; however, contrast agent swallowing studies using fluoroscopy are often more reliable for identification of the connection between the trachea, bronchus or lung and the esophagus. All images should be carefully evaluated for leakage of contrast agent outside the esophagus. If a fistula is suspected and not noted on an initial esophagram, it might be necessary to dilute the barium contrast medium (1:1) as dilution of the barium sulfate suspension decreases the viscosity and therefore allows visualization of smaller defects in the esophageal wall.

Additional imaging techniques, such as contrast-enhanced CT, might help to further define the precise location and size of a fistula. In humans, the use of air as a negative contrast agent to outline the esophagus has further helped to demonstrate the presence of the fistula.

Tumors of the Esophagus

Tumors of the esophagus are rare, likely accounting for less than 0.5% of the tumors reported in cancers in dogs. Similar epidemiologic studies in cats are currently lacking. Clinical signs of esophagus disease such as regurgitation are often only observed when the tumor has grown to such a size that it is causing obstruction of the esophagus.

In the dog, leiomyomas or leiomyosarcomas affecting the lower esophageal sphincter have been described (Figure 48.8). Aggressive neoplasms of the esophagus are extremely rare in dogs in areas not endemic for *Spirocerca lupi*. Extremely rarely, squamous cell carcinomas, neuroendocrine carcinoma or adenocarcinomas of the esophagus have been reported in the dog and cat.

Endoscopy of the esophagus may allow identification of esophageal masses. Similarly, contrast radiography will allow outlining of smaller masses. If the mass is large, it is likely to be noted on survey radiographs (see Figure 48.8). Additionally, tumors in the caudal esophagus might also be noted during an abdominal ultrasound exam, when the cardia of the stomach is evaluated.

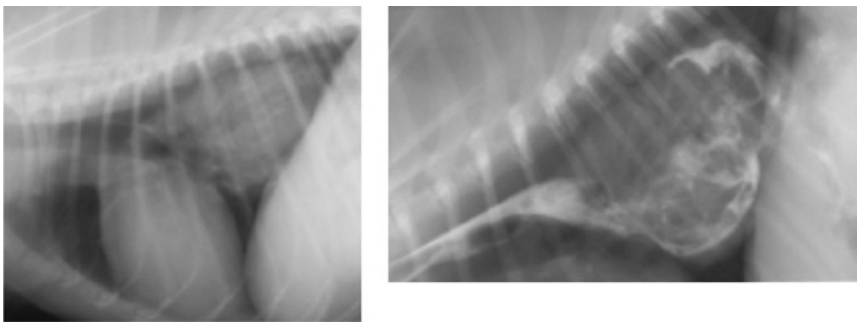

Figure 48.8 Neoplasia of the caudal esophagus. In the caudal mediastinum, a soft tissue attenuating mass is noted. On a barium esophagram, ventral displacement of the esophagus and an irregular contrast pattern are noted outlining a soft tissue attenuating structure. A small amount of contrast agent is noted in the stomach.

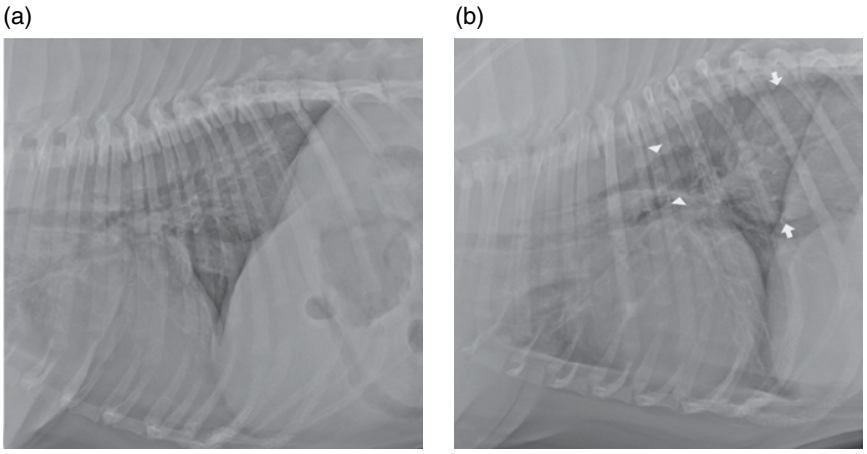

Figure 48.9 Sliding hiatal hernia (type 1 hiatal hernia) in a dog, which presented for thoracic radiographs to evaluate for the presence of pulmonary metastatic disease. (a) Right lateral radiograph. The stomach is in normal position but part of the stomach is summating cranially with the right diaphragmatic crus. (b) Left lateral radiograph. Part of the stomach is cranially positioned (*arrow*) and the esophagus is dilated (*arrowheads*).

Masses of the esophagus may lead to hypertrophic osteopathy, which might be noted on imaging studies before an esophagus lesion is identified.

Abnormalities of the Gastroesophageal Junction

Gastroesophageal Intussusception

Gastroesophageal intussusception is rare, and is caused by invagination of the stomach without or with other abdominal organs into the esophagus. This intussusception is only possible if a predisposing condition such as a megaesophagus, dilation of the esophageal sphincter or chronic vomiting is present.

Radiographically, a well-defined soft tissue mass is present in the caudal esophagus. Rugal folds might be seen within the soft tissue mass. Dilation of the more orad esophagus might be noted. The stomach or part of it might be absent on abdominal radiographs. Sonographically, no stomach or only part of the stomach might be identified in the abdomen. The cardia of the stomach might be severely dilated.

Hiatal Hernia

Diaphragmatic hernias are relatively common abnormalities. These hernias can involve the esophagus in hiatal hernias (Figure 48.9) and paraesophageal hernia, or the entry of stomach and abdominal viscera in peritoneopericardial hernias. Hiatal hernias may occur as transient or persistent hernias. Transient or sliding hernia is the most common form of hernia diagnosed in dogs and cats, where it is most frequently diagnosed in young animals. Occasionally, it is also noted in adult animals, in whom it is more likely to be an acquired form. The acquired form can occur secondary to trauma or severe upper respiratory disease. Commonly represented dog breeds include the English bulldog and SharPei. In cats, domestic shorthairs are more commonly affected. Animals with hiatal hernias may present with signs of regurgitation, hypersalivation, vomiting, and delayed growth. Sliding hernia may be difficult to diagnose due to its intermittent nature.

Radiographically, a dilated esophagus and abnormally cranial position of the stomach may be noted. In paraesophageal hernias, the gastroesophageal sphincter/junction remains in the correct position, but the fundus is displaced through the hiatus into the caudal esophagus.

The Stomach

The stomach is the most distensible organ of the digestive system, and plays an important role in the second phase of digestion. The stomach is positioned caudal of the liver and is fixed in position at the diaphragm and

duodenum. The stomach consists of four major anatomic divisions: the cardia, fundus, body, and pylorus. There are two sphincters, one each at the orad and aborad aspects of the stomach. The caudal esophageal sphincter extends into the cardia, while the pylorus is located at the junction between the stomach and duodenum. The pylorus is divided into the pyloric antrum and canal. The pylorus has an important gatekeeper function, only allowing smaller sized particles to exit the stomach into the small intestinal tract.

Radiographic Examination of the Stomach

In a survey radiographic study, the stomach is located predominantly to the left of midline with the cardia located slightly to the left of midline, ventral to the 11th and 12th thoracic vertebrae. The fundus is positioned to the left of midline and just caudal to the liver and diaphragm. The fundus is the only aspect of the stomach which can be in direct contact with the diaphragm. The antrum is usually not distinctly outlined and is located between the fundus and pyloroduodenal junction. The pylorus is located on or to the left of midline in the cat and on midline or to the right of midline in the dog. The gastric axis in the dog is usually perpendicular to the spine or parallel with the ribs. In the cat, it is usually more perpendicular to the spine. In a lateral radiograph, the pylorus is located approximately at the ventral aspect of the ninth rib.

Radiographic attenuation of the stomach is dependent on its content. The stomach usually contains both gas and fluid, but if the stomach is empty or only a small amount of fluid is present in the stomach, it may be difficult to visualize as it summates with the liver. The stomach has rugal folds, which are usually best seen on a contrast study or ultrasound evaluation. Rugal folds within the fundus of the stomach often create a mosaic pattern. In the body of the stomach, the rugal folds are more parallel and in the pylorus the number of rugal folds is reduced. Subjectively, rugal folds in the cat are less prominent than in the dog.

Obtaining multiple projections in various positions of the patient is important when evaluating the stomach radiographically. Changing the position of the stomach affects the position of the gas and fluid in the stomach.

In dorsal recumbency (VD view), gas is located in the gastric body and pyloric antrum and can be noted as a gas opacity structure summating with the stomach at the right and left side of midline. In ventral recumbency (DV view), the gas is present in the fundus of the stomach, which is then the most dorsal aspect of the stomach. In a DV view, a gas opacity structure is noted summating with the left cranial aspect of the stomach in the location of the fundus. In a right lateral recumbency view, the gas is located in the fundus region and the fluid is located in the gastric body/antrum. The fluid in the gastric body/antrum creates a round, circular, soft tissue attenuating area in the cranial abdomen, which is occasionally mistaken for a foreign body in the pylorus or a mass in the cranial abdomen. In the left lateral recumbent view, gas is present in the pyloric region, appearing as a gas opacity oval or triangle-shaped structure in the cranioventral aspect of the abdomen (Figure 48.10).

Ultrasound Examination of the Stomach

An ultrasound examination of the stomach helps evaluate the gastric mucosa and gastric content. If possible, patients should be fasted for 12 hours before an ultrasound examination is performed as food in the stomach might create artifacts. The stomach is positioned caudal to the liver, predominantly central to left of midline, and adjacent to the spleen. The cardia is located to the left of midline and can usually be seen as a thick bulge with a smooth mucosal outline at the border of the thoracic esophagus to fundus. The pylorus is located to the right or on midline in the dog and is usually on or slightly to the left of midline in the cat. The stomach wall thickness ranges from 3 to 5 mm in normal dogs and cats. The pyloric wall thickness in the cat is 3.8–5 mm, which is similar to established gastric wall thickness measurements of 3–5 mm. Under optimal conditions, five layers of the stomach and small intestine are visualized (Figure 48.11). The innermost hyperechoic layer corresponds to the luminal surface of the mucosa. The next hypoechoic layer is the mucosa, which is followed by another hyperechoic thin layer, the submucosa. The outer hypoechoic layer is the muscularis, which is adjacent to the outermost hyperechoic layer, the subserosa/serosal layer.

