To our immediate and extended families,
those that touched our lives and stay in our hearts forever.
At the end of the day, you are what matters most.

And to the birds. They always continue to inspire us to soar to new heights,
both on a personal and professional level.
They truly are magical and wonderful creatures that we are privileged not only to share this world with,
but to also have the opportunity to do better by and for, in health and illness.

Foreword

Drs. Brian Speer and Yvonne van Zeeland have invited many of the leading experts in avian medicine to share with you the latest advances in avian medicine in this second volume of *Current Therapy in Avian Medicine and Surgery*.

As I read through the various chapters of subject material included in this volume, I was awestruck by how far avian medicine and surgery has come in the 50 plus years since my first interest in avian medicine began. The literature at that time consisted of a handful of books, written by amateur avian enthusiasts, anatomists, or physiologists, some representing significant inaccuracies such as the book *Diseases of Canaries* by Robert Stroud (the Bird Man of Alcatraz). The only journal focusing on avian species at that time was the *Journal of Avian Diseases* (first published in 1957), but this largely focused on (commercial) poultry. Treatment protocols were anecdotal and rigid scientific information was basically nonexistent. Medications and equipment were adapted to the best of our knowledge. The state of avian practice was probably comparable to small animal practice in the late 1940s.

Simultaneously, pet birds were becoming "the pet" of the 1970s to 1990s. Millions of birds were being imported into the United States, often in some strikingly deplorable conditions. Those that survived were often malnourished and/or had viral or bacterial diseases. Many of the infectious pathogens responsible for causing disease in these birds were either not known or poorly understood. Nutritional recommendations primarily referred to diets consisting of mixtures of seeds, cuttle bone, maybe some fruits and vegetables, and more seeds, which did little to improve their health.

While the general public and the veterinary communities did not initially recognize avian medicine as being of value, an increasing number of bird "owners" ("caregivers" today) who were committed to the care of their birds began to seek out veterinarians who also shared a passion for birds. At the same time, we as veterinarians began treating birds using the limited resources available and established a community focusing on avian medicine, the Association of Avian Veterinarians (founded in 1980). Through this organization, we continued to more formally share our passion for and knowledge about birds and develop strategies for diagnosing and treating disease in nondomestic avian species. The growing information gained through clinical practice and research in 1989 also resulted in the transformation of our initial *A.A.V. Newsletter* to a more professional journal, the *Journal of the Association of Avian Veterinarians*, which in 1995 was renamed to the *Journal of Avian Medicine and Surgery* that we know today. These publications allowed researchers and clinicians with a desire to share and disseminate information to publish peer-reviewed case studies, treatment protocols, procedures, and techniques to advance the care of our avian patients. Simultaneously, the growing need for specialized care for birds resulted in the establishment of avian veterinary specialty colleges within the framework of the American (ABVP) and European (EBVS) Board of Veterinary Specialization, and the Australian and New Zealand College of Veterinary Scientists (ANZCVZ), securing global recognition and continuing advancement of avian medicine.

Societies have valued birds in many ways, and the international trade in birds, both legal and illegal, was having a significant negative impact on avian species globally. With the introduction of the Migratory Bird Treaty Act (1918) and the Endangered Species Act (1973), a rising societal awareness of and desire to preserve and protect (native) wild birds and their natural habitats developed. As conservation efforts became more refined, they began to have increasingly significant impacts on avian conservation. The mass importation of wild birds into the United States in the mid twentieth century became a societal issue in the 1990s and ultimately resulted in the Wild Bird Importation Act of 1994. This dramatically changed both the demographics and practice of avian medicine. Caregivers increasingly sought out "avian veterinarians" for the improved veterinary care for their birds, ultimately supporting a drive for the continual elevation of the standard of care for all birds. Veterinarians, working with ornithologists, biologists, and conservationists, became integral members of recovery programs for endangered avian species. Largely fueled by knowledge and advances gained from companion avian medicine and surgery, zoological, avicultural, and conservational aspects of avian medicine matured and evolved, benefiting both wild and captive avian species to this date.

As you open these pages of Volume 2, *Current Therapy in Avian Medicine and Surgery*, you will be amazed how thoroughly and competently the content has been compiled by its editors, Drs. Speer and van Zeeland, and the authors. The contents of this volume, alongside the first volume of this textbook, reflects the amazing growth in avian medicine and surgery from its infancy in the 1960s to today. As a small animal/avian practitioner in the 1980s, 80% of the types of cases we treated at that time are no longer seen or at least are seen much less frequently, including diseases and conditions such as scaley leg mites, vitamin A deficiencies, Pacheco's disease, metabolic bone fractures, and so on. If we were to plot the trajectory of care, the curve would almost certainly be at 90 degrees, with many technological, pharmacological, medical, and surgical advances helping to raise the standards of care and therapeutic opportunities for avian patients. And that just relates to the physical care of our patients. Consideration for the psychological or emotional wellbeing of our patients now ranks equal to their physical wellbeing as also reflected by the chapters dedicated to enrichment and minimizing stress in this book.

However, what has remained consistent in avian medicine throughout time is the passion and love for birds within our avian veterinary community. This passion drives researchers to work tirelessly, and authors and lecturers to disseminate

and share their knowledge, which can then be put to use by practitioners and support staff in the daily care of their avian patients. It is also our clients' love for their birds and their trust in our profession that allow us to treat their birds and share these advances. Volume 2 of *Current Therapy in Avian Medicine and Surgery* marks a point in the trajectory of avian medicine. Society has always been and will continue to be passionate about and value birds and it is this passion that will continue to drive the future of avian medicine, which you as a reader are an important part of and contribute to by applying the knowledge presented in this book while caring for your patients.

Bob Groskin, DVM

Preface

Following the publication of Volume 1 of *Current Therapy in Avian Medicine and Surgery* in 2016, there had been a plan to release a new volume about every 5 years. Obviously, this second volume does not follow that anticipated schedule. Complicating matters, including a global pandemic, the challenges of maintaining clinical practice, its management and overseeing new building construction duties, and a host of other personal matters all collectively raised their heads to provide a perfect storm to account for the delay. Nevertheless, we have endured the storms and have made it! We are proud and grateful to have this second volume come out as a joint effort by two editors. The combined skillsets, experience, and efforts of both coeditors have greatly helped to streamline the process, spread out the workload, coordinate, and assemble this second volume. Drafting the initial outline to its final version, recruiting the various international contributors, and working with them to review and edit their manuscripts represents an obvious large editorial effort for the publication of this book. Tying in the individual contributors' information with the overall envisioned framework of the current, previous, and future volumes is and will remain an editorial task that we both look forward to continue as coeditors while moving forward.

In keeping with Brian's original vision—a vision wholeheartedly shared by Yvonne—*Current Therapy in Avian Medicine and Surgery* continues to serve in a key text reference position as a leading source of current material within the broad scope of avian medicine and surgery. Both volumes of this text are written with the target audience of colleagues who are beginning their careers as well as those who are continuing to broaden their understanding and expertise. This second volume contains 12 sections, each exploring advancements in their respective areas, the vast majority bringing forward new, relevant, and in-depth information to add to the content brought forward in Volume 1. The interconnections between topics should be apparent to readers. While each chapter by itself provides important pieces of the whole, it also relies on others to help build a more complete picture of the delivery of avian healthcare, as also indicated by the various cross-references included in the text. Paired with the first volume, readers are bound to recognize the vision of *Current Therapy in Avian Medicine and Surgery*, each subsequent volume being complementary to the prior ones, and neither of them attempting to present the full depth and breadth of the field of avian medicine and surgery in its entirety between two covers. In this light, the outlines for the third, fourth, and fifth volumes of *Current Therapy in Avian Medicine and Surgery* are already shaping, aiming to add valuable new content to our current body of knowledge, and addressing relevant, current topics for the reader.

In the Section 1 of Volume 2, Advances in Practice Management, concepts in practice management are again explored as they were in the first volume. To develop a successful career in avian medicine, awareness of these concepts is important, as is your knowledge of the art and science of what we do. Section 2, Establishing a Diagnosis, explores common imaging modalities and how to get the most out of them, thermal imaging, and the value of necropsy as a part of practice, while Section 3, Therapeutic Intervention, offers a comprehensive overview for practitioners treating avian patients, fundamental guidelines, and a review of general pharmacologic principles, pharmacokinetic modeling approaches, and interpretation of antimicrobial results. This is a much more in-depth review for those colleagues who really want to understand where we currently stand in relation to applying these principles directly to avian practice while planning our therapeutic intervention strategies. Antimicrobial, antibacterial, antifungal, antiparasitic, and antiviral drugs are separately addressed with these same goals. Section 4, Infectious Disease Prevention, reviews the interactions of host, agent, environment and disease, hygiene, and disinfection, as well as current vaccination strategies. Perhaps stating the obvious, infectious disease does not just occur in a vacuum—it typically happens for reasons that can be managed, and is far more than a quest for pathogens only. Section 5, Updates on Infectious Diseases, updates our current understanding of important infectious diseases, including disease caused by avian bornavirus, poxvirus, West Nile Virus and other flaviviruses, campylobacteriosis, chlamydiosis, erysipelas in wild birds, mycoplasmosis, cryptococcosis, trichomoniasis, diplomonad protozoal diseases including giardiasis and spironucleosis, histomoniasis, and cochlosomosis. With the exception of bornavirus, none of these infectious diseases were presented in Volume 1, and as such these chapters will add to those presented in the first volume in a collective manner for your reference. We also dedicated a section to the respiratory system (Section 6), which—similar to the Cardiology chapter in the first volume—provides a focused, system-based in-depth review of avian respiratory anatomy and physiology, diagnostic work-up and diseases of the respiratory tract, complemented by chapters on surgery, endoscopy, and endosurgery of the respiratory system. Section 7, Beaks, Feathers, and Feet, aims to provide the reader with a review of the normal anatomy and physiology of these structures, as well as the etiology and risk factors that can lead to pathology, thereby aiding the reader in gaining an in-depth insight and understanding of the diseases and conditions affecting these anatomic regions. In Section 8, the trauma patient is presented, with individual chapters focusing on triage and stabilization, pain management updates, wound management, and fracture management. Many of the patients initially presented for veterinary assessment are the victims of traumatic injuries, and this is often where our doctor-patient relationship begins in practice. Keeping our abilities current in order to keep these patients alive, stabilize them, and move them toward ultimate release or long-term wellness

management is immensely important in what we do in practice. Section 9, dedicated to embryology, neonatology and pediatrics, is a long-standing area of Brian's personal interest and provides an excellent overview of egg and embryonic development, natural and artificial incubation, and pediatrics in psittacine and other commonly kept birds. Section 10, the welfare section, which was an important part of the first volume and is intended to be an integral part of any volume of *Current Therapy in Avian Medicine and Surgery*, brings two chapters directly applicable to practice: minimizing stress and fear during the physical examination, and the strategic use of enrichment. These chapters are immensely important to the art and science of how we can do best-practice in providing care for our patients. Likewise, Section 11, the conservation section, another standing part of both volumes, focuses on a timely and current topic: anthropogenic and environmental threats to avian wildlife. Included in this section are chapters dedicated to biotoxins, hazards related to man-made structures, petroleum products, anthropogenic toxins, wildfires, and an important one health subject: wild birds and cats. These topics are directly applicable to various aspects of healthcare for the individual bird and conservation medicine, and should be important to us all. Section 12, the final section is dedicated to specific taxonomic groups of birds, that is, the broad group of toucans, hornbills and aracaris, and birds of prey, the latter not specifically dealing with diseases common to these birds, but rather attempting to provide a global view of falconry, its past, present, and future, as we believe it is important for veterinarians dealing with these birds to have a better in-depth understanding of this ancient yet unique cultural sport. As editors, we are quite excited to see these taxonomic groups be presented in this manner for your reading pleasure. This second volume finishes with a series of appendices that include updated information on drugs and approximate doses (with several new drug groups added for your convenience), normal clinical pathological data, and normal biological data, as well as a new appendix presenting chick growth data compiled from previously published reference materials that many colleagues may not have had easy access to, and which have therefore been "brought back from the past" so that their information is not lost to time. As a result, *Current Therapy in Avian Medicine and Surgery* remembers the past, focuses on the present, but also keeps a clear and changing vision of the future in mind.

Acknowledgments

There are many colleagues to whom we are grateful for their influence in the development, guidance, and maturation of our current views of avian medicine and surgery. This volume of *Current Therapy in Avian Medicine and Surgery* would simply not be what it is, without the countless hours of hard work and sacrifice of personal time that each and every one of the contributors devoted to this project. As you will see, their expertise, work, and dedication are the building blocks for the past, present, and future volumes of *Current Therapy in Avian Medicine and Surgery*. Thank you, sincerely, to every single one of you.

Thanks are also needed for many others who have been directly and indirectly involved. Greg Harrison, who authored the first text on *Clinical Avian Medicine and Surgery* in 1986 and who was, in so many ways, a visionary and considerably ahead of his time in helping meet the need to unify medical knowledge and surgery. To this day, Greg continues his solid support, providing a guiding light for so many of us avian veterinarians. Walter Rosskopf, who helped pave the way so many years ago when Brian started his career in avian medicine and began to see how much could be medically considered and done for birds. For Yvonne, Gerry Dorrestein and Nico Schoemaker both had foundational roles as friends and mentors, sparking her fire for avian medicine and showing her the endless possibilities of what can be, if you do it well. James Harris, who shared the excitement and passion for learning and the scientific methods that serve as the foundations for moving our profession forward, but also had a big impact on a personal level. We sometimes get so caught up in things that we do not always realize that the personal relationships we continue to develop with colleagues and clients are among the most important things to cherish and keep close to our core, but James emphasized the value and importance of these relationships. So thank you James for demonstrating for us these important things, and teaching, by example, how you can grow as an individual while nurturing these personal relationships. The entire staff of our daily work environments, the Medical Center for Birds and Division of Zoological Medicine, must also be acknowledged and thanked, as their support was instrumental in enabling us to pursue this and other projects in the past. Other friends and colleagues should certainly also be named, those who have had formative roles and impacted our lives, personally and professionally, including—but not limited to—David Phalen, Jamie Samour, Bob Groskin, Tom Tully, Joanne Paul-Murphy, Murray Fowler, Michelle Hawkins, Neil Forbes, Scott Echols, Susan Orosz, Marina Krautwald-Junghanns, Bob Doneley, James Carpenter, Nigel Harcourt-Brown, Michael Lierz, John Chitty, Lauren Powers, Brenna Fitzgerald, Susan Clubb, Branson Ritchie, Helene Pendl, Pat Redig, Avery Bennett, Julie Murad, Irene Pepperberg, Chris Davis, Ted Lafeber, Keven Flammer, Helga Gerlach, Petra Zsivanovits, Deborah Monks, Tom Dutton, and Susan Friedman. Not all of you are still with us, but your words, your examples shown and shared, your thoughtful comments, tokens of kindness and support, constructive critiques and coaching, and your willingness to share your approaches to avian medicine and life in general, have guided us and continue to guide us constantly. Every single day.

A project of this size and scope represents innumerable hours of effort to coordinate, edit, and bring to fruition. This would not be possible without those who have supported us personally throughout this effort. We both agree that without a doubt, our spouses, Denise and John, must be acknowledged. They deserve a gold medal for their friendship and willingness to share life's journey with us, to always be there as an anchor in our lives. The practice of veterinary medicine is so much more than just a job; it is a passion and a true career for most of us. Our veterinary careers, and where they take us within the veterinary profession, are undeniably important, but without family and friends to share our journey in life with, our lives simply are not complete. Thank you, Denise, for completing, patiently mentoring, and guiding me, and helping to keep me on track and see what is needed to maintain and nurture those ever-changing and delicate balances needed in our lives together. Thank you, John, for teaching me how meaningful those little things are in life, that two are always stronger than one, and that love really does help overcome the most difficult times. Thank you as well to Robin and Cody, for being there with your dad through this all, and for the little things that you do that are the essence of what family is. From the day you were born, you have been, and will always remain, Daddy's little girl and Dad's favorite (and only) son.

Both of us have a clear understanding of the importance of our early childhood memories and how these shape our personalities and lives. Our parents have played a key role in this process and must therefore be recognized. So thank you, Verl and Lucille, Harrie and Mieke, for supporting us in achieving our goals and dreams; for raising us to be passionate, honest, and fair and do what we can to do the right thing; for teaching us that perseverance goes a long way in helping to achieve your goals, even if that is the harder road to take. And it's not just our immediate family, but also our extended families, our friends, that complement, enrich, and help to shape our lives. Nico, Frederique, and Raymon, you have proven yourselves to be true friends-for-life, offering helpful advice, providing a listening ear or shoulder to cry on whenever needed, and helping me (and John) get through what, undoubtedly, have been the toughest times of our lives. Fenna, Patricia, Melina, Aylis, and Ensar, I am blessed to have had Kees and still have you as my in-law family, and continue to be grateful for the time we spend together. After losing John, you have helped me to appreciate and enjoy life again, and I consider you as important as my own flesh and blood.

Wrapping up the final portions for the book and writing these acknowledgments gave us some time to reflect on the

journey that resulted in the creation of this second volume. I, Yvonne, still vividly remember the day that you, Brian, contacted me to invite me as coeditor for *Current Therapy*. It was the best Christmas present ever! I very much enjoyed working alongside someone that I consider one of my biggest role models and mentors, and would never have imagined the joy that this privilege could bring. Thank you so much for taking me on this journey, for the great teamwork, the many inspiring discussions, and the equally large number of bad jokes, which always bring a smile to my face! But most of all, thank you for your friendship and guidance throughout the years, which helped me grow, both as a person and professional. Likewise, I, Brian, am equally grateful for your, Yvonne's, friendship, and admire your hard work, incredible organizing skills, contagious passion, and relentless dedication to the profession, which have only grown stronger as we have worked on this project. In the many years we have known each other, you have grown to become a role model and mentor for me too, exemplifying that this role not necessarily has to be fulfilled by your senior. I am excited to see what the future will bring, planning the next volumes of *Current Therapy* together.

Looking back, we never imagined at the start of this project how rough the journey was going to be, with life throwing many challenges at us to pull us off course, and with many losses incurred along the way. John, Kees, and mom: we must continue life's journey without you, but promise to stay strong, never give up, take care of each other, and try and make our lives the best they can be. Dad and Taylor, we will carry on and do our best to get organized and stay on schedule. Dona, we know that you are still with us at every family meal, helping to plan the next, even before dessert is served. You are missed greatly, but forever in our hearts and thoughts. Thank you all for touching our lives.

Brian & Yvonne

CHAPTER 1

Practice Management: Developing a Career as an Avian Veterinarian

Len Donato • Marianne Donato • R. Eric Miller • Bruce J. Nixon

INTRODUCTION

A career in avian clinical practice can be quite rewarding. In addition to what is seen in private practice, there are times that avian clinicians will play a role in public health, work to help preserve endangered species, aid government programs, and perform research. Avian medicine and surgery is a highly specialized field that fills a need not only for our society but also on a day-to-day basis for our clients and patients. Despite the great personal rewards that go with private practice and avian medicine, there are many challenges. For example, there are concerns about maintaining and continually improving the level of patient care, successfully generating meaningful revenue and income, preserving longevity as a clinician in the field, and possibilities for effective retirement planning. Successful management of all of these aspects can bring greater personal, professional, and financial rewards to the practitioner pursuing a career in avian medicine.

When making the decision to pursue a career in avian medicine, certain questions have to be answered:

1. *What kinds of birds do you want to see?* Some practitioners elect to see any bird that can be kept as a pet. Others prefer to work with wild birds, hence working with wildlife rehabilitators and falconers may be the mainstay of a veterinarian's avian practice. Providing healthcare and management recommendations for zoologic collections and aviculturists is another potential pathway that fits under the broad umbrella of avian medical practice. Poultry healthcare is yet another option, whether that becomes only backyard chickens or production flock management.
2. *What percentage of the caseload do you want to be birds?* Some practitioners may aim to only treat birds owned by their previously established dog- or cat-owning clients. Other practitioners choose to focus all of their energy on birds, and rarely if ever see any other species, or choose to treat birds as a component of a larger variety of other exotic species in their practices.
3. *What level of medicine and surgery do you want to provide?* There are many practitioners who are happy with providing service for general health evaluations, nail trims, and wing trimming procedures. In these practices, birds with medical issues are usually referred to a facility that sees birds regularly. Clinicians that are interested in treating medical and surgical cases should ensure to clearly outline the level of diagnostic and surgical capabilities for potential clients. Similarly, it is important to decide whether hospitalization services will be available, whether the hospital will cover overnight care, and if so, whether it will be open to the public for 24-hour emergencies.

Answering these questions will help define at least the beginning of your career working with birds in clinical practice. After outlining the parameters, be sure to record them. Referring back to them regularly will keep you on track to achieve those goals. This exercise will also help you plan for continuing education, equipment acquisition, physical plant design, staffing needs, inventory management, and marketing strategy. The answers to these questions may change as your career advances. That is very normal, as healthcare providers typically evolve throughout their careers.

GAINING KNOWLEDGE

There are many opportunities for continuing education in the field of avian clinical medicine and surgery. Defining the goals as previously outlined will aid to determine which type of education will best serve and fit your needs.

Independent Study

Having good, current resources available to help with everyday practice is crucial. There are many quick reference guides to have on hand, as well as more detailed textbooks as outlined in Box 1.1. Having easy access to hard or digital copies of your reference material is paramount. There are veterinary online forums through social media or paid subscription that can help keep a practitioner up-to-date on current trends in

avian medicine, follow thought patterns through a case, communicate with colleagues, or get access to scientific papers. As with any online forum, be mindful of the information and check your sources. Peer-reviewed journals and articles are available and should be a part of any avian library you have assembled.

Continuing Education

Continuing education allows veterinarians to gain detailed knowledge for credit in a focused area of study, in this case avian medicine and surgery. There are many online and in-person opportunities, as detailed in Box 1.2. Many states have restrictions on the amount of continuing education a veterinarian can receive from online seminars. Be sure to check state regulations. Conferences for in-person opportunities also allow for networking with colleagues, which is crucial in nontraditional species medicine. The Association of Avian Veterinarians (AAV), the European Association of Avian Veterinarians (EAAV), and the AAV Australasian Committee (AAVAC) are international organizations of veterinary professionals that offer various educational opportunities and information on national and international meetings that focus on avian medicine and surgery.

American Association of Zoo Veterinarians (AAZV)—annual conference
European Association of Zoo and Wildlife Veterinarians (EAZWV)—annual conference
Some avian pet food companies will host online CE
Many popular companion animal conferences will have exotic pet sessions featuring avian medicine and surgery

Academic Opportunities

There are a number of opportunities to gain exposure and receive advanced training in avian medicine in the academic environment. Veterinary students can volunteer in their extracurricular time to explore areas of interest in veterinary medicine. For avian medicine, that may be at a species-focused practice at least including a significant portion of birds as their caseload at their school or a nearby veterinary hospital. It can also include wildlife facilities, zoos, laboratory animal settings, or even poultry farms. In the clinical years of veterinary school, there may be an in-house service that offers a rotation for the students to get further exposure to avian medicine. Students may also elect to schedule rotations outside of the university, referred to as externships. Externships can take place in private practice, zoos, wildlife rehabilitation centers, veterinary poultry practices, and laboratory animal facilities. Veterinary schools usually have a list of externships for students to review when scheduling their clinical year. Selecting an externship outside of the approved lists will typically require working with student affairs.

Internships and Residencies

If one decides to specialize in avian medicine and surgery, internship and residency opportunities are available and a common path is taken. They are available in academia and private practice. Internships are typically one year in duration and prepare a candidate, primarily through clinical training, literature reviews, and research, for a residency or clinical practice. A residency is advanced training that lasts two to three years and prepares candidates for board examinations that lead to specialization. Internships are usually required to obtain a residency position. In Europe, some training facilities allow application for a residency position following a minimum of two years of work in a highly equipped veterinary clinic. In the United States, the Veterinary Internship and Residency Matching Program (VIRMP) and independent research will help identify the right place for advanced training in avian medicine. Note: Not all internship and residency opportunities are found through VIRMP.

Specialty Board Certification

You can obtain specialty board certifications in avian medicine and surgery. There are several certifying organizations recognized by the AVMA. The American Board of Veterinary Practitioners (ABVP) certifies veterinarians for avian practice. There are also board certifications through the American College of Zoological Medicine (ACZM), the European College of Zoological Medicine (ECZM), and the Australian and New Zealand College of Veterinary Scientists—Avian chapter. The details of these varied options for achieving advanced specialization including avian species are discussed in Volume 1 of this series. The American College of Poultry Veterinarians (ACPV) and the European College of Poultry Veterinary Science (ECPVS) provide certification specifically for poultry flocks and their management. These organizations require either completion of an internship and an approved residency or a number of years of clinical practice with the species of birds for that category. All specialty boards have their own requirements, but most involve writing articles for a peer-reviewed journal or preparing case reports that are reviewed by the certifying entity. An examination is also administered to candidates testing in-depth knowledge of birds in the specialty category. In addition, various countries offer national recognition in avian and/or exotic animal medicine and surgery through certification at an intermediate level (e.g., Germany, Spain, United Kingdom).

AVIAN HOSPITAL DESIGN

Avian/exotic exclusive practices are becoming increasingly popular, especially in large metropolitan areas. The majority of avian practitioners work in practices that also see other species, often including dogs and cats. Design for these clinics should be highly specialized and often there is an emphasis on incorporating avian design elements into multispecies facilities.

Waiting Room Design

Species segregation is a priority in a hospital that sees birds, and many, if not most, multispecies hospitals already have this incorporated into their design element. Unfortunately, however, these areas are usually segregated into dog and cat, without a designated area for birds, let alone a separate area for bird species. This creates a potentially dangerous situation in which birds may be exposed to either loud and often very large predators or small yet incredibly efficient predators with a predisposition for bird prey. Therefore, waiting rooms in mixed species practices should be designed to have a specific bird area. This begins with clear signage before the client enters the lobby and should be reinforced by receptionists strictly directing clients into designated areas (Figure 1.1). Despite all efforts to have a segregated waiting room, there will always be emergencies and walk-in appointments, but even with those, every effort should be made to reinforce species segregation. All clients should be instructed prior to visits to keep their birds confined to a carrier, as many avian clients tend to carry their birds on their shoulder without proper, safe confinement. Veterinarians in the position of designing or remodeling a waiting room should consider a segregated space for birds. For existing lobbies, the only practical option will be to add a vertical divider in whatever part of the lobby seems to be the most inconspicuous. Receptionists will need to remain alert to clients if they are out of direct line of sight.

Ideally, birds should not be in waiting rooms beyond initial greetings. Rather, they should be directed immediately into an examination room with closed doors to reduce stress, ensure patient safety, and reduce the risk of infectious disease transmission to other birds and clients (in case of a possible zoonosis). Check-in and check-out procedures should be accomplished while client and patient are within the confines of that safe space. This of course assumes that the hospital has the capabilities to efficiently maintain an appointment schedule with a surplus of examination rooms.

Ceiling fans pose a threat to flighted birds and therefore should be removed completely. It is not sufficient to keep any such fans turned off as many bird owners will notice them immediately and question either your commitment to or

FIGURE 1.1 External signage directing clients to species-specific areas. (Courtesy B. Nixon.)

knowledge of avian patients. Ceiling height can also become a major frustration if a bird escapes from its enclosure or the handler. Many hospitals use very tall ceilings and numerous windows in the waiting area as a design element. Any practice that sees even a moderate number of birds will inevitably suffer the anxiety of an escaped, flighted bird. Having escapees perched 18 feet off the ground or flying into windows is not an amusing situation, thus reception staff must be relentless in their insistence that all birds brought into the hospital must be in an enclosure of some kind. Receptionists should offer towels or blankets to cover the cage or carrier to reduce anxiety. Offering possibilities to elevate the carrier rather than placing it on the ground as well as playing music in the background to reduce anxiety from sudden noises may be helpful as well (see Chapter 46).

Examination Rooms

Most examination room designs work quite well with avian patients. Simplicity in design elements leads to simplicity of maintenance. Built-in benches are preferred to free-standing chairs as birds—once released—will often perch on the backs of chairs. Chairs or other furniture may be stained with droppings from birds perching on them or become ragged from the ravages of anxious or bored psittacines nibbling chunks out of them. As a result, furniture in the examination room should be made of material that is chew-resistant and is easy to clean, like metal.

Upper cabinets that extend to the ceiling preclude flighted birds from perching on top (Figure 1.2). If existing cabinets do not extend to the ceiling, a cabinetmaker can easily install blanks atop existing millwork to achieve this effect (Figure 1.3). For new construction, laminated millwork is a superior choice to stained wood for ease of maintenance and resistance to beak damage. Stainless steel is often used as a tabletop and although some may not appreciate the visual appeal of bare metal, it is indisputable that the material is practically indestructible and easy to clean. Screen or mesh can be inserted inside heating, ventilation, and air conditioning vents to prevent small, flighted birds from escaping into the ductwork. Windows in the examination rooms may be problematic for birds, potentially serving as a means of injury should the birds fly into them. As a result, these should preferably be covered with opaque window films, blinds, screens, or similarly functional alternatives.

FIGURE 1.2 Patient out of reach on top of a cabinet in the examination room. (Courtesy B. Nixon.)

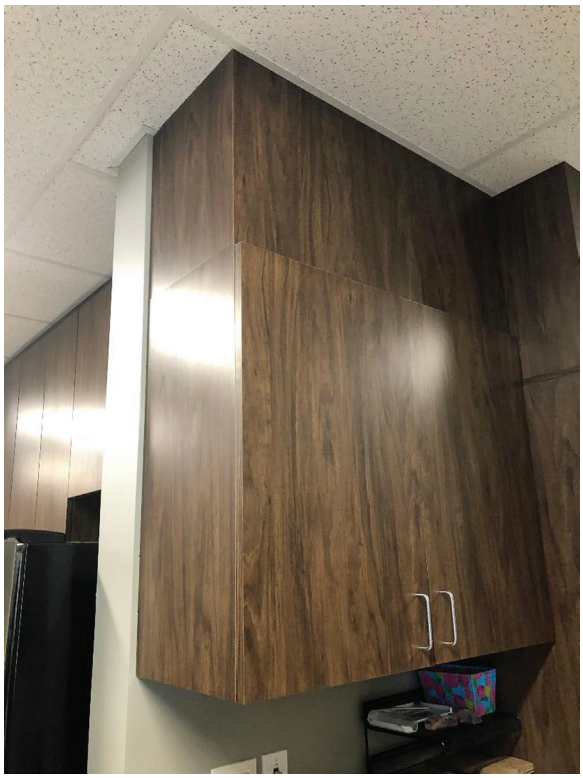

FIGURE 1.3 False panel placed on top of a cabinet to prevent flighted birds from perching out of reach. (Courtesy B. Nixon.)

Overhead light emitting diode (LED) lighting has largely replaced incandescent and fluorescent lights and is a superior choice in virtually every way (color, brightness, and energy efficiency). Having an electrician replace existing fluorescent lights with LED fixtures is surprisingly inexpensive and fast. While the electrician is in the building, you can also have them install motion-activated wall switches to increase energy efficiency even more. In new construction, both LED lighting and motion-activated wall switches will usually be required by local ordinance. Adding a dimmer switch can be handy for easing capture of freed birds in the examination room.

Some avian practitioners prefer to do thorough examinations and even some diagnostic sampling in the examination room itself to enable clients to see as much as possible of what is done with their bird compared to transporting the patient into a separate treatment area. In these situations, it may be wise to install specialty examination lights that can be used as a spot or flood and positioned where needed.

Treatment Areas

If possible, it is best to have at least one designated treatment table in an area segregated from the bustle and noise of most multispecies animal hospitals. The lack of such a space in hospitals is what may lead some practitioners to do much of their hands-on work in the examination rooms. In new construction and most remodeling projects, a segregated avian treatment table can usually be fit in without much difficulty, as it requires very little space. In fact, a small treatment space can be used to the clinician's advantage with flighted birds to keep them contained. As birds may overheat easily when handled for some procedures, it is convenient to be able to set them on the floor immediately afterward or on the table in a well-ventilated container. A small, quiet, separate space allows them to safely calm and cool down.

In many hospitals, an existing isolation room can be used as the treatment area for birds. These rooms are often empty and underutilized. They can be readily customized into becoming a combined isolation/avian treatment area. Even small practices with closet-sized isolation rooms can consider having only one large cage on the ground floor with a countertop built upon it (Figure 1.4).

Incubators are indispensable items in practices that see birds as being self-contained units that can control heat and deliver oxygen. Most can also monitor and adjust humidity and deliver nebulization. Unfortunately, these units require a great deal of counterspace in the treatment area and many of these units cannot be stacked. Counterspace is usually premium real estate in most practices already, particularly in the treatment room. There is no magical fix for increasing counterspace. Even in new construction, you will usually be limited by the length of your walls, less doorways. This frustration can sometimes be solved by recruiting the services of an interior designer who specializes in commercial buildings. Some of these professionals are expert organizers and can free up counterspace in imaginative and functional ways, such as installing wall shelving to place incubator units.

Avian Wards

A completely segregated avian ward is the ultimate in hospitalized patient housing, if space permits. New construction should be able to efficiently locate an avian-specific ward (ideally multiple wards) with an observation window off the treatment room. If an observation window is not possible, then consider installing webcams that can allow observation without having to enter the room. Even some remodels may be able to carve space for an avian ward, as the space requirements are not unreasonable. The ward will require at least 5 feet of width to accommodate cages and countertops and leave free workspace for clinic staff (Figure 1.5). The purpose of the ward is to provide a quiet, controlled environment for convalescing birds, easy access for staff, and to provide strict isolation for birds that may have contagious disease. Because of the possibility of contagious diseases, it is not a good idea to combine the avian treatment area into the avian ward. Doing so will force the practitioner into identifying yet another space to hospitalize birds with known or suspected contagious disease.

Controlling air quality in an avian ward can be accomplished in several ways. In most situations, the avian ward will

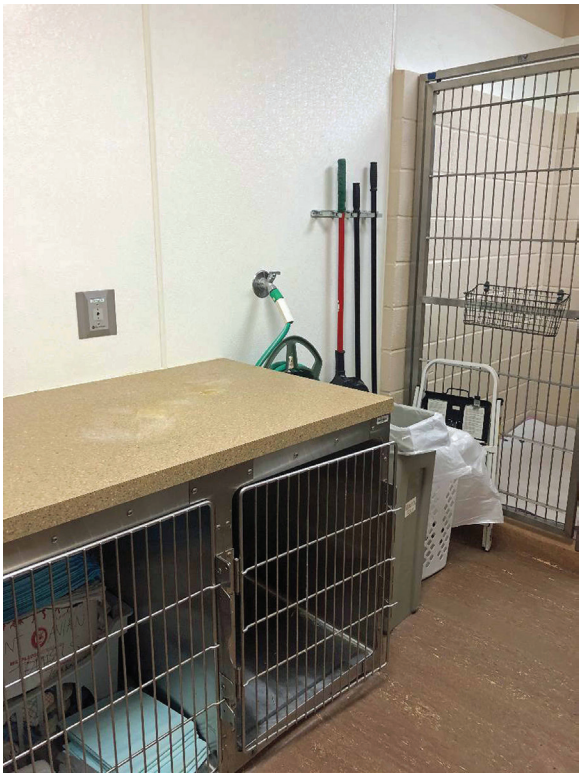

FIGURE 1.4 Improvization of a treatment space. (Courtesy B. Nixon.)

FIGURE 1.5 Avian ward with an observation window. (Courtesy B. Nixon.)

be connected to the heating/air conditioning system being used throughout the building. Many bird species shed large amounts of dander that can quickly clog air filters. Thus, it is essential to have routine replacement of these filters included in your hospital or clinic maintenance plan. Initially, you can aim for quarterly replacement, and monitoring the condition of the replaced filters will help determine whether maintenance needs to be scheduled more or less frequently. Free-standing *HEPA* (high-efficiency particulate air) filters can also be used within avian wards, especially those that do not *have high air* change rates. When choosing this option, do not make the mistake of choosing small or inexpensive units as they will not be able to handle the volume of bird dander or volume of air to fully filter the air. New construction will almost certainly require the use of a mechanical engineer to design your heating and cooling system. Remodels or retrofits can use the services of a commercial heating/air conditioning company experienced with hospital, dental, physician, and/or veterinary facilities. Take the time to study and understand your system including the temperature ranges needed within each zone, air change rates, air velocity at head level, the use of ERVs (energy recovery ventilators), and the number and types of air filters. Mistakes are costly, time-consuming, and frustrating for the practice owner and the staff.

The ambient temperature needed in avian wards is typically warmer than in other areas of the hospital. It is not reasonable to have working areas of the hospital be as warm as the ward. Have a separate thermostat (zone) for the avian ward or use a supplemental heating unit as a means of maintaining temperature that is safe for your patients. Consider wall units or split air conditioning systems as the room can be separate from all other systems and provide safe temperature control. Monitor temperature with the unit's thermostat and a separate stand-alone thermometer. Most avian wards can be kept at 80°F (27°C) depending on species; if tighter temperature regulation is needed, then incubators should be used.

Other Considerations

Flooring

Hospital flooring is often the number one question asked at hospital design continuing education events. There are simply no right or wrong answers; the choices are determined by cost, aesthetics, owner preferences, and functionality. Most hospitals have multiple types of flooring throughout the facility. What is offered here is the opinion of one of the authors based on several decades of working in, visiting, designing, and building veterinary facilities, both large and small.

Waiting rooms and lobbies should be the most aesthetically pleasing area within your hospital. As such, natural stone such as slate is quite beautiful and durable. Porcelain tiles are available in an astonishing variety of styles, textures, and colors. Stained concrete should be strongly considered in new construction.