Gastrography

Indications for contrast studies of the stomach (gastrography) include vomiting, regurgitation, a history of foreign body consumption, chronic weight loss, bloating, and anorexia. Contraindications for performing gastrography include suspected gastric rupture, large amounts of ingesta or large amounts of fluid in the stomach. A potential contraindication could be a rigid stomach as overfilling of the stomach might cause vomiting, resulting in aspiration. Before a gastrography is performed, survey radiographs of the abdomen should be obtained. For all gastrography studies, 12 hours of fasting of the patient is recommended to reduce the risk of artifacts caused by food or other material in the stomach. Most of the study can be performed without sedation of the patient; however, if the patient is not sufficiently

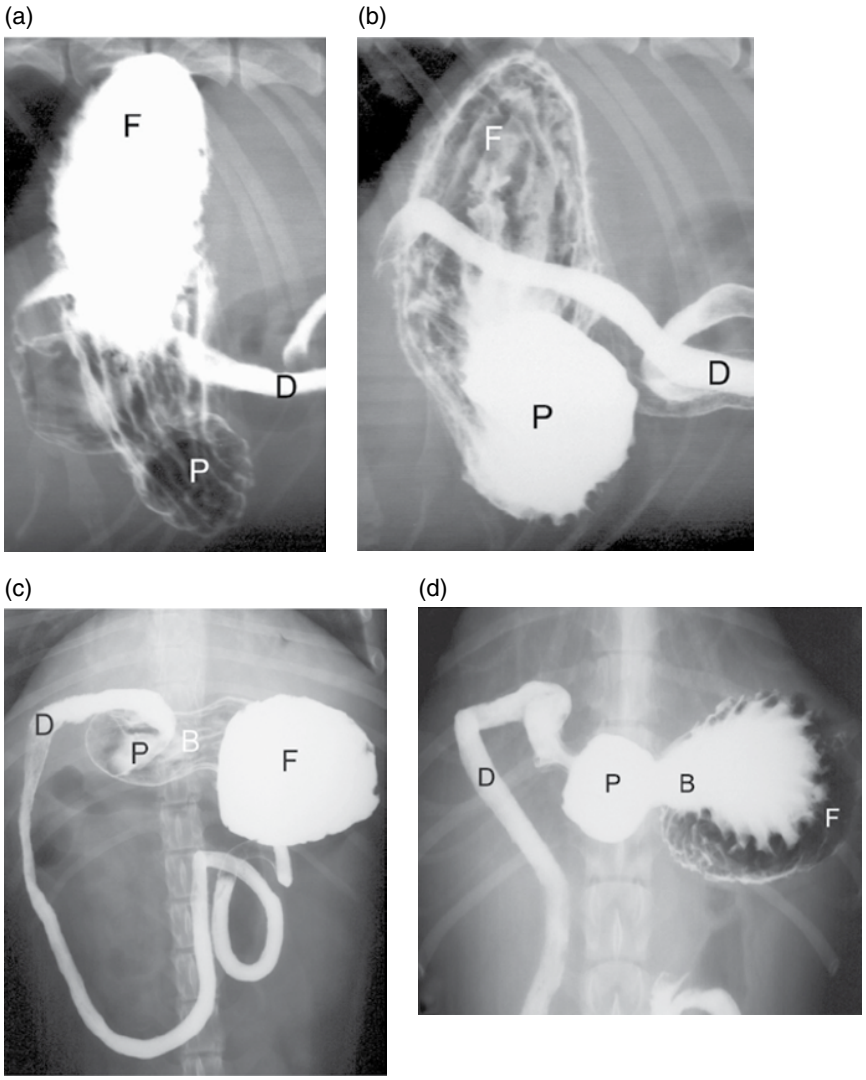

Figure 48.10 The movement of gastric content is dependent on the patient positioning. In a left lateral radiograph (a), fluid (barium contrast agent) is located in the fundus (F) of the stomach and the pylorus (P) is gas filled. In a right lateral radiograph (b), fluid is in the pylorus (P) and gas is in the fundus (F). In a ventrodorsal radiograph (c), fluid is in the fundus and gas is in the gastric body (b) and pyloric antrum. In a dorsoventral radiograph (d), gas is in the fundus and fluid is located in the gastric body (b) to pyloric area.

relaxed, mild sedation should be administered, ideally one which does not or only minimally affects gastrointestinal motility. Contrast studies of the stomach can be performed using negative contrast agents, positive contrast agents or as a double contrast study.

Negative contrast studies of the stomach are mainly performed to evaluate for the presence of a gastric foreign body or to evaluate the location of the stomach. Orogastric intubation is performed, followed by filling the stomach with room air at a dose of 6–12 mL/kg bodyweight, or filling the stomach until it is palpably distended. Alternatively, a carbonated beverage can be given into the buccal pouch (at least 30–60 mL) if the patient does not drink it voluntarily. After distension of the stomach is achieved, four views of the abdomen should be obtained. If a foreign body in the pyloric antrum is suspected, a horizontal beam view with the patient in left lateral recumbency might help to better outline the foreign body.

Positive contrast gastrography is performed by using either barium sulfate suspension or an iodinated contrast agent to outline the stomach. An iodinated contrast agent should be used if a perforation of the stomach is suspected or if surgery is planned immediately after the positive contrast agent study. Iodinated contrast agents provide less coating of the gastric wall compared to barium sulfate suspension. For large dogs, use 5–7 mL/kg bodyweight barium sulfate 30% weight to volume suspension and for small dogs or cats 8–12 mL/kg bodyweight barium sulfate suspension. In cats, the recommended barium sulfate suspension volume can range up to 20 mL/kg.

Orogastric intubation for application of the contrast agent is recommended to reduce the risk of aspiration. Otherwise, the contrast agent can be placed in the buccal pouch using a syringe, but if the patient struggles the procedure should be stopped and orogastric tube placement should be considered. If ionic iodinated contrast

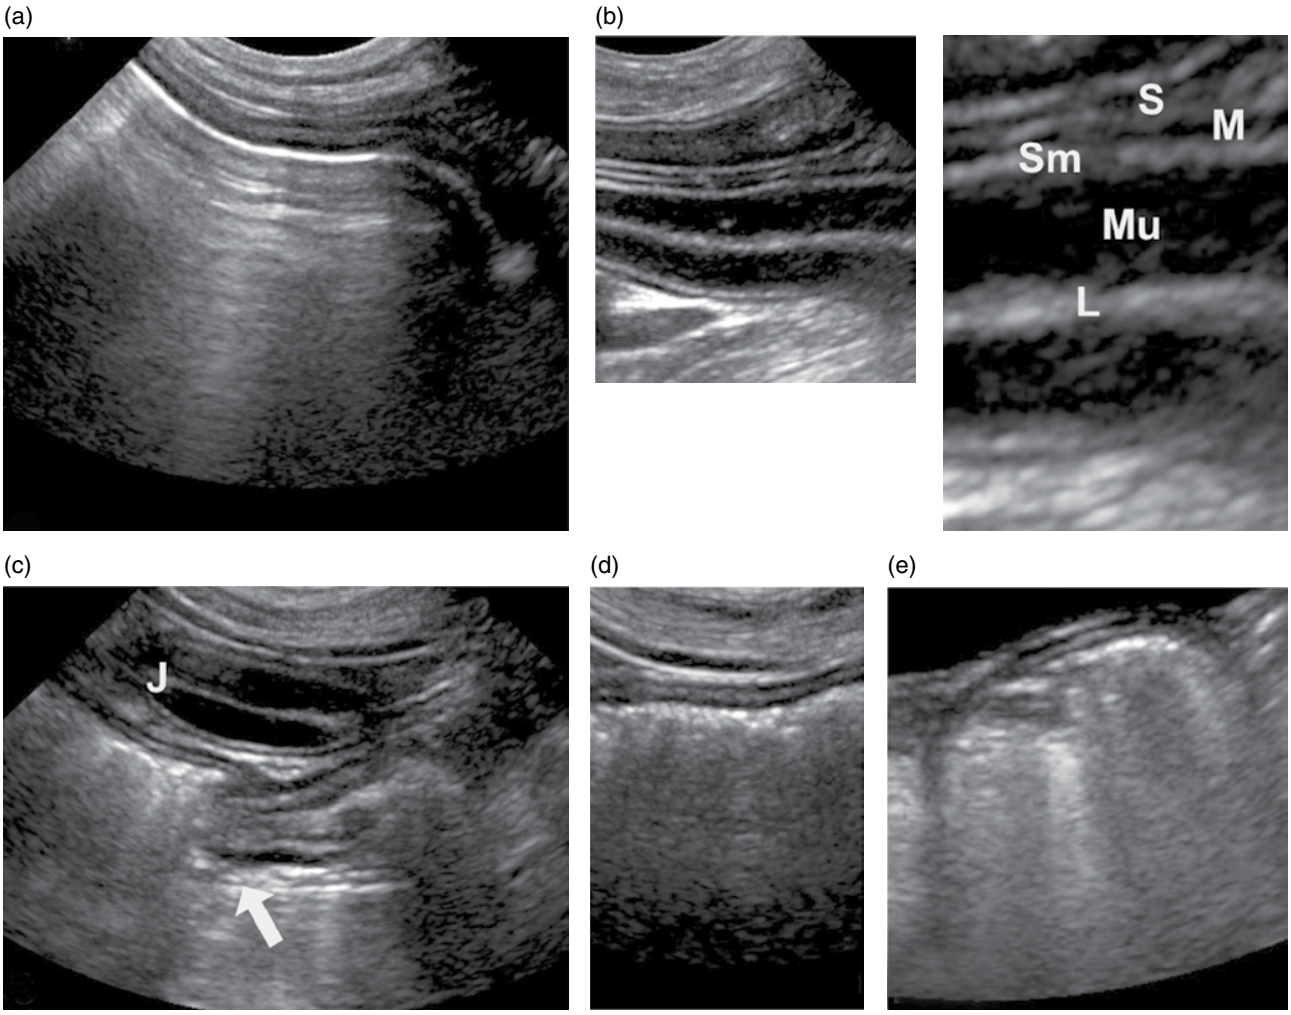

Figure 48.11 Normal gastrointestinal ultrasound images. Longitudinal ultrasound image of the stomach wall (a). Only the wall in the near field can be evaluated, as gas is present in the stomach causing reverberation artifacts and therefore limiting visualizing of the far wall. Longitudinal ultrasound image of the duodenum (b). The individual layers and lumen (L) are marked on a magnified image. Mu, mucosa; Sm, submucosa; M, muscularis; S, serosa. Longitudinal ultrasound image of the ileocolic junction (c) marked by an arrow. On the right side of the image is the ileum and on the left side is the ascending colon containing a small amount of gas. Between the ileocolic junction and the abdominal wall, a segment of jejunum (J) is noted. Longitudinal image of the ileum (d) and transverse image of the colon (e). The mucosa of the ileum is thinner when compared to the duodenum and jejunum. The colon wall is thinner and the individual wall layers are more similar in thickness.

agents are used, extreme caution is necessary to reduce the risk of aspiration as most ionic iodinated contrast agents designed for the gastrointestinal tract are hyperosmolar and draw in water, causing severe pulmonary edema when aspirated. Iodinated contrast agents are used at a dose of 2–3 mL/kg bodyweight. The iodinated contrast agent can also be diluted 1:4, but then the dose should be increased to 6–12 mL/kg bodyweight. Four views of the abdomen should be obtained to evaluate the stomach. A sufficient degree of distension of the stomach must be achieved to obtain a good-quality study.

The four views of the abdomen result in different appearances of the stomach due to the effect of gravity; the contrast agent will be positioned in the dependent aspect of the stomach and gas will be positioned in the nondependent aspect of the stomach similar to the distribution of water and gas in a four-view survey radiographic study. On the VD view, the barium sulfate suspension is located in the fundus region on the left and in the pyloric region in the right side of the abdomen. The body of the stomach is filled with air. In a DV view, the barium sulfate suspension is present in the body of the stomach and the fundus and pyloric area are gas filled. In a right lateral view, the barium sulfate suspension is located in the pyloric area and gas is noted in the body and fundus of the stomach. In a left lateral view, the

barium sulfate suspension is in the gastric fundus, while air fills the body and pyloric area of the stomach. Borders of the gastric wall to luminal contrast agent filling are normally distinct and well defined.

The diameter of the pylorus is usually approximately half that of the body of the stomach; if it is larger than that, disease of the pyloric canal may be present. The peristaltic wave normally runs from the fundus to the pylorus. During peristalsis, symmetric narrowing of the gastric fundus to pylorus wall may be noted.

Expected times for gastric emptying of contrast are quite variable. After administration of liquid barium sulfate suspension, emptying of the stomach should occur within the first 5–10 minutes, latest by 30 minutes. The stomach should be completely empty by a maximum of 2.5–3.5 hours in the dog and 15–60 minutes in the cat, if the barium was not mixed with food. Food material empties more slowly from the stomach and it can take up to 12 hours to observe a completely empty stomach. Emptying of the contrast agent from the stomach can also occur very rapidly if the stomach was empty and the dog fasted when the contrast study was started. Delayed gastric emptying can be noted in normal animals secondary to sedation, anesthesia, and anxiety. Delayed gastric emptying is frequently observed in anxious cats. Delayed gastric emptying can be noted in a wide range of diseases including gastritis, pancreatitis, neoplasia of the gastric or duodenum wall, and foreign bodies, to name a few.

Double contrast studies of the stomach are usually performed if a mucosal lesion (e.g., ulcer, gastritis, neoplasia) or presence of a foreign body is suspected. As this procedure can take more time than a simple gastrogram, sedation should be considered. Placement of an orogastric tube reduces the risk of aspiration of contrast agent and allows administration of air into the stomach. For a double contrast gastrography study, 1.5–3 mL/kg bodyweight barium 30% volume to weight suspension is given before 20 mL/kg air is added. Four radiographic views of the abdomen should be obtained. It is often helpful to gently roll the patient to achieve an even coating of the gastric wall before the four views are obtained.

Gastric Dilation

In gastric dilation, the stomach is distended without change in shape and position. This can be acute, secondary to aerophagia, gastritis, outflow obstruction, medical treatment, or chronic, secondary to a chronic obstructive process of the pylorus or proximal duodenum.

On a survey radiograph, a hugely dilated stomach with fluid and gas is noted (Figure 48.12). If the stomach is mainly fluid dilated, the radiographic diagnosis of gastric dilation may be more difficult as the stomach may appear as a soft tissue attenuating mass and can therefore not easily be distinguished from the liver. In these cases, caudal displacement of the colon and the location and shape of the soft tissue opacity might help to establish that the stomach is dilated. It is important to remember that not all patients with a gastric dilation have a mechanical obstruction. Additionally, gastric dilation may occur secondary to a mechanical obstruction of the duodenum, or secondary to pancreatitis.

The key to differentiation of gastric dilation from gastric dilation volvulus is the position of the pylorus. This is best determined by evaluating the right and left lateral recumbent views of the abdomen. In gastric dilation, the pylorus and duodenum in a right lateral recumbent view should be predominantly fluid filled, and in a left lateral recumbent view usually contain variable amounts of gas.

Gastric Dilation Volvulus

Gastric dilation volvulus is a frequently encountered, acute life-threatening disease in dogs. Gastric dilation volvulus rarely occurs in cats.

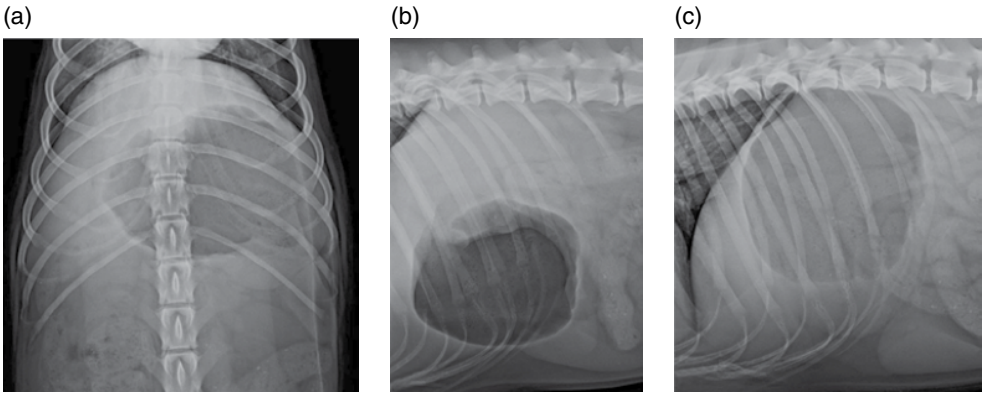

Figure 48.12 Gastric dilation. Ventrodorsal (a), left lateral (b), and right lateral (c) radiographs of the abdomen of a dog. Gas and fluid dilation of the stomach is noted. The stomach is in correct position. No compartmentalization is noted.

In gastric dilation volvulus, the stomach is usually abnormally distended, containing food, fluid and gas, and has an unusual shape and position (Figure 48.13). Often a rapid decision needs to be made on whether the stomach is rotated and dilated or only dilated. On abdominal radiographs, compartmentalization of the stomach is noted ("Smurf's head," "Popeye's arm"); if this happens, the stomach can appear to consist of two cavities, resulting from the dorsal and leftwards displacement of the gas-filled pylorus. The fundus tends to be ventrally and rightwards positioned, if a 360° rotation is not present. The right lateral radiographic view is often considered the most helpful view as it shows both abnormal gas filling and displacement of the pylorus and cranial duodenum (see Figure 48.13). In a normal right lateral view, the pylorus is typically fluid filled. In gastric dilation volvulus, however, gas is located in the pylorus and proximal duodenum.

The lack of gas distension of the stomach does not preclude the presence of gastric volvulus. If a previous gastric decompression has been performed, gastric volvulus might be present for days to weeks or might be seen at initial presentation. The radiographic principles mentioned before remain, with the exception of a lack of marked distension of the stomach.

The presence of gas in the gastric wall (pneumatosis) or peritoneal cavity (pneumoperitoneum) is a very strong indicator for gastric wall necrosis (Figure 48.14) if no prior treatment, such as gastric decompression, has been performed. However, it is important to remember that radiographs are not very sensitive for evaluation of gastric wall necrosis. Gas in the gastric wall might also be noted during an ultrasound exam and if gas is present, additional abdominal radiographs should be obtained, to evaluate the position of the stomach.

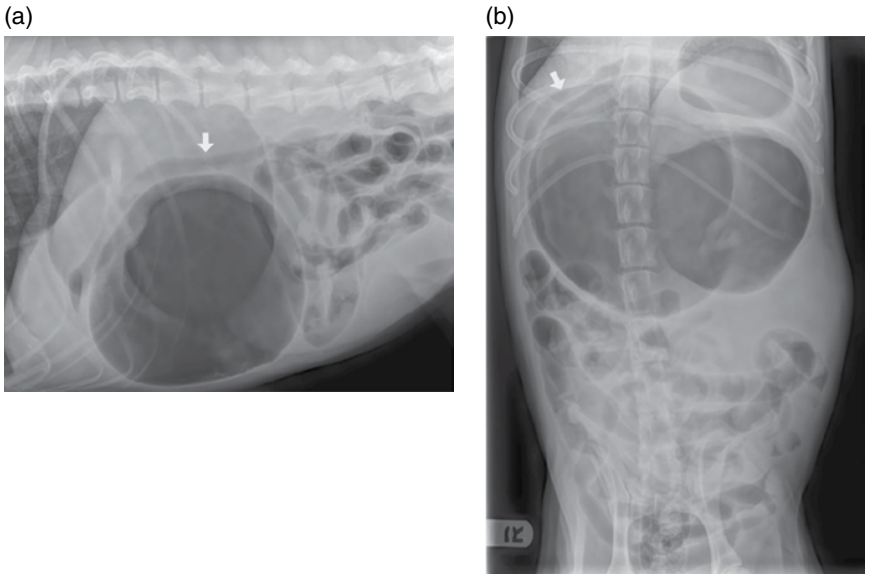

Figure 48.13 Gastric dilation volvulus. Right lateral (a) and VD (b) radiograph of the abdomen demonstrating a moderate gas distension of the stomach with compartmentalization of the stomach classic for gastric dilation volvulus. The duodenum is dorsally and laterally displaced (*arrow*).

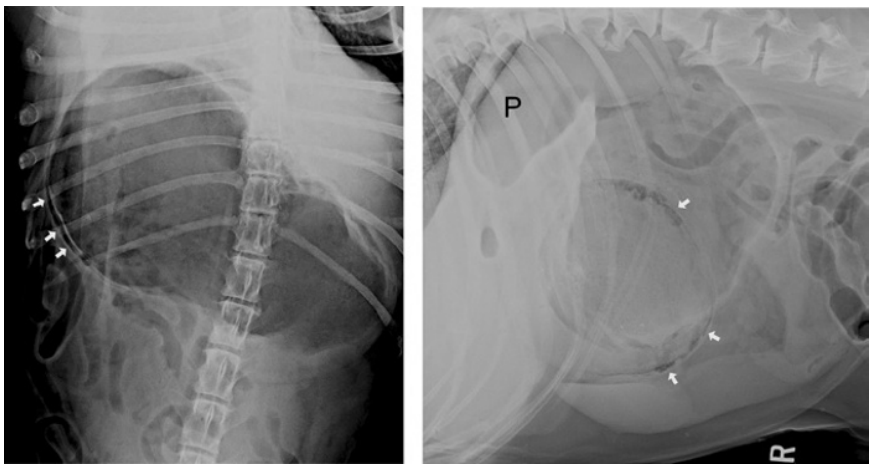

Figure 48.14 Gastric pneumatosis in a Doberman with gastric dilation volvulus. Ventrodorsal and lateral radiographs illustrating an abnormally positioned stomach. The pylorus (P) is dorsally displaced. Thin linear gas patterns are noted in the gastric wall consistent with gastric pneumatosis, which is highly suspicious for gastric wall necrosis secondary to the volvulus.

If gastric dilation volvulus is present, no further imaging is necessary and emergency procedures should be performed to decompress the stomach.

Chronic Gastric Outlet/Pyloric Obstruction

Chronic gastric outlet (pyloric) obstruction occurs relatively frequently secondary to either congenital or acquired pyloric stenosis or abnormal function of the pylorus. Pyloric obstruction is more frequently encountered in dogs than in cats. Radiographic recognition of gastric outlet obstruction often depends on the degree of distension and content of the stomach, and duration of the disease. Furthermore, positioning of the patient during radiography and frequency of vomiting affect the radiographic appearance of pyloric obstruction. Most frequently, the stomach is distended with gas and fluid, which can easily be noted on radiographs (Figure 48.15). It is important to remember that not all patients with a gastric dilation have a mechanical obstruction of the pylorus.

Gastric dilation may also occur secondary to mechanical obstruction of the duodenum or with concurrent pancreatitis. Left recumbent lateral views can help to decide if a duodenal obstructive lesion is present, as gas in the duodenum may be able to outline the cause of the obstruction. Additionally, in chronic obstructive gastropathy a "gravel sign" indicating retention of small mineral attenuating material particles in the stomach can sometimes be seen.

Contrast studies of the stomach or an ultrasound examination are often needed to establish the cause and site of outflow obstruction of the stomach. Contrast radiography of the stomach in cases of chronic obstructive gastropathy may reveal delayed gastric emptying, focal intraluminal contrast sparing areas in the pyloric antrum with incomplete filling and blunting of the pyloric canal. If contrast medium remains in the stomach 3–4 hours after administration, this usually indicates pyloric obstructive disease. Intraluminal filling defects in the pyloric antrum are often caused by thickened mucosal fold(s) extending into the lumen. The shape and radiographic appearance of the contrast agent filling of the pylorus have been described with various signs including the "beak," "tit," and "string" signs. Lack of filling or only partial filling of the pyloric canal has been described as the "beak" sign, where only a small amount of contrast agent extends in the form of a beak into the pyloric canal. The "tit" sign has been used when a small outpouching remains at the lesser curvature secondary to peristaltic waves. The "string" sign has been used when contrast agent extends through the pyloric canal but is concentrically narrowed secondary to circumferential thickening of the pylorus wall.