For working areas of the hospital, one of the author has found rubber sheet flooring to be almost ideal. This material is thick and has some give, which makes it forgiving to walk upon and also deadens sound. It is available in a variety of colors and patterns that are distributed through the entire thickness of the material, meaning that even a deep gouge into the material is almost invisible. The product is heat welded so that you have effectively one solid piece of flooring with no gaps. Even more importantly, it can be flash coved 4 to 6 inches up the wall (Figure 1.6). This eliminates the need for baseboards, which collect all manner of liquid and other debris under and behind them and inevitably become disgusting foci of decay. Rubber sheet flooring is maintained with simple mopping, and no stripping, buffing, or annual top layer applications are needed. The biggest downside to rubber sheet flooring is cost; however, the material should last the lifetime of the building with no need for replacement. Another potential problem with rubber flooring is that moisture migration upwards from a concrete slab could cause bubbles to develop.

FIGURE 1.6 Rubber flooring flash-cove up the wall in lieu of baseboards. (Courtesy B. Nixon.)

Sheet vinyl is commonly used in working areas of veterinary hospitals, primarily due to its lower cost. It can be flash coved, and should be, in lieu of baseboards, but the material stiffens and cracks over time and the coving eventually fails, as do the seams that connect the sheeting.

Epoxy flooring is widely used in kennel and run areas and throughout a clinic or hospital. The material is certainly durable and the incorporation of "chips" within the material can give both texture and pattern. It can be spoon coved up the wall to eliminate the need for baseboards. In the experience of one of authors, this flooring becomes dingy or unevenly discolored with time regardless of scrubbing or pressure washing. It can be unforgiving on feet and is noisy. A newer process using polyurea basecoat and polyaspartic clear coat appears to be a superior alternative to traditional epoxy.

Noise

Minimizing loud noises for our avian patients will reduce stress and promote a friendlier environment. Behavioral changes by the staff to reduce noise will be reviewed later in the chapter.

Changes to the physical plant can help reduce noise. Increased drywall thickness and insulation between walls should be considered throughout the hospital, but especially for avian-specific areas. If possible, bird wards and bird-only examination rooms can be located out of the flow of main traffic and away from barking dogs if the practice is a multispecies facility. Select surfaces that absorb sound. Ceiling tiles have a noise reduction coefficient (NRC) of 0 to 1.0, which represents a percentage of noise absorbed. If the NRC of a tile is 0.2, 20% of the noise is absorbed and 80% is reflected. Decorative tiles can also be put on walls to reduce noise and have the same rating system as ceiling tiles. Furniture, paintings, and other fixtures also reduce noise as is evidenced by the echo in an empty house. Use any physically possible tactic to reduce noise or use soft ambient music to dampen sudden noises.

Permits/local ordinances

When remodeling or starting a new construction project, be sure to follow all local ordinances and have proper permitting and inspections. This cardinal rule is commonly broken with remodeling. While it may seem like a simple project, construction frequently goes awry and another set of experienced eyes on the project is crucial. Proper inspections may save a big disaster later.

EQUIPMENT

To practice quality avian medicine and surgery, it is essential to have proper equipment available. Whether and which equipment is necessary will be determined by your pre-set goals of percentage of the practice that is composed of bird care and to what medical and surgical level you want to practice avian medicine. As an example, an endoscope is not needed if the goal is to see healthy birds and refer ill patients to specialists. An existing multispecies practice will have many of the items on hand already. Regular maintenance should be scheduled to ensure that equipment is maintained in good working order and is replaced if it is malfunctioning and cannot be repaired.

Here is a comprehensive list of equipment by potential goals that may be defined.

Examination and Routine Care

- Gram scale: Have a scale that goes up to 2000 g and one that can accommodate larger birds, if you are seeing those. Preferably, birds should not be weighed in pounds or ounces; grams and kilograms are much more accurate. Perch stands for the scale can make weighing easier if the bird is comfortable using it. Human baby scales are inexpensive and very helpful for weighing many larger, non-perching species. Otherwise, clear plastic containers with securable lids and air circulation can be used to keep a patient restricted but monitored and observed safely while being weighed.
- Nail clippers of varying sizes: You may also want to have a handheld cautery pen to prevent bleeding for small birds weighing less than 120 g.
- Scissors of varying sizes: Used to cut feathers for wing trims (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 22, Advancements in Management of the Welfare of Avian Species).

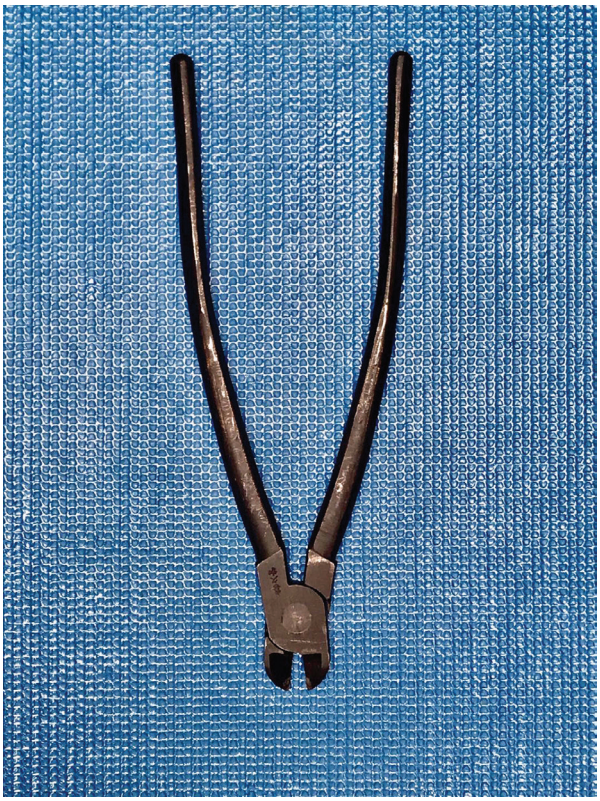

FIGURE 1.7 Band removal cutting tool. (Courtesy L. Donato.)

- Rotary hand tool: These are very helpful for large bird nails or for rhamphothecal shaping procedures (see Chapter 31).
- Band cutters: Used to cut and remove leg bands, when indicated (Figure 1.7).
- Dental high-speed drill: This is used to remove leg bands that are too thick for standard band cutters. This drill can also be used to remove leg bands that have embedded in swollen tissue from trauma.
- Paper towels, washcloths, hand towels, bath towels: These are used to hold birds for examination or other procedures.
- Oral speculum: Can be used to help maintain an open mouth for oral examination, sample collection, or tube feeding if necessary (Figure 1.8).
- Pediatric or neonatal stethoscope/ophthalmoscope/otoscope: These are important tools for any avian physical examination, particularly the more common, small species seen in companion bird practice.
- Net: This will aid in catching escaped birds. Nets can be modified to have a soft, supportive ring that holds the net webbing so birds are not injured during the recovery process. Foam or insulating pipe material are options for this modification. A telescopic handle to extend the net is advised (Figure 1.9).
- Microchip reader: When placing microchips or if lost birds are brought to your facility, a reader will be needed to confirm the microchip number.
- Microtransponder chips: These are also known as p-Chips. They are small enough to implant in a small bird, as the standard microchip is sizable and will damage pectoral muscles of smaller birds.

FIGURE 1.9 Soft ringed capture net. (Courtesy Y. van Zeeland.)

Advanced Medical Care and Hospitalization

- Red rubber catheters: These are used for tube feeding for nutritional support, obtaining samples from the crop, and some surgical procedures.
- Metal crop feeding tubes with rounded tips: These are also used for feeding nutrient-deficient birds.
- Bird collars: There are times that some birds may require placement of a response-block mechanism to prevent access to wounds as a part of their treatment plan. Collars can be purchased or homemade. The patient should be monitored for adequate time following placement to obtain assurance that it can eat, drink, and adequately function prior to discharge.
- Small- and large-tipped culture swabs, Gram stain and modified Wright stain, frosted slides: These are for laboratory processing. Use a reference laboratory that specifically works with birds. Call their specialist to discuss best practices for sample collection and processing.
- Needles and intravenous catheters from 18 to 30 gauge: Bird species seen in private practice can vary in size greatly.
- Nebulizer: Medication can be delivered to the respiratory tract with a nebulizer. This is commonly used as an adjunct in treatment for aspergillosis (see Chapter 8) but has many indications.
- Thermal support and oxygen supplementation: Heat lamps and incubators are excellent heat sources for hospitalized birds. Incubators have the option to be used as a nebulization or oxygen chamber. Circulating air thermal blankets are great additions for maintaining temperature during surgery.
- Housing: As previously discussed, a separate avian ward should be available. There are many types of housing possibilities for birds while hospitalized. All caging should be avian specific, as other modified types may have spaces too large so birds can escape or areas where the patients can get injured. Depending on space available, countertop incubators may be used or smaller bird cages. A heat source should be able to be used safely with the caging or have one incorporated. Any type of housing should be easily cleaned and maintained in good working order.
- In-house chemistry analyzer: Emergencies are common and waiting for lab work may not be in the best interest of the bird. A system that is able to use a small amount of blood is best. Some patients may not have great blood volume due to size or illness.

Anesthesia and Surgery

- Small anesthetic face masks: They come in many sizes, but commonly they need to be modified with bandage wrap and small hole cut in the center for the smaller patient to efficiently receive inhalant anesthetic gas or oxygen.
- Uncuffed endotracheal tubes: Sizes typically range from 1.0 mm to 7.0 mm (3 to 22 French). Larger and smaller sizes can be fashioned from catheters of any size, or cuffed endotracheal tubes can be used without inflating the cuff. Inflation of cuffed endotracheal tubes can cause necrosis if inflated against the complete tracheal rings present in avian patients (Figure 1.10).

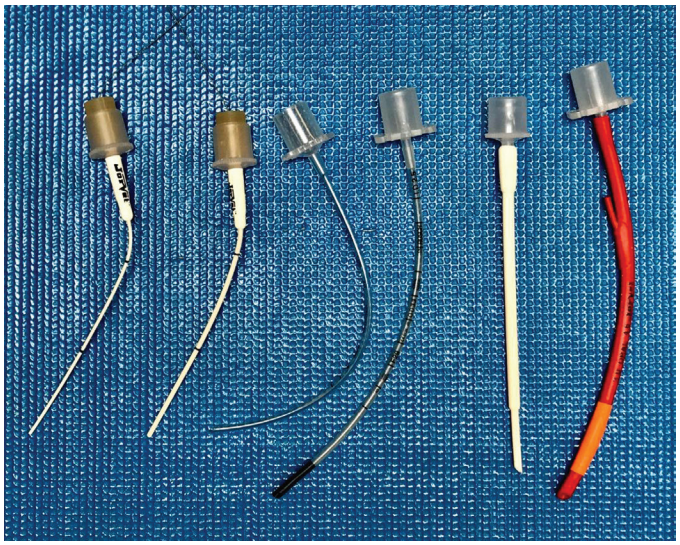

FIGURE 1.10 Uncuffed endotracheal tubes. (Courtesy L. Donato.)

FIGURE 1.11 Therapeutic laser. (Courtesy L. Donato.)

- Therapeutic laser: This can help with pain and inflammation associated with trauma, wound management, osteoarthritis, and other medical conditions deemed appropriate by the treating veterinarian (Figure 1.11).
- Nonrebreathing anesthesia circuit: Using these for anesthesia allows us to make rapid changes to concentrations of inhalant gas.
- Isoflurane and/or sevoflurane vaporizers: These are the best inhalant anesthetics for use in birds.
- ECG: Monitors the electrical activity of the heart during anesthesia.
- Doppler probe: This will give an audible reading of blood flow through peripheral vessels. Pressures can also be obtained in larger patients.
- Capnography equipment: This typically attaches to the endotracheal tube to measure levels of carbon dioxide. This is an important parameter for birds that was reviewed in the anesthesia section (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 19, Anesthesia).
- Magnifying head loupes: During surgery, these help to provide an improved field of view through magnification; some also have a separate light source.
- Radiosurgery/electrosurgery unit: This is an excellent tool to have during surgery to control hemostasis, particularly in smaller patients.
- Surgical laser: Some surgeons like a surgical laser for birds as it can help with hemostasis similarly to electrocautery. If doing endosurgery, a surgical laser can be used in conjunction with a telescope and operating sheath.
- Sterilized cotton-tipped applicators and surgical hemostatic clips: These items will help identify and control bleeding during surgery. Hemostatic clips come in many sizes. The surgeon can establish the sizes they would use most commonly.
- Clear surgical drapes: Seeing our smaller birds can be challenging with the surgeon and potentially an assistant present. A clear drape gives the anesthetist the opportunity to visualize respiration, blink response, mucous membrane color, and be sure there is no endotracheal tube migration.
- Surgical instruments: This can range from basic surgical packs used for dogs and cats to very specialized instruments for microsurgery. It will depend on the type of surgery being performed and the comfort level of the surgeon (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 21, Surgery).
- Endoscopic equipment: There are varied sizes and types of endoscopes, but the most commonly used for birds is a 2.7-mm rigid scope with a 30-degree angle at the end for improved viewing. The telescope with sheath and instrumentation can be used for viewing, obtaining samples for culture, cytology, and biopsy, retrieving gastrointestinal foreign bodies, or performing surgical procedures (Figure 1.12).

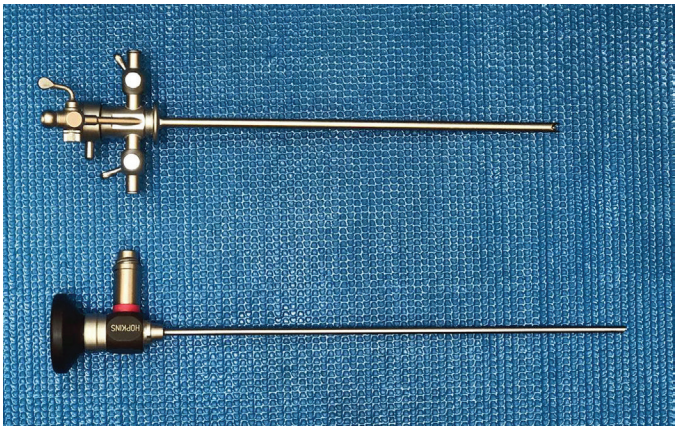

FIGURE 1.12 A 2.7-mm rigid endoscope with operating sheath. (Courtesy L. Donato.)

Imaging (See Also Chapter 2)

- Digital radiography (DR): This produces high-quality images in small avian patients that other types of radiography would not provide. Having dental digital radiography available is also quite helpful.
- Ultrasound: Because air can block ultrasonic waves, this imaging modality requires an absence of air in the region of the examined anatomy. Ultrasonography is commonly useful in cases with coelomic fluid or organomegaly; ultrasound is also of great value for cardiac examination.
- Fluoroscopy: This imaging modality is being increasingly utilized, with its availability increased through the increased popularity of computed tomography (CT) imaging that has a fluoroscopic function. Helpful in evaluating real-time function of the gastrointestinal system, and it is also of benefit in some orthopedic procedures.
- CT: This has become more readily available for the everyday practitioner. The image quality is incredible, and areas of interest can be viewed three dimensionally. Skeletal and respiratory tracts are most easily evaluated; however, soft

FIGURE 1.13 Computed tomography scanner. (Courtesy L. Donato.)

tissue can be imaged very well with the use of intravenous contrast agents (Figure 1.13).

STAFF

Staffing for an avian practice or multispecies practice that sees birds is a crucial part of the puzzle, if not the most important. Everyone from owner to veterinarian to receptionist to technician has to be interested and excited about incorporating avian medicine into the practice. If their interest is not present, it will show in client and patient interactions, which is not an impression the client should be left feeling (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 24, Practice Management and Risk Management). It can also affect care where uninvolved technicians may avoid handling, cleaning a cage, or performing treatments. Staff interested in avian medicine may view the ones not interested in a negative way as well. Making a plan to identify the right candidates, outlining expectations at time of hire, establishing a proper training protocol, and understanding what it takes to keep good staff will minimize staffing concerns at an avian practice. Associate veterinarians that have an interest in avian medicine should ask about the steps of this process when selecting a practice that supports their interests and therefore is a good fit for them.

Profile of Candidates

Candidates will include veterinarians, office staff, technicians, and kennel employees. Posting available positions is done mainly online, and the most popular sites should be identified for your locale. When advertising for a position, be sure the posting mentions the percentage breakdown of the different species in the practice. This will begin the process of whittling down the candidates that will be the best fit.

When you receive a resume, follow a basic screening process to identify normal initial concerns such as proper organization, grammar, large gaps of unemployment, and longevity at prior jobs. Then look into previous experience that correlates with the main duties the new employee would be performing. Previously having worked with birds can be a significant advantage when reviewing resumes to identify the next staff member. It demonstrates interest, which can be a big hurdle in finding the best candidate to hire. It is not all important though, so do not make the mistake of hiring for experience over personality and attitude. If someone has great interpersonal skills and a willingness to learn, along with a personality that will fit in well with the culture and client demographic, that person is uncommon and should be hired. In the practice of one of the authors, almost no new hires have had any significant avian veterinary experiences prior to their hire, but have excelled with their work on birds.

Hiring Candidates

Once a set of candidates has been selected for the interview process, it is time to identify if your mission and a potential new employee will be a match. Follow all interview processes that normally take place. With regard to birds and a candidate's interest, this is a good opportunity for a tour of the facility. During the tour of the hospital, the candidate will be shown all areas of the facility, which will include the segregated area of reception for birds, the avian wards, and they will likely see equipment for avian patients around the facility. This will aid in getting your message across that birds are important, just like the other species seen at the practice. Having a clear and concise mission statement that spells out all of the species that come as patients clearly defines how a hospital feels about birds. This mission statement should be in the handbook as well as posted in the common area for employees to see on a daily basis. This signage should be brought to the candidate's attention during the tour.

Once the right candidate is found and both parties believe this is a great fit, hiring can take place. Have the proper onboarding procedures and associated paperwork, which would include signing an acknowledgment of reading and understanding the employee handbook. This is where the mission statement and commitment to birds will be found. All other hiring procedures are to be followed. A lawyer should review the employee handbook yearly to be sure any changes comply with the law, and the same goes for a contract for an associate veterinarian. Be sure the employee handbook and any contracts clearly outline expectations for all parties.

Training

Working with birds can be both challenging and immensely rewarding. It requires specialized knowledge that is ever changing. A consistent and sustained training program is all important. For staff beginning in avian medicine, in-house seminars are a great way to build confidence. They are specific to the staff member's everyday job and give them a feeling of competence while learning on the job. Some examples of in-house continuing education seminars include proper diets and

diet conversion, low stress handling, restraint and treatment methods, wing and nail trims, and common normal and abnormal behaviors (see Chapter 46 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). These sessions can get much more complex, including topics such as phlebotomy, radiographic positioning, anesthesia, and common medical issues. Sending staff members to continuing education at local and national meetings is beneficial and depends on their longevity and value to the practice. Staff members are an investment and having a written plan on how to invest in them is crucial for their development, as well as the development of the avian portion of your practice. The important part is to not let the staff become stagnant and to stimulate their curiosity about avian medicine and their roles in providing this care for your practice. It will pay off in the long run for patient care and staff fulfillment with their careers.

Employee Retention

Retaining good employees starts with identification of the right employee that, as mentioned, is not necessarily about experience, but willingness and desire by the candidate. Identifying the right candidate is the most important step to retaining that employee. Spell out expectations so there is no misunderstanding of the goals at hand. Keeping them engaged and getting them to be confident in their daily tasks through ongoing education and training is more important than pay and benefits. With that being said, stay competitive with compensation and benefits because you want to take care of the people that take care of you, your patients, and your business.

AFTER-HOURS EMERGENCIES

As a veterinarian that has birds as part or all of the practice, accommodations have to be made for after-hour emergencies. Most state governments have regulations about providing care for patients after closing. That could include being on-call, having an in-house emergency hospital, or providing phone numbers for emergency hospitals. There are overall few veterinarians in many locations who prefer to handle their own after-hour emergencies. Being on-call may be that one is available to talk, but then sends to an emergency facility if deemed necessary. It may also be an option that the doctor meets the owner at the hospital, but the hospital is not officially open. Sometimes a hospital may elect to be open all night in addition to the day practice. Typically, when a hospital dedicates resources to having their own emergency service, they hire additional staff to work overnight or they may be available by being on-call. Practices successful enough to have internships or residencies, and which rely on them to handle emergencies for their clients, are in an enviable position to accept avian emergencies. Some avian veterinarians may pool resources with other veterinarians in your area to spread out the emergency workload. The group can rotate nights and weekend availability or even designate a location and fully staff overnight if the average number of cases seen is high enough.

Most of the avian veterinarians practice on other species and most would relish the opportunity to pass emergencies along to a competent dependable emergency room (ER). This opportunity will rarely just land in your lap, as it almost always requires considerable investment of your time to get such a luxury initiated and maintained. If your practice is located in a metropolitan area, then there may already be avian-boarded specialists or avian/exotic specialty practices in your area. This will usually be your best starting point. If they are using their own interns or residents to handle emergencies, they may be willing to see yours as well. The price of going in this direction is that you will inevitably and permanently lose some clients to the practice where you are referring your emergencies. This will happen regardless of the good intentions of the referral practice. If you cannot tolerate some small shrinkage of your client base, then it is wise to take this option off the table *a priori* and not risk creating a rift with your colleagues.

This leaves you with the final option of identifying an ER in your area that will at least consider accepting birds. The key to this strategy is getting an ER to make a long-term commitment. You will need to identify the one person, the Chief of Staff, Director, or owner, who has the ability to make a decision for the ER as a whole and who will agree to meet with you. Assuming you have cleared this hurdle, which is no small feat in itself, your work has just begun. First, you should determine why you were even granted a meeting. An owner may be interested in the additional income, or a director may have personal interest or experience with birds. Your colleague may just have been polite and did not want to risk losing seeing your dog and cat patients if they had given you a gruff "no way." Knowing their motivation to agree to meet with you will help determine how to get them on board.

Your next hurdle will likely be some version of "I have some ER staff who are willing to see birds, but I can't force my doctors to see them if they don't want to." This will be your opportunity to ask that if you are successful in getting their current staff to agree to see birds, will the ER commit to accepting birds now and in the future as they add new staff and doctors. In other words, you will promise to get their current staff up to speed if they promise to disclose to future employees that the ER treats bird emergencies.

Obviously, the next step is convincing all the existing ER doctors to see birds. This is going to be your most formidable challenge. Most ER doctors will have either no interest or no experience with birds, and some may outright loathe seeing them. The emphasis to motivate those doctors should be the following:

1. You are asking them to provide first aid, not become an expert in bird medicine. Most bird emergencies fall into the categories of trauma (including blood feathers), reproductive (especially dystocia), respiratory (tail bobbing and dyspnea), gastrointestinal (regurgitation and diarrhea), and the catch-all phrase of "bird at the bottom of the cage" (see also Chapters 28 and 34).
2. You can provide algorithms that can clearly and quickly follow through a diagnostic path and result in a treatment plan. You will also provide the ER with some reference books at your expense to keep in their library. Direct the ER to appropriate forums on the VIN (Veterinary Information Network) and supply them with an avian/exotic formulary. Make a Quick Reference chart of the most used drugs, their indications, and dosages.
3. You will be available by phone to answer questions, review radiographs or other diagnostic information, and develop

a treatment plan. You must not shirk this responsibility. The first time an unstable bird arrives at the ER and the admitting doctor is in need of help and cannot contact you, that may as well be the last bird emergency they will ever admit. Take this seriously. If you are going to be indisposed for any amount of time, call the ER first. If you are going on vacation, make sure an associate or colleague is available. If you commit to this part, then you will earn their trust and eventual loyalty to the mission of seeing bird emergencies. Over time, texts can be used preferentially, with phone calls being used for more complicated cases.

4. You must provide a series of in-person, hands-on wet labs for the entire ER staff including receptionists, technicians, and doctors. Bring birds to these demonstrations or request that ER staff bring any birds they own personally, if they are comfortable doing so. To instill confidence, see if different species are available with differing handling challenges, so staff are not surprised when numerous species come in the door. This is for basic history taking, handling, and working through each of the algorithms you have provided. You will need to provide refresher courses at least annually as new personnel rotate into the ER. There are many online resources that have excellent training resources.
5. You must become familiar with the ER facility and may need to assist with acquisition of essential equipment such as incubators. Provide vendor information to be sure they have medications commonly used in birds. Help assemble a minor surgery pack for birds. Provide the ER with brochures, handouts, or other literature that they can provide to owners. Remember that the AAV has an abundance of informational material designed for clients.

Every practitioner is going to have to make a calculation of whether the above venture is worthwhile. A practice that sees one or two birds a day may well decide to provide bird owners with a special number, possibly even the veterinarian's personal cell number, and see their own patient's emergencies themselves. Otherwise, you will have to identify that particular ER willing to help and then nurture them essentially for the life of your practice.

There is one stellar upside to taking the time to train an ER to see avian emergencies; you will have a new source of referrals to your practice. Once an ER has established a reputation in your area as always accepting birds, then other ERs are usually eager to refer them to your preferred location. The ER's website can include an invitation to bird owners with emergencies. An ER thus established can quickly see a remarkable number of patients. Many, if not most, of these clients will have no regular veterinarian. You can bet that if you have taken the time to train and encourage your ER, they will be more than happy to refer all of these people to your practice for follow-up. You should not underestimate what a potential asset this can be to the growth of your own avian practice.

LOW STRESS INTERACTION

After the decision making of how to set up your avian practice based on your predetermined goals, let us outline how to make your avian patients comfortable in the hospital environment. Typically, birds are comprised of mainly prey species and do not handle stress very well. Even predator species, like raptors, undergo significant stress when brought to the veterinary office. There is a certification for avian practice for those focusing on making the environment as low stress as possible. Benefits as listed by the Fear Free certifying organization are in Box 1.3. Fear Free principles can be applied to everyday practice to provide the most calming environment for our avian patients. Physical plant adaptations, aware and informed staff, minimizing noise, and behavior intervention strategies all can help birds tolerate our facilities and hopefully prevent significant effects of stress (see also Chapters 46 and 47).

BOX 1.3 BENEFITS OF A LOW-STRESS ENVIRONMENT

- Reduce or remove anxiety triggers that can cause pets to become fearful at home, in transport, and at the veterinary hospital
- Help owners deliver calm pets to your hospital
- Enhance the quality of medicine in your practice
- Increase compliance
- Improve safety for the veterinary team

PRIVATE PRACTICE: MANAGING INCOME AND EXPENSES

Whether you are an owner or associate, you need to be more business savvy than veterinarians who exclusively treat dogs and cats. The avian practitioner has a few barriers to becoming profitable. The average transaction fee can be lower than for canine and feline patients, as birds do not regularly receive vaccinations, flea and tick preventatives, or heartworm products.[1] In addition, the number of patient visits per year may be less than what is seen in canine and feline practice. If diets are sold, they cost less than large bags of dog or cat food. Ancillary services and products for dogs and cats can be up to 12.5% of revenue, with an average of 10%.[2] This may include boarding, daycare, grooming, and products such as shampoos, skin care products, over-the-counter foods, collars and leads, litter, chew products, and toys. Pet birds may not always require these products or services to the same extent as their canine and feline counterparts. Some practitioners furthermore believe that they should charge less because the patients are smaller, which contributes to a lower average client transaction fee (ACT). However, generally more rather than less time is scheduled for bird appointments in order to obtain their more complex husbandry information, thus actually resulting in higher costs associated with the visit, although those are rarely charged to the owner.

It has also been found that over 40% of dog and cat owners indicated that cost prevented them from getting care for their pets and many seek out lower cost options.[3] Bird clients will also take advantage of lower costs provided though bird stores and breeders using routine grooming services, boarding, and obtaining diets from them. Potential clients may also look to online forums without veterinarian moderators for medical advice. All these factors erode client and patient numbers and revenue generated per client. To make private practice more

profitable for avian veterinarians, effective management strategies are needed.

Strategy Versus Tactics

By defining goals of how you desire to practice avian medicine, decisions can be made on how to become profitable. By answering questions about what our avian practice should look like and developing a written plan, we can then develop a strategy. It is important to differentiate strategy versus tactics. The overall action or plan is what is referred to as strategy. Tactics are the smaller steps one takes to achieve parts of the plan.

Before discussing techniques to become more profitable, there must be an understanding that patient care and client service is the most important goal. If we do what is best for the patient, profitability is not far behind. When the patient comes first, trust is built between you and the client. This trust is invaluable and results in returning clients and referrals. Importantly, this is why we went to veterinary school in the first place. When reviewing the strategy in your plan and the management tactics, it will become obvious that the patient is thought about each step of the way.

Managing Income

Although managing expenses is important, it is not the main road to success. Historically, expenses are what owners worry about most, but one cannot save one's way to retirement. Managing income has the greatest impact on your profitability. To understand income, there is a simple formula:

Number of transactions (n) × average client transaction fee (ACT) = gross revenue[1]

It is important to understand the components that make up both factors in the equation and the best ways they can be affected to produce higher income or gross revenue.

Increasing the number of transactions (n)

The first part of the equation reflects how many transactions occur in a defined time frame. If a practice wants to see more birds, that is an overall strategy that is part of the defined plan. Several different tactics can be used to achieve the goal of increasing "n," which include using efficient time management techniques, taking advantage of reminder systems, setting up recall systems for patient care, and implementing a solid marketing plan.

Time management. This is one of the biggest problems for avian veterinarians. Time is a precious commodity and should not be wasted. Having extra time allows opportunities to see additional cases, which increases "n." Additional benefits of effective time management also give us time to focus on marketing strategies, train staff, research clinical or management topics, and have meaningful time off. Three significant ways to optimize time include executing proper delegation, also known as staff leveraging, implementing proper scheduling techniques, and having a paperless or "paper-light" practice.

Staff leveraging. Delegation is defined in Webster's Dictionary as "the act of empowering to act for another." Within the veterinary profession, it is referred to as staff leveraging. Whether you are an associate veterinarian or owner, staff leveraging can make your life easier. Veterinarians are the only ones who can examine patients, obtain diagnoses, and perform surgery. Additionally, advanced follow-up cannot be done by other staff members, including discussion of abnormal laboratory results and complex treatment plans. Delegating properly also allows the avian veterinarian to see more patients during the day, which increases the "n" in the gross revenue equation. It can also increase the ACT by giving the veterinarian the opportunity to build trust with the client, contemplate possible etiologies of disease, and choose helpful diagnostics pertinent to cases. All other tasks should be delegated to staff. Empowering the staff allows your hospital to run smoothly and makes your staff feel that you trust and need them. It gives them a sense of team and prevents burnout, which is quite prevalent in veterinary medicine.[4] A happy staff is a productive staff. It boosts team members' morale and helps reduce turnover. Turnover can also affect profit, which has been estimated to cost approximately 6 to 9 months of the employee salary per year.[5] There is an obvious benefit to both the practice and the staff when delegation is properly implemented.[6]

There are many barriers to implementing delegation. Veterinarians tend to be the type of people who want to do everything themselves and can be perfectionists. It may also be because we feel that a staff member is not adequately trained, or that we feel better when we are "there." We may tell ourselves, "I'm already here" or "Everyone else is doing other things." We can get in our own way and it is a habit that has to be broken.[7] The differences between doctor-centered practices and client-centered practices are explored in *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 24, Practice Management and Risk Management. These excuses are used in a variety of practice settings daily but are quite common when diagnostics for birds are needed, including phlebotomy, taking radiographic images, and administration of anesthesia. Overcome these barriers with an attitude of empowering your staff, educating them, and fighting the urge to want to be involved in everything. Delegate only what you are comfortable with, but you should get comfortable with a lot. Even teach your staff members to delegate in an appropriate way.

As a hospital owner or an associate veterinarian, we know how to give staff tasks, but do we do it effectively? There is a fine balance, and delegation has steps to follow just as any medical or surgical procedure. Ask these questions each time you delegate and leverage the staff.[8,9]

1. Does the person have knowledge of the task?
   If the staff member does not know the basics behind the task, they will be sure to fail. Do they know the practice standard for the project they have been given? Education is the key here. This can take the form of a quick discussion, an in-house seminar, or a continuing education conference. Something as simple as getting together with your staff for 10 to 15 minutes can have tremendous rewards. A common example is that many practices that treat bird patients often task staff to discuss husbandry with the clients. Hospitals and clinics that have avian patients will routinely have in-house seminars to educate staff on dietary requirements for different types of birds so that communication is clear and consistent between staff members and clients.
2. Is the staff member interested in the job?
   This may seem like an obvious statement but is a concept that is commonly overlooked. Keeping the task related

to their position generally avoids this problem. Typically, one would not have a veterinary technician have bookkeeping responsibilities. Also, personality can play a role in delegation of tasks. Having an introvert in charge of client communication may not be the best fit. The reason that staff members still work with your hospital is that they get satisfaction from their everyday tasks. Take advantage of their interests and strengths. When identifying a task to delegate, meet with the staff member to gauge interest. Getting their input will be extremely valuable.

3. Are the expectations clear?
   Communication is the key here. Review what you want to have happen and put it in writing, whether that is in formal meeting notes or a quick memo for the staff member to review. That is done in the form of a treatment sheet for hospitalized patients. Why should other important tasks not be in written form? Too many times, we ask for things to get done and expect everyone to know what we want. Our expectations are high. If there is poor communication, the expectations can never be met.
4. What is a reasonable timetable?
   This is a skill that comes with experience and knowledge of the task and the person performing the task. Setting unrealistic expectations will only set up the team members for failure. If there is a husbandry issue, give the staff members enough time for a thorough discussion to take place with the owner. Shortening the staff members' time ultimately makes them fail at their task, which hurts the patient. In the end, this requires more time to be dedicated because the situation has to be revisited.
5. Did I give the proper authority necessary and let them own the project or task?
   This empowers an employee and allows them to achieve the goal. They become proud of their work and then want to take on more. This does not mean that the employee should not be monitored, but you can step back if the other points of delegation have been met. Depending on the project, it may require communication with others in the hospital, so they know the plan of action and who is responsible.
6. Will I be available if help is needed?
   This can be challenging because there is a fine balance of giving the staff member help and completing most of the project for them. This is when we may start to make excuses to just do the task ourselves. Fight that urge. This is another opportunity to educate and empower your staff members. This is what training is all about, train and train again.
7. Was there proper follow-up?
   Ask the staff member if everything went well with the task. This is a chance for you to make sure the work was completed and to learn what problems were encountered. Input is crucial. This is not only an evaluation of the staff member but also the process and end result. Evaluate objectively if there are metrics that can be measured. The process can be measured by direct observation, survey, or even by testing depending on the level of task.
8. Did I praise?
   This can be the most important part of the process of delegating. Team members want to be acknowledged. Just remember, it is not the "reward," but more the recognition. It can be as simple as a "thank you," giving a gift certificate, or baking some cookies. Just be genuine.

Now that we know how to delegate, who do we utilize? As an associate, it will typically be the internal staff that was hired by the hospital owner or administrative staff. As an owner, there will also be external support for the overall functioning of the clinic or hospital.

Internal staff

MANAGEMENT. One of the more important keys to this puzzle is the manager. This person can free a veterinarian from paperwork and provide the time and freedom to practice quality medicine and surgery. Hospital size will determine if a bookkeeper, office manager, hospital administrator, or someone in between is needed. It is generally accepted that management staff is paid approximately 3% of the gross revenue.[10] That number will define the type of person or people needed. Take time to research your needs and then choose the candidate. This person will change the quality of your practice, and your life. With someone else doing the office work, you are left to focus on doctoring your patients and informing your clients. Veterinarians who do not use their managers efficiently also have lower transaction fees.

The most delegated duties are accounts receivable, scheduling, hiring and firing employees, updating fees, and developing marketing materials. Other delegated tasks include ordering medicines and supplies, payroll, managing benefits, monitoring client and traffic flow, accounts payable, computer maintenance, problem-solving, staff meetings, ensuring regulatory compliance, and staff training. For office personnel to be more efficient for the hospital, they too should learn how to delegate tasks.

TECHNICAL STAFF. The number of technicians needs to be considered. Having too few will make a veterinarian's life very stressful at work. Patients will not be seen in a timely manner or appointment schedules will have to be adjusted to accommodate. Either way the number of patients seen will decrease. To evaluate your current situation, ask yourself these questions: Is an assistant putting the next bird in an examination room? Is the assistant getting a complete history and weight? Are the technicians getting the wings trimmed and collecting the laboratory samples as needed? Is the technician or assistant talking to the other owner about diet and then filling medications? The answers to all of these questions should be "yes." If there is a "no," evaluate the number and knowledge of the staff. Also, evaluate your ability to delegate technical tasks. A great way to insult your team is to make them feel as if they should not do a grooming procedure or obtain a blood sample. Technicians trim nails and get blood from dogs, why not birds? Train them. Trust them.

RECEPTIONISTS. The receptionist plays a crucial role in avian practice. They are the first contact for the client and the point of sale, which can make reception a common bottleneck in veterinary practices. Ensure they are properly trained so that they will ask questions and demonstrate genuine interest in the client and their bird rather than just answering the question that is posed. They should be able to do this in an efficient, but caring way. This builds trust, and the phone call

is more likely to turn into an appointment or other service. Reception handles phone calls so that the veterinarian is not swamped with calls about basic husbandry or simple medical issues. Good receptionists know how to delegate calls to the technicians, office staff, and finally the veterinarian. As receptionists are the main guardians of the schedule, their skills will lead to efficient scheduling. That in turn increases the number of patients helped and transactions per hour. Reception can make or break your quality of life at your practice.