On an ultrasound exam, mucosal or muscular thickening of the pylorus wall may be noted and may help to differentiate between various etiologies of chronic outlet obstruction. In dogs with chronic pyloric hypertrophy, the hypertrophic muscularis may appear as a thick, hypoechoic layer (Figures 48.15 and 48.16). Sonographically, the measured thickness of the muscularis may help to categorize disease severity. The muscularis thickness in the pylorus is greater than 3 mm in mild to moderate hypertrophy and greater than 8 mm in severe chronic pyloric stenosis in dogs. Forceful, but ineffective, peristaltic contractions that fail to propel contents into the duodenum may be seen in some patients with gastric outflow obstruction.

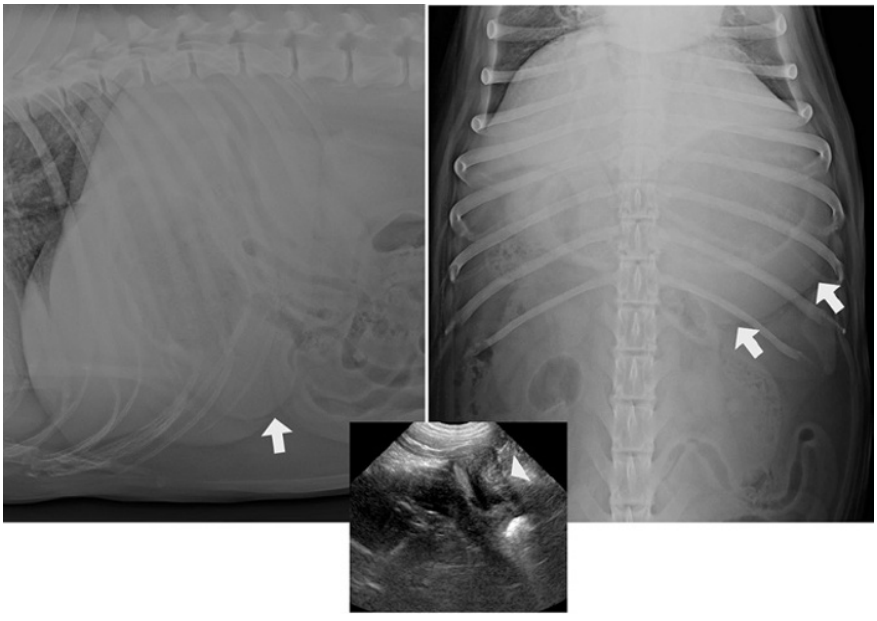

Figure 48.15 Ventrodorsal and left lateral radiographs of the abdomen of a vomiting dog. Moderate dilation of the stomach with fluid and gas is noted (*arrows*). The gastric wall appears subjectively thickened. An abdominal ultrasound exam revealed moderate thickening of the pylorus wall (*arrowhead*) with loss of wall layering.

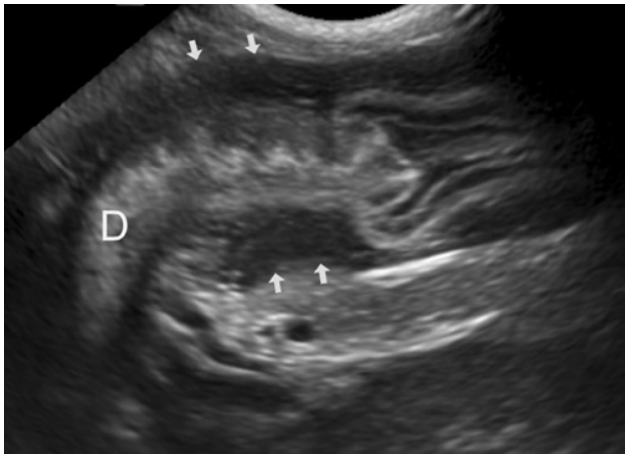

Figure 48.16 Longitudinal ultrasound image of the stomach of a dog with a history of chronic vomiting. Moderate thickening of the pylorus wall (*arrows*) with narrowing and irregularity of the luminal aspect is noted. D, duodenum.

Foreign Bodies

Gastrointestinal foreign bodies are a common diagnosis in dogs and cats presenting for emergency veterinary care (Figure 48.17). It can often be a challenge to diagnose gastrointestinal foreign bodies and decide if immediate surgery is indicated. Preferably, before an imaging study of the stomach is performed, the animal should be fasted for 12 hours. Accumulation of a small amount of fluid or gas in the stomach is normal even after fasting for 12 hours. Mineral or metal attenuating material in the stomach is easily recognized on survey radiographs. Mineral attenuating material in the stomach could be secondary to medical treatment of the patient, for instance with medications containing bismuth or kaolin, or this material could indicate delayed gastric emptying secondary to a chronic obstructive process involving the pylorus ("gravel sign"). Metal attenuating material in the stomach might not always cause obstructive signs, but might be toxic due to containing, for example, heavy metals such as zinc. Therefore, in patients with intravascular hemolysis, abdominal radiographs may be indicated to evaluate for the presence of metallic foreign objects. It is important to remember that aluminum is relatively radiolucent, unlike a lot of other metals, and is therefore difficult to detect on a survey radiograph.

Foreign bodies that are not mineral or metal attenuating can be challenging to detect. If foreign body ingestion is suspected, multiple views of the abdomen should be obtained. The gravity dependence of the fluid and gas in the stomach may help to outline a foreign body. If no foreign body is identified, contrast radiography, ultrasound or CT might provide more information. On a contrast radiographic study, foreign bodies are noted as a filling defect and this defect can be mobile within the stomach. However, if the object is large and/or the stomach is very empty, this object might not move much when changing the position of the stomach and might appear lodged in the stomach. Additionally, porous foreign bodies, such as cloth material or foam, may retain contrast agent and might be seen at the end of a contrast study, when most of the contrast agent has left the stomach.

On ultrasound, gastric foreign bodies are often hyperechoic with complete distal acoustic shadowing. If they contain gas, areas of incomplete distal acoustic shadowing can be noted. Additionally, they also may be recognized by their shape. Similar to radiography, foreign bodies usually move when repositioning the patient, but when the foreign body is large, it may show only minimal mobility within the stomach.

Gastrointestinal perforation is less frequently seen with foreign body ingestion, but has been reported when sharp objects such as wood sticks, skewers, needles (Figure 48.18) or multiple magnets are swallowed.

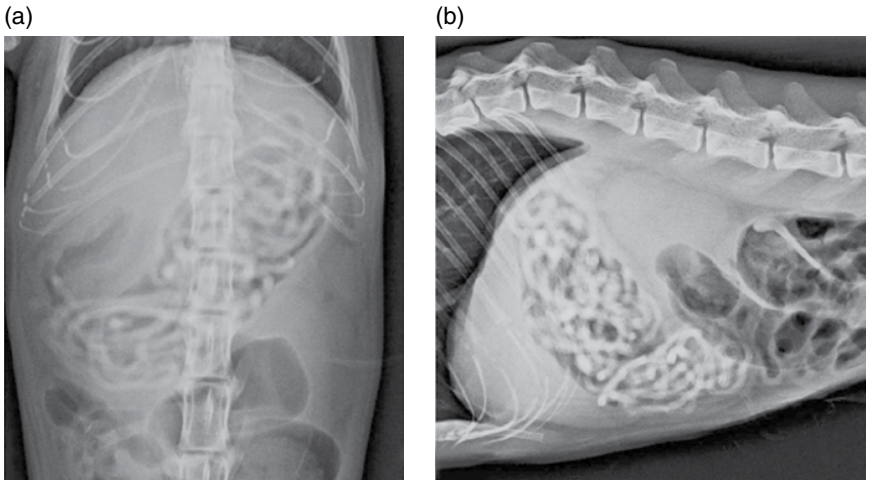

Figure 48.17 Multiple gastric foreign bodies are noted in the ventrodorsal and lateral radiograph of the abdomen of the cat. The foreign bodies represented multiple rubber hair bands ("scrunchies").

Figure 48.18 Longitudinal ultrasound image of a thin, hyperechoic, linear foreign body perforating from the pylorus area of the stomach (*arrowheads*) into the pancreas (P). The adjacent mesenteric fat is hyperechoic suggestive of secondary focal peritonitis. The foreign body was surgically removed and was a sewing needle.

Gastrointestinal perforation is suspected when peritoneal gas, with or without peritoneal fluid, is present either radio- or sonographically. Additionally, on ultrasound an increased echogenicity of the mesenteric fat can be noted. Occasionally gastrointestinal perforation secondary to a foreign body may not occur acutely or cause acute symptoms. Sometimes these foreign bodies lead to distant chronic inflammatory processes, which result in the occurrence of abscesses at unusual sites or radiolucencies or mass effects on a radiograph months to years later.

It should be remembered that more than one object could have been ingested and the search for foreign bodies should not be stopped at the stomach, but continued through the entire gastrointestinal tract.

Gastric Ulcers

Gastric ulcers might be seen on a contrast study of the stomach or ultrasound examination. In a gastrographic study, an outpouching of the gastric wall or defect with adjacent increased thickness of the gastric wall might be noted ("crater sign"). Additionally, the wall of the stomach adjacent to the ulcer might be rigid, which is best seen using fluoroscopy.

On an ultrasound exam, similar imaging features can be noted, including focal thickening of the gastric wall with a central area of decreased wall thickening ("crater"), loss of normal wall layering, decreased motility of the gastric wall, and retention of fluid in the stomach. Additionally, small focal areas of hyperechogenicity with reverberation artifacts suggesting microbubbles may be present in the central aspect of the ulcer.

Inflammatory Conditions of the Stomach and Duodenum

Imaging Features of Gastritis

On survey radiographs, large rugae may be noted; this may be most noticeable at the greater curvature of the stomach. On a contrast radiographic study, large rugae extending luminally and resulting in contrast-sparing areas are often present.

Sonographically, focal or circumferential wall thickening, loss of wall layering and, especially in chronic disease, a mass effect can be noted. Regional lymph node involvement may be present. Inflammatory disease of the stomach may appear similar to neoplastic or immune-mediated disease or uremic gastropathy on ultrasound (Figure 48.19).

Tumors of the Stomach

Primary gastric tumors are rare in the dog and cat and account in the dog for less than 1% of all malignancies. Benign (e.g., polyps, adenomas) and malignant (e.g., adenocarcinoma, lymphosarcoma, fibrosarcoma, leiomyosarcoma, gastrointestinal stromal tumor) neoplasias have been described. In the dog adenocarcinoma and in the cat lymphoma are the most frequently diagnosed gastric tumors. Most of the gastric tumors are epithelial in origin and most frequently affect the distal two-thirds of the stomach. Benign masses such as polyps are more commonly seen in the pyloric antrum and are often unnoticed until an imaging exam or endoscopy is performed. Gastric tumors can cause a pyloric outflow obstruction or affect normal gastric motility. Gastric adenocarcinomas in dogs can also present with ulceration of the gastric wall.

Radiographic Features of Gastric Tumors

Survey radiographs are often not sufficient to diagnose gastric wall tumors, even when all four views of the abdomen are obtained. On survey radiography, focal areas of gastric wall thickening, loss of normal rugal folds, and masses protruding into the lumen might be noted. Pyloric outflow obstruction might be noted, which can be characterized by a fluid-distended stomach and/or mass effect in the pyloric area. Usually survey radiographs need to be followed by contrast radiography, ultrasound or, when available, CT to further evaluate the stomach and stage the disease.

On a contrast radiographic study, intraluminal masses typically cause signs such as a filling defect in the contrast medium, abnormal appearance of the rugae, focal unusual distension of the gastric wall, a lack of peristalsis or delayed gastric emptying.

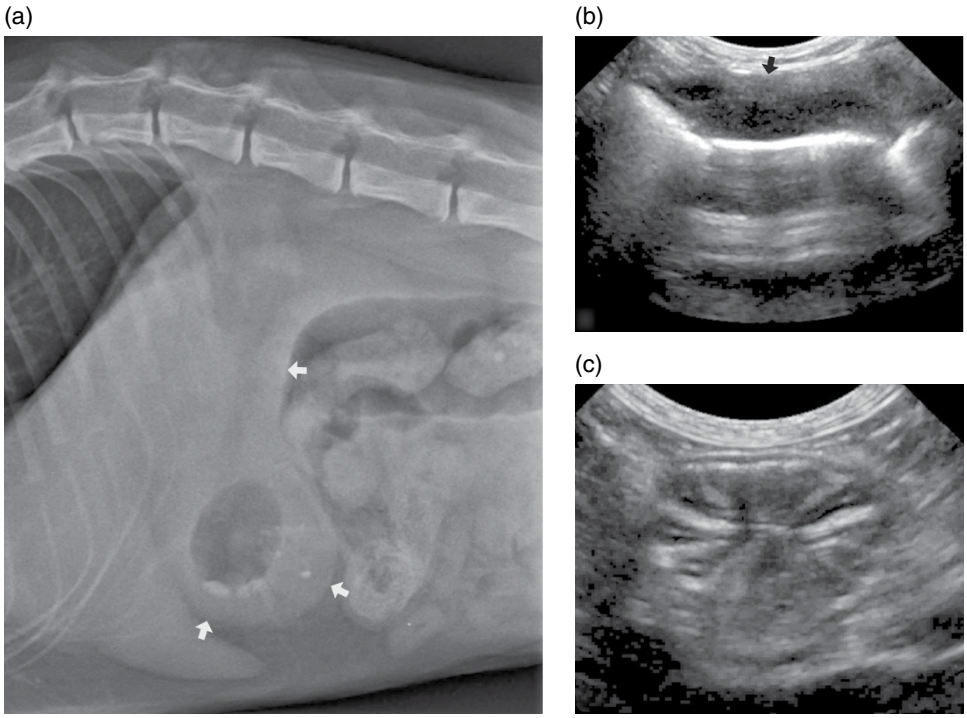

Figure 48.19 Eosinophilic gastritis in a cat. Lateral radiograph (a) of the cranial abdomen is suggestive of a moderate thickening of the gastric wall, which was confirmed on an ultrasound exam (b) of the stomach. On the longitudinal ultrasound image, moderate to severe thickening of the gastric wall with loss of wall layering and reduced echogenicity is noted. Part of the fundus of the stomach shows a normal wall architecture as illustrated in the ultrasound image (c).

Ultrasound Features of Gastric Tumors

An ultrasound examination of the stomach can be useful in diagnostic assessment for gastric neoplasia. However, ultrasound examination of the stomach may be limited by the presence of gas. Repositioning of the patient and thus moving the gas will improve evaluation of the gastric wall. The sensitivity of detection of gastric wall masses using ultrasound has been reported to range between approximately 50% and 80% and is dependent on the experience of the operator. The presence of fluid in the stomach, which also can be administered prior to the ultrasound examination, may reduce the presence of air artifacts and therefore enhance the visualization of gastric wall pathology.

Ultrasound examinations of gastric wall tumors often demonstrate a variety of features, including loss of gastric wall layering, masses arising from certain wall layers, presence of cavitations, asymmetric or symmetric thickening of the wall, and the presence of peritoneal fluid (Figure 48.20). Extension of the mass through the serosal surface may be noted, most commonly seen with carcinoma. Additionally, the involvement of regional lymph nodes, liver, spleen, and intestine can be evaluated for staging the disease. Ultrasound has been used to attempt to differentiate between various gastric neoplasms, but poor correlation with histology was noted. Ultrasound-guided fine needle aspirates may be helpful to accurately diagnose a gastric neoplasm.

Figure 48.20 Longitudinal ultrasound image of the stomach of a cat. A large, eccentric gastric wall thickening with loss of normal wall architecture and distortion of the wall is noted. Peritoneal fluid is present. This was most concerning for neoplasia. Fine needle aspirates confirmed a gastric carcinoma.

Computed Tomographic Features of Gastric Tumors

Computed tomography and magnetic resonance tomography are commonly used in human patients to stage gastric tumors, but currently no similar studies are available in veterinary patients. Computed tomography can be

helpful to evaluate the extent of the gastric lesion and stage disease. On CT images, a thickened gastric wall, loss of wall layering, and contrast enhancement of the wall might be seen. Additionally, enlargement and contrast enhancement of regional lymph nodes can be noted. However, the CT criteria for gastric neoplasia might also be seen in other benign disease such as gastritis.

Gastrointestinal Bleeding

A variety of diseases can result in gastrointestinal bleeding. If the bleeding is caused by an ulceration or mass, contrast radiography and ultrasound may identify the site of the bleeding. However, if minimal wall alteration is present, contrast radiography and ultrasound might not identify the cause of bleeding.

Small Intestine

The small intestine consists of three segments: the duodenum, jejunum, and ileum. The segments of the small intestine in the dog and cat do not have characteristic mucosal folds. The long mesentery of the small intestines provides only a limited fixation of the small intestine.

Radiographic Examination of the Small Intestine

The descending duodenum shows the most consistent positioning of the small intestinal segments and is located in the right craniolateral abdomen, running parallel to the abdominal wall from just ventral to the right kidney to the level of the 4th–5th lumbar vertebrae, where it turns medially. The ascending duodenum runs from the caudal duodenal flexure cranially and towards midline. The jejunum is the largest portion of the small intestine and is relatively evenly distributed throughout the abdomen, from caudal to the stomach to cranial to the urinary bladder. If the dog is very deep chested and the gastrointestinal tract very empty, loops of small intestine might be noted adjacent to the dorsal aspect of the diaphragm. In obese animals, the small intestine is often located more centrally in the abdomen due to displacement by peritoneal fat.

In the cat, a large falciform fat pad may lead to caudal displacement of the small intestine. The aborad portion of the ileum might be visualized at the ileocecocolic junction, which lies in a VD view right of midline at the level of the second lumbar vertebra and in a lateral view ventral of the approximately fourth lumbar vertebra. The jejunum and ileum are otherwise indistinguishable radiographically. The duodenum can be minimally wider than the jejunum and ileum.

Usually the small intestinal segments are of very similar width and little variation in diameter is present. The normal small intestinal diameter in the dog is usually less than 1.4 times the height of the midportion of the fifth lumbar vertebral body or less than twice the width of the 12th rib. In the cat, the normal small intestinal diameter should be less than 12 mm. In the cat, the small intestinal tract might have a more "string of pearls" appearance, when compared to the dog. It is critical to differentiate the small intestine from the large intestine when decisions about an increased small intestinal diameter are made.

If an animal has not eaten, the small intestines contain a mixture of fluid and gas. In the dog, typically up to two-thirds of the small intestinal loops are gas filled and in the cat usually very little gas is present in the small intestine. Gas usually redistributes through the intestinal tract relative to the position of the animal. In the left lateral view, gas is often present in the duodenum as it is located dorsally and on the right. However, positional radiographs are less valuable for the redistribution of gas in the small intestine compared to the stomach. The small intestine can also contain small mineral or metal attenuation structures depending on the diet, or if an animal is an indiscriminate eater or is receiving medication. The visualization of medications in the intestinal tract is dependent on their size and attenuation. Some medications contain mineral to metal opaque material; examples include calcium carbonate, iodinated compounds, iron-containing preparations, potassium, and aluminum.

Gentle compression techniques using a wooden spatula or spoon while obtaining abdominal radiographs can be helpful to further evaluate segments of small intestine, by reducing the summation from other abdominal structures.

Ultrasound Examination of the Small Intestine

Similar to radiography, the descending duodenum is the most consistently positioned section of the small intestine and can therefore easily be followed using ultrasound. The duodenum can typically be visualized extending from the pylorus along the medial aspect of the right abdominal wall caudally. After the caudal duodenal flexure, the ascending duodenum can be followed medially, but its aborad aspect cannot be differentiated from the jejunum. The jejunum is usually relatively evenly distributed throughout the abdomen.

Throughout the duodenum and jejunum, the mucosa is normally the thickest layer (Figure 48.21). The other layers of the small intestinal wall are similar in thickness and thinner than the mucosa.

Figure 48.21 Longitudinal ultrasound image of the descending duodenum. The mucosa is the thickest layer of the duodenum wall. A hyperechoic area extending towards the serosal surface of the wall is noted. This is only noted on one side of the wall and consistent with a Peyer's patch and should not be confused with an ulcer or perforation.

The total wall thickness is thinner in smaller dogs than in large-sized dogs, ranging from 2.9–4.7 mm in small dogs, 3.0–5.5 mm in medium-sized dogs to 3.1–5.7 mm in large-sized dogs, respectively. In cats, the small intestinal wall usually ranges between 2 and 3 mm. Similar to contrast radiography, care must be taken that, in the descending duodenum, Peyer's patches (see Figure 48.21) are not misinterpreted as duodenal ulcers.

The mean number of peristaltic contractions noted in the stomach and proximal duodenum is 4–5 contractions per minute. In the midabdominal small intestinal tract, 1–3 contractions per minute are expected.

Contrast Radiography of the Small Intestine

Ultrasound has often replaced the need for contrast radiographic studies as these studies of the small intestinal tract are often laborious and time-consuming. However, if ultrasound is not available, contrast radiography is helpful to evaluate luminal diameter, wall thickness, mucosal surface, luminal content, and position of the intestinal tract. This is especially helpful in patients in which the abdominal serosal detail is decreased, due to their young age, emaciation, or a disease process. Furthermore, contrast radiography can provide additional information for evaluating intestinal transit times.

Before an upper gastrointestinal contrast study is performed, orthogonal survey radiographs of the abdomen should be done. If dilation of the intestine is present, suggesting ileus, a contrast study might be contraindicated. If the ileus is functional, the contrast agent will usually move very slowly through the intestinal tract and if a mechanical ileus (due to an obstructing foreign body, for instance) is present, the time required to complete a thorough contrast radiographic study may inappropriately delay surgery. If, based on radiographs, an intestinal perforation is suspected, the patient should be referred to surgery. However, if an intestinal perforation is suspected and on survey radiographs no signs of perforation such as peritoneal gas are noted, a contrast radiographic study may provide useful additional information. Usually intestinal contrast studies are performed using barium sulfate suspension; however, if a perforation is suspected, an iodinated contrast agent may be preferred.