ASSOCIATE VETERINARIANS. If enough well-trained, nonveterinary staff is available, evaluate if another associate is needed. Determine if a full- or part-time veterinarian is appropriate, and if he or she will practice on dogs, cats, or all species. Typically, if 80% of the schedule is full consistently, that is a good time to add an associate. A single doctor practice may need to add one before that so there is adequate coverage for any missed time by the owner. The addition of an associate veterinarian will allow the hospital to increase its number of transactions. Again, this has to be a careful, well-thought-out addition to the team. Over time, with good training and mentoring, the long-term associate will hone their skills and provide consistent care that reflects the practice's medical philosophy. The benefit of this is less management, which leaves the practice owner time for other responsibilities. A less obvious benefit is that a long-term associate provides balance. With a dependable associate, you can afford to exercise your entrepreneurial spirit. Rather than focusing on day-to-day effort of providing services, you can step back and look at the practice's direction. With this big picture view, you may find more creative solutions to persistent challenges. This associate should also be trained in the practice's protocols for delegation of tasks.

External support. There are veterinarians who elect to do much of their own financial and legal duties without realizing they do not have the expertise needed. A little research is done and then they believe it will be fine. This sounds like some of our clientele. This process takes considerable time in and out of the office and the best outcome is unlikely to be achieved. Payroll companies, accountants, financial consultants, and lawyers should be used to their potential. An office manager can organize this team. The veterinarian can see patients, while the office manager is getting information to the outside support staff. The time and headaches saved far outweigh the seeming cost benefits.

While staff can be used for some building upkeep, weekly cleaning services, maintenance, anesthesia, and microscope checks can be delegated to outside companies. When these duties are thrust upon the busy staff, this can distract them from taking care of our patients.

Scheduling. A schedule has to be built in the proper manner to fit your clinic or hospital doctor's schedule so that time is managed properly. Without a very good schedule, your day can turn into a mess. Good scheduling improves time management, which will allow you to see more patients, increasing your "n." The schedule has to fit your style. Do you work well with multiple cases going on at the same time, or do you need to have your head clear for the next case? Do you tend to be very chatty, or are you moving along with urgency? We all can answer yes to these questions but know your tendencies so you can make the best plan for a schedule as possible.

Building a schedule starts with knowing when your clients need services. Typically, patients are seen in the morning until noon, then there is some sort of gap to accommodate breaks for veterinarians and staff, and then appointments start for the afternoon or evening. Surgery will be added in the gap between appointments or there may be a surgery day for each doctor. Whatever style fits your caseload, client need, and number of doctors and staff should be adopted.

Within the general blocks of surgery and clinical appointments, individual time slots have to be defined. The number of surgeries that are scheduled will depend on how many surgeries are performed on a weekly basis, number of doctors in the practice, and skilled leveraged staff. As the avian component of your practice is growing, these factors will change, and the schedule should be adjusted for growth accordingly.

Individual clinical appointments also have to be outlined. Each appointment has to have a placeholder in the schedule. Is that going to be every 15, 20, or 30 minutes, or some other defined time frame that works for you? Do you want to consider if new or sick birds get longer appointments? Do you want to have emergency or "catch-up spots" in the schedule? One strategy that leverages staff that practices can implement is a layered or high-density scheduling. This is when, at the beginning of an appointment, the technical staff will spend 5 minutes with the client getting basic information and some history. The next step is that the doctor will spend 10 minutes with the client and patient getting more detailed history, performing an examination, and developing a plan. After that the doctor passes the appointment back to the technician to get outpatient diagnostic samples collected or discuss with the client behavior change recommendations or diet changes. Layering starts when the doctor is with the client and patient, the technician starts the process with the next client and patient in another room by getting basic information and history. Then the doctor comes into that room with the second patient, and the technician goes back into the room with the first patient (Figure 1.14). Time frames can be extended to accommodate appointment length that the hospital has adopted as their norm. More patients can be seen when working in this efficient manner.

Paperless or paper-"Light" practice. One way to increase efficiency and lower costs associated with human resources and office supplies is to convert paper patient files to a paperless system. This system will utilize your practice management software (PMS) along with other process flow tools to cut out the need for handwritten records. Ideally, anything handwritten to a client and/or patient paper folder is now recorded in your PMS. The real efficiency with converting to this new way to manage your information process flow is seen around time management. If you choose a paper-light method to manage your patient files, this means that you will still utilize your PMS for your client database and most record keeping, but you may choose to keep some items in a paper file as well.

To illustrate the efficient benefit of going paperless, as an experiment one of the authors asked reception staff of a four-doctor hospital to start a timer when they were asked to look for a patient file in a paper record practice. When they found the patient file, they stopped the timer. It was discovered that within a 12-hour day, receptionists spent 3 hours looking for files. This does not include the time a doctor or technician

TIme	Exam room 1	Exam room 2
9:00		Blocked off
	Cockatoo: Exam, break, wing nail trim	
9:20		Macaw: Initial exam, poss broken leg
9:40		
	Budgie: Exam, not eating, on bottom of cage	
10:00		
		Cockatiel: Recheck liver values
10:20		
	African grey: Exam, feather picking	
10:40		
		Conure: CT scan consult
11:00		
	Chicken: Exam, wellness	
11:20		
11:40	Catch up	Catch up
Key:	Veterinary assistant: Take history, trim nails, provide general treatments	
	Doctor1: Exam and specific treatment protocols	

FIGURE 1.14 Layered scheduling of patient visits can be helpful to increase practice efficiency.

spent looking for files. After switching to a paperless system, customer service improved dramatically because there was less time looking for files on desks or in obscure places within the hospital. Receptionists could get answers to client concerns of the moment, as the information could be called up on their computer screen in real time. Another wonderful benefit to going paperless is that records become legible. Templates make filling out an examination much faster and more efficient. Electronic records can be gathered to share with specialty hospitals, which can be sent by email rather than having to spend time and money using a fax machine that requires more paper, not to mention the price of toner. In the above example, paper waste was significantly reduced resulting in fewer trips to the recycling dumpster, which can account for savings in trash removal.

Additional benefits to utilizing PMS to go paperless extend to your lab work. Clinical pathology results can be imported from in-house laboratory equipment or external reference labs as soon as the results are ready. Signature pads for numerous electronic forms can be incorporated into the system, as well as credit card processing. Veterinary software or applications can help manage inventory by accurate counts, automating shopping or "need" lists, and giving alerts when an item is low. Time clocks are also included with PMS, so staff can clock-in when they log into the system upon arrival. In most cases, those same clock-in features extend to security tracking where you are able to generate reports on what functions users are performing within your software. This is beneficial if you are suspecting that someone is inappropriately using the clock-in system, or even in a case of suspected theft. Veterinary paperless applications typically have an audit trail to identify changes that were made within the system. Additionally, generating financial reports by inventory, treatment procedures, doctor activity, or area of the business such as boarding becomes very easy and allows you to focus on important details of your practice to achieve your goals.

Having a paperless or paper-light practice saves time for all staff and doctors, but what will be needed? Must-haves include a server that is located either in-house or offsite, or a cloud-based system that utilizes the internet to deliver your PMS as an "app"; examination room stations to enter data while with clients ranging from desktops, laptops, or even tablets; a wired network, reliable internet access particularly when utilizing cloud technology; and onsite and offsite backup capabilities. Getting whatever data in the current system to the new system is simplified with the veterinary software company converting any necessary data, so their help will be paramount.

If you run your practice with paper files and are thinking of going paperless, a consideration to the overall management

of the conversion will be if a decision is made to scan all previous records for a patient or "draw a line in the sand" and start entering all data anew. If the decision is made to scan all previous paper records to your new paperless system, consider which key staff members will dedicate hours of time to this project. Depending on the number of files, the completion of the work may take quite some time. Training for existing staff members is crucial when making the switch from paper to paperless, as well as for new staff members who may be learning the system for the first time. Some team members may have used the system at a previous job but will need to learn how your hospital integrates the system into everyday practice. As each PMS suite is different and so are your individual practice's goals, it will be helpful for you to map out what areas of the software you plan to utilize in relation to the way your clients and patients actually flow through your healthcare and customer service processes within your hospital. In addition, because you are an avian veterinarian, it would be important to keep in mind that when shopping for software, some packages may not cater to the healthcare delivery systems for birds. Customization is key in regard to species and breed lists, as well as the ability to work with lab-specific data within the software.

Overall, the conversion to paperless or paper-light record keeping is a lengthy process that takes time to plan and execute. The results of the project include freeing up many hours per week where staff can redirect their time to more efficient activities. Rather than the employee spending 3 or more hours a day looking for misplaced or misfiled patient records, a receptionist can redirect their energy to making appointment confirmation or follow-up calls, and other revenue-generating activities. Customer service and patient care will improve. Ultimately, the expense and time required to go paperless is well worth the increased efficiency, time, and monetary savings that your hospital will enjoy once the conversion is complete.

Client reminders. Client reminders will increase "n" by creating another point of contact with our current bird owners. This can take form of an email, text, personalized newsletter, or traditionally, a postcard. Your PMS should have a section to build regular reminder templates for yearly examinations, vaccination schedules, behavior programs, senior wellness, or other medical plans that you have tailored for the patient. In addition, you may prefer to set up semi-regular reminders for grooming appointments for birds if a client regularly requests certain services or you feel are required. This is becoming more commonplace in avian medicine, and continually reviewing and applying reminders for your avian patients will boost revenue by increasing the number of visits. An annual screening program can uncover diseases in apparently healthy dogs and cats, thus boosting your level of medical care and your revenue. The same concept should be explored, applied, and maximized for avian patients whereby regular reminders for these programs are sent to the client.

There are several ways to send reminders. Among the most efficient is having a company that links to the veterinary software application for your practice and have them send the reminders by email, text, or postcard. This not only gets the reminders out in a timely manner but also delegates a time-consuming job to an outside source. Some service providers bundle reminders with other digital marketing plans to maximize their partnership with your hospital and provide aggressive pricing for their competitors. Alternatively, this job can also be carried out by your staff. The benefit of doing them on your own is determined by weighing all costs, time involved, PMS capabilities, and timeliness of delivery.

Recall system. One expense that your veterinary practice incurs each month is your phone bill. The following statement sounds counterintuitive, but as we continue on this topic, you will see the logic: you want your phone bill to increase! A higher phone bill equates to clients returning to your practice for ongoing care. If you see a new client for an initial wellness examination and identify a specific concern, would you just have the client check out without a plan to manage their concern? You would be proactive and follow-up with them, likely with a call. Most veterinary software applications have a built-in system that allows the users to input callbacks for their patients. This means a veterinarian or staff member will have access to a list of clients that need follow-up each day. Do not just call a client when they call you. If you find yourself saying, "Let me know" or "Give me a call if there is a problem," you are missing an opportunity. Recalls by design are meant to know what is happening with any given patient. There is no guess work. We have all talked to clients who do not truly assess their bird's health until we start asking questions.

Most veterinarians will make follow-up calls for sick patients, but a call for any issue is a good call. Call for the ill cases, but also for rhamphothecal shaping procedures, annual or semiannual laboratory testing or imaging studies, weight checks, 1 day postsurgery, diet conversions, medication administration, chronic medical conditions, and behavior modification monitoring. Any concern, no matter how small, should be called to be sure things are going the way we as veterinarians would want. Technicians and receptionists can call less critical cases, but if you as the veterinarian have the opportunity, make the calls yourself. While delegating is important, this is one task that will be very rewarding all around if you are able to make the call personally. "I wish my doctor would call me" and "Can you be my doctor?" are commonly said by clients when we call.

Recalls increase "n" by a few different means, one of which is you are showing you care when you call. Not only is it a great follow-up for the patient, but also it builds a trust between your hospital and the client that will last for years. When there is trust and a bond, you will get the call the next time there is an issue with their bird. If the patient is not progressing as well as expecte d, you will know and get a recheck scheduled. Many clients will not call and wonder why their bird is not improving or they may not recognize that it is not going well until detailed questions are asked. This will lead to more appointments, diagnostics being performed, and medicine being dispensed, all while doing what is best for the patient. The other way recalls help is that when you first start working with birds, you know technically what should work according to the books, but that may not be the reality. Client input is imperative to your learning process. If you are not receiving the input, you will not know if the medicine or surgery worked well. You will learn what challenges the owners have while administering medication or changing diet. We tend to be teachers to our clients, but we should not forget that they teach us as well.

Your practice should generate daily follow-up call lists. The cost of a higher phone bill is a welcome expense when you consider the increased patient visits and positive perceived value of your practice. Clients really appreciate it when their doctor calls to check on them, and it shows your commitment to providing the most comprehensive and compassionate care. These calls build trust, education for the client and veterinarian, healthier birds, and more patients for the long term.

Marketing. Managing a successful veterinary practice involves strategic planning within and between several functional areas of the business; just a few of those areas include finance, human resources, inventory, operations, and marketing. The hospital's marketing strategy should provide a clear depiction of the specific elements that set your practice apart from the crowd. The marketing strategy's key elements ideally include defined internal and external marketing components, brand messaging, print- and digital-based marketing tools, word-of-mouth communications, and social media. All these marketing mediums work together to reach and engage different types of consumers that would benefit from your services. The success of these marketing efforts depends in part on the practice owner's understanding of the spending power they have with which to dedicate to campaigns, as well as expenditures in other functional areas, relative to gross revenue. Having a general understanding of the different types of marketing tools and their costs will help a practice owner determine specific marketing mediums to focus on relative to their overall return on investment.

Internal marketing. Marketing your veterinary practice starts with internal efforts that define the standout features and beneficial attributes of your hospital or clinic. When we internally market, we treat our internal staff as the client, in effect "selling" the significance of our products and services to our team as a means to create a unified marketing foundation that will be communicated by your practice as one message.[11] The internal marketing effort is ongoing so that any changes to products, services, or new capabilities are communicated to clients through your staff. Internal marketing seeks to communicate and unify the message of what your practice is at the core of its belief system, specific abilities, and its process of executing animal care. The continual effort should highlight your core mission, methods, and tools you will use to deliver your services. Hospital design, process and procedure protocols, technology, operations management, your team's expertise, and the company's culture and values all contribute to how you deliver your care; therefore, these internal attributes can and should be highlighted as positive features that set your business apart from other practices. Whether you have an ABVP-certified avian practice diplomate on your team or your nursing team is highly skilled in treatment and handling of birds of all sizes, the overall marketing strategy should emphasize these key offerings as a means to elevate the perception of expertise of your practice in comparison to others in your local demographic area. Internal marketing seeks to ensure that your team understands the value that your hospital's unique attributes provide and contribute to the staff's ability to perform services. Their understanding that your practice's unique qualifier as an avian veterinarian surrounded by a skilled team builds the well-defined mission and vision focus that the staff will adapt as its cultural foundation. This unified core value system will help staff execute the overall strategy of the practice owners.

The first step to building an Internal marketing scheme can start with defining your mission statement. What is the purpose of your practice beyond the obvious goal to provide healthcare to birds? It goes without saying that you are in business for pet healthcare; but what is important to you as a service provider? What do you want clients to know about your beliefs as a veterinarian? Whether it is your compassionate care, your specific medical philosophy, or your respect for client concerns, the mission statement is a few sentences defining your commitment to your clients and pets. An example could include a statement like, "We at 'x' hospital strive to provide complete and compassionate avian medical services that focus on proper client education to support happy and healthy lives for both the birds and their owners." Once you have this statement finalized, you now have a philosophical foundation on which to build your internal marketing scheme for your team where you outline how you plan to fulfill your mission statement's intended goal. Continual review of your mission and values will achieve and maintain a cultural understanding and acceptance of your vision, mission, and capabilities. This is vital to a clinic's overall marketing strategy, because ultimately the staff is acting on your behalf to broadcast this unified message to your clients.

External marketing. External marketing efforts seek to bring awareness of your hospital or clinic capabilities to the consumer. Just as you sold your mission, vision, and level of capability to your staff through internal marketing, you will sell those same concepts to your current and future client base. Several tools help build a successful external marketing strategy that includes brand recognition, print marketing, phone on-hold programs, referral programs for clients, word of mouth through local veterinarians and pet organizations, postcard and/or e-reminder systems, recall programs, and digital marketing efforts. These external efforts seek not only to broadcast the attributes that set the practice apart, but also, perhaps more importantly in today's technology-driven world, to establish consumer loyalty and to solicit feedback about services, experiences, and opinions that can lead to further enhancements for the practice. Utilizing marketing tools that work to boost client engagement can solidify the doctor-client relationship and increase the client's perception of your value. That client's loyalty will create a bonus marketing tool where the client will become an advocate for your practice!

Brand recognition. Creating a solid brand foundation helps to build a visual representation of your hospital. Your color scheme, logo, and printed templates provide brand recognition for your clients when you apply them to all visual marketing efforts throughout your business. It is therefore important to create these templates and logos with the goal of utilizing them uniformly throughout all practice marketing efforts. Educational materials, signage, fonts, logos, staff uniforms, and even paint color schemes within your hospital should all be consistent to create a homogeneous and familiar feel to your service delivery, with additional care to create a clear differentiation of your clinic as an avian veterinary practice. For example, an obvious way to define your brand would be to craft your logo with birds depicted. With a solid visual representation, your marketing material will highlight your specialization as an avian practice. There are several ways to

effectively showcase your brand and the unique traits of your practice. Utilizing both visual and word-of-mouth tools will provide a thorough representation. Some of these tools include the following.

Print marketing. Use your logo, streamlined font, and color schemes across all printed material, including:

- Brochure about your practice's history and service offerings, with hours, contact information;
- Business cards that include all doctor contact information and brief description of services;
- Signage that uses your colors and fonts;
- Scrubs or other uniforms that marry with the visual representation of your practice; and
- Pet handouts about husbandry that are formatted using your marketing template.

Inexpensive options for creating these materials exist online. If you are comfortable enough designing them on your own, there are many websites that help with inexpensive bulk pricing for printed materials. If you prefer, you can hire a print marketing company to draft content for you, but obviously, this will be at a higher cost.

Phone on-hold programming. Incorporating an on-hold recorded messaging system to help to call out specific services, events, or other offerings unique to birds is a useful way to educate clients on your unique capabilities while they wait. On-hold messaging services are provided on a monthly basis where a recorded message can be created with looping content that you can customize to your unique offerings and concerns of the moment. For example, if you provide boarding, you can call out specific holiday times in your on-hold message to remind owners to make sure they book their reservation before you fill up. You can also call out specific services such as bird grooming or that you provide international travel documentation for pets. This service is low cost and easy to customize. The company will provide you with a sample menu of topics to choose from, and you can also make sure your website, social media pages, or other online content are called out in the recording.

Referral programs. Referral programs are a great way to engage clients in supporting your practice by word of mouth and are a large source of new clients.[12] Creating a referral program is simple: come up with a reward for clients to receive if they refer someone to your practice and create a tracking process for referrals. For example, a great way to learn if a client was referred to you is to place the question on a new client form that gets filled out at the first visit.

> *How did you hear about our practice?*

The new client enters either the name of the person who referred them, or another source like your website, or a search engine. Once you have the name of the person who referred them, you can gift them with a credit on their account or something else, like a coffee shop gift card of a small amount. Little gestures of thanks can be a great way to further engage your client base. The bonus of asking this question is that you can create an ongoing study of real trending data on how clients find you.

Local veterinarians. Being an avian practitioner will afford you opportunities to become the trusted veterinarian where colleagues will be willing to refer bird cases. Offering your expertise and services to surrounding vets will elevate your practice as a unique service provider to your local veterinary community. A great way to market your practice in this arena is to periodically send out branded newsletters with any important updates or to drop off your brochures and business cards to other practices that may have an occasion to send bird cases elsewhere. Spreading the word about your unique capabilities will establish your practice as the go-to veterinarian for referrals.

Bird stores/bird clubs/wildlife rehabilitators. Partnering with local pet stores and rescue organizations that handle birds will generate referrals. Becoming a trusted veterinarian to pet stores by providing general care at perhaps a slight discount (i.e., 10% off services) will help pets receive proper healthcare. While it is not recommended to discount services, most corporate pet stores will ask for one. It can be considered an advertising expense or part of the referral program that is in place. Local bird clubs are a valuable source of clients, and the members look for any educational opportunities that will help keep their pets healthy. Spend time speaking at these clubs, and you will see the benefits by helping more families with birds and an increase in clients. The same is true for wildlife rehabilitation organizations. These facilities receive countless wild animals and need access to healthcare to nurse patients back to health and release them back into the wild. Your expertise as an avian practitioner means that hawks, eagles, and other wild birds will benefit from your services when partnered with a rescue group that rehabilitates raptors and wild birds. This is another marketing opportunity for the practice highlighting goodwill, sense of community, and environmental awareness.

Digital marketing tools. The communication tool with arguably the widest reach is technology-based through use of the Internet. Gone are the days of taking out a color advertisement in the Yellow Pages. Today's most successful marketing tools reside online and provide living, real-time statistical data to help practice owners understand who is looking for you, when, how often, and why. A website is the grown-up version of that phone book advertisement where veterinarians can showcase their unique services and capabilities and communicate any other specific information such as the addition of a doctor or piece of diagnostic equipment that increases perceived value to target clients. Websites can incorporate search engine optimization (SEO) tools, which increase visibility in searches by using keywords and code to elevate your website on search result listings. For example, by utilizing *bird* or *avian vet* along with your town name as keywords that are coded within your website, you elevate your webpage to a higher spot in search results when a client enters those words *<town>*, *<bird veterinarian>*, in their search bar. As an avian veterinarian, your website will naturally contain these and other species and location-specific keywords that will aid in utilizing SEO to elevate your practice and create visibility to bird owners in your local market. Some built-in website management tools even include call-tracking analytics to help you understand where calls are coming from and show peak call time data. If you are reading this and becoming overwhelmed at all of the potential work this means for you, do not worry—you already have enough to do! While SEO does generate demographic and consumer activity reports for your review, you otherwise will not be adding more work to your pile if you employ these digital tools because they are automated

and run without your input. You can choose to review regular reports through website tools, though it is probable that the web service will generate that data for you on a continual basis.

In addition to your own website, other sites that support growth of your online presence include popular review sites, as well as social media sites. These online partners can contribute to statistical data or analytics, by providing details about click-throughs, which occur when a client visits any of these sites and clicks on a link to be redirected to your content, or clicks on your phone number to place a call to your hospital from their mobile phone. It is useful to review these data to see where clients are located and how often they are clicking-through to gain an understanding of the percentage of calls and subsequent visits that result from your internet presence. Some light maintenance is required from your side where you need to respond to reviews and monitor client feedback to handle any concerns presented for public viewing. Engaging with clients online in this way is very valuable to positively managing your online reputation. It is recommended to delegate this task to one of your office personnel. Once the data are collected, analyze them to determine if they fit with your current marketing strategy or if there is a need to make changes to achieve your overall goals.

Social media. In addition to having an electronic "billboard" in the form of your website, it is important to recognize social media as a major avenue for direct communication between you and your clients. Social media sites and your website's blog section all provide additional ways for you to deliver specific content and engage with your target audience. Avian-specific messaging can elevate your perceived value in your local veterinary marketplace as the first choice for treatment of birds. Also, the social media content allows you to broadcast custom subject matter to your audience where you can post about your staff, special pets, equipment upgrades, changes to hours due to weather, and other need-to-know information. Although social media is generally a free service, you can elect to pay a small fee to run ads that may achieve a greater reach to current and potential clients who may engage with the ad and seek out your services. Some social media sites also provide insights into visitor engagement by reporting on page visits, "Likes," and click-throughs. To properly monitor these tools, do recognize that you or a staff member will have to set aside a few hours per week to regularly post content, reply to client engagements, and review analytics on social media, which goes back to budgeting for marketing costs. Social media only works to engage clients if you are actively tending to the content and analytics results, and you must consider your time's value and payroll costs associated with this in relation to the return on investment that your newfound client engagements will bring. These sites are very client facing and they perform for your business, but you must pay regular attention to them. Less is more with regard to posting content—you want to engage scrolling clients with a picture or video and then post your comments with a brief explanation. Whether it is an employee promotion or the addition of a bird-specific laboratory testing capability, you should grab attention with a visual item and then follow through with your commentary. Remember, engagement is everything. Posts that ask questions or request feedback are a great way to increase your social media presence.

Other client engagement e-tools. Taking advantage of an e-marketing suite of services helps create a level of online engagement between you and your clients. This engagement is really important to some groups of people who through technology are seeking a more involved level of communication with their practitioners because it really enhances their perception that they are an active partner in their pet's healthcare. E-marketing tools can include a mobile phone app that provides access to pet records with notifications; a client survey tool to invite feedback; a reminder tool that sends out appointment notifications on your behalf that can be via mobile phone text and/or email in real-time capability; and regular newsletters that can include stock prewritten or custom content. The client survey tool has an additional benefit—if the client fills out the survey and it submits a positive rating, the client will automatically be invited to rate your practice on popular review sites, which increases a more favorable online reputation.

It can be daunting to think about the digital side to marketing, particularly if you are not technologically savvy. The important thing is not to be overwhelmed. There are plenty of reputable digital marketing companies who cater to veterinarians with packaged offerings for these services. Tailored plans can be created to suit just what you need, and payment for these bundles can be managed over a short-term or longer-time span. It would be best to receive quotes and demonstrations from a few different companies to make sure you are building an e-marketing package that best fits your needs and budget. For example, you may not want to employ their services to manage your social media content, which will lower your package cost, but require more weekly maintenance from you.

Marketing budgeting. With an understanding of the different types of marketing tools available, it is necessary to create a marketing budget that is comfortable for your practice. Cost analysis for these activities should include sending out monthly reminder postcards and associated postage, print marketing, on-hold messaging, your website hosting company fees, the electronic suite of services that include the mobile phone app, the survey feedback tool, automated newsletter capabilities, and wage costs of staff to manage social media and other tools as necessary. Most of the technology-based bundled offerings are available as a monthly or annual pricing structure with a signed contract, and most of these marketing organizations will offer a considerable discount for prepayment. Your goal is to spend within your budget's means in order to increase client awareness and utilization of the specialized services available at your avian practice. Typical costs for advertising and promotion of services would be 7% of total revenue (Table 1.1).[13]

Ultimately, communicating your range of service offerings and avian healthcare special interests through multiple avenues will reach several different types of clients to increase perceived value and thereby contribute to increased revenue and client/patient counts. Planning a marketing strategy starts with your own goals. Defining how you want your practice to grow as well as communicating that goal to your staff is the first step in your marketing plan. Spreading awareness of those goals comes next where you and your staff present a homogeneous message of your brand to current and potential clients through in-house communications, print marketing,

TABLE 1.1

Practice Expenses as a Percentage of Gross Revenue

Promotion of Services/Advertising	0.7%[13]
Medical Supplies	17.5%[13]
Other COGS	5.9%[13]
Laboratory Fees	3.6%[13]
Rent (Location Dependent)	7.8%[22]
Total Labor Expense	39.6%[22]
Other Employee Benefits	0.5–3.4%[22]
Other Operational Fees	4.0%[13]
Net Profit	20–30%[18]

word of mouth, and digital avenues. Examining your revenue relative to expenses in other areas will help determine how much you can comfortably spend on marketing efforts and should also help you decide what tools to focus efforts on when creating and maintaining a marketing scheme that continually contributes to positively trending client and patient statistics and a favorable return on investment.

Increasing average client transaction fee

An increase in ACT makes a big difference in gross revenue without seeing more cases. In our equation, number of transactions (n) × average client transaction fee (ACT) = gross revenue[1], ACT is easier to increase by $5.00 than what it takes to get five new clients. Price increases, charging appropriately, practicing quality medicine, addressing missed fees, and adding in ancillary services are efficient and productive ways to increase ACT.

Price increases. Increasing the fees will directly boost revenue. If this is done appropriately, it can be easy and effortless for both veterinarian and client. Increases should be scheduled minimally yearly for services like examinations and surgery. Laboratory fees should be increased yearly or if the labs used increase their fees more frequently. Inventory items should be increased as the distributor or wholesaler increases them. Medications can increase dramatically from one bill to the next because of a manufacturing issue, supply chain disruption, or demand has changed. Be sure to monitor your expenses all around to manage price increases properly.

When increasing fees, it is crucial to educate employees of how and why this increase occurred, so that they can relay this to the client if questioned. When educating employees, it is important to explain how the fees are determined and what costs the practice incurs to offer patients high-quality care.[14] This will aid in comforting clients when they are well informed of the high-quality care they are receiving for their payment.

Services should be based on value, and this works very well when pricing surgery, examinations, and boarding.[14,15] Ask yourself, "What is my time and skill worth"? Do not feel guilty, as it is expensive to practice quality avian medicine. Review your bills to remind yourself of that fact. Typical fee structure for laboratory tests is the cost of the test at least doubled, with the possible addition of a nominal blood draw fee. Inventory and medications are usually priced around two to two-and-a-half times the hospital cost.[15] There is usually a pharmacy packaging fee to cover costs such as ordering time, filling the medication, labels, drams, or other containers. Others may elect to have a minimum pharmacy fee because some products may be very inexpensive, but still require work to have in the hospital and deliver to the owner.

Charge appropriately. It is important to remember that it is expensive to practice quality avian medicine and surgery. Many avian veterinarians will have lower fees, or feel they need to charge less for a budgerigar than a grey parrot than a cat or dog. Technician time, radiographs, anesthesia, surgery, and appointment times are essentially equal for those two birds and can easily be greater than for a cat or dog. The fees should reflect that fact. You are charging for your materials, knowledge, and time. Remember that a smaller patient does not equal a smaller fee. Discounts are detrimental, as they minimize our value as veterinarians as well as the profit we work so hard to maintain and grow. Charging proper fees is not only appropriate given your skills and education, but also necessary to properly invest in your staff, hospital, and building to provide the best for your patients.

Practice quality medicine. We all strive to practice quality medicine and surgery. This is the greatest part of our careers; not only does that satisfy our desire to be an avian veterinarian but it is also what allows us to be profitable. Having a strong knowledge and skillset base for avian practice allows us to offer a variety of services like preventative care, inhospital diagnostics, radiology, ultrasound, CT, endoscopy, soft tissue surgery, orthopedics, behavior consultations, and senior wellness programs. These can function to increase the average transaction fee dramatically and provide opportunities for the exciting, career-enhancing problems and procedures we seek. To gain this knowledge, attend and participate in meaningful continuing education. Do not just meet the minimum requirements. There are many opportunities as discussed earlier in this chapter and elsewhere in this book.

Address missed fees. Missed invoice items occur at every practice. For one reason or another, fees are missed. By conducting an audit of what fees are missed and identifying the reason why they are missed, the average fee per transaction can easily increase. Once the cause is determined, policies can be instituted to reduce or eliminate missed fees. Veterinary software can help track and reduce human error, which is another advantage to becoming paperless or paper "light." You should implement a system, whether paperless or not, that you and your staff are comfortable using to track missed fees.

Additional services and products. Any program or service that is offered can add to the bottom line. In avian medicine, best practices include postpurchase screening, routine blood testing, and comprehensive senior programs. Another service may include behavior modification. Generally, consultation for behavior is more costly than a regular appointment as it is more time consuming. These services will increase not only the number of transactions but also the average transaction fee. Many avian veterinarians will have formulated avian pellets in the hospital for sale. This is many times added onto a final bill, which increases the average transaction. Adding ancillary services is where you can pursue other interests or get creative. Grief counselors, boarding with additional services like play time, and the sale of toys, grooming equipment, and diets are some examples of services you can offer your

clients that are not only good for their birds but also will add to your profit.

Managing Expenses

As mentioned previously, increasing income is the best way to make your hospital profitable. This should be the main area of focus, but do not forget about expenses. The main goals when watching expenses are to not be wasteful and to be responsible with spending. This sounds very obvious, but when reviewing practice expenses, it is common to find a lot of waste and unnecessary spending. When evaluating expenses, they should be compared to gross revenue to get an expense ratio or percentage. Table 1.1 outlines expense percentages that a veterinary practice should maintain. If you can improve upon those percentages, profits will increase. Review of these percentages monthly will keep a hospital on track.

Many costs are relatively fixed, and there is not much you can do to change them, such as utilities, waste removal, and postage. Have a manager shop for the best prices for these and other relatively fixed expenses. Activities like these are not a cost-effective use of owner time. There are two main expenses that can be changed through effective management to become more profitable: inventory control and payroll costs. Rent is another expense you can exert some degree of control over. Once set, rental expenses can be challenging to change, so this should be well thought out prior to signing a lease.

Inventory management

There are many veterinarians that want what they want with regard to medication in the hospital, but this must be managed so as not to have excess inventory and spending. There are several systems in place that practices use to monitor inventory. Those systems can be automated through veterinary software, or they can be manual counts and physically tracking inventory. Whatever system is used, it should be monitored to minimize waste in the form of expired medication, having excess on hand, or loss through theft. It is best to assign a staff member and a backup to manage inventory.[16] Controlled substances require additional documentation that meets government standards and licensing requirements, which tends to get veterinary hospitals to manage them very tightly. Note that there are numerous medications that will be important to have on hand when seeing avian patients that will likely include compounded forms. These will likely require special attention to source these items at reasonable costs and shipping lead times.

Whatever systems are used to track inventory, consider implementation of just-in-time (JIT) ordering. JIT was recognized by Honda Corporation to have parts for vehicles ordered as they were needed.[17] The ideal situation is that as soon as something is needed, it "appears" and then it is used or sold. Because pharmacy items and medical supplies do not just appear, the systems in place should account for ordering and shipping lead times. With online ordering systems and overnight shipping that most vendors have available, minimal stock needs to be kept on the shelves. The rapid ordering and delivery allow us to act like a big corporation, just the way Honda has developed for managing inventory.

JIT prevents excess inventory, which has a cost. That cost is the amount equal to the physical product that is constantly sitting on the shelves unused. Extra inventory also takes up space and the money generated per square foot decreases for what a hospital or clinic can produce. Order what you need by checking history for sales of an inventory item, which can be done through your PMS, as well as through your distributor accounts.[16] See how often you sell those products and then order accordingly. Financially responsible practices typically spend roughly 17.5% of gross revenue on medical supplies (Table 1.1).[13] Continue to check your percentage and alter ordering habits appropriately. This also includes regularly reviewing product pricing and sources to ensure you are purchasing the most cost-effective product. It is also worth negotiating discounts with distributors. Many will also offer discounts for paying invoices by automatic debit from a business bank account.

The use of online pharmacies will also decrease what is on hand. For medications uncommonly dispensed, consider working with an online pharmacy that is aligned with your hospital where some profit can be realized by the practice. There are also compounding pharmacies that will mail directly to the owner's home. Take advantage of these resources to minimize stock on hand that does not rotate with regularity, while still earning revenue for the hospital.

Payroll

Payroll expenses are a factor of how efficiently a practice runs and the pay rate of employees. The percentage of gross revenue for all of payroll should be 40% or lower, with 20% going to veterinarians and 20% dedicated to all other staff. Many practices have too many employees or nonproductive employees. Following the rules of staff leveraging will help manage both of those issues. A starting point to evaluate the number of staff is a doctor-to-staff ratio of 1:4.1.[13] Identifying excess, like inventory, is vital to having a productive, fully functioning, and happy staff. Proper scheduling prevents overtime and burnout, both of which increase payroll.

To establish the pay rate per employee, there are resources available that evaluate pay by year, position, and area of the country. You can find these with the Veterinary Hospital Managers Association by having someone in the practice as a member of the organization. It is very worthwhile to be a member as an owner, interested associate, hospital administrator, or office manager.

Rent

Rental expense can be one of the more complicated calculations to determine. A quick calculation for rent would be 5% to 6% of gross revenue. Major metropolitan areas may command a higher rent closer to 8% or more. If you own the property and the veterinary practice, you may go above that percentage to pay your property loan and have an additional distribution to you through rent. In this scenario, one must keep in mind reasonable rent when you go to sell the veterinary practice goodwill. At the time of practice sale, excess rent will either count against your profitability and subsequently value, or it will be added back to the profits, and you will have offered a less valuable lease as the building owner.

Another more accurate way to calculate rent is to have a commercial real estate professional establish a proper rental rate. They will collect per square footage data from the surrounding areas and match that to your hospital.

If you own the real property and want to sell or establish value for the asset, the rental rate is used to calculate the value of the property. A 7000 sq ft building that has a veterinary hospital rents space at $15/sq ft as researched in the surrounding markets. That equals a yearly rent of $105,000 (7000 × 15). An investor purchasing the property would like a return on the investment of a certain percent or capitalization rate. A starting capitalization rate for veterinary real estate can be 8%, although that number can vary greatly depending on the length of lease, guarantees, coverage of taxes and repairs, and many other factors. The value to the investor in this example is the yearly rent of $105,000 and divides by 0.08 (8%). That equals a value of $1,312,500 for the real property. If another investor finds the terms of the lease very favorable, they may offer a 7% capitalization rate, which gives a value for the real property of $1,500,000 (105,000/0.07).

The impact of having a proper lease and paying reasonable rent not only affects the profit of the veterinary practice on a monthly and yearly basis but also impacts on the value of the practice and the building, if also owned by you. Involving real estate professionals, lawyers, and accountants is paramount when establishing a lease between other parties or your own entity.

PRIVATE PRACTICE: VETERINARIAN CAREER PLANNING

When starting to work with birds in private practice, veterinarians are looking for a fulfilling career of caring for patients, relieving their suffering, and hopefully earning an acceptable income while doing so. This goes for associates and owners alike, even though they can have very different roles. Each veterinarian will have their own challenges, but there are some commonalities among the individuals in each group.

Associate Challenges

Job selection

Associate veterinarians have the responsibility to find the perfect fit for them. When wanting to work with birds, the options start to become limited. Not every small animal hospital wants to work with birds. Some may think they do until it starts happening, as the execution of medicine and surgery for birds can become quite challenging managerially. Some hospitals may not fully realize that until they start working with them. The questions discussed earlier in the chapter should be asked again. What percentage of birds do you want to see at your practice relative to other types of patients? What level of medicine and surgery do you want to perform? These are important questions that should be answered prior to the job search, and then apply to hospitals that meet your criteria. Invariably you will have many criteria like location, hours, pay scale, and many others.

It is best to have a place established in the broad and general avian community. These owners are committed to working with birds. When an inexperienced associate is asked to start the avian part of the practice, roadblocks present themselves. Owners may not persevere through those tough times and may abandon the idea of seeing bird patients altogether. Starting on your own in a practice may be the only option, but it is generally not the preferred way.