It is preferable that the patient is fasted before an intestinal contrast imaging study is performed. Sedation can affect the transit time of the contrast agent, and if necessary the effect of sedation must be considered. In dogs, acepromazine has shown minimal effects on intestinal motility, while providing a reasonable level of sedation. In cats, a combination of diazepam and ketamine shows a similarly low effect on intestinal motility while providing an acceptable level of sedation, and is preferable to acepromazine.

To perform a contrast study, the barium sulfate suspension or iodinated contrast agent is administered either through an orogastric tube or orally using a syringe. Orogastric tubing is preferred as it reduces the risk of aspiration. It is important to remember that if an ionic iodinated contrast agent is used, aspiration can lead to fatal pulmonary edema and therefore great care should be taken if these agents are used, especially in patients with a known history of swallowing problems or being prone to aspiration. The recommended volume of barium sulfate suspension is 8–12 mL/kg bodyweight for small or medium-sized dogs, 5–7 mL/kg for large-sized dogs, and 12–20 mL/kg for cats. Radiographs should be obtained at regular intervals. As mentioned earlier, for the stomach all four views of the abdomen should be obtained. However, for the small intestinal tract, orthogonal views are often sufficient. Usually radiographs at 0, 15, and 30 minutes and one, two, and three hours post contrast agent administration are obtained, until the contrast agent has reached the colon. Barium sulfate contrast agent can usually be seen in the duodenum within 15 minutes and in the jejunum within 30 minutes. After 90–120 minutes, it is common to see contrast at the level of the ileocecocolic junction. After 3–5 hours, it is common to see the contrast agent within the ileum and colon. Usually, in the dog using barium, the transit time for the small intestine ranges from two to four hours and emptying of the small intestine is typically noted around five hours post administration. In the cat, the transit of barium is faster and ranges from one to two hours.

If an iodinated contrast agent is used, it is usually given in a dose of 2–3 mL/kg bodyweight or approximately 700 mg iodine/kg bodyweight. Iodinated contrast agents can be diluted 1:1. They have a faster transit time through

the intestinal tract, and reach the colon in approximately half the time when compared with barium sulfate contrast agents. As the iodinated contrast agents transit more rapidly through the gastrointestinal tract, radiographic views should be obtained more frequently, usually every 10–30 minutes. As mentioned earlier, barium sulfate is inert and not metabolized by the gastrointestinal tract; however, iodinated contrast agents are absorbed by the mucosa of the intestinal tract and therefore the luminal contrast rapidly declines over time, making diagnosis of an intestinal lesion more difficult.

In the normal duodenum of the dog, small indentations of the contrast agent ("pseudoulceration") might be seen in the antimesenteric border of the wall. This is normal, and results from the presence of Peyer's patches. In the cat, a strong beading of the small intestine ("string of pearls" appearance) might be noted (Figure 48.22).

Barium-impregnated polyethylene spheres (BIPS) have been used in the past, but are now rarely used. Their main indications are in the evaluation of transit time of the gastrointestinal tract; however, their transit times were variable and as no coating of the intestinal wall is achieved, the indications for the use of BIPS are limited.

Figure 48.22 Upper gastrointestinal contrast radiographic study of a cat. Strong beading of the small intestine is noted ("string of pearls" appearance; *white arrow*). This is normal in the cat.

Inflammatory Disorders of the Small Intestine

Inflammatory bowel disease is a broad term encompassing all disease resulting in an inflammatory process of the intestinal wall. On survey radiographs, usually no abnormality is noted. It is important to remember that on survey radiographs, an increase in thickness of the small intestinal wall is difficult to impossible to assess as the presence of fluid and mucus within the intestinal tract can mimic intestinal wall thickening in loops of intestine with normal wall thickness. On contrast radiographic studies, a rapid transit of barium contrast agent might be noted. Additionally, the mucosal surface might be irregular and there might be a loss of normal fimbriation of the mucosa. Enteritis may be generalized or only involve segments of the small intestinal tract. Usually no ileus is present.

Ultrasound Features of Inflammatory Disease of the Small Intestine

The most common ultrasound finding noted in inflammatory disease is an increase in wall thickness with persistently preserved normal wall architecture. It is important to note that this is a nonspecific finding. Additionally, in enteritis the intestinal wall can be normal. It is reported that in dogs, duodenum wall measurements up to 6 mm and jejunum wall thickness measurements up to 7 mm may be normal.

In inflammatory disease, thickening of the intestinal wall can be local or generalized and as this is similarly noted in patients with intestinal neoplasia, it can be challenging to differentiate patients with neoplastic from patients with inflammatory disease using imaging alone. As an example, in feline patients with gastrointestinal eosinophilic sclerosing fibroplasia, focal, mixed echogenic masses with central hyperechoic areas and loss of wall layering have been described. These central hyperechoic areas within the masses were suspected to correspond to the areas of fibrosis noted on histopathology. These masses distort the normal intestinal wall architecture, which is frequently described with neoplastic intestinal disease. Another inflammatory example that can feature focal nonsymmetric thickening of the intestinal wall with altered or loss of normal wall layering is mast cell disease. In most animals with inflammatory intestinal disease, when increased wall thickness of the intestines is noted, the wall layering remains preserved and the thickening tends to be symmetric and circumferential.

Sonographically, in some patients it can be noted that only individual layers are affected and increased in thickness or altered in echogenicity. In cats, an increase in the muscularis layer thickness has been reported with chronic enteritis, but again, this finding is nonspecific as

Table 48.1 Common imaging findings assessed using ultrasound, contrast radiography or computed tomography in benign versus malignant intestinal wall thickening

Benign	Malignant
Symmetric	Asymmetric
Circumferential	Eccentric
Mild to moderate	Moderate to severe
Usually segmental or diffuse	Usually focal
	Frequently abrupt transition
Usually normal lumen width	Often focally narrowed intestinal lumen
Preserved wall layering	Lost wall layering
No or mildly enlarged lymph nodes	Moderately to severely enlarged lymph nodes

it has also been seen in normal patients or patients with neoplastic disease.

Hyperechoic lines within the mucosa which are perpendicular to the luminal surface have been associated with lacteal dilation in patients with protein-losing enteropathy and lymphangiectasia. In most of these patients, wall layering of the intestine is persistently preserved. Rarely, these hyperechoic lines have been noted in patients with neoplasia.

In some patients with inflammatory bowel disease, a mild increase in size of the jejunal lymph nodes might be noted (up to 10 mm in diameter; normal up to 5 mm in diameter). A more severe enlargement of jejunal lymph nodes is more suggestive of a neoplastic than an inflammatory process (Table 48.1).

Small Intestinal Obstruction (Mechanical Ileus)

Radiographic findings in small intestinal obstruction are dependent on the extent (incomplete or complete), location, and duration of obstruction. Small intestinal obstruction can occur secondary to foreign material, intestinal neoplasia or a mass causing compression of the intestinal lumen. Mineral or metal attenuating foreign bodies are radiographically easily detected but non-mineralized and nonmetallic foreign bodies within the intestinal lumen or masses of the small intestinal tract can be challenging to detect. Care should also be taken that mineralizations in the mesenteric fat (mesenteric fat necrosis, "Bates bodies") summating with loops of intestine are not confused with an intestinal foreign body (Figure 48.23). Bates bodies are usually an incidental finding and are more frequently seen in cats than in dogs.

Radiographic findings with mechanical intestinal obstruction include intestinal distension, visible foreign material, and stacking of small intestinal loops. Ambiguous radiographs may require additional imaging or repeat radiographs for optimum assessment. The most common sign utilized to diagnose mechanical obstruction is the presence of variations in the appearance of segments of small intestine (Figure 48.24). Typically, more orad loops are dilated and aborad to the obstruction there is a normal-sized population of small intestinal loops.

Various methods to assess the small intestinal diameter have been suggested, including comparison of the largest small intestinal diameter with the shortest height of the fifth lumbar vertebral body. A ratio of less than 1.6 is considered the upper limit of normal small intestinal diameter in dogs. If the values are below 1.6 an obstructive process is very unlikely. The higher the ratio,

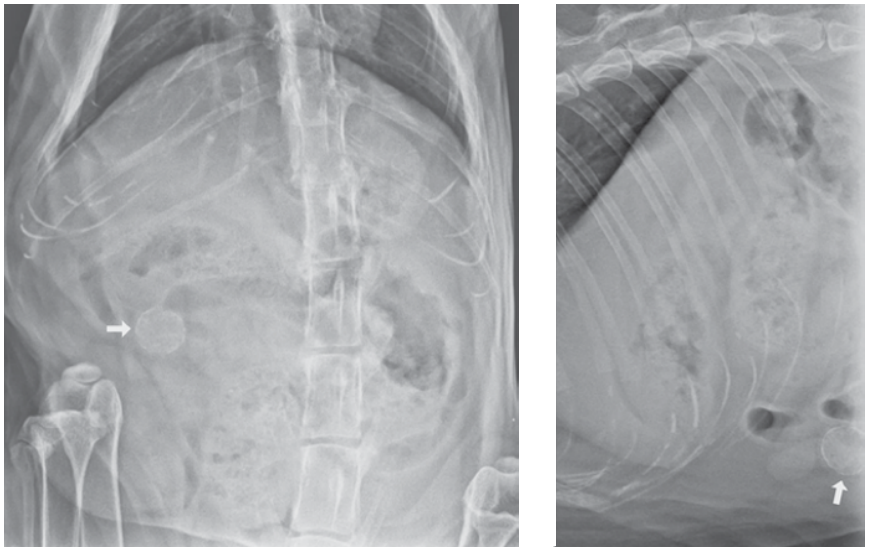

Figure 48.23 Focal calcified peritoneal body ("Bates body"). Dorsoventral and lateral radiograph of the cranial abdomen in a cat, which underwent thoracic radiographs for evaluation of the cardiopulmonary structures. In the midventral abdomen, a mineral attenuating round structure is noted, which is summating with loops of small intestine and should not be confused with an intraluminal foreign body. There is no small intestinal dilation.

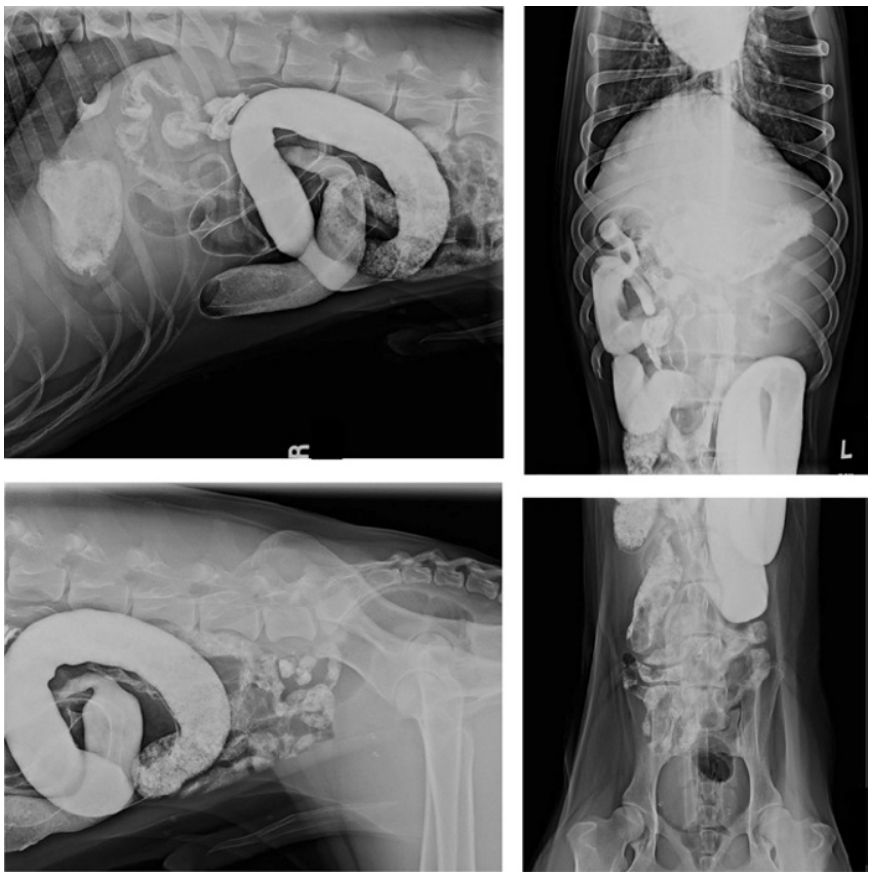

Figure 48.24 Small intestinal mechanical ileus. Lateral and VD radiographs of the abdomen post upper gastrointestinal barium study illustrate a severe dilation of a midabdominal segment of jejunum. On one end of the dilated jejunum, a curved radiolucent area is noted. In surgery, a hoof foreign body and 30 cm of devitalized jejunum were removed.

the more likely a mechanical obstruction is present. Another evaluation technique compares the largest small intestinal diameter with the width of the 12th rib, with two times the width of the 12th rib considered the upper normal limit. In the cat, the small intestinal diameter should not be greater than 1.2 cm. Another measurement technique described in cats calculates a ratio of the maximum width of a loop of small intestine, measured from outer to outer wall, divided by the dorsoventral height of the cranial endplate of the second lumbar vertebra with both measured on a lateral radiograph of the abdomen. Ratios lower than 2.0 were more likely associated with a nonobstructive intestinal process and with ratios larger than 3.0, the increased small intestinal diameter was more than 70% likely to be associated with an obstructive intestinal process (Table 48.2).

Single measurements should not be used as the sole criterion for diagnosis of mechanical obstruction; other radiographic findings and the history of the patient should be evaluated when considering the differential diagnoses. If the radiographic findings are equivocal and repeat radiographs are obtained, the presence of radiopaque foreign material in a similar location over a 24–48-hour period should increase the suspicion of mechanical ileus.

Table 48.2 Useful guidelines for evaluating the normal small intestinal diameter

Measurement	"Rule of thumb"
Compared to shortest height of the 2nd or 5th lumbar vertebra	Less than 1.6 times
Compared to width of the 12th rib	Less than 2 times
Compared to other normal small intestinal loops	Less than 2 times
Small intestinal diameter	In the cat less than 1.2 cm

Small Intestinal Foreign Body

Radiographically, radiopaque foreign bodies are the easiest to identify. Foreign bodies containing air, especially when creating a characteristic pattern such as in peach pits, walnuts, or corncobs, can easily be identified radiographically. If the foreign body leads to a complete obstruction of the small intestine, an orad dilation of the small intestine with normal intestinal diameter distal to the obstruction is typically noted. However, if the obstruction is incomplete or long-standing, minimal or no small intestinal dilation might be present.

In an ultrasound examination of the small intestine, foreign material in the intestinal tract often appears hyperechoic with strong distal complete acoustic shadowing. These shadowing structures often do not move with peristalsis and fluid distension of the small intestine orad to the lesion is often observed. Foreign bodies may have a distinct shape and surface, which allows differentiation of them from food material.

Linear Foreign Body

Linear foreign bodies cause plication of the small intestine and are usually the result of swallowing a linear object and fixation of part of the foreign material orally or in the stomach. In the cat, linear foreign bodies are often fixated around the caudal aspect of the tongue. In the dog, most linear foreign bodies are restrained by material in the stomach.

Classic radiographic features of linear foreign body obstruction include plication or "bunching" of the small intestine and the presence of intestinal intraluminal gas with an abnormal angular or tear drop shape (Figure 48.25). Perforation of the small intestine can occur, and in addition to bunching of the small intestines, a reduced serosal detail and free peritoneal gas may be seen (Figure 48.26).

Sonographically, an abnormal tortuous path of the small intestine, often the duodenum, with a central hyperechoic, linear structure might be noted. Additionally, an object with strong distal shadowing might be seen in the pylorus of the stomach.

Intussusception

Intestinal intussusception can be gastroduondenal, jejunojejunal (Figure 48.27), ileocolic, cecocolic, and colonocolic.

Radiographically, severely dilated loops of intestine might be noted. Sometimes a soft tissue attenuation mass with orad gas in a convex shape is seen.

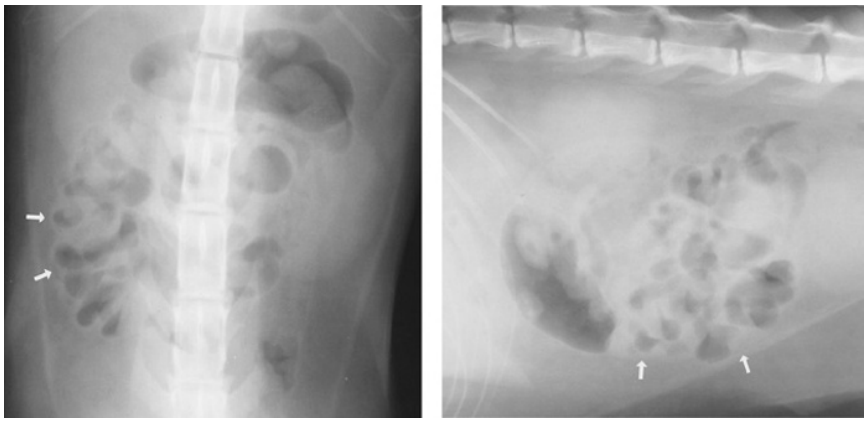

Figure 48.25 Linear foreign body. Ventrodorsal and lateral radiographs of the abdomen of a cat illustrating multiple bunched-up loops of small intestine. On cross-section, the luminal gas of the bunched-up small intestinal loops has an abnormal tear drop shape. Both findings are classic for linear foreign body.

(a) (b)

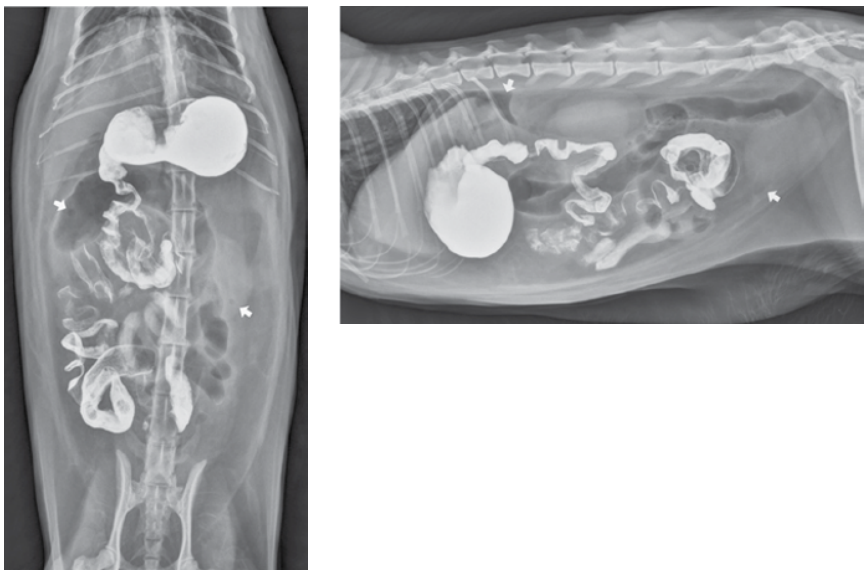

Figure 48.26 Linear foreign body with perforation. Ventrodorsal (a) and lateral (b) radiographs of the abdomen post upper gastrointestinal barium contrast study demonstrate bunched-up loops of small intestine, some with a tear drop shape of the luminal gas. The reduced serosal detail and peritoneal gas (*arrows*) are consistent with perforation.

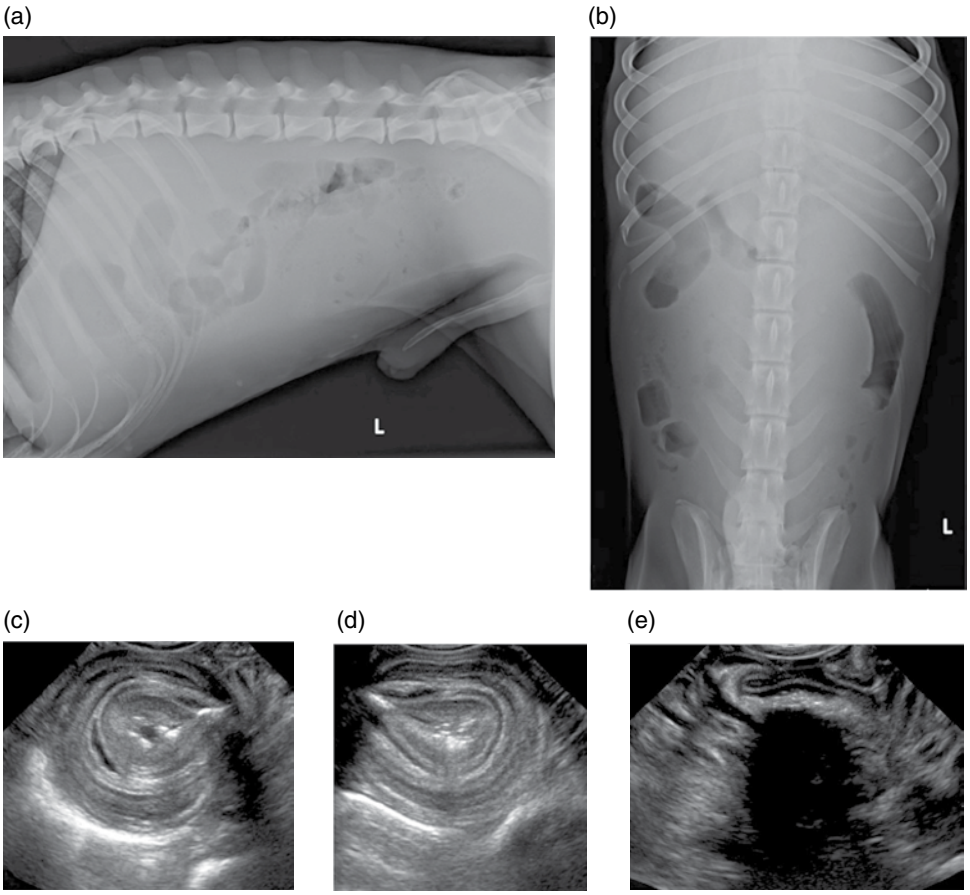

Figure 48.27 Jejunojejunal intussusception. Lateral (a) and ventrodorsal (b) radiographs of a thin dog. A reduced serosal detail is present. Gas-dilated loops of small intestine are noted in the cranial abdomen. In the caudal abdomen, a soft tissue attenuating mass effect with very small, irregular shaped loops of small intestine is noted. Transverse (c,d) ultrasound images revealed a series of hypoechoic and hyperechoic concentric rings with a small amount of central fluid and gas consistent with an intussusception. Additionally, in one segment of jejunum, hyperechoic distal shadowing material (e) consistent with foreign material is present.

Ultrasound may reveal a series of hyperechoic and hypoechoic concentric rings with a central hyperechoic area on transverse images ("target" or "onion ring" sign). On longitudinal ultrasound images, a similar pattern of hyperechoic and hypoechoic lines may be noted, in addition to circumferential inward folding of the intestinal wall at the site of the intussusception.