It is important to prioritize what is important to you and be sure to listen to yourself as you look for employment. Fortunately, if it is not a great fit, you can do something different. If birds are a priority, spend time in the interview asking about how you can develop your career doing just that.

Proper compensation

Typically, associates are paid in a few different ways. They can receive a salary that is based on the area of the country of the practice and experience of the associate. There are survey publications that have that information for veterinarians from the previous year(s) so all parties know a competitive salary range.

Production is another way to be paid, which includes everything generated by the associate, but considers any benefits received like paid time off, continuing education, any licensing, continuing education, and other agreed-upon items. An associate may be paid 18% of production, but benefits could increase that percentage to 25%. A calculation is completed at the end of the contract year to determine what monies are paid. In this scenario, there is a base salary throughout the year with 18% to 25% of production as the total compensation. Usually, the associate is owed money in this scenario, but if there is excessive time off, money could potentially be owed back to the practice.

ProSal is a scenario where the associate is offered a base salary with a percentage of production beyond the base. This is a positive for the associate, as they will never owe money to the practice. It also rewards hard work and good medicine and surgery. Remember that if we do what is right for the patient, money and profit will follow. Standard ProSal is calculated monthly so the second pay for the month is adjusted based on the previous month.[18] Several permutations of ProSal remuneration exist, so it is important to perform calculations ahead of signing a contract. A lawyer and an accountant can not only help estimate yearly pay but also use a veterinary salary resource guide to be sure the pay is fair.

Retirement

The goal is to be able to live comfortably during retirement. Because associates often will not make salaries similar to practice owners, they have to make sure to start early and contribute often to proper investments. Also, there can be large student loans that prohibit what seems like a meaningful contribution to retirement investments. There are numerous aspects to retirement planning that require a written plan. Retirement is not just about saving money. It is also about looking at investment sources of income to aid you during retirement. Eliminating debt, having a proper estate plan, and protecting your assets are also important and will help make retirement much more enjoyable. Choose a financial planner to assist you in your retirement planning process; this is not a process that should be managed yourself.

Owner Challenges

The day you decide to become an owner of a veterinary practice is both exhilarating and terrifying at the same time. The exhilaration comes from the fact that you are now in charge of making decisions and can practice medicine the way you see fit. The terrifying part comes into play when you realize that you did not learn any of the necessary skills that you need to become a successful owner in veterinary school. They did

not teach how to market and promote, manage finances, handle people, hire personnel, understand business and legal documents, or set up business systems so the organization can run efficiently. There is great joy in creating a business and having that business financially serve your household. Ownership also provides you the opportunity to accelerate your personal wealth building and become financially free much earlier than if you were to remain an associate. But you first must understand each of the roles you play to navigate the pitfalls of practice ownership.

The three roles

In every business, there are three roles that must be worn. These roles would be those of the owner, the executive, and the practitioner.[19] Any business owner must know how to calmly wear these three roles and ensure they are being worn in their organization. The success of the business is directly proportional to these three roles being played well by individuals within the organization.

The practitioner role. Most veterinary owners started off as practitioners in their practice. They went to school for an ungodly number of years to learn the skills necessary to treat and help patients. This is the most natural role you play in your business. The importance of this role cannot be overstated. If you are not a good practitioner, you will not be in business very long. The list of responsibilities is as follows:

- Delivers the care and medical expertise to the public
- Develops standardized protocols of how to deliver the company product
- Provides consistent results with patients
- Provides high-quality service to the patients
- Is highly educated in their field
- Strives to innovate and make their field better

If you plan on continuing to treat patients, you must calmly and confidently wear this role. In addition, you need to ensure the other associate doctors are acting as professional practitioners. While no two people treat the same, there needs to be consistency in how you treat the public from associate doctor to associate doctor. The protocols need to be standard. If an associate wants to treat a certain way that is not in alignment with your philosophy, they need to start their own practice. You should always be looking for ways to improve your technical skills and innovate. True professionals are constantly looking for methods to make things better.

The executive role. An executive could be said to be someone who has the responsibility to manage others to ensure they perform the work to produce the company's product or service. This is probably the least liked role for most practice owners. Most practice owners simply do not like managing others. The reason they do not like the executive role is they have had the least amount of training in how to perform this function. Being a good executive is not thoroughly taught in medical training. Even in residency and specialty training programs in avian practice, this function in an executive role is not required as part of the training and is therefore not commonly taught. Yet, the executive role and having competent executives in your business is the make or break of whether your organization will expand or contract. Among the responsibilities of the executive role are the following:

- Organizing and carrying out the intentions of the owner(s)
- Establishing policy and procedure for all staff
- Training all staff on a standard management system
- Being responsible for the gross revenue and profit
- Being responsible for marketing, promotion, and sales
- Being responsible for execution of strategic plan for expansion and production

While all these functions seem overwhelming to most solo practitioners and one-doctor practices (and it is), having competent and cooperative executives can take a large amount of pressure off the owner to "do everything" and allow for actual business growth to occur. The beautiful part of this is you do not have to create a "perfect" job description for every executive. If you hire the right people from the top down and give them just a little direction and purpose, they will create things you never even thought of. A lot of business owners are afraid to hire a full-time CEO or other executives for fear of eating into their profit margins. This is short-sighted and a myth. The most profitable and well-run practices one of the authors has seen operating with over a 25% profit margin all have done executive training and have hired executives to get others to get work done.

You will see a very large resistance wave come your way when you decide to really wear this executive role in your business, but if you can blast through it, you will see massive growth and increased time for you to pursue other life goals and ambitions.

The owner role. By far the most fun role you can wear is that of the owner. When you first had the idea and a goal for what you wanted your business to look like, you were playing the owner role. The owner's role is the visionary. This is the role where you get to create and dream. It is the role that many practice owners unfortunately neglect to wear properly because the practitioner and executive roles eat up all of your time and attention. But if you do not carve out time to do this role, you will find yourself stuck in second gear and will likely never achieve the financial wherewithal you dreamed about when you decided to start your business. Wearing the owner role correctly means you set up the business to serve the goals, purposes, and needs of the household, and creating a business that provides maximum value to your household. Value does not just mean money; it means time, wealth, relationships, friendships, acknowledgments, and achievement. A business must bring all of these "value" items to the household, and it is the owner's responsibility to do so. Among the responsibilities of owner role are the following:

- Establishing goals and purposes, mission, and vision
- Establishing standards and culture
- Establishing legal and regulatory compliance
- Creating maximum enterprise value in the business
- Acting as a professional investor
- Using household financial planning to meet the financial objectives of the household members.

When you are truly wearing your "owner" hat, you are focusing most of your time on expansion activities, ensuring the business compliance and regulatory activities are up-to-date and secure, and ensuring the business is providing the proper value to the household based upon the risk you took for putting the business in existence.

Of the three roles, focusing on your owner and executive roles will always provide for more compensation and expansion of revenue than focusing on your practitioner role. The reason most veterinary owners never get their practice

revenues to the $2- to $5-million-dollar revenue range is they focus too much on the practitioner role and never get out of treating on a day-to-day basis.

From a practicality standpoint, it is very difficult to play all three roles in your business. You will need to delegate one to two of these roles in your organization to others if you want to become "unstuck." You must always wear the "owner hat," and you cannot give that responsibility away if you own the business. Therefore, the decision comes down to whether you want to be an owner-executive or an owner-practitioner. If you want to be an owner-executive, then you must ensure the associates are excellent practitioners and deliver the products of the organization very well. If you choose to be an owner-practitioner, you must ensure you build an executive team that can motivate, plan, and execute the strategic plan of the organization to expand while you focus on treating full time. Pick two of the roles for best success.

Your Practice Is an Investment, Not a Job

For most veterinary owners, their practice is the main income source for their household. While you never want to rely on one income source forever, it is an economic reality that the business needs to provide a tremendous amount of value to the household. This comes in the form of business profits, rental income, and eventually the proceeds from the practice sale. To get maximum value from the business, you need to treat it as an investment and not just a place to work.[20]

Warren Buffet is a master investor. He has a mindset that if he is going to invest in a company, it needs to produce enough value to exceed the risk he took in utilizing his own money. As a practice owner, you must maintain a similar point of view. Many owners have poured enormous amounts of money to either acquire their practices or start them from scratch. Either way, there was no guarantee of success when starting down this road. Unlike investing in the stock market, it is possible to control the returns you get from your practice. Most practice owners have the belief that they can expect only 10% to 12% profits from their veterinary practice and some think 15% to 20% is reasonable. Elite practice owners demand a 25% to 30% profit margin from their business. This is done through a combination of excellent marketing and promotion, strong sales, excellent delivery, and strict money management where the profits are considered a necessary expense. Elite practice owners understand how important their business profits are to the overall value of their business. To illustrate, here is an example of a poorly run, well-run, and extremely well-run veterinary practice (Figure 1.15).

As you can see, the difference in cash flow and overall investment value from a poorly run and extremely well-run practice is staggering. These elite owners do not have some secret knowledge that was locked in a vault. They just understood they needed to invest their money in certain areas in order to ensure the business could achieve maximum value for themselves, their family, and their community. These areas include the following:

1. Practice management and business consulting
   Investing in increasing your ability to run a business is probably the best investment you can make. Having a proven business consultant who understands business systems and can help prevent you from making bad business decisions is worth potentially millions of dollars.

Valuation scenarios of $1,000,000 annual revenue practice

Not well managed	Well managed	Very well managed
10% profit margin = $100,000	15% profit margin = $150,000	20% profit margin = $200,000
@2–3x multiple **$200k–$300k value**	@2–3x multiple **$300k–$450k value**	@3–4x multiple **$600k–$800k value**

Difference of not well managed and very well managed: Loss of $400–$500k

FIGURE 1.15 Difference in value of not well-managed and very well managed practice. (Eric Miller 2024, © 2024 Sage Assets LLC. Published with permission.)

2. Staff training
   No one can have a sustainable business by doing it alone. You need to invest in your people. That means spending money on training your staff so they can do their jobs better. This is the *only* way you will truly be able to step away from your practice and have it run profitably without you having to monitor it full time. If you want to be able to take a 2-month vacation and come back to a practice that is growing, train your staff.
3. Real estate
   Patients and employees want a safe and aesthetic place to come to every day. It is imperative that you invest in your facility to make it a warm and inviting place. For most owners, it is highly advisable to own your practice building in an established or growing area. By owning the building, you can get certain tax benefits and can continue to collect the rent even after you have sold the practice to another veterinarian or corporate buyer.
4. Tax, financial, and legal management
   The most elite owners have a coordinated team of financial professionals who help them navigate the financial pitfalls one can encounter. This means having a top-notch accountant and tax strategist who minimize your taxes, an industry-specific financial planner who shows you how to channel the business profits to your household to increase your personal net worth, and an attorney who helps with your legal affairs and keeps your business compliant and your assets protected.

The most elite owners are willing to spend hundreds of thousands of dollars on the above because they understand they are likely to get a return of 10 times of their investment. To build a profitable, sustainable, and transferable practice, it is vital that you invest heavily in these four areas.

Exit and Retirement

Every practice owner must confront the reality that there will come a time when they will need to exit their business. Your exit can either be a positive experience or it can be a stressful and sad event. The choice is mostly yours. The key factors are how well you plan your exit and diligently work toward the event no matter how many years in the future it might be. You

do not start planning your exit 2 months before it happens; you start now, even if you are just starting ownership. The first step is exploring the seven different ways in which you can exit your practice and figuring out the strategy that makes the most sense for you.[21]

1. Die with your boots on
   As it sounds, this is where you simply keep working up until the day you die. Some practice owners simply cannot walk away. If this is your exit of choice, just be sure to ease the burden of disposing the practice from your heirs by having your estate plan in place, which provides a detailed and step-by-step process for them to follow.
2. Close the doors
   Utilizing this strategy, you simply close the practice down. This is the saddest method and least valuable manner of exiting your practice because it provides no value for your household. This method is only doable if you have accumulated enough wealth outside of the business that can make up for the loss of income from the practice.
3. Sell to a competitor
   It is unlikely that your practice is the only practice in town. If this is the case, you may be able to sell your practice to a competitor. You can get a relatively fair market value price for your practice. The downside is that you are likely to be out of a job and there is no future value of the business available.
4. Associate or management buy-in or buy-out
   With this method, you are choosing to sell to your upper management or a successor associate. In most cases, the people buying your practice will not have all the resources necessary to buy the practice outright. You will most likely need to use the business as collateral, and they will pay you over a period of time through the business profits. The upside is that you can minimize your tax liability and still maintain control of the business until the purchase is complete. The downside is that if your successors are not well trained on how to run a business, you could be forced to reassume full control at a time where you were looking to reduce hours and retire.
5. Private equity or corporate groups
   The veterinary industry is a very lucrative and profitable industry. Good businesses in good locations with multiple doctors and high-profit margins will always be the target of corporate and private equity groups. These groups will pay relatively high multiples of EBITDA (earnings before interest, taxes, depreciation, and amortization) for well-run practices. They will generally require the owner to stay on for some time to make sure the transition runs smoothly. In addition, they will pay a lump sum for the practice, which reduces the risk to the seller. The seller may also get an option to leave some of their value in the corporation and take advantage of future growth. These groups are sometimes painted in a bad light for their "greed" and "profit-first" approach. This is not always the case. There are numerous examples of corporate groups who enhance business and make the environment better for their employees and patients.
6. Employee stock ownership plan
   This is a highly specialized type of strategy where a practice owner will set a legally qualified retirement plan that will allow their employees to purchase the company stock and eventually take over. The owner will still maintain strategic control of the business and keep their salary and perks. The downside is the expense to administer this type of approach. You would need to have over $1,000,000 of net income (not gross revenue) to justify the expense of setting up this type of plan.
7. Gifting strategies
   There may be circumstances where an owner simply wants to gift company stock to their family or employees. This is generally done where the owner has a high level of financial resources and is not dependent on the sale proceeds to fund retirement. Gifting is done as an effort to minimize certain types of taxes and to ensure the practice legacy continues.

Whatever exit strategy you choose, it is imperative that you build your practice to transition for maximum value. That value should be created for you and your family, your staff, the successor owner, the community, and your patients. This is not a zero-sum game, meaning everyone should win in this transaction. Those owners who only look out for themselves come to regret their choices later on in life. Make it a win-win proposal for everyone and you will be rewarded!

Lastly, it is possible for you to retire with dignity and enough resources, so you never have to worry about money again. For this to occur, you cannot assume the sale of the business will fund your retirement 100%. The single most important action you can take to ensure your business sale is not the only funding of your retirement, is to set up an automatic and systematic payment to your household of 10% of the business revenue. This means, if you are doing $1,000,000 a year in gross revenue, that $100,000 is coming right off the top and being allocated into a wealth storage account for the benefit of the household. This is simply an account that will be used to store money that is designed to create other income streams for the household and act as an emergency fund during a financial crisis. A competent financial advisor will help you prudently invest that money to ensure it is not wasted or subject to huge losses. This one action is the most powerful financial action you can take to provide financial security for your family. Do not underestimate the power of putting your profit first. It will allow you to create financial freedom.

SUMMARY

The practice of avian medicine and surgery is present in every corner of the globe. The medicine and the management that allows delivery of services are not necessarily handled differently by comparison in different geographic areas. While there are nuances in many areas of management between states, provinces, and countries, the basic business principles still apply. The topics discussed are not difficult concepts, and understanding them seems inherent. Developing an overall strategy, communicating that philosophy, and implementing the management tactics are the most challenging parts of having a wonderfully rewarding and profitable career in avian medicine. Having a written plan along each step of the way and continually reviewing that plan with your team and yourself will allow you to achieve your professional and financial goals whether you are an owner or an associate veterinarian.

CHAPTER 2

Common Imaging Modalities: Selecting the Right Modality and Getting the Most Out of Your Imaging

Sophie E. Dennison

Visit eBooks.Health.Elsevier.com for a complete set of references.

GENERAL CONCEPTS OF DIGITAL IMAGING

In the last decade, there has been significant progression in veterinary medical digital imaging, with increased availability and diminished cost to the practitioner for almost all digital imaging modalities. This availability has been accompanied by more reasonable costs associated with digital media storage. Digital images are part of the medical record, and all images must be saved according to local veterinary medical board or equivalent governing body requirements. Hard film records of ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) images can be made and stored in the same way as screen-film radiographs. Diagnostic images acquired as digital media should be saved as DICOM (Digital Imaging and COmmunications in Medicine) files, and studies must be carefully labeled with unique patient identifiers (name and/or ID) prior to starting the study as well as ensuring that the date and time of acquisition are correct. Most digital imaging systems do not (and should not) permit alteration of patient identifiers after the study has been started due to potential medicolegal ramifications.[1] Digital image resolution and DICOM guidelines for digital imaging have been published by the American College of Veterinary Radiology (ACVR) and are available at www.acvr.org. DICOMs are large data files that are the accepted standard for medical imaging storage and interpretation.[1] Interpretations from compressed image files such as jpeg are discouraged as some data are irreversibly lost. This can lead to errors of interpretation particularly in very small patients where compression may affect resolution.[1] The use of cataloged image storage on a PACS (Picture Archiving and Communication System) is recommended to ensure that studies can be quickly identified.[2] Many PACS are now available as cloud systems that remove the cost of hardware and need for additional backup systems, as well as increasing accessibility for authorized users without exposing internal IT networks. Data corruption can occur at many levels and quality assurance is a necessity to ensure that studies are of diagnostic quality at the time of imaging, that the entire study is sent to the PACS, and that an adequate PACS system is in place to protect data. DICOM imaging software is used to view DICOM images and both open-source and license-based software are available for use on Mac and PC.[3] Examples of popular open-source DICOM software for Mac include Horos (www.horosproject.com) and for PCs Radiant Viewer (www.radiantviewer.com) and MicroDicom (www.microdicom.com). All digital imaging, regardless of the modality used, should be evaluated on a high-resolution screen in an environment optimized for image evaluation. Ideally, a dedicated high-resolution workstation in an area that can be darkened/shaded and that is quiet and away from distraction is suggested. In many busy hospital situations this can be challenging to achieve, but bright background lighting, noise, and distraction can contribute to misinterpretation.

Diagnostic imaging will always be limited if patient positioning and modality technique are not optimized for every study. Standardized patient positioning and technique reduce frustration, help remove iatrogenic artifacts, and improve the accuracy of the interpretation, as studies from the same patient or another patient being used for comparison can be compared side by side.

INTRODUCTION TO RADIOGRAPHY

Diagnostic radiography has been available since the early 20th century following the discovery of x-rays in the late 19th century. Radiographs are the images produced after an image detector is exposed to an x-ray beam that has been passed through a patient. X-ray photon attenuation varies by tissue resulting in the five radiographic opacities: metal, bone, soft tissue/fluid, fat, and gas. Screen-film has been used for the

production of radiographs from the discovery of x-rays to beyond the advent of digital radiography. Digital radiography became available for medical imaging in 1980 although screen-film radiography prevailed as the main form of radiography used in veterinary medicine until the last decade and screen-film imaging remains in veterinary use today in some practices.

Screen-Film Radiography

Screen-film radiography refers to the traditional emulsion film system used to capture, store, and present radiographic images after exposure to an x-ray beam. Double-sided or single-sided emulsion film is placed in a cassette that contains intensifying screen(s) that reduce the amount of radiation needed for a diagnostic image. Single emulsion film is preferred for very small patients as it has higher spatial resolution and will produce sharper images than double emulsion film where the two superimposed emulsions on either side of a transparent base can cause very slight blurring of margins. When x-rays, gamma rays, heat, or light interact with silver bromide in the film, it results in the release of bromide into the emulsion gel and deposits of ionized silver known as "sensitivity specks" form the latent image. The film is then developed and fixed producing a visible image using manual, semi-automatic, or automatic developer systems. Developing is the conversion of the silver ions in the emulsion to black metallic silver that is visible to the eye. Fixing is the removal of unexposed silver halide crystals from the film making the image permanent and hardening of the emulsion to prevent damage.[4]

Nonexposed radiographic film must be protected from light and heat to prevent accidental activation of sensitivity specks that result in fog on the final radiograph. Loaded cassettes and film storage boxes should be opened carefully in red light, temperature-controlled dark rooms and film handled gently. When replacing film in the cassette, ensure that dirt, dust, hair, or other debris are not trapped inside the cassette as these will also create artifacts on the film.[4]

Digital Radiography

Two main forms of digital radiography technologies exist: computed radiography (CR) and direct radiography (DR). The image detector in digital radiography is used to capture the latent image which is then processed and stored and presented via digital medium. Technique charts used for digital radiography are extremely simplified compared to screen-film, making the systems very appealing and more user-friendly. Digital radiography images have a wide dynamic range that allows manipulation of the image post-processing and greatly reduces the number of retakes needed due to technique.

The theory behind CR is like traditional screen-film radiography. In CR, the image detector is an image plate contained within a cassette that contains photostimulable crystals similar to the intensifying screen in traditional cassettes. When exposed to x-rays, the image plate temporarily absorbs and stores the x-ray photon energy as a latent image that is read out pixel by pixel via a laser beam in a scanner. The laser beam releases the stored energy as light that is detected by photodiodes within the scanner and converted into a digital image. The time from image detector exposure to image presentation takes at least 45 seconds and is slightly faster than traditional screen-film using a fully automated developer system. The image plate should be processed quickly after exposure to prevent image degradation, and image plates should be passed through the scanner between exposures to remove all remaining latent image, even if a long period of time has passed. Damage to CR cassettes and image plates can occur during handling, and dirt may enter the cassettes leading to artifacts on the final image. CR image plates and screens are more expensive to replace than screen-film but less expensive than DR flat panel detectors.[5,6]

DR is the alternative form of digital radiography to CR. X-ray photons that reach the image detector (usually a flat panel) are converted into electrical charges which are then converted into an image via direct or indirect technology. Direct technology is based on a photoconductor, typically selenium, converting x-ray photons into electrical charges stored in a thin-film transistor array and processed to form the image. Indirect technology systems utilize a light sensitive system that has a layered construction comprising a scintillator layer (usually gadolinium), amorphous silicon photodiode layer, and thin-film transistor array. Indirect technology has better optical properties and better quantum efficiency than direct technology and is more widely available. The production of an image using a DR system is essentially real time with only a few seconds lag between image detector exposure and presentation of a digital image. Contrary to screen-film systems and CR image detectors, DR flat panel detectors are quite fragile and expensive to replace.[5,6]

Clinical images acquired in medium-sized birds via any digital radiography technology are at least equal to and often supersede perceived conventional screen-film image quality, despite medical physics studies showing that spatial resolution of CR is slightly less than screen-film.[5,7] This perception of improved image quality is due to the wide dynamic range that means all tissues can be optimally displayed on the same image after adjustment of window width (WW) and window level (WL) (brightness and contrast). This and other manipulations of the image such as enlargement or inversion result in greater user satisfaction.[3] Over- and underexposure do still occur but have a very different appearance on digital imaging compared to screen-film techniques (see section on Selected Radiographic Artifacts). Digital radiography has removed some of the technical skills required to produce diagnostic images and with that operators may be less conscientious about technique selection and less aware of the radiation risk to themselves. Continued training in and use of the ALARA principle (as low as reasonably achievable) for radiographic technique as well as enforcement of local requirements for personal radiation safety is encouraged.

Patient Positioning for Radiographic Imaging

Patient rotation can affect assessment of some coelomic organs, and optimal and repeatable positioning permits the most accurate assessment and comparison, especially in birds that undergo serial studies.[8] The use of radiolucent restraints and positioning aids such as tape, rope, or foam wedges/troughs, can be used to prevent motion and optimize positioning, and chemical restraint (either sedation or anesthesia) can be utilized to minimize stress. On the lateral view projections, the coracoids and femoral heads should be very close or superimposed on each other (Figure 2.1), whereas on the dorsoventral (DV)/ventrodorsal (VD) view, the spine should be superimposed on the sternum/keel.[8] Studies have shown that an erect (standing) DV view may be adequate for some anatomic evaluations in the critically ill bird where sedation and anesthesia or restraint to permit a VD projection are contraindicated.[9] If acquiring standing DV views, clinicians should be aware that measurements of the heart will be larger

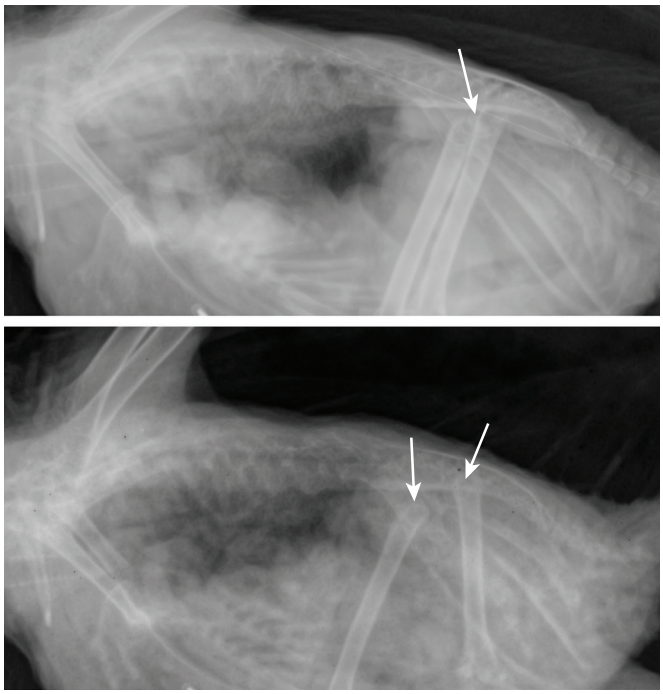

FIGURE 2.1 Lateral radiographic projections acquired in lateral recumbency showing optimized positioning with near superimposition of the coxofemoral joints (*arrow,* top image) and separation of the coxofemoral joints (*arrows,* bottom image) when rotation is present.

on the DV projection due to magnification effects, and evaluation of the respiratory tract is more limited than on the VD view. The erect DV is considered adequate for evaluation of the heart and upper gastrointestinal (GI) tract.[9]

Historically, radiographic units were fixed in position for vertical beam image acquisition, where the x-ray tube sits over a table pointing to the ground and the image detector is placed either on or under the table perpendicular to the primary beam. The patient is positioned on the table and then repositioned for the different projections. However, more recently, many systems have a movable x-ray tube and a movable or removable image detector that permits vertical and horizontal beam image acquisition (Figure 2.2). Horizontal beam lateral projections are beneficial for avian patients as they remove iatrogenic organ displacement (Figure 2.3) that could result in misinterpretation.[10] Horizontal beam radiographs are acquired by positioning the patient in sternal recumbency or standing with the x-ray tube positioned on one side of the patient and the image detector on the other, parallel to the table (Figure 2.2) using radiolucent tubes or containers. Interpreters should be aware of variations in appearance of organs in images acquired in standing compared to ventral/sternal recumbency (Figure 2.4).

Peer-reviewed texts are available that demonstrate normal avian radiographic anatomy in some species including the cockatiel (*Nymphicus hollandicus*),[11] Amazon parrot (*Amazona* sp.),[12] galliform species,[13] anserine species,[14] diurnal raptors,[15] and the barn owl (*Tyto alba*).[16]

Advantages of Radiography

Radiographic equipment is available in most veterinary hospitals making it extremely accessible. The vast majority of companion bird species will fit within the margins of the radiographic cassette/image detector, thus requiring only two exposures and making radiography a very rapid and inexpensive test. In the case of severe respiratory disease, fractures/luxations, some coelomic effusive disease processes, or GI tract ileus, a diagnosis can often be made immediately.

FIGURE 2.2 Photograph demonstrating use of a horizontal beam technique to acquire orthogonal views in a standing penguin. The penguin is restrained inside a radiolucent cylinder. The same technique is used for restraint for C-arm fluoroscopy or CBCT-incorporated fluoroscopy. *CBCT,* Cone beam computed tomography.

Disadvantages of Radiography

Patient size can be challenging due to the very small size of many avian species requiring examination. Superimposition of structures combined with relatively low inherent patient contrast especially in the caudal coelom, can make radiographic interpretation of avian patients challenging. Digital radiography and the ability to enlarge images have helped but do not escape the limitations of superimposition that can obscure pathology. For very large birds, multiple overlapping exposures may be needed to cover the entire body for each projection. Anesthesia or sedation may be necessary to achieve optimized diagnostic quality studies and minimize patient stress.

Direct Clinical Applications of Radiography

- Evaluation of the axial and appendicular skeleton
- Evaluation of respiratory tract
- Evaluation of the coelomic cavities for evidence of fluid, egg binding, or organomegaly
- Evaluation for radiopaque foreign material (gunshot/trauma, ingested)
- Contrast studies (anatomical and functional studies)[17]

Selected Radiographic Artifacts

Several texts are available that explain screen-film radiography artifacts[18] and digital radiography artifacts[19,20] in detail. The most observed artifacts in digital radiography are overexposure, underexposure, incorrect placement of the imaging detector/digital plate, and lines or stripes across the image.

Overexposure may be due to excessively high kVp (peak kV), mAs (the combination of mA and time of exposure), or both and occurs when x-ray photons saturate the image

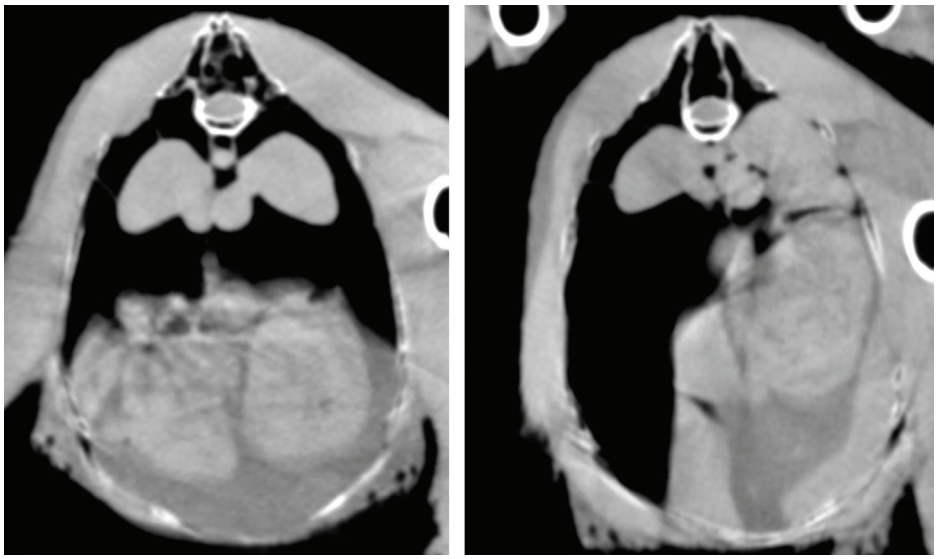

FIGURE 2.3 CT images demonstrating the varying position of internal organs when positioned in sternal (left image) and left lateral (right image). *CT*, Computed tomography.

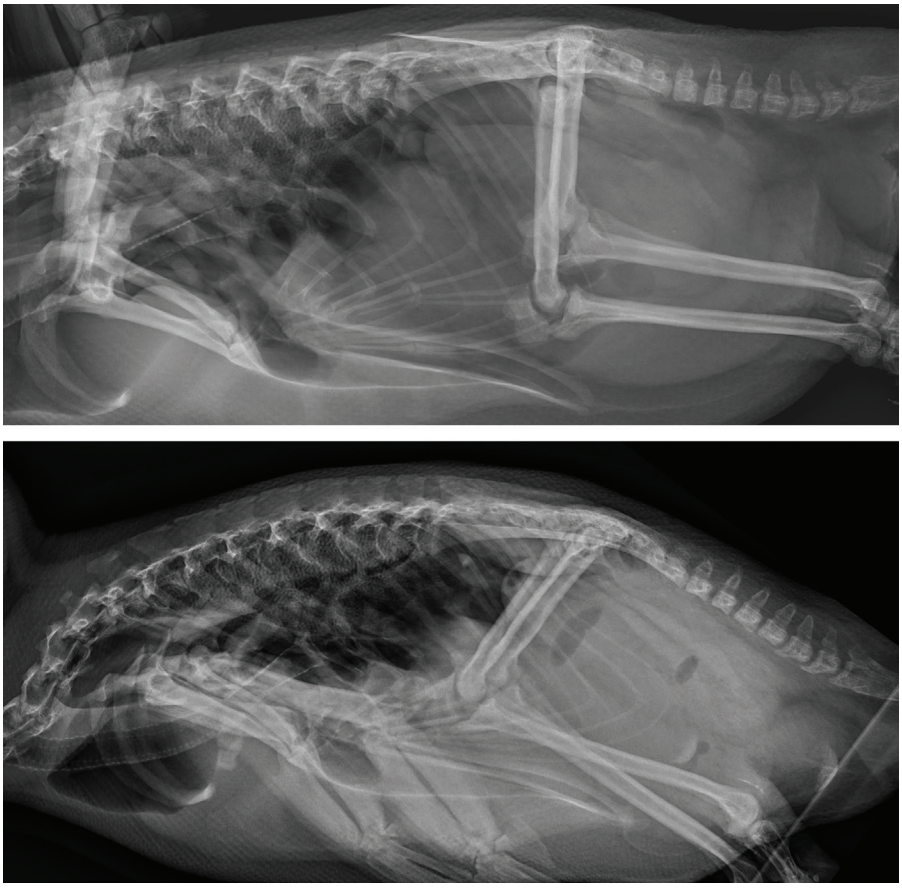

FIGURE 2.4 Lateral projections of a penguin. The top image was acquired in lateral recumbency and gives the impression of increased soft tissues in the caudal coelomic cavities. The bottom image is the same penguin with the lateral view acquired standing via horizontal beam.

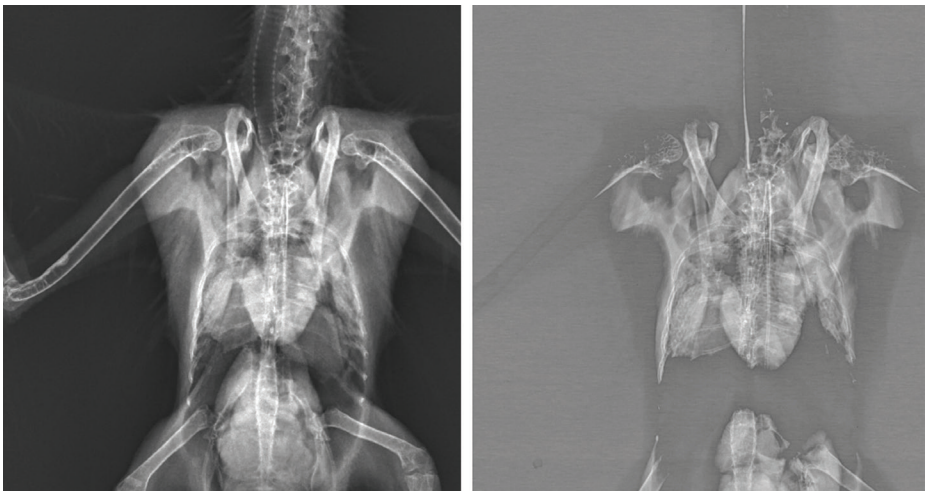

FIGURE 2.5 Optimized radiographic technique is shown on the left. The right image demonstrates burn out of soft tissues, and in this case also bone, due to higher than necessary technique and saturation of the image detectors. Regions with burn out cannot be adjusted and evaluated, as the data do not exist.

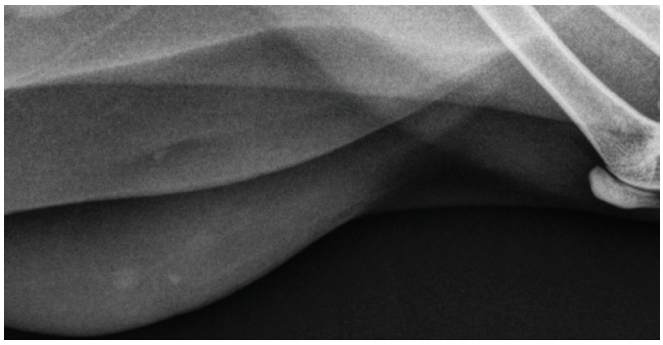

FIGURE 2.6 Underexposure is recognized as a grainy appearance extending across the soft tissues, demonstrated here in a domestic cat.

detector, resulting in areas with little or no detail (Figure 2.5). Overexposure will affect the entire image but is most evident by its effect on anatomy and may not appear uniform. This artifact is corrected by reducing the technique (kVp and/or mAs) to a level appropriate for the patient.

Underexposure or noise occurs when inadequate technique is used to overcome the electronic noise present within the system. This can result in diminished image quality with the overall appearance of speckling or graininess (Figure 2.6) that can obscure subtle pathology. Underexposure will affect the entire image and can be identified in regions with and without. This artifact is corrected by increasing the technique.

Incorrect image detector placement (Figure 2.7) can occur when image detectors are accidentally flipped so that the back of the plate faces toward the x-ray generator. In this case, the x-ray photons pass through the electronics of the system before hitting the scintillator and contribute to the image. This artifact is rectified by orientating the detector correctly toward the x-ray tube.

CR readout errors occur most frequently when dirt or dust is present on the light path assembly within the scanner (Figure 2.8) creating a perpendicular line through the image. This may resolve itself or require cleaning.