Tumors of the Small Intestine

Intestinal tumors account for approximately 3–10% of the tumors in cats and dogs. Approximately 75% of feline intestinal tumors are caused by lymphoma, compared to approximately 30% of intestinal tumors in the dog. In dogs, adenocarcinoma, lymphoma, and tumors of smooth muscle origin are most frequently seen.

If the intestinal neoplasm is small in size and does not cause obstructive disease, abdominal radiographs are often normal. If the intestinal mass is large or causes obstructive disease, radiographic signs consistent with mechanical ileus are noted. On contrast radiographic studies, circumferential narrowing of the lumen of the small intestine might be present.

Ultrasonographic findings in intestinal tumors vary widely and include focal or diffuse intestinal wall thickening, loss of normal wall layering, increased thickness of the wall layers, altered echogenicity (Figure 48.28), and loss of peristalsis. However, minimal sonographic or no sonographic changes of the intestinal wall have also been noted in lymphoma. Involvement of regional lymph nodes may be present, characterized by increased size, altered shape, and echogenicity. These observations may increase the suspicion for intestinal neoplasia, and help stage disease.

Intestinal Adhesions

There is limited information about the imaging of adhesions in veterinary patients. If intestinal adhesions lead to mechanical ileus, dilated loops of small intestine may be noted. Radiographically, stacking of loops of small intestine, which do not change position with repositioning

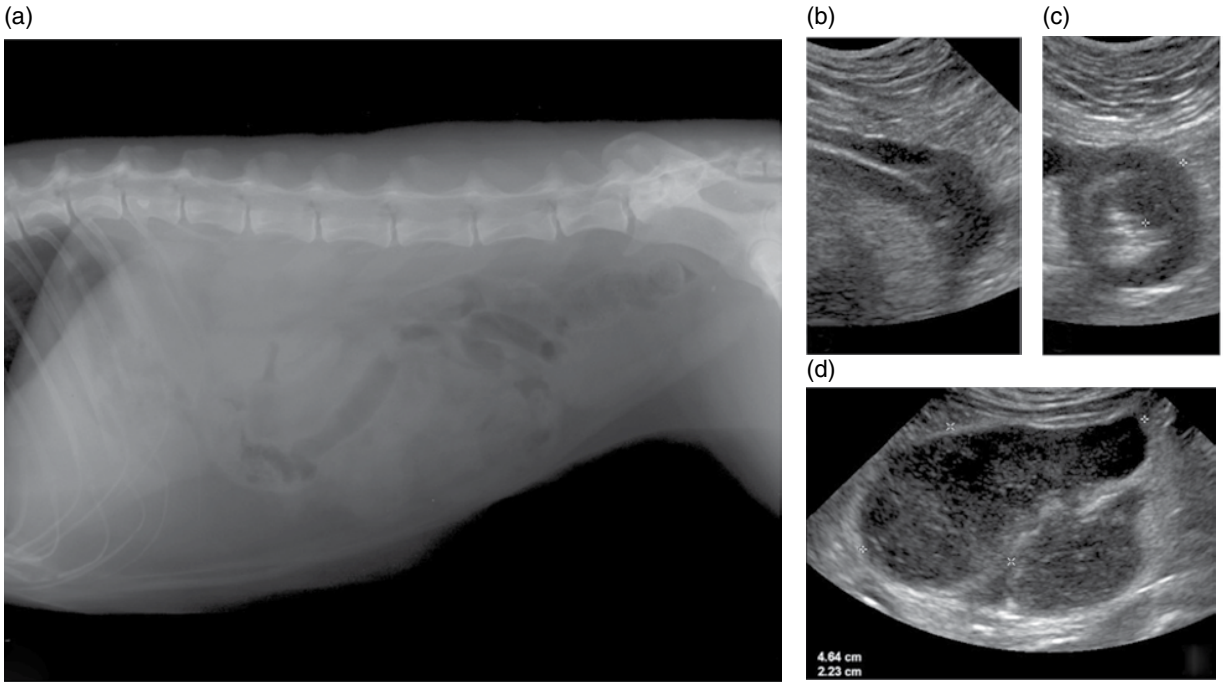

Figure 48.28 Intestinal lymphoma. Lateral radiograph (a) of the abdomen of a cat. In the midabdomen, a soft tissue attenuating mass effect is noted and segments of small intestine are dorsally displaced. On longitudinal (b) and transverse (c) images of the jejunum, a focal, eccentric wall thickening with loss of wall architecture and reduced echogenicity is noted. The jejunal lymph nodes (d) are severely enlarged and heterogeneously hypoechoic. The severe lymphadenopathy in combination with the jejunal wall changes is highly suspicious for neoplasia such as lymphoma, which was confirmed with cytologic samples obtained with ultrasound guidance.

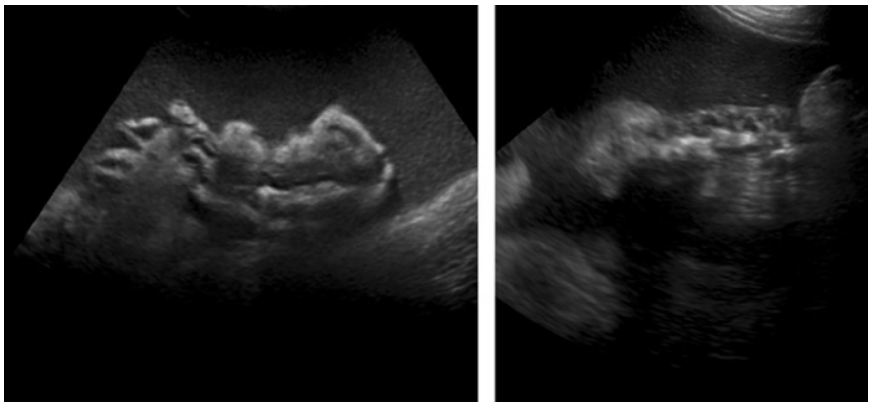

Figure 48.29 Longitudinal ultrasound images demonstrating severely corrugated loops of jejunum with peripheral hyperechoic tissue. A large amount of echogenic peritoneal fluid is present. The patient had a severe peritonitis secondary to perforating gunshot wound of the abdomen.

of the patient or repeat radiographs, may be present. In human patients, the lack of peritoneal fat between the loops of small intestine and abdominal wall has been described as a potential indicator for adhesions. On ultrasound, corrugation of small intestinal loops or lack of mobility of loops in the abdomen may be noted (Figure 48.29). Additionally, hyperechoic strands of tissue connecting segments of small intestine with each other or the abdominal wall may be present.

Intestinal Herniation

Intestinal herniation can occur through a defect in the mesentery, abdominal or body wall, perineum or diaphragm. The position of the small intestine is usually easily assessed using orthogonal radiographs. If there is a loss of serosal detail such as in young or emaciated patients or when peritoneal fluid is present, contrast radiography or ultrasound may be required to evaluate the position of the small intestine.

Small Intestinal Volvulus and/or Torsion

Small intestinal volvulus and/or torsion are rare in dogs and have seldom been described in cats. In cases of intestinal volvulus, the intestines rotate around the mesenteric axis, causing vascular compromise. Rotation along the long axis of the intestine is termed *torsion*.

Both intestinal volvulus and torsion can occur concurrently. The most commonly involved segment of small intestine in an intestinal volvulus of the dog is the jejunum. Radiographic findings in the early phases of this disease are vague and nonspecific. It is not uncommon that radiographs are normal. In the later phases of disease, generalized dilation of the intestines (paralytic ileus) may be noted; sometimes a circular position of the intestines might be present.

Paralytic (Functional) Ileus

Paralytic or functional ileus is a dysfunction of the musculature of the gastrointestinal tract resulting in dysmotility due to a variety of causes (neurologic, metabolic, vascular impairment, toxic).

Establishing a radiographic diagnosis of functional intestinal ileus can be challenging. The most common radiographic finding is a diffusely dilated small intestinal tract. Focal dilation of the small intestinal tract is more commonly noted with mechanical obstruction but there is likely a commonality between these two diseases.

A barium contrast radiographic study can be performed and a diffuse dilation of the intestinal tract may be noted; however, the lack of motility might result in incomplete transport of the barium through the intestinal tract and therefore in an incomplete evaluation of the intestinal tract, or leave the false impression of obstruction. Ultrasound might provide more information as it allows evaluation for the presence of intestinal peristalsis in addition to identifying intraluminal or intramural lesions. Sonographically amotile and stiff intestinal walls may be noted.

Intestinal Ulceration/Perforation

Survey radiographs can be normal in intestinal ulceration and perforation. However, in perforation, frequently either peritoneal free gas and/or fluid can be seen. Ulcerative disease of the intestinal tract is most commonly seen in the duodenum. As the normal Peyer's patches present in the duodenum can appear as focal areas of thickening ("pseudoulcers") on ultrasonographic and contrast radiographic studies, care must be taken to not confuse this normal finding with disease. In a contrast radiographic study in ulcerative disease, focal thickening of the intestinal wall with variable outpouchings can be noted. If perforation has occurred, contrast leakage into the peritoneal cavity may be present.

On ultrasound examination of patients with ulceration, regional thickening of the intestinal wall with small hyperechoic speckles representing gas in the intestinal wall may be present. If perforation of the intestinal wall is present, these hyerechoic speckles can be traced through the intestinal wall into the surrounding mesenteric fat and peritoneal cavity. Additional ultrasonographic findings noted with intestinal perforation can include adjacent hyperechoic (bright) mesenteric fat, peritoneal fluid, reduced gastrointestinal motility, corrugation of the intestinal tract, and regional lymphadenopathy.

Postoperative Appearance of the Stomach and Small Intestine

The most common reasons for obtaining postoperative radiographs include the evaluation of feeding tube placement (gastric, gastrojejunal, etc.) or if the patient is not improving as expected post surgery. Postoperative imaging studies are also used to determine a baseline appearance, which may result in easier detection of postoperative complications. The evaluation of postoperative imaging studies can be challenging and it is crucially important to be familiar with the anatomic and physiologic changes that occur during as well as postoperatively and be familiar with the surgical technique used.

Radiography is often used as a first technique to evaluate for the extent of peritoneal gas and fluid, position of the stomach and intestines as well as the presence and position of surgical devices including drains and tubes. As noted previously, functional ileus of the stomach and intestines occurs commonly post surgery and can result in vomiting, diarrhea or constipation. Radiography, ultrasound, and CT can all be used to evaluate for the presence of free peritoneal gas. Radiography is currently the most commonly used technique, but a small volume of free abdominal gas can be difficult to recognize on conventional radiographs made with a vertically directed X-ray beam because the gas bubbles are small and irregular in shape and may be misinterpreted as bowel gas unless they are located in a region where gastrointestinal structures are normally not located. Radiographs can be obtained with a horizontal X-ray beam, with the patient either in dorsal recumbency, so that the gas accumulates beneath the abdominal wall, or in lateral recumbency, so that the gas rises to the highest aspect of the abdomen and can usually be found under the abdominal wall in the craniodorsal abdomen. Most of the peritoneal gas is absorbed in 3–7 days, but it has been reported that peritoneal gas might be noted on radiographs for up to 25 days post surgery. Ultrasound is a highly sensitive technique to evaluate for the presence of peritoneal gas, but in studies in human patients, it has been noted that the ability to detect gas is highly operator dependent.