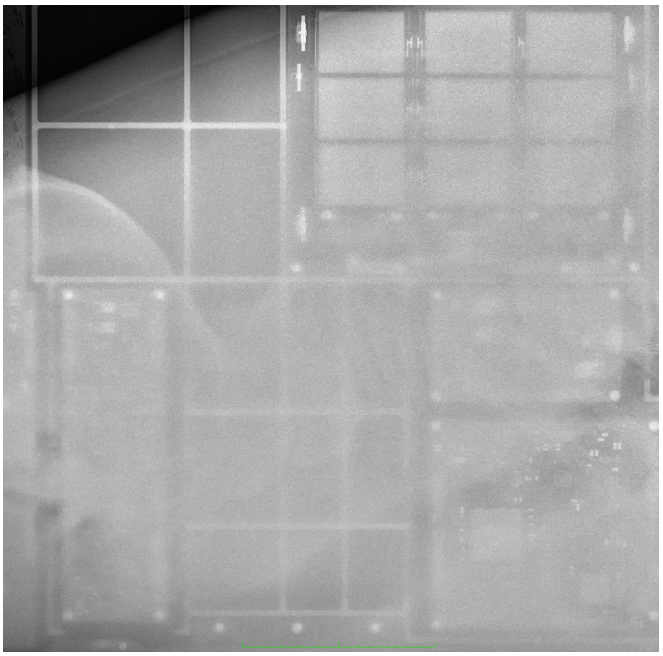

FIGURE 2.7 The plate was placed upside down with the backside facing the x-ray tube resulting in the electronics creating part of the image as the beam passed through them before reaching the detectors.

INTRODUCTION TO FLUOROSCOPY

Fluoroscopy development progressed alongside radiography and came into clinical use after the development of image intensifiers in 1937, with greater use once images could be viewed via television in 1948. The first C-arm fluoroscopic machine was developed by Philips in 1955. Digital fluoroscopy was first introduced in the late 1970s and became more widely available in 1980 enabling the use of masking or subtraction imaging, tools which greatly improved dynamic angiogram, pyelogram, and GI tract contrast studies.[21] Digital fluoroscopy

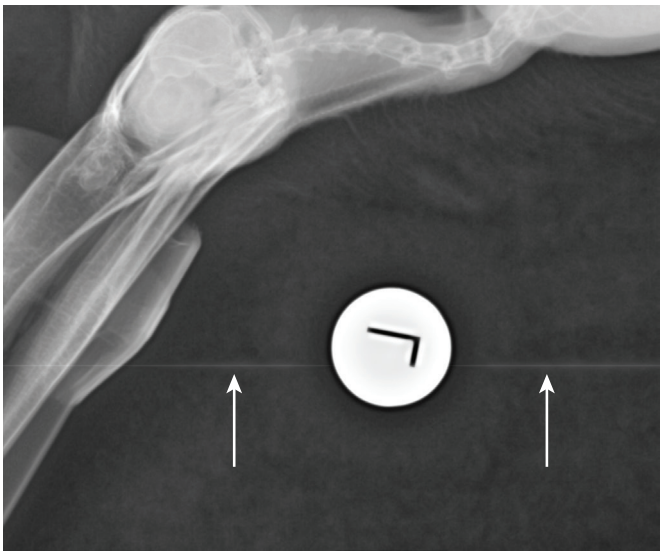

FIGURE 2.8 The white streak seen on this CR image and highlighted by the two arrows is due to dirt within the scanner lying in the light path. *CR,* Computed radiography.

has been recently incorporated into some high-definition volume imaging computed tomography units (HDVI CT) available on the veterinary market, resulting in easier addition of this imaging modality for veterinarians to utilize.

Positioning for Fluoroscopy

Small birds undergoing upper GI contrast studies are usually restricted in a radiolucent box rather than specifically positioned and restrained, as for standing radiographs.[22,23] C-arm fluoroscopic units are then moved around the box to acquire multiple projections, similar to standing radiography (Figure 2.2). Birds being imaged with fluoroscopy using CT units with this capacity can similarly be positioned in small radiolucent boxes on the CT gantry, and the imaging unit is similarly moved around the patient.

Advantages of Fluoroscopy

The main use of fluoroscopy in avian medicine is for evaluation of GI tract motility where fluoroscopy permits real-time dynamic evaluation of the GI tract and the quality, character, and direction of GI tract contractions and contents can be determined. Physical restraint, conscious sedation or anesthesia are often not needed for many studies. Fluoroscopic imaging removes any negative effects of dorsal or lateral recumbency on GI motility and respiration by not requiring any form of patient handling or stress-evoking procedures to optimize patient positioning. Anesthesia is often required for angiography studies. Subtraction techniques may be helpful in some studies.

Disadvantages of Fluoroscopy

Fluoroscopic imaging is similar to radiography in that it is a two-dimensional (2D) representation of three-dimensional (3D) structures, and the problems associated with superimposition of structures therefore remain present, although as for radiography, acquisition of multiple projections is beneficial for interpretation to help counteract the effects of superimposition. Fluoroscopic equipment has lower inherent spatial resolution than can be achieved with radiography or CT, which may limit its use in very small patients, and patients are exposed to relatively large radiation doses. Patient movement may be problematic. GI tract contrast studies may require an empty GI tract before the study is started to eliminate filling defects from food that could mimic pathology and because food in the GI tract will affect the transit time of contrast medium.

Direct Clinical Applications of Fluoroscopy

- Upper GI contrast studies, particularly evaluation of motility[22]
- Intraoperative evaluation of implant placement for fracture repair
- Intravenous (IV) pyelogram
- Angiography
- Quick assessment of patients for the presence of metallic foreign materials without necessitating restraint

INTRODUCTION TO CONTRAST STUDIES

Contrast studies have been used in avian medicine to delineate the GI tract and cloaca and for imaging of the kidneys and ureters. Images can be captured using radiography, fluoroscopy, or CT following administration of contrast medium. In addition to observation of anatomical abnormalities and determining GI transit times, fluoroscopic evaluation has the benefit of dynamic observation of GI contractility and motility following oral administration of contrast medium, and of vasculature anatomy and subjective renal clearance/ureteral opacification following IV or intraosseous administration of contrast medium. CT has the benefit of acquiring images without superimposition of structures and requires a lower concentration of positive contrast medium, but dynamic real-time observation is more limited. Texts are available that describe the details of acquiring a diagnostic contrast study as well as providing time ranges for normal GI tract transit of both barium and iohexol.[17,23,24]

Upper Gastrointestinal Tract Contrast Studies

Upper GI contrast studies typically involve monitoring of contrast traveling from crop to cloaca and can be used to help determine if a mass identified within the intestinal peritoneal cavity is GI in origin, to determine if mechanical obstruction of the GI tract is present, to determine if proventriculus distension is present, and to evaluate GI tract motility times. Studies are performed using positive contrast medium and both barium sulfate and iohexol have been used. Barium dosage of 20 to 30 mL/kg of 25% to 30% weight to volume barium suspension has been described as administered via crop gavage. The volumes administered for some GI fluoroscopic contrast studies may be less. The GI tract should be allowed to empty prior to the study by withholding food for approximately 4 hours, although this may not be necessary in birds who are actively regurgitating, as food present in the GI tract may cause artifacts of filling defects and can affect transit times for the contrast medium.

Average normal GI transit for barium from crop to cloaca is 3 hours. Iohexol 240 mgI/mL diluted 1:1 with water and a total final dosage of 20 to 30 mL/kg has also been used successfully. Iohexol has a more rapid GI transit time compared to barium of 1 hour from crop to cloaca. Iohexol is preferable if GI perforation is a concern or if there is a high likelihood

of proceeding to surgery or endoscopy following the study. Iohexol is hypertonic and will move fluid into the intestinal tract and gradually dilute through the duration of the study, and patients should be appropriately hydrated prior to use. Anecdotally, injectable anesthetic and sedative protocols may cause delayed gastric emptying, while isoflurane has not been noted to significantly affect transit times. Detailed texts are available describing the techniques and timing of serial radiographic and fluoroscopic image acquisition.[17,23,24] If CT is to be used for image capture, iodinated contrast medium is suggested and should be diluted to 25% to 50% of the doses suggested here to help prevent detrimental beam hardening artifact. Beam hardening artifacts on CT are unavoidable with barium suspension even if diluted.

Cloacagrams

Cloacagrams are useful to evaluate for cloacal masses or ulceration/mural defects associated with cloacitis. These studies may be performed using positive contrast (barium or iohexol) or negative contrast (room air or CO_2) administered retrograde directly into the cloaca or by extending out a positive contrast upper GI study or IV pyelogram until the cloaca is filled. If a retrograde cloacagram is selected, only sufficient contrast to fill the cloaca is needed as excessive pressure may result in retrograde movement of contrast and cloacal contents.

Intravenous Pyelogram

Intravenous pyelograms (IVPs) can be performed via IV injection of contrast at the same 600 to 800 mgI/kg dose rate as used for CT. If the medial metatarsal vein is used, the ipsilateral kidney and ureter will contrast enhance preferentially, rapidly, and with greater opacity via the renal portal system, which can be very useful if unilateral disease is suspected. If bilateral disease is suspected, an ulnar vein injection is suggested so the renal and ureteral opacities can be compared to each other as part of the interpretation. The same contrast medium dose is suggested for radiographic, fluoroscopic, or CT capture of the study in this case.

Angiography

Angiography can be used to identify vascular and perfusion abnormalities. As with contrast CT, IVP, and some fluoroscopic imaging procedures, contrast administration methodology is similar. Anesthesia is typically required. A dose of 2 mL/kg of iohexol (240 mg/mL) (Omnipaque, GE healthcare Inc., Princeton, NJ) is administered through an IV catheter at a rate of 1 to 2 mL/kg per second during video acquisition at a rate of 30 frames per second for best resolution.[25]

Sinusography

Sinusography has been used to identify structural abnormalities in the nasal passageways, choana, and infraorbital sinus.[26] With the bird anesthetized and intubated, choanal atresia was confirmed by radiographic imaging in an umbrella cockatoo and grey parrot by administering 0.2 to 0.5 mL of iohexol 300 (Omnipaque, Winthrop, New York).

INTRODUCTION TO ULTRASOUND

Ultrasound was first discovered in 1880 when a piezoelectric effect was identified in certain crystals. Ultrasound in the medical field was first developed for therapeutic effects in the late 1920s and diagnostic use began in 1942. The first B-mode scanner was developed in 1965 and Doppler became available in 1976.

Ultrasound uses the transmission and reflection of sound in the range of 1 to 50 MHz to create images. The interaction of the sound beam with soft tissues is complex, and reflection, scatter, and absorption of sound all contribute to the final image. Higher sound frequencies undergo greater absorption in tissues than lower frequencies and have higher axial spatial resolution. Thus, higher frequencies are used for evaluating tissues closer to the transducer and lower frequencies used for tissues at greater depth, further from the transducer. Most cart-based or portable ultrasound system transducers have a broad range of frequencies and can be used to varying depths. The internal array of piezoelectric transducers dictates the use. Linear array transducers are typically used for B-mode (brightness) imaging, which is the typical grayscale mode used for anatomical/structural evaluation of organs, and phased array for M-mode (motion) imaging, which is the mode used during echocardiography. Transducers can have varying footprints/shapes and sizes. Microconvex transducers that have a small, curved footprint are most amenable to avian patients and frequently have a frequency range of approximately 3 to 10 MHz (Figure 2.9). Some ultrasound systems have software that facilitates Doppler studies. These can be used to estimate blood flow velocities, confirm that a structure is vascular or intravascular, and determine the direction of blood flow within a vessel, and are most useful for but not exclusive to echocardiography.[27]

Recently, new hand-held ultrasound technologies have become available in addition to cart-based and portable ultrasound machines. Hand-held systems use USB-based transducers that contain either piezoelectric crystals or newer chip-based technology and attach to a smart phone or other hand-held smart device. Images are displayed and stored via brand-specific software downloaded as an app. Many of these hand-held point-of-care devices have been developed and are FDA-approved for use in the human medical field and are gradually filtering into the veterinary market. Chip-based ultrasound technology permits a much wider range of frequencies and the ability to select B-mode and M-mode applications in a single transducer. Anecdotally, images from hand-held devices are predictably perceived as inferior to cart-based or portable machines; however, peer-reviewed published clinical comparisons in diagnosis of clinical disease are not yet available.[28]

When performing an ultrasound study, the depth of the field should be adjusted to optimize each organ or area as is evaluated. Focal points define the level at which axial spatial resolution is most accurate. The optimal focal point position varies slightly by ultrasound system but as a rule of thumb should be positioned just below or at the level of the deep margin of the structure/region of interest. The depth of tissue displayed on the screen should also be optimized so that the patient's anatomy is seen across the screen rather than all in the very near field. For very small patients, the use of a standoff may be useful or necessary to increase the distance between the organ(s) of interest and the transducer so the focal point and depth can be appropriately adjusted. Commercially available standoffs made of gel can be purchased; however, anything that will transmit the sound beam without significant

FIGURE 2.9 Three commonly available transducers are shown. Curvilinear (left), linear (middle), and microconvex (right). The microconvex is often the most useful scanner in companion birds as the footprint is smaller than the linear and curvilinear transducers, and the shape of the head is the easiest to angle into acoustic windows when they are available. The numbers on the transducers represent the range of frequencies in MHz each transducer can emit.

interaction such as a bag of IV fluids or a water bath can also be used, as the sole purpose of the standoff is to move the patient's anatomy away from the transducer. Gain and time gain compensation (TGC) can be adjusted to make the entire image (gain) or specific regions of the image (TGC) brighter via amplification of returning sound; however, this will not create image data where none is available. If the sound beam is not adequately penetrating tissues, the size of the electrical pulses (power) can be increased but this will affect thermal index (TI) and mechanical index (MI). These indices describe the likelihood of thermal (tissue heating) and mechanical (most frequently described as cavitation or hemorrhage) hazards in vivo due to the ultrasound beam and are displayed on the active screen.[29] Ultrasound is generally considered to be a very safe imaging modality; however, TI or MI greater than 1.0 combined with extended duration studies focused on a small area should be avoided.[29] Organs should be evaluated as entirely as acoustic windows permit and whenever possible in two planes: the short and long axes of the organ. Recording cine loops of the examination can be very helpful for later review, and at a minimum, representative static images or loops of the study should be stored as part of the medical record.

Patient Positioning for Ultrasound Imaging

In avian patients, acoustic windows to the coelomic cavities can be found ventrally between the sternum and pubis and laterally through the flank (Figure 2.10). The size of the patient and the size of the transducer footprint will determine which acoustic windows are most useful, and not all windows will be available in all patients. Patients are usually restrained

FIGURE 2.10 Ultrasound examination in an anesthetized pigeon using a microconvex transducer via the ventral acoustic window. (Image courtesy Dr. Shachar Malka, Long Island Bird and Exotics Clinic, NY.)

in an upright position or in dorsal recumbency (Figure 2.11) but can be adjusted as needed. Sedation or anesthesia may be necessary in some patients to prevent unnecessary stress and permit positioning. Ultrasound coupling gel or alcohol is needed to optimize contact between the transducer and the

FIGURE 2.11 Ultrasound examination in an awake patient using the ventral acoustic window and a high-resolution linear transducer. (Image courtesy Dr. Shachar Malka, Long Island Bird and Exotics Clinic, NY.)

patient but should be used cautiously to prevent hypothermia especially in smaller patients.

Advantages of Ultrasound Imaging

Ultrasound permits further evaluation of individual coelomic organ internal architecture and identification of internal architectural changes, when organs are accessible, than does radiography and survey CT. Ultrasound may help determine the origin of a mass when a mass effect is suspected radiographically and can be used to confirm the presence of coelomic effusion.[30–32] Ultrasound guidance for tissue sampling is invaluable in ensuring that representative samples are acquired, and that other structures are not inadvertently sampled or traumatized.[33] Ultrasound is the only imaging modality currently that can provide functional cardiac data (echocardiography) in birds.

Disadvantages of Ultrasound Imaging

The acoustic windows for ultrasound imaging in some species can be small due to skeletal anatomy and the presence of air sacs. This small size reduces further when air sac hyperinflation is present or in the presence of pneumocoelom or subcutaneous emphysema. Gas-filled GI structures may further limit evaluation of coelomic organs. Sedation or anesthesia may be necessary for patient compliance and to reduce stress. The use of coupling agents may cause hypothermia in smaller birds.

Direct Clinical Applications of Avian Ultrasound

- Structural and functional studies of the heart
- Evaluation of the coelomic cavities for the presence of fluid
- Evaluation of the liver[32,34]
- Evaluation of the urogenital tract[31,34]
- Evaluation of the intestinal tract[34]
- Evaluation of superficial subcutaneous masses
- Guidance for tissue sampling[33]
- Ocular and retrobulbar examination[35]
- Intracranial evaluation in thin-skulled birds or incompletely ossified skulls/open fontanelles

Selected Ultrasound Artifacts

Artifacts produced on grayscale, B-mode ultrasound images may occur due to physics, the ultrasound transducer, technical selections, or from the patient. The most frequently observed artifacts are those associated with gas due to poor contact at the skin or the effects of gas as a true reflector. Other artifacts such as mirror image artifact or partial volume artifact occur because of the physics of the sound beam.

Partial volume averaging occurs because there is thickness to the sound beam and it can result in slight misplacement of sound reflections, for example, giving the impression of echogenic fluid when an organ is partially captured in the same image as anechoic fluid. This can often be resolved by adjusting focal zone to the level of the artifact narrowing the beam and often removing the artifact, or by turning the transducer 90 degrees.

Mirror image artifact (Figure 2.12) occurs when the sound beam hits a highly reflective surface but the beam is redirected increasing the return journey. This causes the data to be placed further away from the transducer in the image. This is most observed where the craniolateral liver lies adjacent to

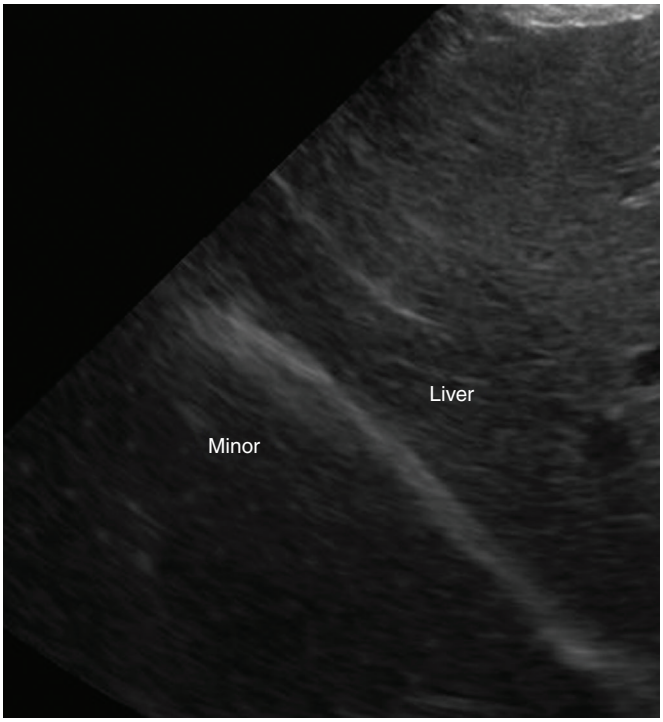

FIGURE 2.12 Mirror image artifact. A portion of the liver is duplicated due to an indirect return of the sound beam to the transducer, and liver tissue is displayed deep to the true liver margin.

air sacs and can result in both the liver and the liver's reflection being displayed.

Reverberation artifacts (Figures 2.13 and 2.14) occur when the sound beam hits a strong reflector. If there is incomplete contact at the skin and gas lies between the transducer and the patient, reverberation artifact will be observed, seen as recurrent horizontal lines through the image with uniform spacing and caused by the beam repeatedly bouncing between the transducer and reflector. Small gas bubbles present within, and trapping small volumes of fluid causes ring-down artifact, which occurs because of constant reverberation of the sound beam between the bubbles, and the constant return of sound to the transducer. Ring-down artifact is seen as a thin ladder-like artifact and is distinguished from comet tail artifact as the artifact extends to the depths of the image and does not taper. Comet tail artifact is a specific form of reverberation artifact that occurs when the sound beam meets highly reflective structures in close proximity and bounces between them. It is most frequently seen with crystalline structures such as pieces of grit within the GI tract or pieces of eggshell retained within the oviduct. Comet tails are distinguished from ring down by their tapering shape.

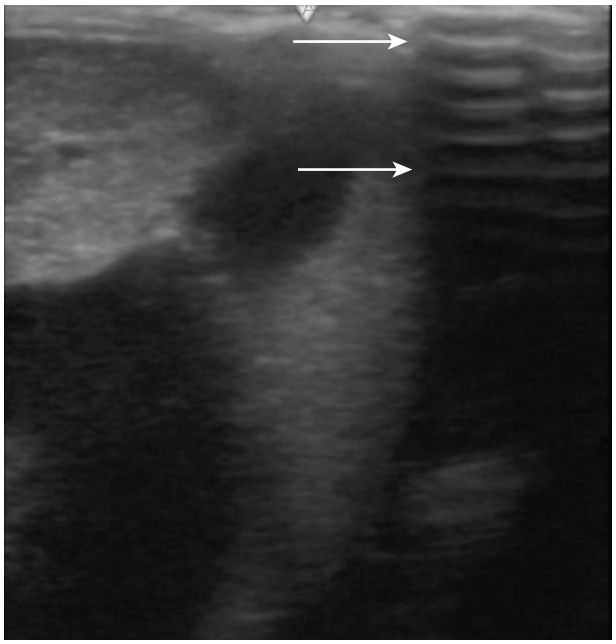

FIGURE 2.13 Reverberation artifact due to poor contact between the transducer and patient's skin is shown, highlighted by the two arrows. The sound bounces between the transducer and air trapped between the transducer and patient resulting in bright horizontal lines at regular intervals being displayed as part of the image.

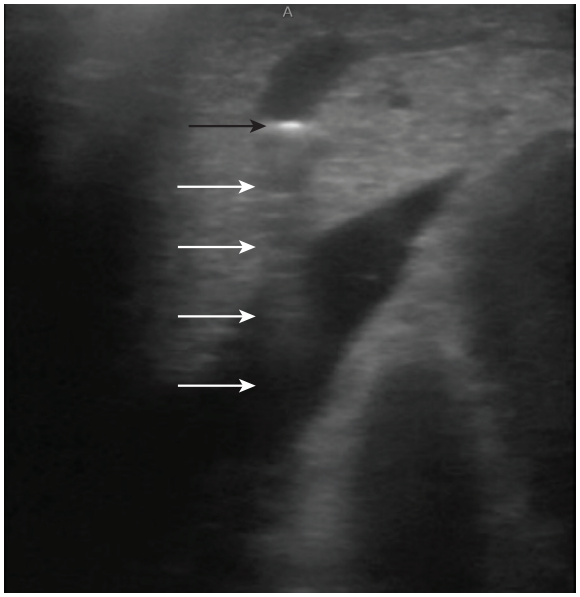

FIGURE 2.14 Ring-down artifact is a form of reverberation artifact and in this case is due to intravascular gas bubbles *(black arrow)*. The artifact occurs because of the sound beam bouncing between the reflectors (gas bubbles) with a constant release of sound back to the transducer.

INTRODUCTION TO COMPUTED TOMOGRAPHY

CT was first developed in the late 1960s and the first images of a brain in vivo acquired in 1971. CT became more widely available in human medicine around 1980 and really started to grow in veterinary medicine in the late 1990s. Slip ring technology was introduced in 1990 allowing continuous gantry rotation. Helical scanning with multirow CT scanners followed with greatly reduced scan time and improved spatial resolution. The first 16-row scanners were available in 2002, 64-row scanners in 2004, and 320-row detector scanners in 2010.[36] These CT scanners were all developed based on the use of a traditional fan-shaped x-ray beam and a table that moves through a gantry. For the purposes of this chapter, this technology is referred to as "fan beam."

Cone beam CT (CBCT) was originally developed in 1996 for dental and extremity imaging applications. In this technology, the data are acquired as a volume or stack rather than image by image by utilizing a cone beam–shaped x-ray beam. Volume acquisition means a large area can be covered with fewer rotations of the gantry, and multiple stacks of data can be acquired and merged together to cover an entire area of interest. Data are reconstructed by the system to provide a series of images. There is very high spatial resolution possible with these systems with excellent imaging of the bone and gas-filled structures, but the quality of soft tissue imaging is diminished compared to fan beam CT due to a relative increase in scatter radiation.[37] Recently, in the veterinary medical market, an offshoot technology has been developed from CBCT technology. Bone and respiratory tract definition is excellent on these scanners and CBCT developers continue to make efforts to improve soft tissue imaging capabilities. CBCT soft tissue capabilities lag behind fan beam image quality in general and are very scanner- and software-dependent. A basic comparison of traditional fan beam and CBCT scanners is provided in Table 2.1 and is summarized from publicly available marketing data.

CT permits superior evaluation of internal structures compared to radiography by removing superimposition of structures and permitting distinction between fluid and soft tissues via differences in attenuation.[38] CT may be preferable to ultrasound in some patients that lack adequate acoustic windows. Despite the improvement over radiography, evaluation of soft tissues on survey CT remains limited and can be greatly

TABLE 2.1

Basic Comparison Between Cone Beam Computed Tomography and Traditional Fan Beam Computed Tomography

	CBCT	Fan Beam CT
Power requirements	Standard single-phase 240 V	Three-phase 480 V
Dedicated lead lined room	No	Yes
Footprint size of scanner	Small	Large
Table weight limits (patient)	204 kg	136 kg older scanners; 204 kg is now standard
Gantry functional size	50 cm	Up to 90 cm megabore; 50–60 cm is standard
Maximum display field of view	32 cm	Up to 60 cm megabore; 40–50 cm in standard scanners
Maximum resolution	Isotropic 0.09 mm	8 rows or less anisotropic 1 mm 16+ row scanners isotropic 0.6 mm High-resolution CT (Siemens) isotropic 0.25 mm**
Relative scan time	Short for one stack. Long when multiple stacks needed.	Generally shorter than HDVI for a whole-body study.
Visualization of soft tissues	Generally poorer than fan beam CT due to more scatter, but varies greatly by vendor. Improves with IV iodinated contrast medium administration.	Generally better than HVDI but still limited. Improves with IV iodinated contrast medium administration.
Visualization of dense structures (bone, teeth)	Excellent. Better than fan beam (better resolution).	Excellent
Visualization of air-filled structures	Excellent. May be better than fan beam (better resolution).	Excellent

CBCT, Cone beam computed tomography; *CT*, computed tomography; *HDVI*, high-definition volume imaging; *IV*, intravenous.
**The high resolution package for Siemens to achieve this slice thickness is not automatically included on older Siemens CT machines and has to be purchased as specific additional software. So trying to make the point its available but may require an additional (not cheap) purchase.

improved via the use of IV nonionic iodinated contrast medium administered into the cutaneous ulnar or medial metatarsal veins. A study evaluating renal enhancement post-IV contrast in pigeons using a traditional fan beam CT scanner determined that a dose of 0.5 mL/kg of 370 mgI/mL contrast medium provided adequate soft tissue opacification.[39] However, few other studies have been performed to determine the optimal dose of contrast medium or optimal timing of the post-contrast scan specific to birds. Extrapolating from other veterinary species, a minimal dose of 400 mgI/kg and a preferable dose of 600 to 800 mgI/kg contrast medium is suggested so that enhancement is adequate on post-IV contrast images. That dose is simplified to 2 mL/kg when using commercially available formulations that range from 240 mgI/mL to 370 mgI/mL. Recent conference proceedings have suggested a total volume of up to 4 mL of contrast medium, injected continuously over a 2-minute period, which effectively increases the duration of circulating contrast medium at a diagnostic concentration. No immediate adverse effects have been described in medium-sized birds, although toxicologic studies at this dosage have yet to be performed.[40] This technique requires either the use of an infusion pump or that personnel remain within the CT scanner room or in close proximity to the CT scanner during scanning. Contrast medium should be injected directly into the IV catheter without dilution. Renal clearance of iodinated contrast medium is rapid in birds, and post-IV contrast scan acquisition should be started at the end of or immediately on completion of the injection without delay. Examples of optimized post-contrast images are shown using fan beam technology CT in Figure 2.15.

Contrast medium injected into the metatarsal vein will pass first through the ipsilateral renal portal system, and asymmetrical renal and ureteral opacification will be seen, with earlier excretion compared to injections given via the ulnar vein (Figure 2.16).

The contrast enhancement seen on CBCT technology images is often relatively less than seen on fan beam technology images due to scatter, longer scan times using CBCT, and rapid excretion of contrast medium that occurs in birds (Figure 2.17).

Severe reactions attributed to iodinated contrast medium are unusual in birds and where possible it is suggested that nonionic formulations should be used, as these tend to cause fewer reactions across species. Cardiovascular fluctuations or abnormalities may be seen immediately following contrast medium administration as well as respiratory depression/apnea and are usually transient. Sudden death has been reported in a small number of sick birds undergoing CT with a temporal association to contrast medium administration and tends to be seen more in smaller patients.[41] The exact cause of death (anesthesia-related, contrast media–related, or due to preexisting disease) is unfortunately often not determined.

Positioning for Computed Tomography

The direction of scan, head or tail first, does not tend to matter in avian species but should be consistent to permit easy linking of serial studies on the workstation for side-by-side comparison. Both sedation and general anesthesia are viable options for patients undergoing fan beam CT.[42] Patients should be placed in sternal recumbency. Dorsal and lateral recumbency should be avoided as it will reduce air sac inflation and relative organ position (Figure 2.3), which will affect interpretation of the air sacs themselves and make distinction and assessment of other coelomic structures more challenging. Wings can be positioned folded against the body wall or used to help support

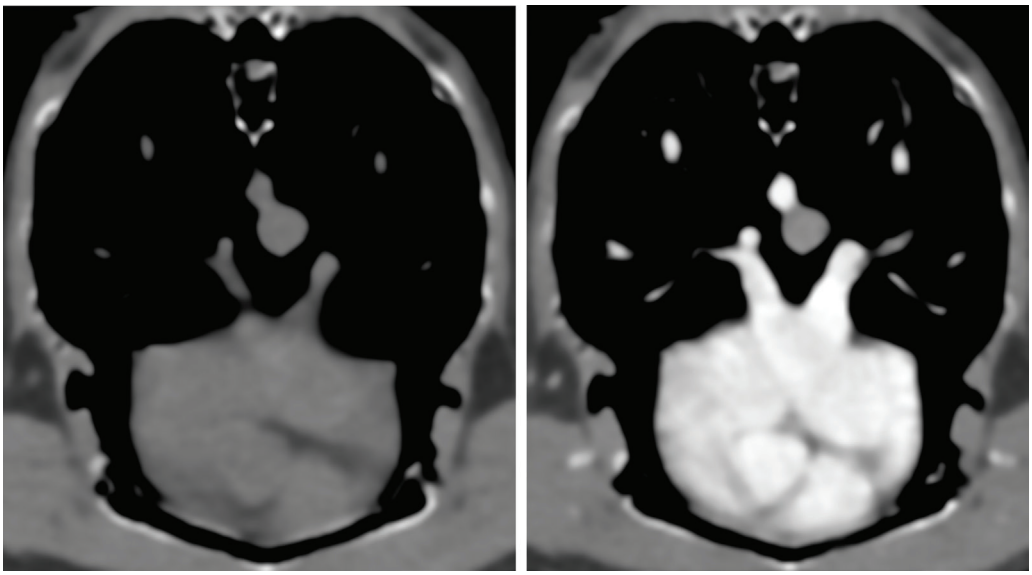

FIGURE 2.15 Pre- and post-IV contrast images acquired using a fan beam CT scanner with a soft tissue or medium-frequency reconstruction algorithm and timed to optimize the post-contrast series. Images are displayed using appropriate soft tissue window width and window level (WW 40, WL 350). *CT*, Computed tomography; *IV*, intravenous.

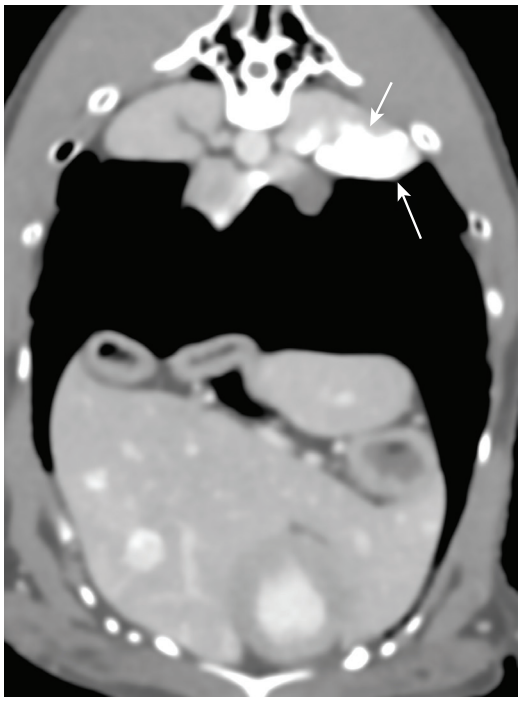

FIGURE 2.16 In this post-IV contrast medium image, the asymmetry seen in the kidneys with increased accumulation in the left kidney (*arrows*, shown on the right side of the image) is due to injection using the ipsilateral metatarsal vein.

the body in a sternal position by placing over the edges of the trough or on top of foam wedges (Figure 2.18).

The head is positioned straight with the beak parallel to the gantry table using radiolucent aids. Localizers are used to define the field of view and data that will be displayed on the final images. Localizers should be set as close to the body as possible to optimize the x- and y-axis resolution without cropping any of the soft tissues (Figure 2.19).

Localizer position should be checked both left to right and dorsal to ventral relative to the patient with the goal of left to right symmetrical positioning. The smaller the field of view, the higher the resolution. Slice thickness selection optimizes the z-axis, and for medium-sized avian patients, it should be no more than 1.5 mm, preferably less to optimize resolution. All three axes (x, y, z) must be optimized for high-resolution native images to be produced (Figures 2.20 and 2.21).

If wing joint or osseous pathology is present or suspected, a standard study is encouraged first with the wings folded against the body as this allows evaluation of wing and pectoral girdle symmetry. This can then be followed by a dedicated wing scan. For the dedicated wing scan, the patient is moved so their body lies perpendicular to the gantry table and the wing is positioned extended along the z-axis/parallel to both the long axis of the gantry table and the table surface to produce a high-resolution study of the wing. As with all studies, localizers and slice thickness should be adjusted to optimize the x, y, and z axes.

Multiplanar reconstructions (MPRs) can be performed post-processing from high-resolution images. These are very useful for localizing challenging lesions, evaluating joints, and can be used to correct unavoidable suboptimal positioning. When suboptimal positioning is present, MPRs can be very time-consuming and laborious to achieve, taking much longer than the time needed initially to correct positioning of the patient. MPRs made from lower resolution images may demonstrate pixilation, blurring, and stepping depending on parameters that were used to acquire the native images, and these artifacts may render them unhelpful (Figure 2.22).

Measurements made from MPRs produced from high-resolution isotropic data are accurate but MPR image measurements lose accuracy when low-resolution or anisotropic

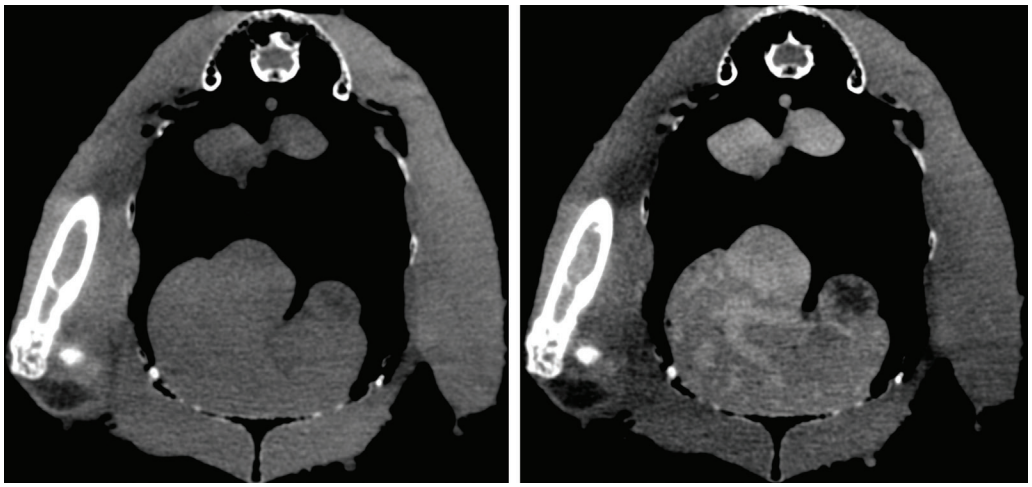

FIGURE 2.17 Examples of CBCT images acquired pre-IV contrast (left) and post-IV contrast (right) and optimized for evaluation. *CBCT*, Cone beam computed tomography; *IV*, intravenous.

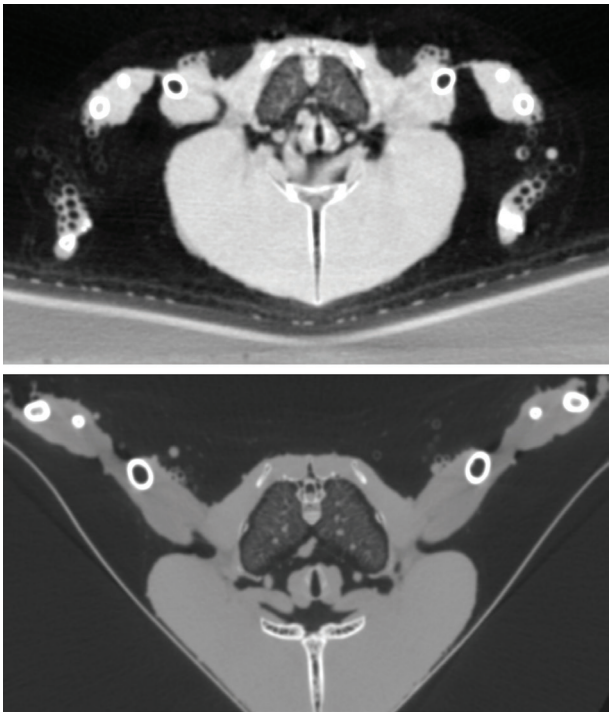

FIGURE 2.18 Transverse CT images with the wings alongside the body (top image) and suspended over the edge of a radiolucent trough (bottom image) to aid positioning. *CT*, Computed tomography.

data are used or if curved MPRs are needed to adjust for suboptimal positioning.

Advantages of Computed Tomography

The main advantage of CT is removal of superimposition of structures compared to radiography which improves conspicuity of structures that may not otherwise be accurately and thoroughly assessed.[43] Beyond that, CT can provide high-resolution studies with excellent evaluation of osseous and air-filled structures/respiratory tract with better evaluation of soft tissues than possible on radiographs, including staging of infectious or neoplastic processes.[43] CT is a rapid advanced imaging modality and scan times are very much faster than MRI; thus, anesthesia time can be kept very short. Any anesthesia or monitoring equipment can be used around CT scanners although monitoring equipment should be kept outside of the scan region. CT supersedes MRI when acute intracranial hemorrhage less than 24 hours old is a concern, for example, in acute head trauma. Acute hemorrhage is indistinguishable from other fluids on MRI but is slightly hyperattenuating to soft tissues on CT until the chemical composition alters around 24 hours post-leakage. CT images can be enlarged, WW and WL adjusted, and data reconstructed in multiple planes to aid interpretation and help plan approaches for surgery or tissue sampling. Images can be displayed as 3D images (3D slab, surface rending, and volumetric reconstructions) which aid with client education and provide an overview of the issues present for people less experienced with 2D CT images. Lastly, CT data can be used for 3D printing under certain circumstances, which may allow complex orthopedic procedures to be tested and prosthetic design and construction (see Chapters 31 and 37).

Disadvantages of Computed Tomography

The quality of soft tissue studies varies depending on the CT technology being used, patient size versus study resolution, and the availability of a post-IV contrast study. Fan beam technology scanners require dedicated rooms and electrical upgrades. The relatively short lifespan of many veterinary species compared to humans means that concerns regarding radiation exposure are generally low; however, as CT use increases, the effects of repeated radiation exposure may become evident and more applicable. CT studies contain a wealth of data, and some understanding and experience are needed to optimize the images displayed post-processing for the most accurate evaluation as well as understanding of CT anatomy. Publications are available that help correlate CT anatomy to gross anatomy[44] but not all avian species variations have been documented to date. High-resolution studies will generate many images, which require high-speed Internet for timely transfer out of the console to the PACS and beyond.

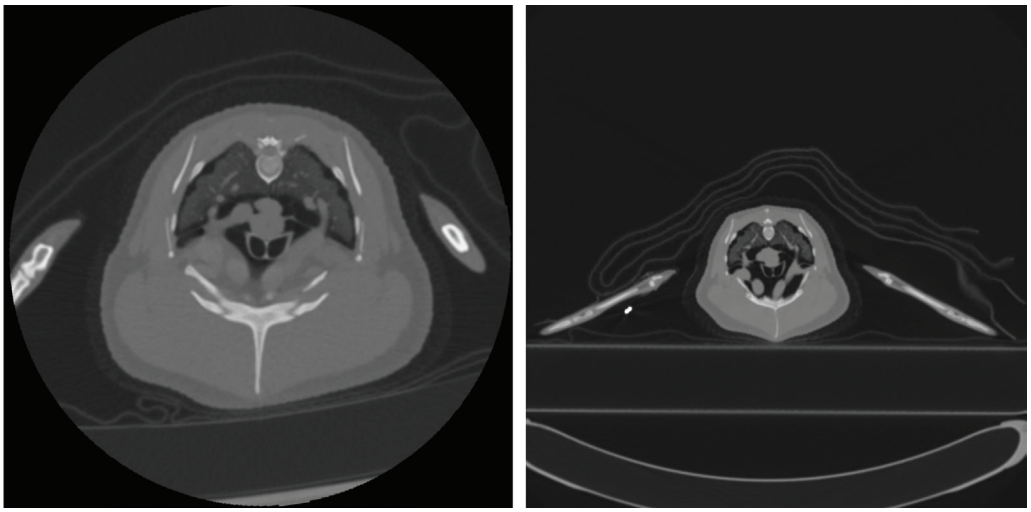

FIGURE 2.19 On the left image, the display field of view localizers (shown by the *gray circular margin*) have been set close to the body wall without cropping soft tissues. This will permit higher resolution images than the setup in the right image where a much larger field of view has been selected. The same total number of pixels is used for both images, so with fewer pixels covering the anatomy on the right, resolution will be lower than on the left when the image is zoomed or reconstructed in alternative planes.

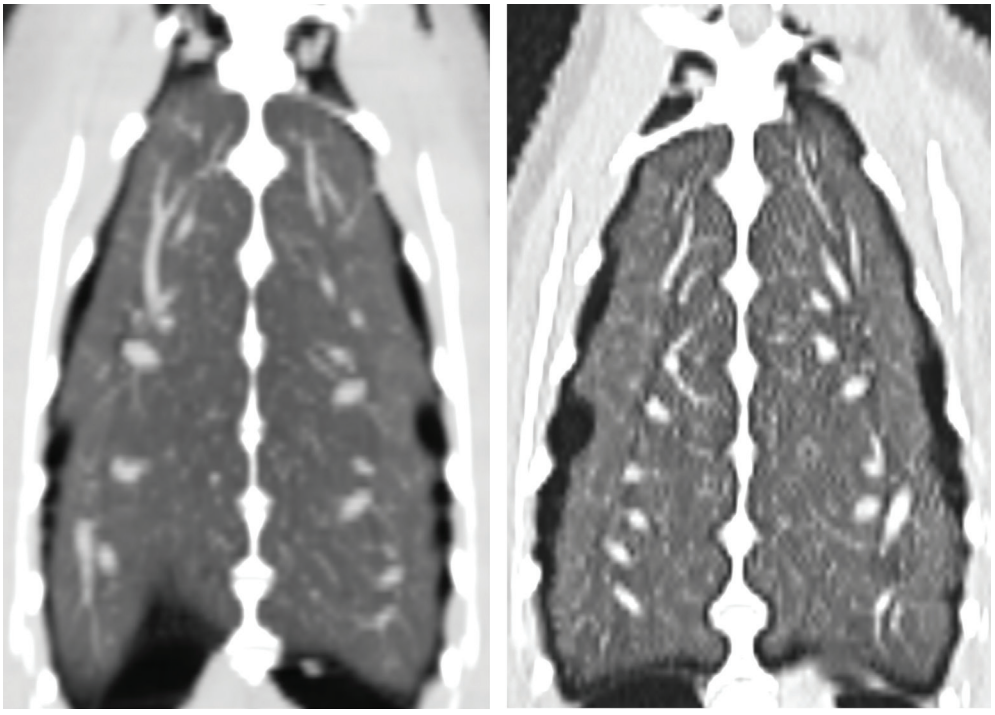

FIGURE 2.20 Dorsal reconstructions made post-processing from the same penguin as in Figure 2.19, with images acquired at 0.75 mm on the left and 2 mm on the right. The vasculature and lung margins have a pixelated or stepped appearance on the right with smoother margins seen on the left.

Direct Clinical Applications of Computed Tomography

- Imaging of axial and appendicular skeletal structures, particularly valuable for imaging of the head[45,46]
- Imaging of the respiratory tract[44,47]
- Imaging of the structures of the coelomic cavities (this may be limited on noncontrast CT but is improved with IV or intraosseus (IO) contrast medium administration)[44]
- Excretory CT urograms
- Angiography and evaluation for atherosclerosis[48]

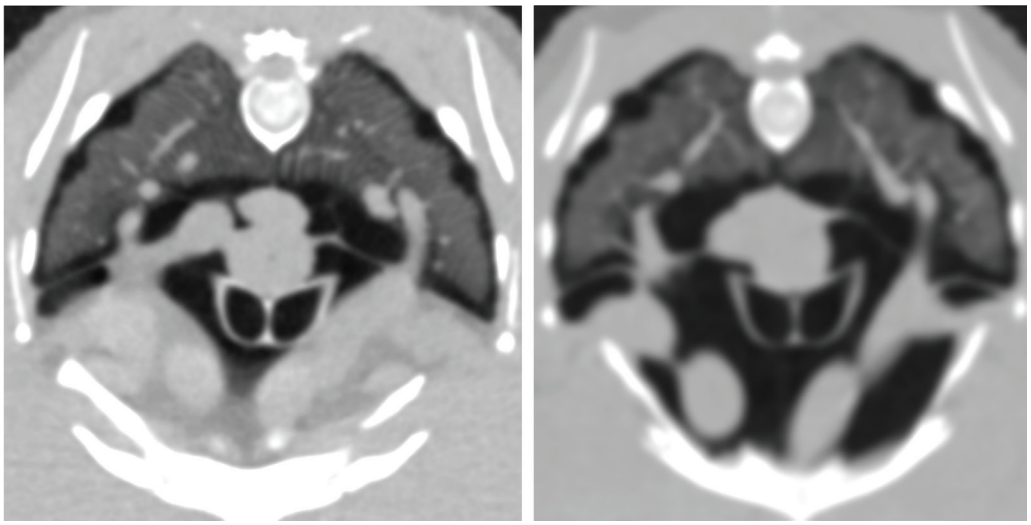

FIGURE 2.21 Transverse images from Figure 2.19. The left image demonstrates better resolution once zoomed in for evaluation because all three planes were optimized during setup. The image on the right from the lower resolution image in Figure 2.19 is blurred in comparison when zoomed to the same size.

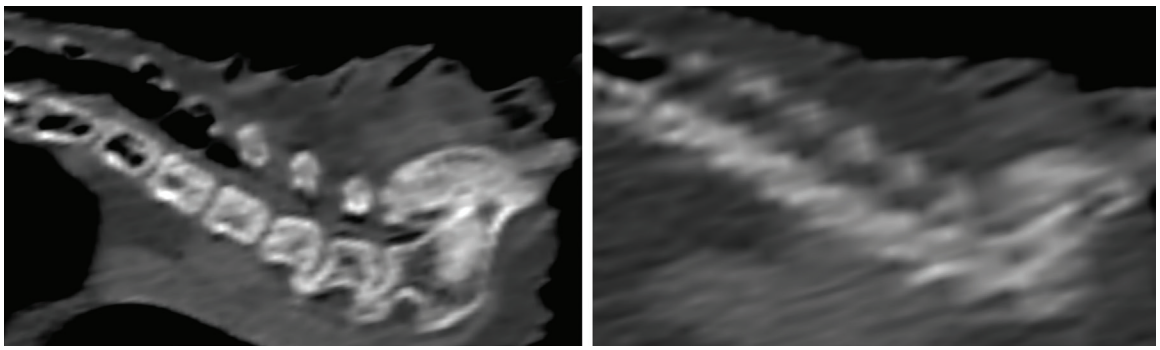

FIGURE 2.22 Sagittal reconstruction performed to evaluate the spine with adequate resolution (left image) and inadequate resolution (right image) to be helpful in the interpretation. The resolution of multiplanar reconstructions is limited by the original resolution acquired.

- Identification of intracranial hemorrhage in acute trauma <24 hours
- Guidance for tissue sampling, surgery, and radiation therapy planning

Interpreting Computed Tomography Images

Initial selection of the appropriate reconstruction algorithm and slice thickness for processing of data into images is key for subsequent optimization and accurate interpretation. Fan beam technology images are produced using operator-selected reconstruction algorithms. The names of the reconstructions vary by manufacturer, and in general, soft tissue and bone reconstruction algorithms (medium and high frequency) pre-IV contrast and soft tissue (medium frequency) post-IV contrast are needed for thorough evaluation. As most companion birds are very small in size, thin slice thickness is necessary for optimized resolution relative to body size, and sub–1 mm images are a must. Many fan beam CT scanners can provide 0.5 to 0.625 mm slice thickness images as standard and thinner images with additional high-resolution software when available. CBCT will reconstruct images in the range of 0.15 to 0.3 mm as standard. It should be noted that when using fan beam CT in helical mode, fan beam high-resolution software, or CBCT, the final thin slice images are a mathematically derived predicted representation of what anatomy looks like in each image slice based on the larger data volume, rather than an absolutely true depiction of the anatomy present. Once the reconstructed images are available, they are windowed and leveled by the interpreter to optimize tissue evaluation. Window and level can be repeatedly adjusted, but the algorithm used to create the images cannot be changed once images are created. Bone reconstruction algorithm images are optimized for evaluation of both highly attenuating structures, such as bone, surgical implants, or ingested mineral/metal, and high-contrast, air-filled respiratory tract, and other air/gas-filled structures. Appropriate initial algorithm selection and subsequent window and level adjustment are critical for accurate interpretation of the images. For example, soft tissue or medium-frequency reconstruction algorithms have a softening effect that is used to enhance small differences in attenuation between different

soft tissues. Even if windowed and leveled appropriately for bone, the softening algorithm causes blurring of bone, artificial thickening of cortices, and poor conspicuity of trabecular bone pattern. This means that subtle cortical and trabecular bone lesions can be missed if this reconstruction is used for osseous evaluation. Likewise, a bone reconstruction is a high-frequency reconstruction algorithm that sharpens margins resulting in a large amount of noise when windowed for soft tissue, and soft tissue lesions may be obscured (Figure 2.23).

Hounsfield units (HU) are a quantitative measurement used in fan beam technology and are calibrated relative to water (0 HU) and air (−1000 HU). This means that quantitative HU measurements of tissue can be made and are accurate across time and between scanners. It also means that preset WW and WLs can be created. A general guide for WW and WL for images created via fan beam technology is:

- Soft tissue reconstruction algorithm (pre- and post-IV contrast): WL 40, WW 350
- Bone reconstruction algorithm for bone: WL 300, WW 1500
- Bone reconstruction algorithm for respiratory tract: WL −500, WW 1400

CBCT technology treats the raw data slightly differently, and while there often are operator-selectable options for image processing, usually only a single pre- and post-IV contrast series is reconstructed that can be windowed and leveled to optimize the different tissues. CBCT technology has more latitude within the images than fan beam technology, and while attenuation follows the same trends as fan beam and can be qualitatively compared within a study, absolute values do

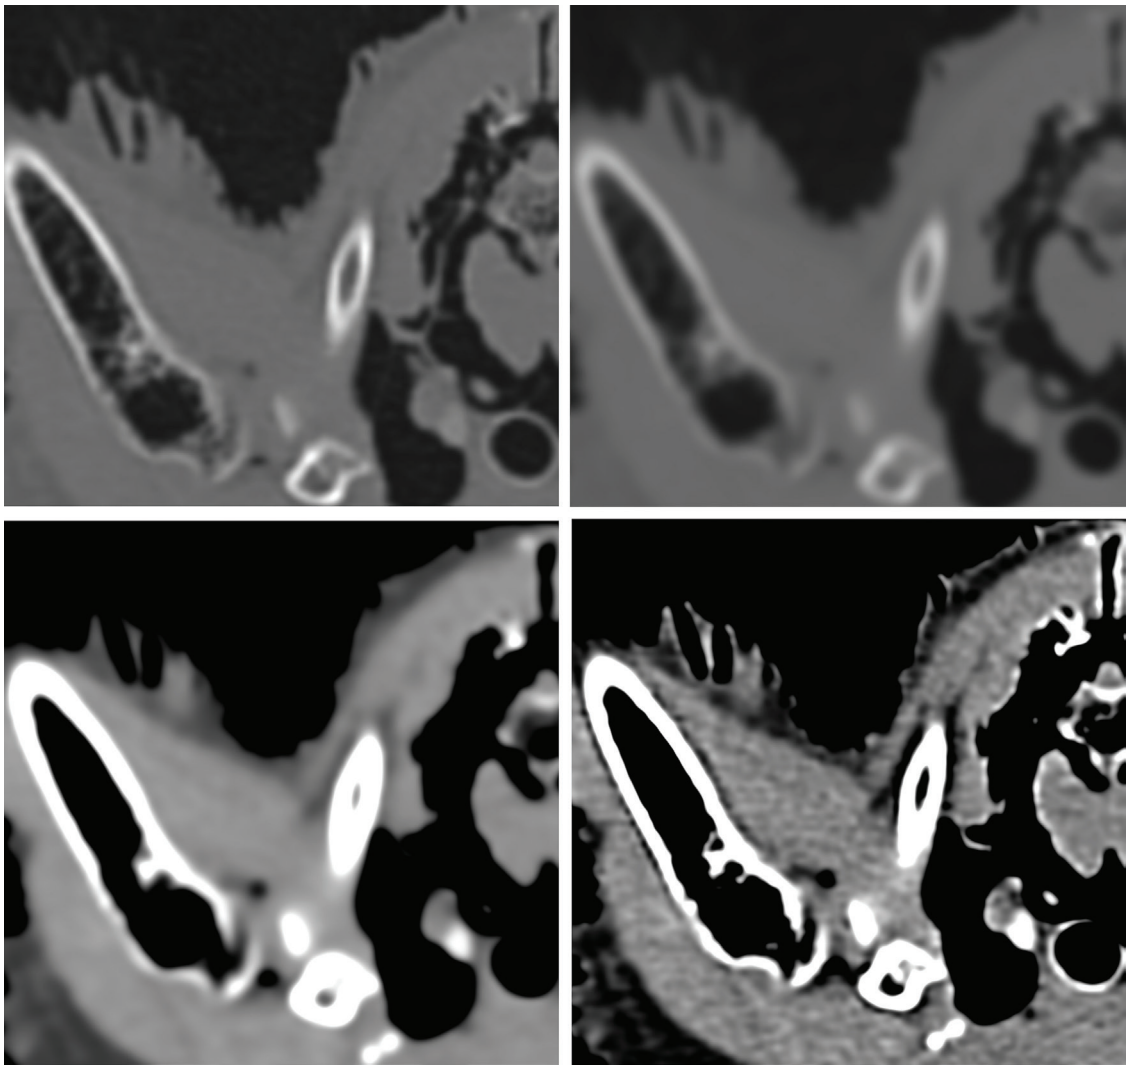

FIGURE 2.23 Fan beam CT technology images. The top row shows images windowed and leveled for assessment of bone. Top left is a bone reconstruction algorithm and shows superior detail of the bone compared to top right which is a soft tissue reconstruction algorithm. On the bottom row, the left image is a soft tissue reconstruction algorithm appropriately windowed and leveled for soft tissue evaluation. Bottom right is the same image acquired using a bone reconstruction algorithm, then windowed and leveled for soft tissue. The soft tissue detail is superior on the left with the right image demonstrating noise and mottling through the soft tissues. *CT,* Computed tomography.

not carry across different studies or different scanners. CBCT images demonstrate less soft tissue distinction and less post-contrast enhancement when compared to fan beam technology (Figure 2.17); however, optimized bone and respiratory tract images are quite similar in appearance between technologies with superior spatial resolution available on CBCT.

Internal anatomy varies among species of birds; however, several excellent texts that correlate anatomical and CT anatomy of specific species are available of the structures of the coelomic cavities,[41] head,[45,46] and respiratory tract,[47] and can be used as helpful references even if not specific to the species being evaluated.

Selected Computed Tomography Artifacts

There are many CT artifacts that can occur and the origin may be physics-based, patient-based, or scanner-based artifacts. Very detailed texts that explain the artifacts according to each origin are available.[49] When recognizing and evaluating artifacts, most clinicians and radiologists see the artifact on the final images and then work backward simply with the desire to resolve the issue. Artifacts that tend to have the same or similar final appearance also tend to have the same resolution regardless of the origin, and as such, artifacts are simply grouped here according to their appearance on the final image. The most frequently observed artifacts are image graininess due to noise (physics, scanner) or photon starvation (physics); streaks due to beam hardening (physics) or metal (patient), undersampling (physics), out-of-field anatomy/incomplete projections (patient), or windmill artifact (scanner, physics); blurriness due to partial volume averaging or algorithm selection (physics); ring artifacts (scanner); and malpositioned images due to patient motion (patient) or a sticky gantry/table (scanner).

A grainy image on CT occurs when inadequate photons reach the image detector after passing through the patient. There are many causes for this, including inadequate technique, allowing system electronic noise to affect the data generated, patient anatomy/size, heating, positioning, or monitoring equipment attenuating the beam. The artifact can also be created when fan beam bone reconstruction algorithm images are inappropriately windowed for soft tissue. In the case of inadequate photons, the artifact significantly degrades image quality (Figure 2.24). An example where this frequently occurs is when a fan beam CT scanner is set to acquire images at a thick slice thickness and then retrospectively thin slices are made. The technique the scanner automatically selected for the thicker images is now inadequate for the thinner slice images and noise occurs. This artifact can be corrected by increasing the technique (kV and/or mA) and by ensuring that the smallest end scan image thickness that will be required is the slice thickness that is natively acquired using an appropriate kV and mA. In the case of fan beam images where graininess is noted on bone reconstruction images but not soft tissue reconstruction images, appropriate windowing and leveling will resolve the appearance.

The blurring of structure margins due to partial volume averaging occurs in both technologies and it occurs in two ways. The first is when tissues of different attenuation both fall into the same voxel resulting in an averaging of the attenuation (Figure 2.23). This may affect conspicuity particularly of margins of lesions or give normal anatomy an abnormal appearance. The second is failure to distinguish margins of closely located structures, for example, distinguishing vasculature on angiography or distinguishing between liver lobe margins. In both cases, blurring of structure margins is noted and will worsen if MPRs are attempted. Partial volume averaging is removed by decreasing the slice thickness to an appropriate size for patient size.

Stripes may be seen on images due to several causes that include beam hardening, undersampling, out-of-field anatomy

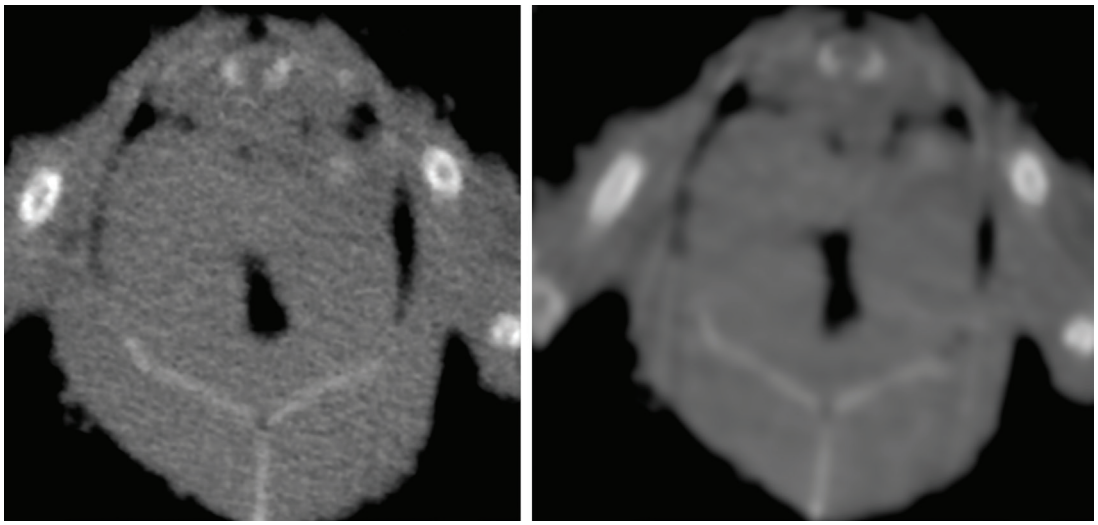

FIGURE 2.24 CBCT images of the femur. The image on the left demonstrates noise resulting in a mottled and grainy appearance to the image compared to the right image. Partial volume averaging is also demonstrated in this image with the image on the left acquired at 0.3 mm slice thickness and on the right at 0.6 mm slice thickness. The reduced distinction between the femoral cortex and medullary cavity is due to inclusion of more tissues in each voxel. *CBCT,* Cone beam computed tomography.

(incomplete projections), and windmill artifacts. Frustratingly, all artifacts can occur simultaneously and may be seen in some form regardless of scanner technology. Beam hardening occurs when a very attenuating structure prevents passage of adequate x-rays to image the adjacent tissue. This can occur due to patient anatomy, internal pathology such as metal ingestion, or when metal-based equipment remains adjacent to the patient in the gantry during scanning or large sandbags are used for positioning. In fan beam technology, the effect will only be observed in the x and y planes at the level of the origin and will not extend through the z-axis beyond the margins of the object causing the artifact. In CBCT, the cone shape of the beam means the effects of the artifact may be seen extending through the volume in the x-, y-, and z-axes depending on where within the volume the object lies. The amount of metal present and its location will determine how much effect it has on the image quality (Figure 2.25). The solution for beam hardening is to remove the offending object from the scan area inside the gantry if at all possible. When the artifact is due to internal material that cannot be removed (shrapnel, surgical implants), increasing the technique (kV and/or mA) and/or increasing the slice thickness slightly will diminish the effect of beam hardening on image quality. In smaller patients, rescanning the patient after repositioning by 90 degrees to lay perpendicular to the gantry table may be feasible and can help produce diagnostic quality images through anatomy most affected by beam hardening. Daily scanner calibration is needed in scanners with built-in filtration hardware or software to help combat beam hardening. This enables them to work to the best of their ability and it is crucial that nothing is in the gantry during these calibration events for the software to work appropriately.

Undersampling artifacts have a slightly different appearance to beam hardening, creating streaks that slightly diverge and widen as they course from their origin to the periphery.

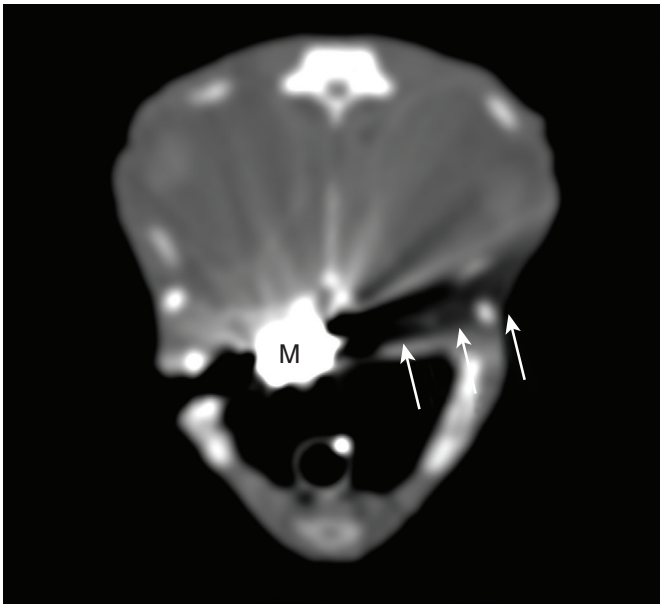

FIGURE 2.25 Beam hardening artifact (*arrows*) due to metal (M) positioned within the oral cavity. The metal greatly attenuates the beam resulting in streaks across the images.

These artifacts occur when the beam angle is nonperpendicular and interacts with highly attenuating structures and at margins between structures with significantly different attenuations. Concurrent partial volume averaging can also occur due to the oblique photon course in larger patients (demonstrated by the widening of the artifact toward the periphery). Figure 2.26 demonstrates some examples of undersampling. These artifacts occur in both technologies but are seen most frequently in CBCT and are commonly referred to as cone beam artifact. Undersampling artifacts are, however, also seen in fan beam technology when very thick slice thicknesses are acquired or if the scan field of view is too small and a portion of the patient is outside of designated scan region. In the latter case, the artifact is more correctly referred to as incomplete projection or out-of-field artifact. Incomplete projection is only an issue in fan beam technology as CBCT scanners automatically scan everything within the gantry. In fan beam technology, both the scan region and the display field of view (final image) can be adjusted. Treating undersampling artifacts in the same way as beam hardening and increasing technique (kV or mA) to increase the number of photons reaching the image detector will improve the appearance if it is significant enough to affect image quality. Ensuring all of the patient is inside the scan field of view will also reduce streaking in cases where anatomy is outside the scan field of view on fan beam CT scanners.

Windmill artifact can be seen on both technologies. It occurs during fan beam technology helical scanning when high pitch results in several detectors intersecting the plane of reconstruction (slice thickness). Equally distanced bright streaks are seen diverging out toward the periphery from focal high-density structures such as the ribs and the streaks "rotate" as the image stack is scrolled through. This is unlikely to occur in many avian CT studies given the small size of the majority of patients and use of low-pitch values and can be mitigated by using a noninteger pitch, for example, selecting a pitch of 3.5 rather than 4 on a four-row CT scanner.[46] Newer helical multislice CT scanners use z-filter helical interpolators to reduce the artifact. A similar image artifact is seen on CBCT around long bones that lie parallel to the z-axis (Figure 2.27).

Another form of beam hardening that was seen occasionally in older scanners is called cupping artifact. This is best demonstrated by a solid cylindrical phantom. The center of the cylinder attenuates the beam more than the edges, and so the center is assigned lower Hounsfield units and a darker shade of gray. It is very unusual to see cupping on images from modern scanners as they have a beam hardening software built in to correct for this. In addition, avian patients' pneumatization of the bones of the head, where the artifact was most typically observed, causes far less attenuation of the beam than in other species. This artifact is now more a testing tool to ensure a beam hardening software is working appropriately using phantoms, than a concern in clinical studies.

A common scanner-based artifact that occurs is ring artifact. This is observed as eccentric circles that partially obscure anatomy with the center of the circle set at the epicenter of the scanner. This artifact occurs due to image detector calibration issues or inhomogeneous image detector sensitivity (Figure 2.28) and can occur in both fan beam and CBCT technologies. Calibration errors in both CBCT and fan beam technology can usually be reduced or

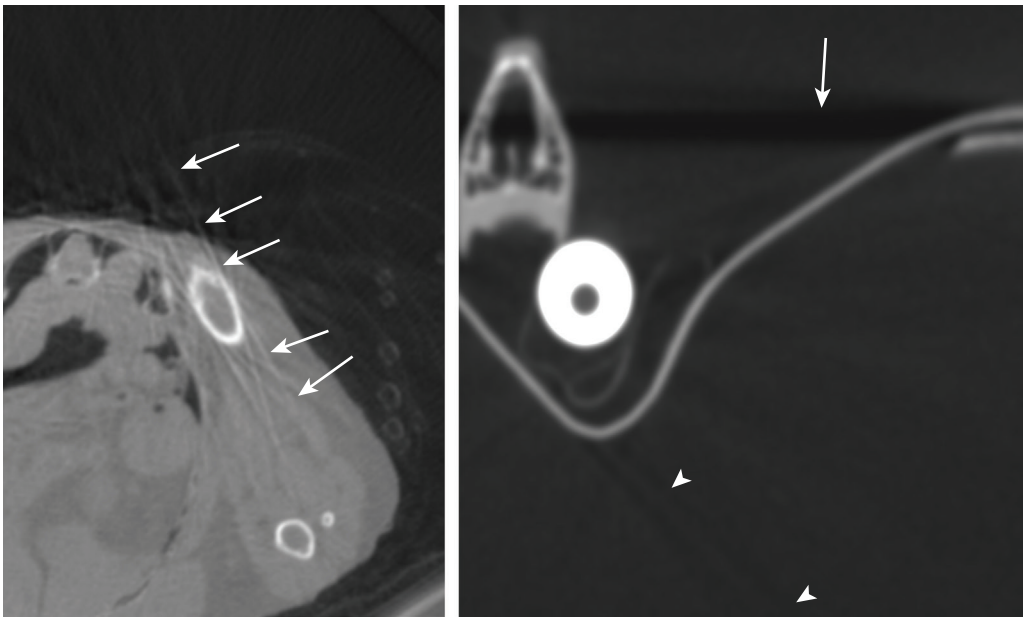

FIGURE 2.26 Examples of streak artifacts (*arrows*) seen on CBCT images due to undersampling. On the left, streaks extend out from the femoral cortices. On the right, streaks are seen coursing horizontally due to the extended edges of the trough and obliquely due to the inner margins of the trough. *CBCT*, Cone beam computed tomography.

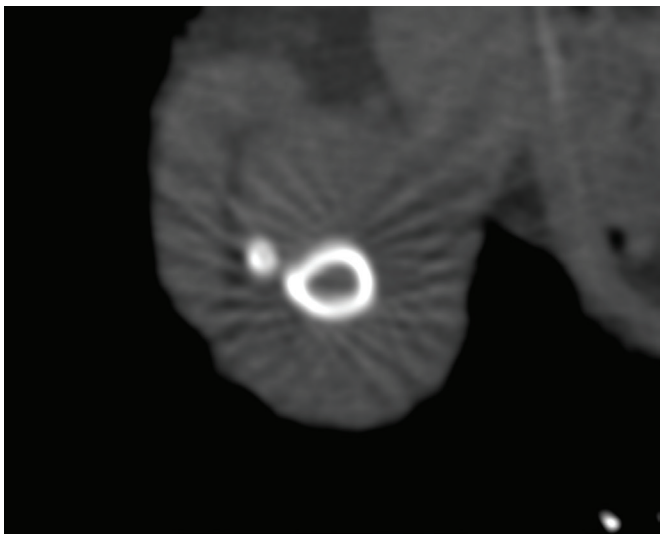

FIGURE 2.27 Windmill-like artifact shown here on a CBCT image as rotating striations or stripes extending outward from a high-density structure. *CBCT*, Cone beam computed tomography.

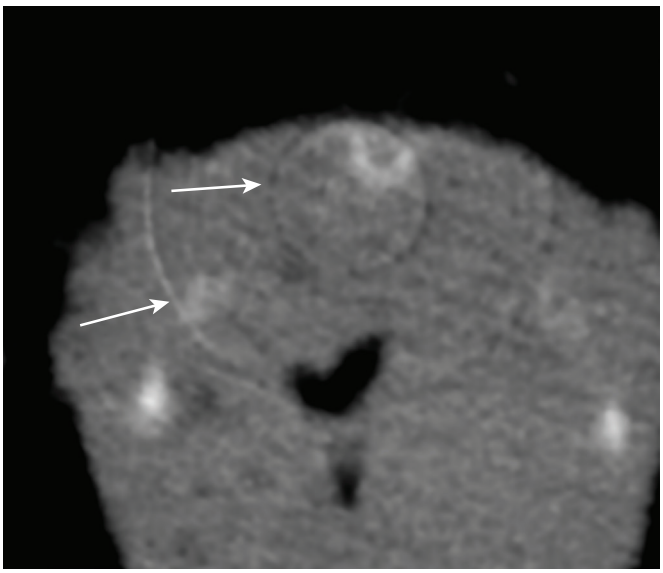

FIGURE 2.28 Ring artifact or detector calibration artifact is seen as *circles* through the image(s) and is highlighted by *arrows*.

prevented by performing the complete daily warmup and calibration test indicated on the individual scanner and by ensuring nothing is present within the gantry while calibration tests take place. If the artifact persists despite calibration, detector(s) may require servicing or replacement.

Motion artifact can occur when the patient moves (breathing, twitching, or gross movements) or when debris gets caught in the CT scanner resulting in irregular or jolting movement of the gantry table (fan beam) or gantry (CBCT) during the scan. The higher the study resolution, the more effect a smaller amount of motion will have on the final image. The likelihood of motion also increases with longer scan times. Motion may be identified most commonly as streaks, varying attenuation, blurring, or duplication or malalignment of anatomy, as shown in Figure 2.29. Some motion, for example, cardiac, respiratory, or GI movement, is unavoidable while other motion is reduced by adequate restraint, sedation, or anesthesia during the study, by minimizing scan times (i.e., faster gantry rotation and/or more x-ray sources) and by ensuring the gantry and table runners are kept clean.

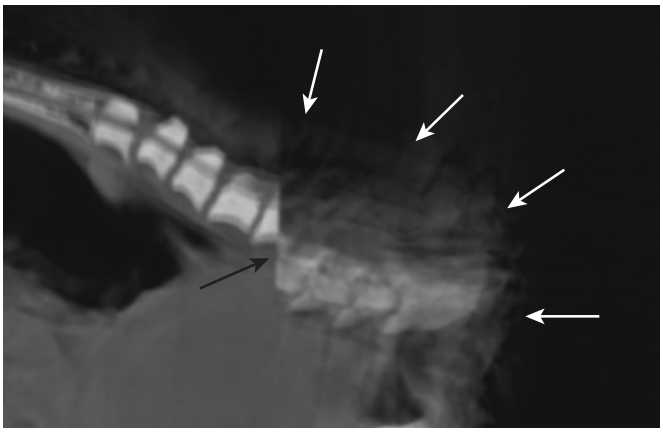

FIGURE 2.29 Motion artifact shown in a stack acquired on CBCT. There is a false step in the anatomy *(black arrow)* and blurring of the distal spine/tail *(white arrows)* because of motion occurring during scanning. *CBCT,* Cone beam computed tomography.

INTRODUCTION TO MAGNETIC RESONANCE IMAGING

MRI was first developed in the late 1930s but was not used for medical purposes until the late 1970s. In the last two decades, there has been increased accessibility and availability of MRI to veterinarians with the development of dedicated outpatient veterinary MRI imaging centers and installation of MRI units in veterinary specialty hospitals. There are several factors to consider when working with or considering installation of MRI scanners. All MRI scanners require a dedicated imaging room with shielding to limit radiofrequency (RF) interference, as well as very efficient air temperature control. Only certified MRI-safe equipment should enter the MRI scanner room including anesthesia equipment. Ferrous metal objects can become high-velocity projectiles once they enter the magnetic field, and nonferrous, non–MRI-certified equipment can affect the scan quality via interference. MRI scanners in clinical use are typically in the range of 0.15 to 3 Tesla (T). MRI scanners up to 1 T are considered low field and over 1 T high field. 1 T and higher MRI scanners have a closed design with a standard bore diameter of 60 cm. MRI scanners in the range 0.15 T to 0.6 T have an open design with a wider functional diameter of 70 cm. Open scanners are permanent magnets that have lower operating costs associated with them compared to closed magnets but may have a more limited selection of sequences. A developing consideration for high-field MRI scanners is that most are resistive or superconductive magnets, and many require helium as a coolant to function efficiently. Helium needs periodic replenishment and helium reserves in the United States are depleting, which may affect long-term availability and cost. MRI scanners with lower helium volumes and lower helium losses as well as helium-free scanners have been developed more recently.

MRI images are produced when protons in water are excited and the energy emitted (signal) is captured by a coil, data collected and converted into an image. Each sequence and each orientation/axis are acquired independently; thus, multiple scans are needed for a complete study contrary to image acquisition in CT. Avian patients have relatively less water/soft tissue compared to similarly sized mammals due to pneumatized bone and a large volume of air present within the respiratory tract. This causes a relatively diminished signal production compared to similarly sized mammals. Open low-field scanners have lower image quality due to poorer signal-to-noise ratio (SNR) when compared to closed high-field scanners using the same scan parameters. Veterinary-specific, low-field models have the benefit of coils that have been developed specifically for veterinary species. These tend to fit animals far better than coils designed for human body parts resulting in a relative improvement in SNR ratio and image quality compared to human coils used in the same system, but image quality will still be lower than a high-field scanner study.[50] In human shoulder studies that compared low- and high-field scanner images, small lesions evident on high-field MRI images that were confirmed at surgery and considered clinically significant were frequently not identified on low-field MRI images.[51] In veterinary-based studies, low-field scanners produced poorer image quality compared to high-field scanners, but images remained diagnostic provided scan time was increased.[52,53] However, it should be noted that those veterinary studies were performed on horse cadaver limbs where extended scan times were inconsequential. SNR ratio in MRI can be improved on both low- and high-field scanners at the expense of spatial resolution (increasing slice thickness and/or field of view) and scan time (increasing the number of excitations [NEX]). Lowering resolution runs the risk of missing pathology. Lengthening scan times increases the likelihood of motion artifacts and requires a longer duration of anesthesia.

Diagnostic MRI studies have been acquired in psittacine birds with chronic sinusitis using a high-field magnet. In that study, the time taken to acquire diagnostic images was not reported and the authors state that only enough sequences (rather than a complete study) were acquired to identify that pathology was present, and that three planes that are considered necessary for a complete study were not acquired.[54]

When metallic implants, identification microchips, ingested metallic material, or shrapnel are present within a patient, there will be susceptibility artifacts and artifacts associated with induced eddy currents that are evident on images. These will vary in their effect on image quality among sequences used and tend to be fewer and less severe when using low-field MRI compared to high-field MRI. MRI-safe metallic implants and equipment do not directly result in image artifacts but can heat within the MRI scanner and result in tissue damage. Nonsurgical metal such as shrapnel or ingested metal may be ferrous and susceptible to both migration and heating. Metal that has been present in tissues for at least 3 months tends to secure in place due to bone proliferation and fibrosis and is typically considered safe for MRI.[47] Rarely, superficial burns have been reported that occurred due to heating of items in contact with the patient such as fluid bags or cords from monitoring equipment.

Gadolinium-based contrast medium is used in MRI and can be used to help characterize lesions and identify active lesions. The dose of gadolinium extrapolated from other veterinary species is 0.1 mmol/kg injected IV via the cutaneous ulnar or medial metatarsal veins. The effects of gadolinium contrast medium persist for longer than iodinated contrast medium and can be expected to be evident on MRI images for at least 20 to 30 minutes after administration. Increased signal intensity/contrast enhancement of lesions within the brain and spinal cord parenchyma following gadolinium administration

is indicative of disruption of the blood-brain barrier.[50] No adverse reactions to gadolinium have been reported in birds.

Patient Positioning for Magnetic Resonance Imaging

Patients must be motionless with limited accessibility during scanning, and general anesthesia is necessary under most circumstances. Patient positioning will be primarily determined by the scanner and coil system being used combined with patient size. The anatomic area of interest needs to be positioned as close to the coil as possible to maximize SNR ratio and with a straight spine so that midline sagittal images include the entire length of the spinal cord.

Advantages of Magnetic Resonance Imaging

The superior soft tissue contrast resolution produced in MRI images often outweighs the reduced spatial resolution compared to CT. MRI is the modality of choice for central nervous system evaluation. Among sequences, lesions of adequate size compared to slice thickness will be easily identified on MRI.

Disadvantages of Magnetic Resonance Imaging

MRI is very susceptible to artifacts from environmental, hardware, software, and inherent patient causes. Relatively long scan times are to be expected in avian species regardless of the scanner used due to small patient size compounded by fewer water-containing tissues relative to body size than other species. The many air-filled structures, and in particular the air-tissue interfaces around the central nervous system, may limit the use of gradient echo (GRE) sequences which are otherwise helpful for identifying hemorrhage older than 24 hours. The scan time for MRI is long under any circumstances especially when compared to CT, and this not only increases the likelihood of motion artifact but also increases the time the patient is under anesthesia. A full set of sequences for a penguin-sized avian brain study on a high-field scanner should be expected to take at least 35 to 40 minutes without post-contrast sequences and around an hour with post-contrast sequences, while the same study on a low-field magnet will take approximately 30% to 50% longer and may have more limited sequences. General anesthesia is needed for avian patients undergoing MRI to prevent movement. Only MRI-specific equipment can be in the scanner room, and options are quite limited and optimized for human-sized patients rather than small birds. This may add challenges to anesthesia, patient monitoring, and safety. The use of MRI is limited in small patients, as the typical slice thickness selected in MRI to keep reasonable scan times is 2.5 to 3 mm, which is very large relative to all birds and limits use to medium-sized birds or larger. Few MRI acquisitions permit MPRs, and a component of the long scan time is the need to acquire multiple sequences in multiple planes for the most accurate assessment.

Direct Clinical Application of Magnetic Resonance Imaging

- Imaging of the central nervous system[55–57]
- Imaging of the eye[57]
- Imaging of the inner ear[57]
- Imaging of the solid soft tissues of the coelom[56]
- Imaging of chronic sinusitis[54]
- Limited evaluation of the heart (due to motion), respiratory tract, and osseous structures (due to lack of signal). Pathological lesions including granulomas or neoplasia in the bone or lung may be identified on MRI due to the increased soft tissue and increased signal at those locations

Selected Magnetic Resonance Imaging Artifacts

Many MRI artifact peer-reviewed texts[58] as well as online resources providing extensive reviews and examples of artifacts are available. MRI artifacts are frequently sequence-dependent and so their relevance depends on the sequences available and selected. The most observed artifacts that can affect all scanners and sequences to some degree include susceptibility artifact, motion, and aliasing (wrap around) artifact.

Susceptibility artifact can be used as a diagnostic advantage when trying to determine if hemorrhage or other paramagnetic material is present. However, susceptibility artifacts from metal or air-tissue interfaces can obscure anatomy and pathology (Figure 2.30). In some cases, moving the skin and

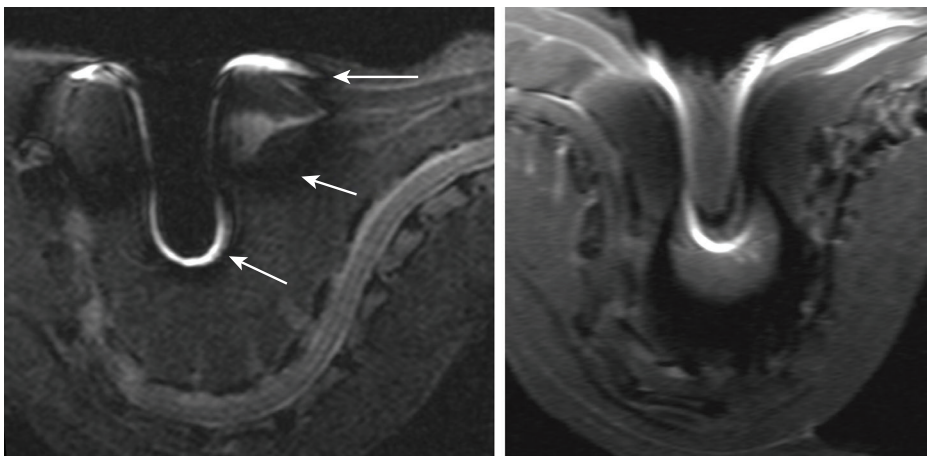

FIGURE 2.30 Examples of susceptibility artifact (highlighted by arrows) from a microchip. In the image on the left, the resultant artifact is significant but does not affect the images of spinal anatomy. On the right, the spinal anatomy is affected by the artifact.

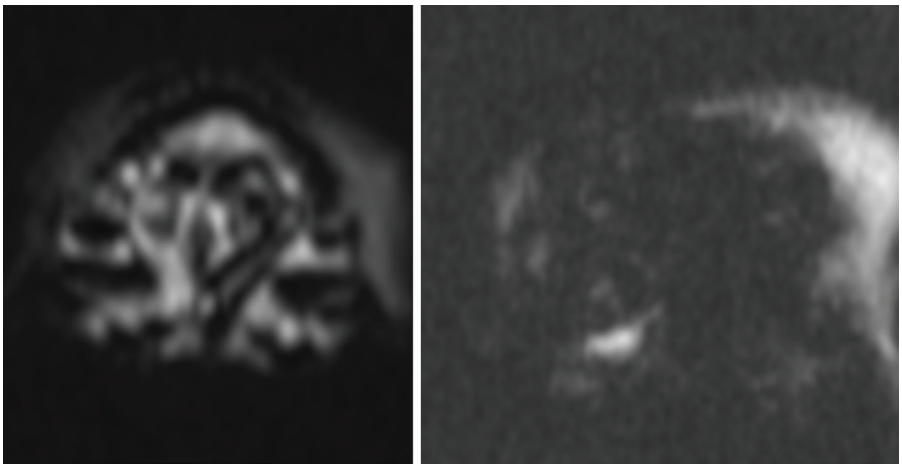

FIGURE 2.31 Transverse (left) and sagittal (right) MRI images acquired using GRE sequences demonstrating the lack of signal observed in part because of the large volume of air/gas present in the scan region. *GRE,* Gradient echo; *MRI,* magnetic resonance imaging.

subcutaneous tissues containing metal can help reduce its effect or move it out of an area of concern. Susceptibility artifacts (Figure 2.31) are enhanced on GRE sequences, and as a result, GRE tends to have more limited use in avian species.

Aliasing as shown in Figure 2.32 occurs when there is anatomy present inside the coil that is outside the selected display field of view. The excluded anatomy may be superimposed on the anatomy of interest or seen along the edge of the image. It is correctable via internal software or by opening out the field of view to include all tissues.

Motion artifact is demonstrated in Figure 2.33 and may occur voluntarily or involuntarily, even under adequate chemical restraint. The most common artifacts seen are eye movement, heart motion, respiratory motion, swallowing, and pulse artifact from arteries. Rapid imaging techniques with or without cardiac or respiratory gating can be used to help reduce this artifact but are challenging to use in avian patients. Changing phase and frequency direction may help move artifacts away from regions of interest.

CONCLUSIONS

Diagnostic imaging can greatly enhance diagnostic capabilities in a multitude of cases. However, appropriate modality selection with optimization of data collection and interpretation is key to gaining as much as possible from each imaging study. In addition, an understanding of the limitations of each modality will help direct the clinician to the most appropriate modality/study for the case in hand. When artifacts occur on diagnostic imaging, an understanding of what may have contributed to them to guide adjustments to resolve or improve them, will greatly enhance the image quality acquired and overall veterinarian satisfaction.

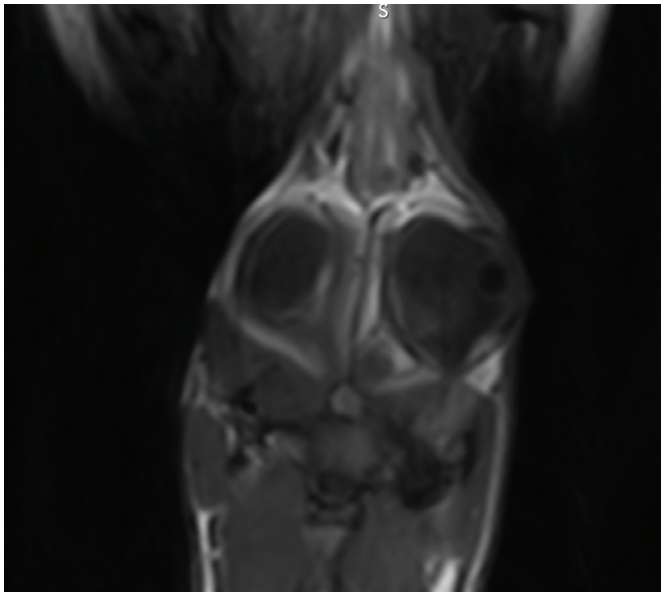

FIGURE 2.32 Aliasing is seen here as anatomy from caudal to the head wrapping around the image and incorrectly superimposed on the rostral head.

CHAPTER 3

Thermal Imaging

Hugues Beaufrère • Kyra L. Mills

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION TO VETERINARY AND AVIAN THERMOGRAPHY

Infrared thermography is an imaging modality that measures infrared radiation (IR) and digitally converts it into grayscale images (artificial color palettes are commonly applied for practicality).[1] As any object above absolute zero (0°K, −273.15°C, −459.67°F) emits IR as a function of its temperature, infrared thermography allows to map variations in temperature across an object surface.[2,3] Biological relevant temperatures generate IR in the long-wave wavelength (8–12 μm), which is invisible to the human eye; thus specific thermal cameras are employed.[2] It is a noncontact, stress-free, and safe imaging method that maps heat in real time. Medical thermography is the use of infrared thermography in a medical context. As heat is generated during inflammatory processes and is affected by the amount of regional vascular perfusion (controlled by vasomotor tone), it can be used as a diagnostic aid for some diseases. Medical thermography only measures surface temperature (or a few mm deep); it will therefore be affected by various factors such as insulation, wetness (water absorbs IR and cools surface down, alcohol also decreases surface temperature), emissivity of the surface, and environmental factors (wind and outside temperature).[2,4] Emissivity is an important parameter and is defined as the ability of an object to emit and absorb IR. An emissivity of 1 means the object is a perfect emitter (black body), and the emissivity of biological tissues, including avian tissues, is close at 0.96 to 0.98.[2]

The American Academy of Thermology (https://aathermology.org) has set forth some veterinary guidelines for infrared thermography.[5] Recommended infrared camera for veterinary examination should have a minimum IR spatial resolution of 320 × 240 pixels (ideally 640 × 480), a thermal precision lower than 0.05°C (50 mK), a thermal sensitivity lower than 0.05°C (50 mK), a temperature coverage encompassing physiological temperatures (20°C–45°C: 68°F–113°F), real-time capture capability, and a software for measurements. Thermal camera requirements are similar for research in avian biology.[2] Thermal cameras are considered low resolution at or below 160 × 120, medium resolution at 320 × 240, and high resolution at 640 × 480. The IR spatial resolution is the main factor affecting IR camera cost. High-resolution cameras are onerous ($15k–70k), especially when marketed for medical use. Medium-resolution cameras or low-resolution cameras marketed for nonmedical uses are more affordable and still give images of diagnostic quality in most circumstances. There are also some low-resolution, smartphone-based cameras that may be used. The author has used a low-resolution camera (FLIR E6, 160 × 120) on multiple cases and found it useful for veterinary purpose and general screening as it still allows detection of clinically significant temperature changes. Besides, the investment in a high-resolution IR camera may not be warranted considering that IR imaging is mainly an adjunct diagnostic tool and rarely diagnostic in itself, so the return on investment may be low for avian practices. The main advantage of using low-resolution cameras is their low cost ($400–2000). However, the disadvantages of using them for diagnostic purpose should be kept in mind. A low resolution means that temperatures will be less accurate because temperature is averaged over larger pixel areas. Consequently, tiny hotspots may not be detectable and the ability to discriminate temperature differences will be lower. However, studies in chickens have shown that low-resolution cameras were still providing biologic information close to what would be achieved with high-resolution cameras.[1]

Interpretation of thermal images requires a good knowledge of thermal biology of the species being imaged, scanned anatomical area, and the thermal pattern of common diseases. First, it is important to standardize the scanning protocol (see AAT guidelines)[5] by selecting a constant environmental temperature (20°C–22°C) and limiting the sources of variation (distance from the camera, wetness, wind, airflow). All examinations need to be performed in a thermoneutral environment (indoors preferentially) prior to restraining the bird (if possible) and prior to touching or manipulating the examined surface (to limit thermal transfer). It is also recommended to scan symmetrical areas for reference (e.g., both legs at the same time, both wings). There are several limitations to thermal imaging to be aware of. First, only the surface temperature can be measured (or a few mm below the feathers).[1,2] Therefore, to be detectable, lesions will have to be on the surface and in poorly insulated areas. The accuracy is also dependent on the equipment if one is interested in absolute temperature measurement. The accuracy of most commercial nonmedical infrared cameras is ±2°C (±3.6°F) or ±2% of temperature reading. The threshold of surface temperature increase or decrease that is considered clinically significant will also affect the correct interpretation of thermal images. For instance, the author considered a difference of 5°C to 7°C

between legs/feet, which is likely a conservative cutoff value and significant in most cases. It is also important to be aware that glass is opaque to IR, meaning that animals cannot be imaged in incubators. Birds that have been in incubators for a certain period of time may also undergo surface thermal changes, which may decrease differences between lesions and normal tissues and make it more difficult to identify lesions. Another way that the interpretation of results may be confounding is during a physical examination and touching of the bird which may lead to heat transfer from the handler to the surface of the skin of the bird. Finally, stress may cause cutaneous vasoconstriction that may confound thermographic interpretation, and prolonged handling may lead to patient overheating,[6–8] which may reduce previously observable temperature differences. Consequently, in pet birds, it is best to perform the thermographic examination before restraint, on a calm animal (it can be performed in the dark for instance), and before placing it in an incubator.

Thus far, veterinary thermography has mainly been employed in mammals, including humans, to monitor fever, overall body temperature, local inflammation, circulatory disorders, pain, detection of tumors (which have a higher metabolism than normal tissue and therefore appear warmer), detection of pregnancy in zoo animals, and assisting in the diagnosis of lameness and musculoskeletal stress in horses. A book chapter devoted to veterinary thermography in zoological medicine is available, but it has limited information on birds.[4]

AVIAN THERMAL BIOLOGY AND THERMOGRAPHIC IMPLICATIONS

Avian thermal biology differs from mammals in several aspects; therefore, it is important for veterinarians or researchers who use this technology to be aware of these, prior to using thermal imaging in birds. Furthermore, species-specific differences in thermal biology may lead to misinterpretation of thermographic patterns. This is a significant limitation as thermography may potentially be applied to hundreds of different species of birds. Aquatic species in particular pose increased challenges to the application of veterinary thermography.

Body Temperature

Like mammals, all birds are endothermic and need to keep their body temperature within a limited range. In general, birds have higher core body temperatures than mammals (approximately 1.9°C–2.4°C higher on average than mammals)[9]. At rest and depending on the species, core body temperature is approximately 35°C to 40.8°C (95°F–105.4°F) in most birds with a mean temperature of about 38.5°C (101.3°F).[9,10] Active birds may have body temperatures up to 44.6°C (112.3°F), and with extreme activity, the temperature can climb as high as 47.7°C (117.9°F) in some birds.[9,11] The average temperature depends on the species and other biological variables. For instance, neonates of altricial species tend to be poikilothermic. Ratites and some aquatic species (Sheniciformes, Procellariiformes) generally have lower temperatures than other birds.[12] Contrary to popular belief, birds also experience fever when having an infection, which leads to increased body temperature.[13,14]

Many avian species are not homeothermic, but instead heterothermic (body temperature is not constant). In most bird species, body temperature varies by 2.5°C to 2.8°C during the day.[11] Avian heterothermy is a metabolic adaptation to conserve energy when not active (at night) or when the outside temperature is low (i.e., in the winter). For instance, nocturnal hypothermia is seen in doves, pigeons, turkey vultures (*Cathartes aura*), Japanese quails (*Coturnix japonica*), and many passerines.[12] Facultative hypothermia in small birds in the winter or boreal environment is common.[15] For example, a common North American bird, the black-capped chickadee (*Poecile atricapillus*), is able to considerably lower its body temperature at night in the winter by as much as 10°C.[16] Hummingbirds, nightjars, swifts, and mousebirds go beyond heterothermy and are able to fall into torpor at night decreasing their metabolism and body temperature even further, as low as 4°C to 7°C in some species.[9,12]

Most animals, including birds, have obligate thermal windows (areas that reflect core body temperature such as the eyes or the cloaca) and facultative thermal windows (areas with varying thermal biology such as the feet, face, skin folds, beak, underside of the wings, and so on) (Figure 3.1). The eye-auricular region is the main obligate thermal windows in birds, and thermography of this region has been used to estimate core body temperature in birds.[2]

Generalities on Insulation and Heat Dissipation

Birds predominantly use feathers for insulation. Most of the avian feathered area has a surface temperature closer to environmental temperatures than to core body temperature.[2] The feathering over the body allows to adjust the thickness of the insulating layer by ptiloerection.[11] The amount of feathering, especially for down feathers, is highly correlated to the species' ecology and habitat, and each bird species has a specific molting pattern. Because of this fact, the use of thermal imaging is limited over feathered areas, especially in arctic species for which most of the body and extremities are feathered. However, thermal imaging

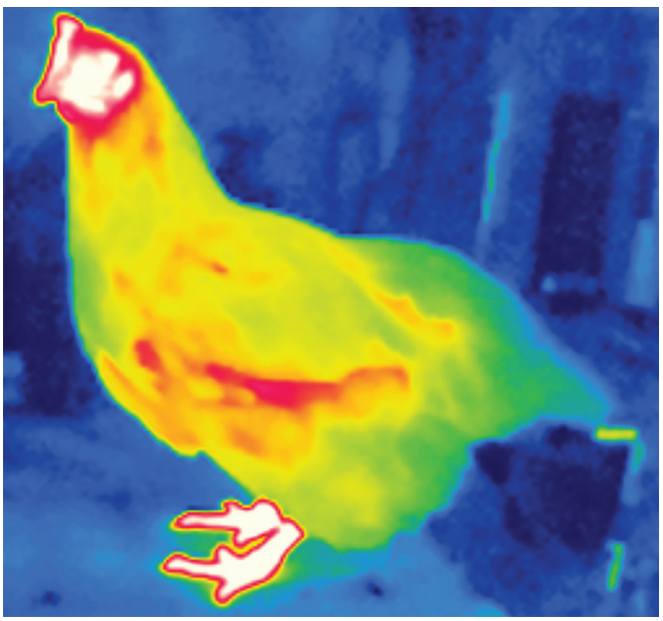

FIGURE 3.1 Normal chicken (*Gallus gallus domesticus*) thermograph. The thermal windows include the head (note the face, beak, comb, wattles, and ear lobes), the feet, and under the wings.

can be used to detect a loss of insulation over the body. Dark feathers and dark feather patterns may also be associated with increased heat detection due to increased absorbance of solar radiation, especially when birds are imaged outside. Birds also shiver like mammals to produce heat. When increasing heat loss is necessary, birds use evaporative water loss through respiratory surfaces, skin, or cloaca. Other species-specific heat dissipation mechanisms include gular fluttering, panting, radiative loss through the beak, and thermal dissipation across areas of bare skin, skin folds, skin protuberances, as well as flippers and feet in aquatic species (see later).[2,12]

Head and Neck

In chickens, the face, comb, wattles, ear lobes, and beak radiate heat directly and may be used for thermoregulation (Figure 3.1).[1] In species with bare head and neck such as ratites, turkeys, vultures, guineafowl, and bald ibises (*Geronticus* spp.), a significant amount of heat can dissipate through these large feather-free areas (Figures 3.2 and 3.3).[2,17–19] In dark birds inhabiting hot environments, such as the bald ibis, it has been hypothesized that the bald head coupled with control of skin blood flow (facial flushing) is associated with the ability to dissipate heat.[20] Facial flushing is also common as a thermoregulatory (and social signaling) mechanism in other bare-faced birds. The lappet-faced vulture (*Torgos tracheliotos*) also has two folds of skin on the neck that are likely used to increase the surface area for thermal exchange. *Gyps* vultures, which have long unfeathered necks, may regulate heat exchange from their neck by changing their neck posture in cold and hot conditions.[17] Some parrots such as macaws (*Ara* spp.) and grey parrots (*Psittacus erithacus*) also have large facial featherless areas that dissipate more heat than other psittacine species (Figure 3.4).

Most birds use their beak as a thermal radiator, and it is particularly marked in toucans and hornbills. The beak morphology and size is not only determined by feeding strategies but is also strongly associated with environmental temperature and thermal ecology in many species of birds.[21–23] Thermal imaging studies in toco toucans (*Ramphastos toco*) have shown that as much as 30% to 60% of body heat is dissipated by blood flow through their large beak.[24] In hornbills, their large bill may also have a similar function depending on species and biotope.[25] This mechanism may be particularly important for species inhabiting hot humid environment, such as toucans, where evaporating heat loss mechanisms are less effective. The role of the beak in heat dissipation is also paramount as a thermal radiator independent of evaporative water loss in species for which water conservation is important.[22] Seabirds with large beaks such as puffins also use their beak as a thermal radiator.[26] Parrots also have large beaks which, while it has not been investigated, may also serve as thermal radiators. In species with a well-developed bill tip organ (such as in Anseriformes), the bill may appear warmer on thermal images (Figure 3.5), which should not be confused with a lesion. Therefore, thermal imaging of the avian beak must be interpreted in the context of individual thermoregulatory status and physiology, especially in species with beak thermoregulatory

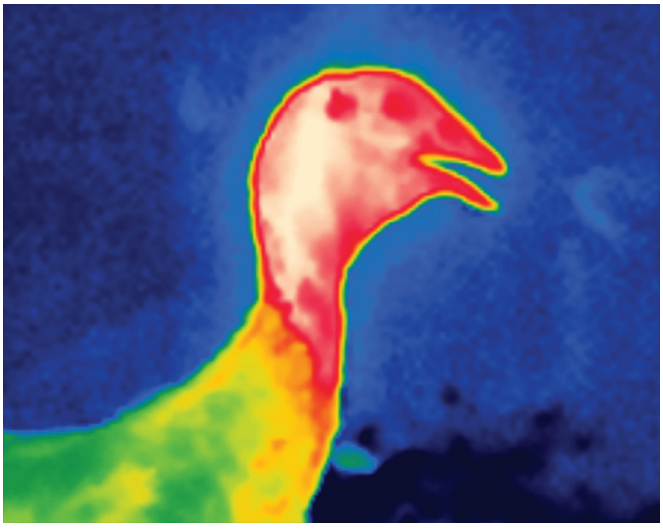

FIGURE 3.2 Normal turkey (*Meleagris gallopavo*) head/neck thermograph. In turkeys, the head and distal neck are featherless and readily radiate heat. This turkey was panting, which is common in meat breed poultry birds that have a low thermotolerance.

adaptations. The casque present in some species may also have a thermoregulatory function, as demonstrated in cassowaries,[19,27] and potentially in other species such as hornbills.

Gular fluttering, as a method of thermoregulation, is predominantly seen in Pelecaniformes (cormorants, pelicans) but is also seen in turkey vultures, quail, nightjars, pigeons, owls, and mousebirds.[12] In doves and pigeons, for instance, the esophagus is well vascularized to increase the efficiency of gular flutters and upper esophageal pulsations and a subcutaneous plexus of veins are present (*plexus venosus intracutaneous collaris*).[28] Gular fluttering is controlled by movements of the hyoid apparatus and is energetically more efficient than panting.[12] The throat area will appear warm on thermal imaging during gular fluttering in these birds, especially if unfeathered. Gular fluttering may occur concurrently to panting.

The Legs and Feet

As the feet of most birds are unfeathered, they will usually appear warmer during thermal imaging (Figure 3.1). However, a good knowledge of normal leg thermal biology in birds should be known as there are several notable exceptions. First, many boreal and arctic birds have feathered tarsi and toes. For instance, most owls, some hawks and eagles, and grouses have feathered tarsi. Snowy owls (*Bubo scandiacus*) and ptarmigans have feathered feet. Thermal imaging of the legs and feet in these species will therefore be severely hampered. Most birds tend to sleep with one foot tucked inside their plumage (unipedal sleeping/resting), which will increase its temperature and lead to noticeable differences between the feet on thermal imaging.

Furthermore, most birds use their legs for thermoregulation.[11,12,19,29] In numerous bird species, there are extensive counter-current heat exchange systems in the legs and feet (called regional heterothermy) at the feather line to decrease heat loss in water or during low environmental temperatures. This is especially pronounced in aquatic birds, wading birds, gulls, and some northern species, in which the temperature of the legs and feet is close to the ambient temperature. There are two main mechanisms that allow this to occur: in some species such as ducks, geese, storks, cranes, penguins, and flamingos, the heat exchange system takes the form of a rete system of arteriovenous anastomosis, the *rete tibiotarsale*, at the level of the tibiotarsus and intertarsal joint.[30] In flamingos, in which it is the most developed, this *rete* includes more than 60 arteries and 40 veins and is therefore very efficient (Figure 3.6). It is also present in chickens, owls, and a number of short-legged birds, but is a more simplistic system in these species. In other species such as herons, gulls, and other Charadriiformes (most small wading birds), the heat exchange system is not a rete but rather simply composed of counter-current veins along arteries.[30] Species with a rete may be able to control blood flow within the rete, whereas non-rete species do not have such control. Consequently, the legs and feet of these birds may appear cooler in thermal images than the rest of the body and the feet of other birds. Even in warmer conditions, the feet of these birds may be closer to environmental temperature than body temperature, especially in non-rete species.

In penguins and other birds such as ratites,[19] the opposite occurs, where the feet may appear warmer in thermal images, as the feet are important thermal radiators in warm conditions. In addition, some birds such as New World vultures (Cathartiformes) and some storks urinate on their feet as a

FIGURE 3.6 Thermal image of a flock of flamingos. Note that the legs are of similar temperature of the environment due to their highly efficient rete tibiotarsale.

cooling mechanism; this is called urohidrosis.[12] To reduce leg thermal loss, many birds may also assume a squatting position, thereby covering their legs with body contour feathers.

The Special Case of Poultry

Poultry are a special case as they have been selected over decades for increasing metabolism and growth. This came at the expense of thermoregulation and cardiovascular function. Therefore, chickens and turkeys have a low capacity to regulate their body temperature in extreme conditions and have an overall low thermotolerance.[1] Overheating chickens and turkeys typically pant heavily (called thermal tachypnea), which is accompanied by significant evaporative water loss (Figure 3.2). Thermal imaging has been found by the author to have a lower sensitivity for detecting inflammatory changes in poultry for this reason when compared to other species of birds.

Other Adaptations

The females of some bird species develop a brood patch after egg laying that is used for thermal transfer during egg incubation. It is typically located over the ventrum and is an area with reduced feathering. This area is readily visible on thermal imaging (Figure 3.7) and should not be confused with a lesion. Just as some species of birds have arteriovenous anastomosis in the legs to conserve heat, penguins have a similar mechanism in their flippers.

Behavioral adaptations may also be thermally important for some species such as when using communal roosts, huddling (passerines, penguins), and selecting microclimates and shelters. Postural adjustment is also employed by many birds in addition to ptiloerection such as hunching, head retraction (see *Gyps* vultures earlier, but many other birds too), and tucking the head beneath the scapular feathers (as both the head and beak are thermal windows).[12] Furthermore, many birds reduce requirement for thermogenesis by "sunbathing" during which they frequently spread their wings. In addition to reducing ptiloerection and panting, overheated birds frequently slightly open their wings to increase surface area. This behavior is frequently seen in hospitalized birds in incubators when the temperature is too high. Wild birds that need to cool down will also seek shade and water.

AVIAN VETERINARY THERMOGRAPHY

Infrared thermography has not been as widely used in avian medicine yet as it has in mammals. Of the avian medicine articles that have been published, the great majority deal with poultry species,[31–33] aquatic species (penguins, flamingos),[34–37] and birds of prey.[38,39] There is also extensive nonveterinary literature on the use of thermography in the poultry industry[1] and for avian metabolism studies.[2]

In birds, the main indications and reported uses for thermal imaging are listed as follows:

- The use of thermography for unfeathered areas such as the pelvic limbs and the head (in some species): Because feathers cover most of the avian body and thermography only measures surface temperature, this technology does not allow examination of the underlying skin and associated pathologic thermal patterns.
- Feather loss/insulation disorders: A loss in insulation is readily spotted on thermal imaging.
- Flock screening: Individuals within a flock may show different thermographic patterns associated with diseases and lesions.
- Research on avian metabolism, thermal physiology, and in the chicken industry (thermal stress, welfare, building insulation, egg incubation): This topic will not be covered in this publication.

Leg Thermography

By far, the legs are the easiest part of the avian body for using thermal imaging as they are unfeathered in most birds. Furthermore, a range of common diseases occur on the legs and feet such as bumblefoot, wounds, trauma, infection, frostbite, and avascular necrosis. Several studies have investigated the usefulness of infrared thermography in the detection of foot diseases in chickens, turkeys, penguins, flamingos, and raptors.[32,34,35,38,40]

In the poultry industry, pododermatitis is a major health problem and is responsible for significant economic loss. For this reason, several studies have been performed in chickens using infrared thermography. In one study, thermography was used to correlate the development of pododermatitis 2 weeks after thermographic examination (>80% correlation), which was higher

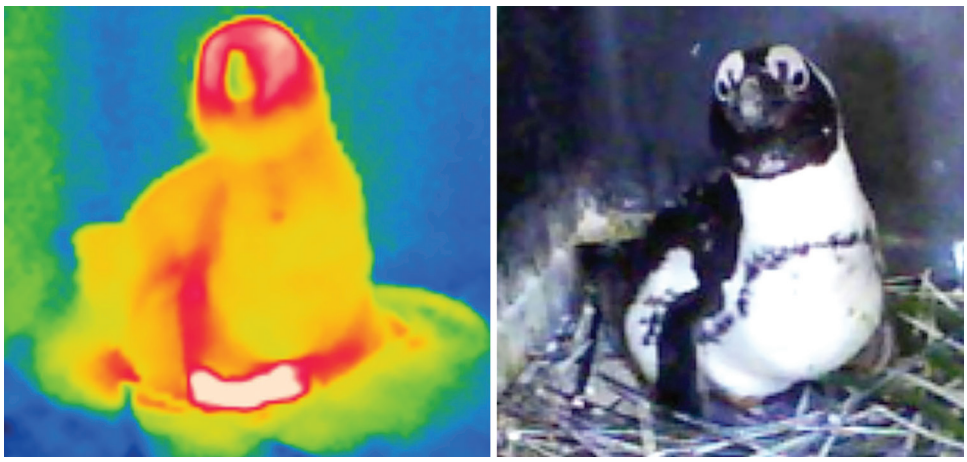

FIGURE 3.7 Black-footed penguin (*Spheniscus demersus*) incubating an egg. Note the increased temperature around the brood patch. Side-by-side thermography and regular image.

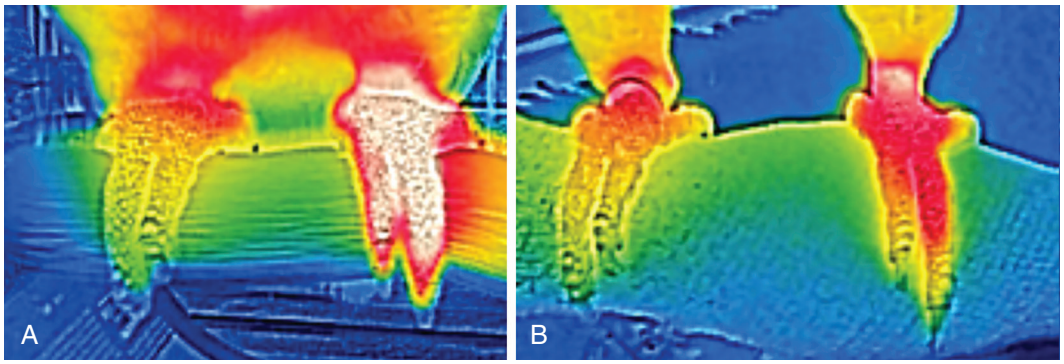

FIGURE 3.8 (A) A grey parrot (*Psittacus erithacus*) that had walked over pieces of glass and had an inflamed left foot; (B) 24 hours after meloxicam (1 mg/kg PO) administration.

than visual inspection alone in subclinical cases.[40] In the same study, bumblefoot was experimentally induced with *Staphylococcus aureus* injection and thermal imaging was also found to be useful in that model.[40] In a different study, still in chickens, the temperature of the plantar lesion was found to decrease with increasing bumblefoot severity because of the development of surface necrosis and scabbing.[32] In turkeys, thermal imaging was found to be a reliable method to detect subclinical footpad dermatitis. However, as observed in chickens, higher degrees of dermatitis were associated with lower surface temperature because of hyperkeratosis or early ischemia.[33]

As mentioned earlier, thermal imaging was expected to be more challenging for the feet of aquatic species because of thermal leg adaptations such as the counter-current heat exchange system and thermal heat dissipators (penguins, ratites, others). As a matter of fact, this was somewhat confirmed in two studies on pododermatitis with mixed results, one in penguins and one in flamingos.[34,35] In both studies, differences were found between feet with active lesions compared with inactive lesions or normal feet, but there was too much variability and overlap between conditions to be clinically applicable.

Information in the literature is scarce on the use of leg thermography in other species, even though they are more commonly seen in practice. A study in raptors found that thermography was useful to detect a decrease in temperature of electrocuted feet over time, which was correlated to the likelihood of avascular necrosis.[39] Another recent study in hawks found that thermographic measurements on the tarsometatarsal region correlated well with the temperature of the plantar surface of the feet.[38] Therefore, this area may be able to be used as a surrogate for inflammation located on the plantar surface (such as with active bumblefoot or wounds) when assessing raptors from a distance.

While the lead author has not published any formal research on this topic, he has extensively used thermal imaging in birds in clinical practice, mainly for conditions affecting the pelvic limb and face. It was found that temperature differences higher than 5°C to 7°C were generally clinically significant. Differences between legs/feet were harder to assess for chickens, as even normal chickens had a tendency to have one leg warmer than the other. However, it was not the case in parrots and raptors. It is also worth mentioning that any difference in feathering between legs or feet will result in temperature differences, reflecting insulation differences.

Inflammatory lesions (infection or trauma) were readily detectable through higher temperatures in a variety of cases such as a grey parrot that walked over pieces of glass (Figure 3.8), active bumblefoot lesions in raptors (Figure 3.9), leg wounds (Figure 3.10) and leg cellulitis in raptors (Figure 3.11), toe wounds (Figure 3.12), and frostbites (Figure 3.13). While some of these diagnoses were still obvious without the use of thermal imaging, what was found to be the most useful with this imaging modality was the ability to monitor the lesion, especially without restraining the birds. The use of antibiotics and/or meloxicam initially, as well as lesion resolution several days later, was associated with sharp decreases in foot temperature (Figure 3.8) allowing to assess therapy efficacy. While the scientific literature had mixed results about the use of thermal imaging for bumblefoot (see earlier), the author has found it useful for differentiating active lesions (active infection, more severe case) (Figure 3.9) from chronic ones (chronic scab formation and low-grade inflammation). Scabs on

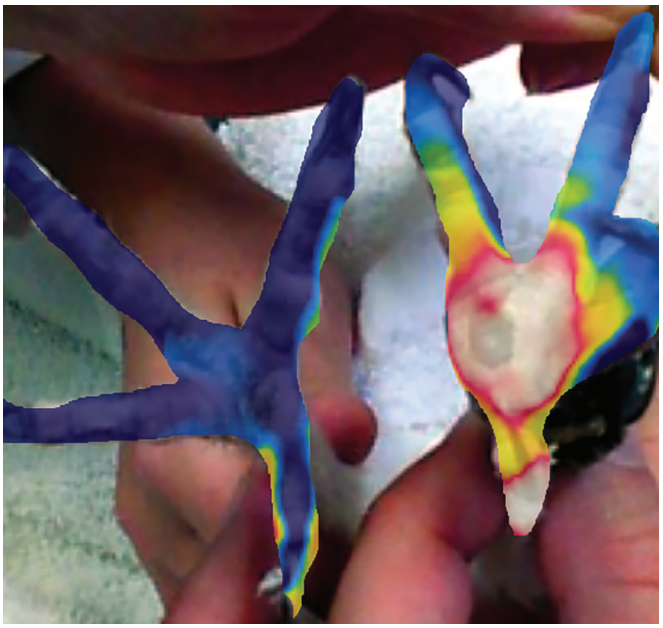

FIGURE 3.9 Bumblefoot lesion in a barn owl (*Tyto alba*). Thermograph overlay on regular picture. The left foot had an active infected lesion that was much warmer than the contralateral foot.

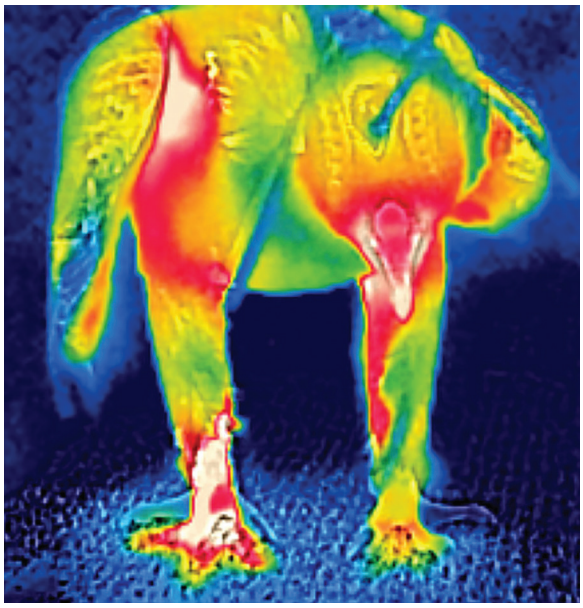

FIGURE 3.10 Golden eagle (*Aquila chrysaetos*) that was imaged in its carrier prior to physical examination. Note the warm left foot. A distal tarsometatarsal deep wound was found on physical examination.

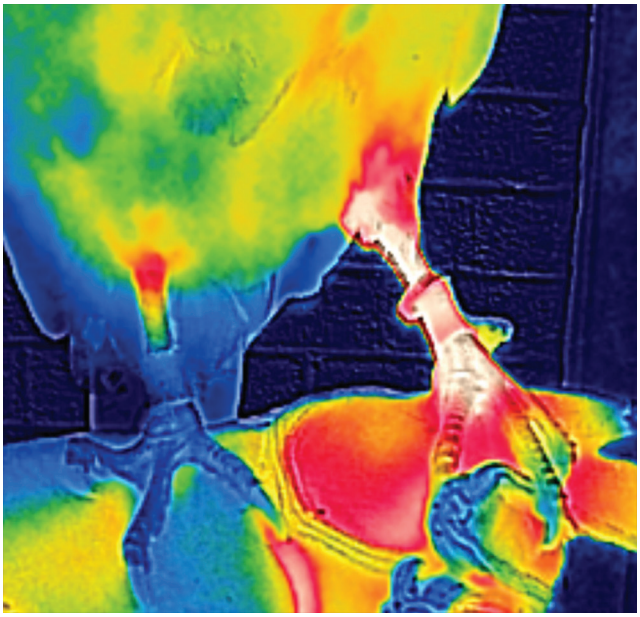

FIGURE 3.11 Cellulitis of the left leg in a Harris hawk (*Parabuteo unicinctus*) presented for lameness. The physical examination and radiographic images of the leg were unremarkable.

the plantar surface of the central metatarsal pad of chronic lesions had a tendency to be cooler than the contralateral foot, as described in the literature. In one case of a unilateral bumblefoot lesion in a peregrine falcon, the lesion was of a similar temperature than the contralateral foot, but after anesthesia leading to a mild decrease in core body temperature, the lesion was evident on thermal imaging. Most frostbite lesions, when mild, lead to an increase in temperature of the affected foot consecutive to inflammation (Figure 3.13). In several cases of lameness or decreased leg

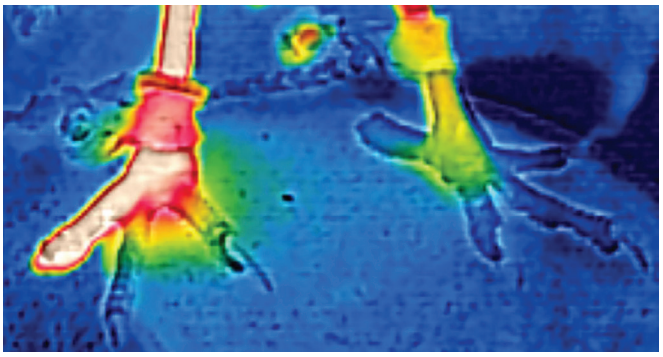

FIGURE 3.12 Distal phalangeal luxation on digit IV of right foot in a Harris hawk (*Parabuteo unicinctus*). Only the affected toe is warm with heat coming with the increased blood flow to the area from the more proximal leg.

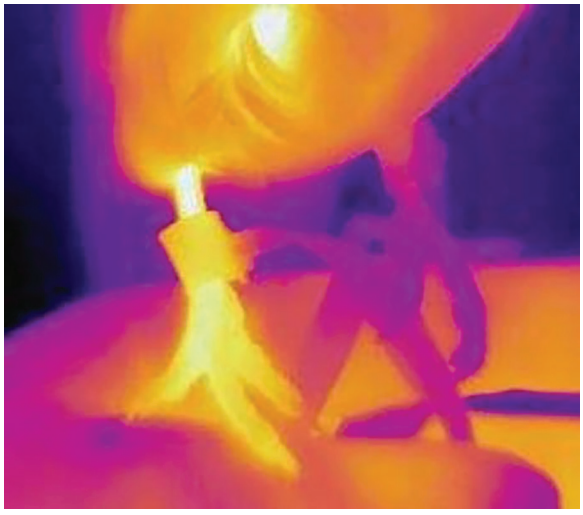

FIGURE 3.13 Frostbite in an American kestrel (*Falco sparverius*). The left frostbitten leg is warmer than the right due to inflammation from the acute phase of the injury.

use in raptors, thermal imaging readily detected increased temperature of the affected leg or foot when the physical examination and radiographs were normal (Figure 3.11). These cases were interpreted as cellulitis (especially with concomitant inflammatory leukogram) or soft tissue trauma. Thermal imaging was found to be useful to assess the evolution of these issues as physical examination and other imaging modalities were unremarkable and could not be used for monitoring.

Several cases of avascular necrosis were also diagnosed with thermal imaging. These were mainly secondary to leg band constriction, other types of constriction (constricting wound, hair, nest materials) (Figure 3.14), self-mutilation (Figure 3.15), severe frostbite, or trauma. The method is particularly useful as it may be difficult to assess tissue viability solely on physical examination. Similar findings were reported in cases of electrocution in raptors (see earlier). In a case of toe infection in an American kestrel (*Falco sparverius*), repeated thermal imaging revealed that the foot first became warmer consecutive to the infection-induced inflammation, but later one of the toes progressed to be cold as necrosis developed, likely due to the subsequent

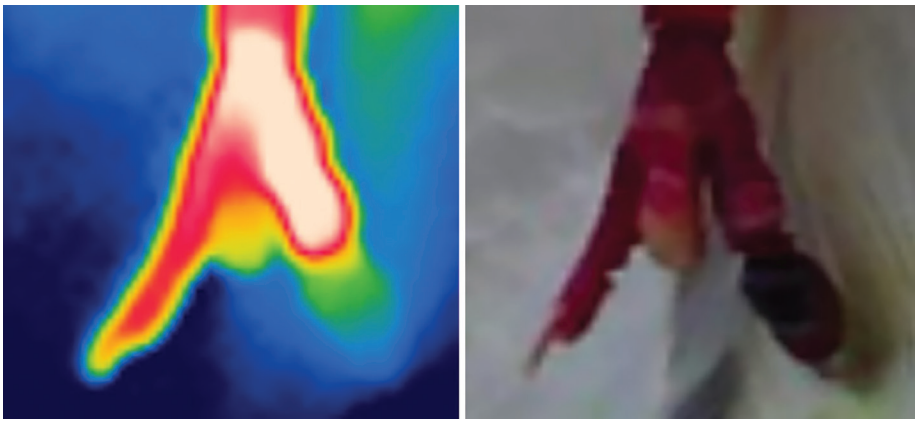

FIGURE 3.14 Toe constriction in a pigeon (*Columba livia domestica*) caused by a constricting wound. Side-by-side thermographic and regular pictures. While no heat from blood flow can be evidenced on the toe distal to the constriction, the proximal aspects of the toe and the leg are warmer indicating inflammation.

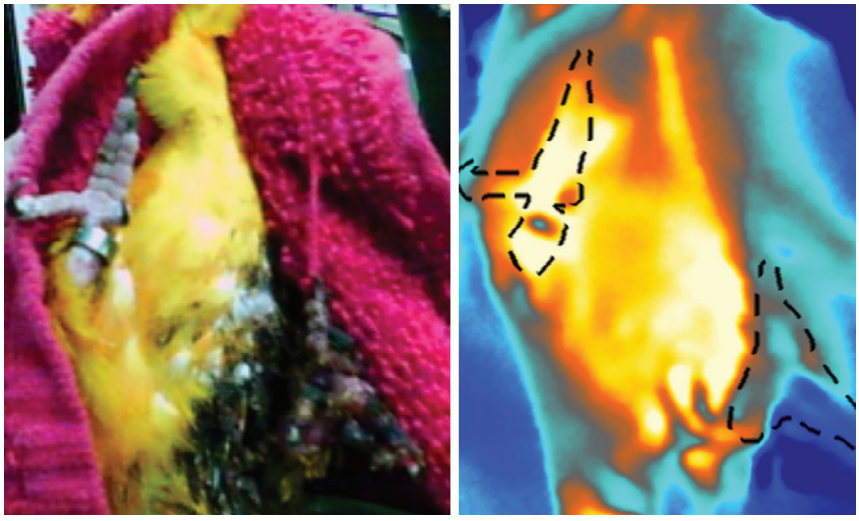

FIGURE 3.15 Avascular necrosis secondary to self-mutilation in a conure. Side-by-side regular and thermographic picture. The feet have been outlined for ease of interpretation.

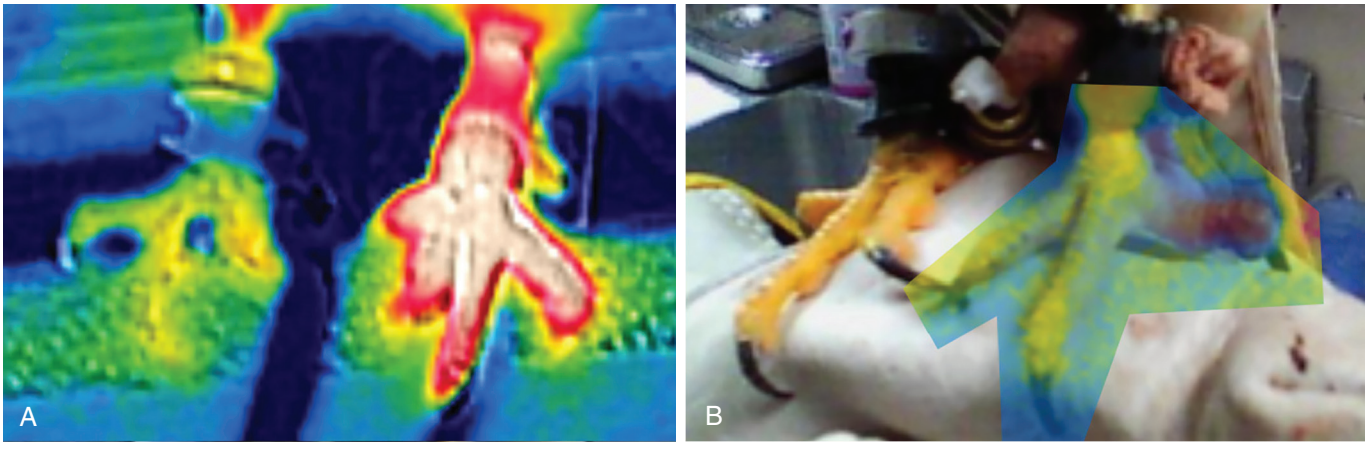

FIGURE 3.16 (A) Foot inflammation likely due to an infection in an American kestrel (*Falco sparverius*). (B) While the foot healed, the fourth digit showed a loss of vascularization likely due to avascular necrosis.

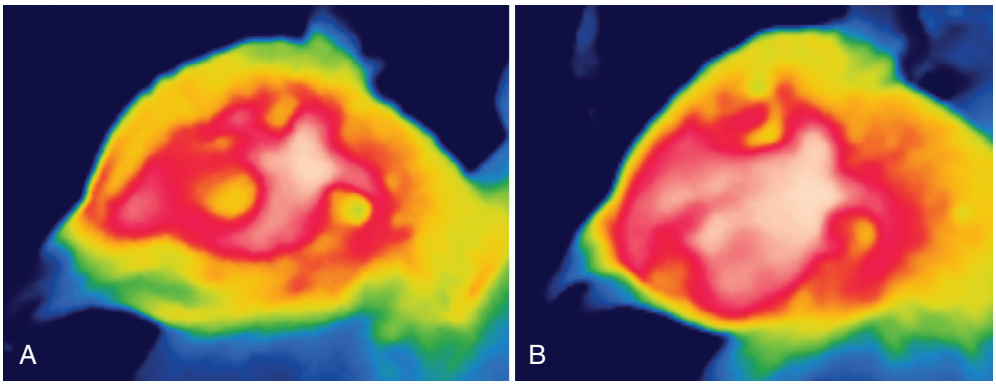

FIGURE 3.17 Peacock (*Pavo cristatus*) with sinusitis. Side-by-side comparison of the normal side (A) and the affected side (B). Note that the affected side was also swollen.

thrombosis (Figure 3.16). This also underscores the usefulness of thermal imaging as a lesion-monitoring tool.

Head Thermography

Head thermography is less useful overall than for the pelvic limb and depends on the level of head feathering as well as the presence of skin folds and facial protuberances (see earlier). Thermography of the head has been used to estimate body temperature noninvasively in several avian species. In chickens, facial temperature measured using a thermal camera strongly correlates with core body temperature.[1] Thus, thermal imaging can be used to detect thermal stress in chickens. In a study in mallards, internal body temperature was estimated by plucking a small area on top of the head and performing thermography on the scalp.[41] In most of these cases, infrared thermography accurately estimated core body temperature within 1°C. In Arctic species housed in zoos in the spring and summer, infrared thermography of the head could also be potentially useful to screen for thermal stress.

In parrots, some species have small bare skin patches on the face such as grey parrots or large ones such as macaws (Figure 3.4). They seem to act as facultative thermal windows in various circumstances in these species. Thus, facial temperatures may be more easily performed on these species. Since the infraorbital sinus in birds is immediately below the skin, sinusitis may manifest as increased temperature in the subocular area. Infraorbital sinusitis readily leads to increased temperatures on the affected side (Figure 3.17). However, reduced feathering and dermatitis on the affected side (from exudate and scratching) may also lead to an ipsilateral increased observable temperature.

As the beak is such an important thermoregulatory organ in birds (see earlier), it can theoretically be used to assess thermal status or stress in birds. In overgrown rhamphothecas, thermal imaging may be used to get a general idea of where significant vascularization stops and may assist in corrective beak trimming (Figure 3.18). However, this should be used with caution as thermography only measures surface temperature. Beak and soft tissue trauma are generally associated with warm lesions on the thermographic images. With beak tip fractures or other fractures, thermography may be used to assess the viability of the distal fragment (Figure 3.19).

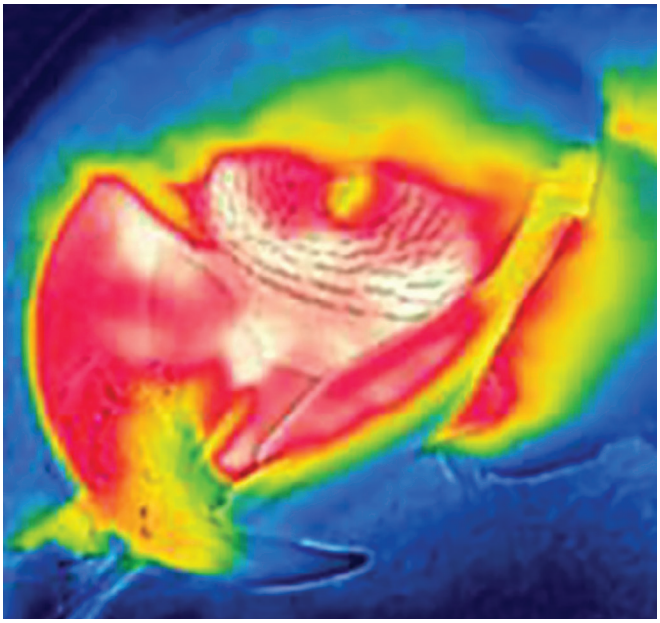

FIGURE 3.18 Green-winged macaw (*Ara chloropterus*) with rhamphotecal overgrowth. See the potential demarcation between the overgrown keratin and the rest of the beak.

Wing Thermography

Wing thermography is not commonly used because of the intense feather coverage. However, the underside of the wing tends to be less feathered and significant heat may be released from that site. It has in fact been used for metabolic studies in flying birds.[2]

Thermography was used on a case report in a Chilean flamingo (*Phoenicopterus chilensis*) with avascular wing necrosis following acute trauma.[36] A thermographic camera was used to image the underside of the wing. Vascular compromise was confirmed with fluorescein angiography. A similar use was reported in a Spanish imperial eagle (*Aquila adalberti*) with wing electrocution and radial fracture.[42]

In penguins, flippers were found to be much warmer in molting individuals.[37]

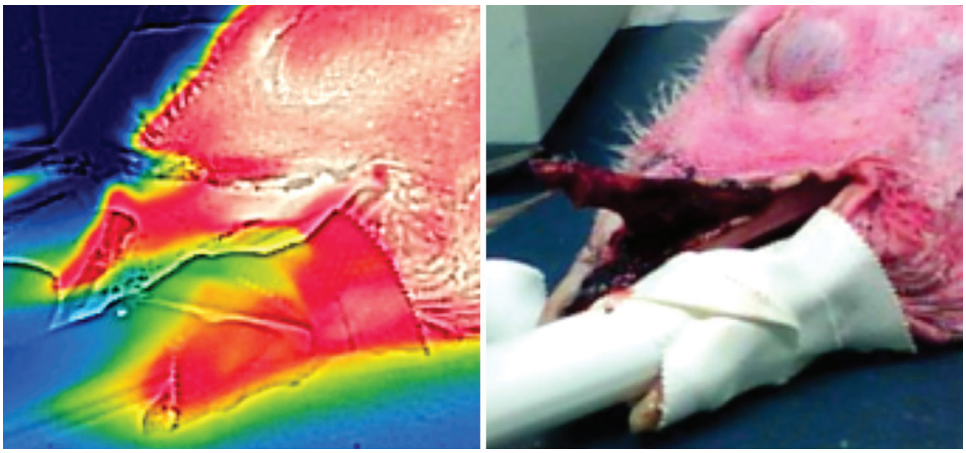

FIGURE 3.19 Turkey (*Meleagris gallopavo*) with beak fracture following an animal bite. Side-by-side thermographic and regular picture. Note that the avulsed part (part of palate with some soft tissue) does not seem to have any vascularization; it was thus excised prior to debridement and reconstruction.

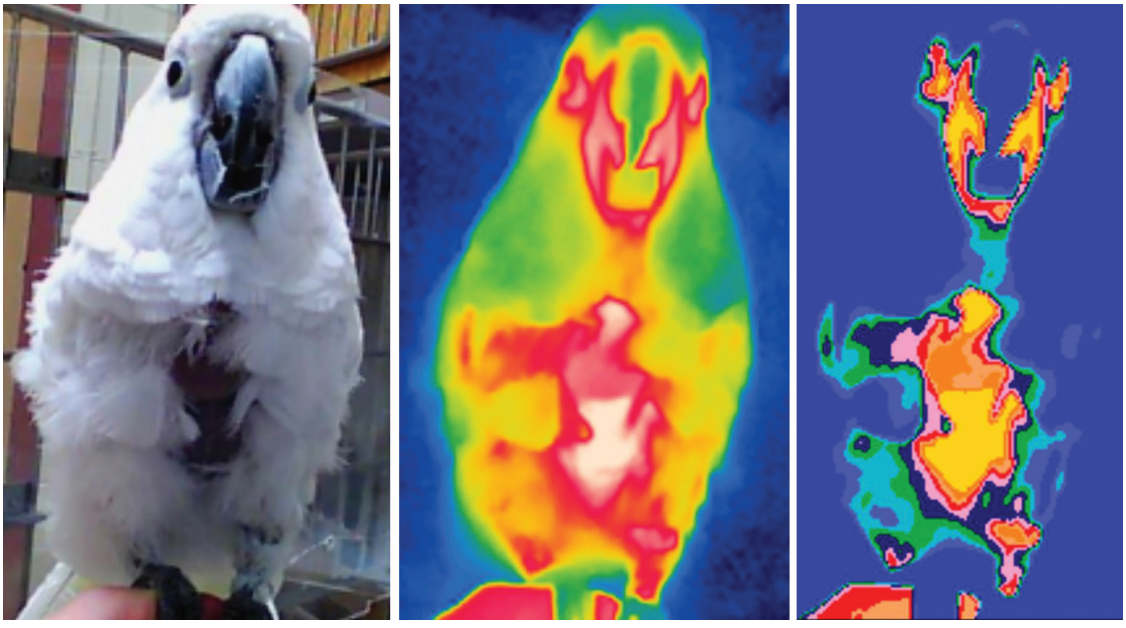

FIGURE 3.20 Umbrella cockatoo (*Cacatua alba*) with mild-to-moderate feather damaging behavior over the pectoral and ventral areas. Side-by-side comparisons of a regular picture, a conventional thermal image, and a thermal image after thresholding that could potentially be used in place of a feather score.

Plumage Thermography

Another indication for infrared thermography in avian medicine is assessment of feather covering and insulation. This modality has mainly been used in birds affected by oil and prior to release, to screen for focal areas of insulation and waterproofing loss, typically associated with residual oil (see Oiled Bird Response).[37]

In parrots, a thermographic picture may be used as a proxy for plumage scoring as hotspots are correlated to feather loss (Figure 3.20). Feather damaging behavior is common in a number of psittacine species and thermal imaging may provide a quick and easy way to monitor progress noninvasively. However, this approach has not yet been compared to plumage scoring[43] and assessed for repeatability. It will also likely have to be standardized across examinations for consistency and comparability. Interestingly, infrared thermography has been used in chickens for that exact purpose. In a study assessing the effect of different housings on feather damage, the feather damage scoring system was replaced by a thermal image of the body.[44]

Oiled Bird Response

The use of infrared thermography for research and response in wildlife exposed to oil, although in its infancy, has shown great promise. The ability to map external heat without capturing the animals is especially beneficial in an oiled wildlife

rehabilitation setting. Since the commercial availability of infrared thermography cameras, they have been used in several research projects evaluating their potential for remote assessment of waterproofing in seabirds and sea otters. The primary cause of acute debilitation and mortality in seabirds impacted by petroleum and other oils is the loss of waterproofing and subsequent heat loss. Removal of oil through washing/rinsing and rehabilitative care can lead to the restoration of the waterproofing properties of feathers, although frequent handling of the animal post-wash to evaluate waterproofing can increase stress to an already stressed animal. In addition to adding stress, assessing waterproofing is time-consuming and can be somewhat subjective. The ability to track the return of water repellency can be extremely beneficial for the animal and for those providing care for oiled wildlife. Infrared thermography can be used to detect, quantify, and photographically display the body's surface temperature from a distance and has the potential to be a more sensitive indicator of waterproofing than behavioral observations alone.[37,45] With large areas of oiled plumage, thermography may detect widespread insulation and heat loss over the body. Smaller areas of waterproofing loss may also be readily detected using this technique (Figure 3.21).

In addition to being used for identifying waterproofing issues, infrared thermography images can also be useful for revealing areas of inflammation and healing in aquatic birds. An infrared thermography camera was used for this purpose to examine the ventral midline incision on a Western grebe (*Aechmophorus occidentalis*) after surgery.[46] The heat loss from this area on the bird (indicative of inflammation) was not evident on day 9 post-surgery when it is evident from a thermograph that the incision site had healed.

Since so little information was available on the effects of chemical dispersants and chemically dispersed oil on bird waterproofing, the Oiled Wildlife Care Network (University of California, Davis) conducted a research study to examine the physical effects of chemical dispersant and chemically dispersed oil on the feathers of the common murre (*Uria aalge*).[47] The main goals of this research were to expose birds to chemical dispersant and dispersed oil and assess structural changes to these feathers (Figure 3.22). Results suggest that chemical dispersants could potentially cause significant waterproofing issues in

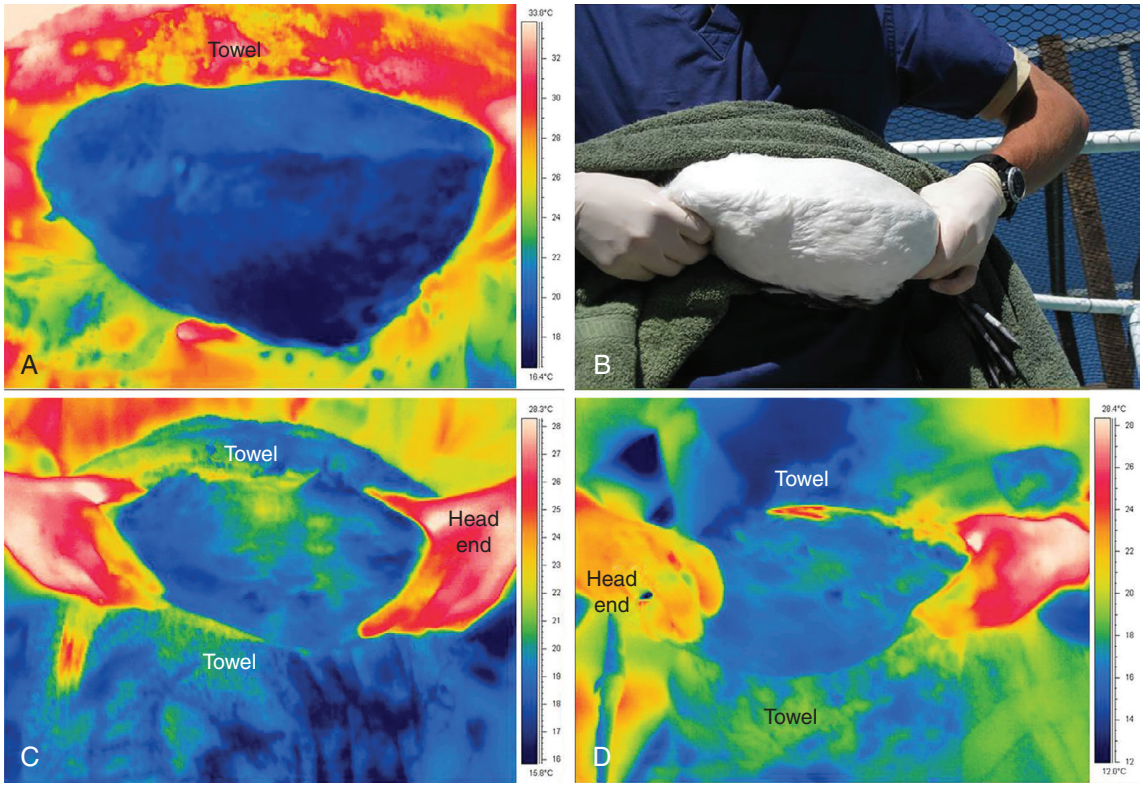

FIGURE 3.21 Assessment of waterproofing on the ventral surface of seabirds during an oil spill response using infrared thermography. (A) Thermographic photo of the ventral surface of a Pacific loon (*Gavia pacifica*) after spending its first post-wash night in a pool. Upon physical examination, no wet spots were found (100% waterproof). (B) Paired digital photo of the bird on photo A being held for an infrared thermographic waterproofing check. (C) Infrared thermographic photo of the ventrum of the same bird during a different waterproofing check. No wet spots were found; the *green areas* on the ventrum are actual residual warmth from heat conductive transfer from the handler's hands during restraint. (D) A different bird, a Western grebe (*Aechmophorus occidentalis*), is being imaged after being in a pool for 2 hours. Warmer spots (*greens and yellows*) on the ventrum matched the "wet-to-skin" areas (nonwaterproof) observed clinically. (Reproduced with permission from OWCN, University of California, Davis.)

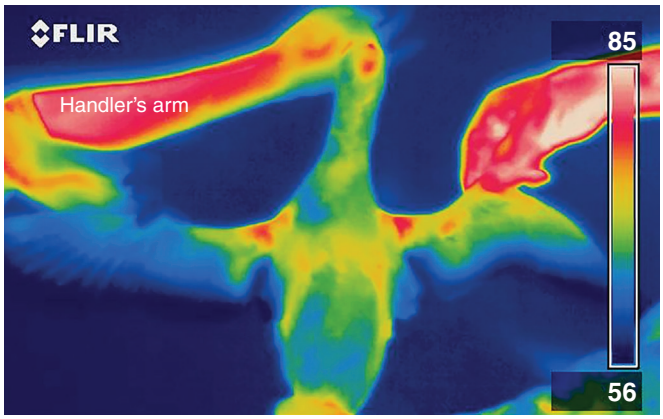

FIGURE 3.22 Thermographic image of a common murre (*Uria aalge*) being examined for feather waterproofing following exposure to chemically dispersed oil. The areas in the image in *orange* and *red* indicate areas with loss of waterproofing (heat escaping indicated by the "warmer" colors).

aquatic birds by disrupting the feather structure. Infrared thermography was used to determine loss of waterproofing following exposure to dispersants and chemically dispersed oil, and the return to waterproofing.

Flock Screening

When imaging a flock of birds, individual birds may stand out because of different thermal signature than the rest of the flock (Figure 3.23). These birds can be further assessed by physical examination without having to physically examine the entire flock. However, molting birds may also display different thermographs than nonmolting birds and individuals may try to dissipate heat for various reasons (after exercise, stress, recent flying, etc.).[37] In aquatic birds, recent swimming may also lead to colder individuals than the rest of the flock. Thus, these differences may not always be related to clinical abnormalities.

Infrared thermography may also be considered useful to screen a flock for thermal stress as it is done in the poultry industry. Conversely, for tropical species housed indoors during the winter, thermal imaging can be used to assess signs of thermal struggle or even the insulation of the building and aviary.

CONCLUSION

In conclusion, while infrared thermography may only have value as an adjunct diagnostic modality, to the author's opinion, it is useful as a monitoring tool for inflammatory or necrotic lesions as well as for monitoring treatment efficacy. For medical thermography of the pelvic limbs, a temperature increase over 5°C appears to be clinically significant. However, the avian veterinarian should be mindful of the multiple thermal adaptations of birds, especially regarding their feet. For these reasons, it is best to perform the thermographic examination in a controlled indoor environment and prior to any stress, restraint, and placing birds into incubators. The use of thermal imaging to monitor feather damaging in psittacine birds and captive flocks of birds should also be further explored.

Disclosure statement: Parts of this chapter were published in the ABVP 2019 symposium proceedings.

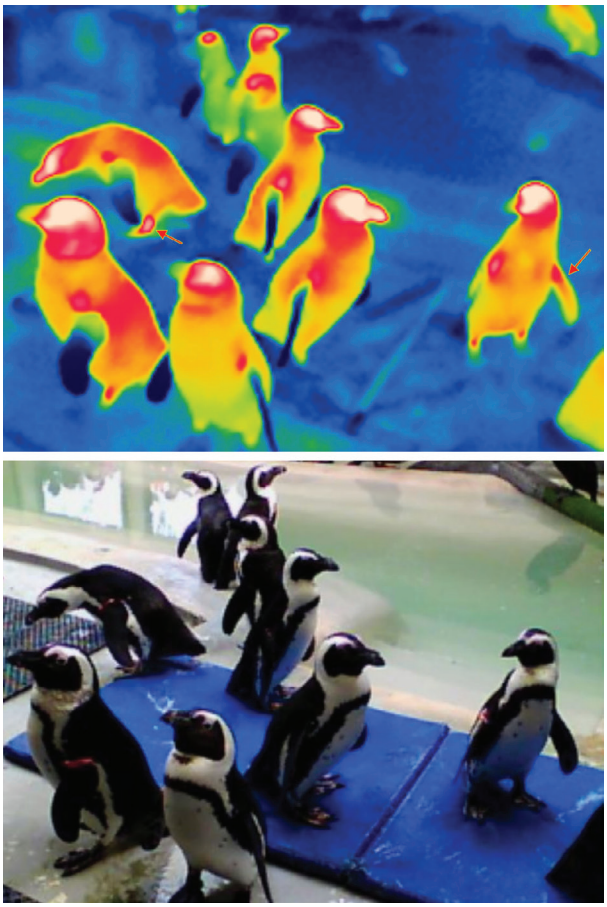

FIGURE 3.23 Thermographic image of a flock of black-footed penguins (*Spheniscus demersus*). Note that compared to the rest of the flock, one penguin shows a warmer flipper and another one a warmer foot *(red arrows)*. Note that the top of the flipper in penguins is always warmer than the body, likely related to a heat exchanger mechanism for the flipper.

CHAPTER 4

The Value of Necropsy

Judy St. Leger • *Alexandria Mena*

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

The value of diagnostic testing for the living patient is clear—the results establish diagnosis, direct treatment, suggest a prognosis, and provide information about the patient, contact animals and people, and even overall management. A complete blood count, serum chemistry, and various cytologic evaluations are the foundations of clinical pathology; bacterial and fungal cultures and sensitivities identify pathogens and direct treatment; polymerase chain reaction (PCR) testing is routine for various infectious and parasitic diseases and directs both prognosis and therapy. How can a necropsy provide value for avian clinicians?

The necropsy not only tells us why a bird has died but also defines the extent of the disease, identifies concurrent or predisposing issues, and directs actions to protect or improve the health of cohort birds. Furthermore, the necropsy can provide valuable closure for an owner or keeper as well as the veterinary staff who has suffered the loss of the bird, when it is offered and performed in a caring, compassionate manner. An important component of the process of accepting and processing loss can be provided with a factual understanding of the cause of death through necropsy. Veterinary health care providers can also benefit from this information, and review of their clinical and diagnostic thought processes that were utilized during the provision of health care prior to death. This chapter aims to provide an overview of the importance of necropsy as a tool, and provides important details on how veterinarians can work best with their pathologist to help them obtain the most out of a necropsy.

WHY A NECROPSY IS VALUABLE

There are many reasons for a necropsy to be considered part of complete medical care. The top 10 list is provided in Box 4.1. In essence, these reasons can be categorized into three categories: (1) patient focused when the aim of the necropsy is to learn more about the specific patient; (2) professional focused when the value of the necropsy is most obvious for the professional team; and (3) owner focused when the necropsy mostly aims to help the owner obtain critical information for either legal or management actions.

The value of a necropsy in the diagnostic evaluation of the patient that has died is self-evident. First and foremost, it establishes a cause of death. This examination may be requested from an owner, breeder, or wildlife rehabilitator interested in evaluating a bird found dead. The client may call with questions about what to do after a bird has died. This is an opportunity to suggest a necropsy evaluation. History may be suggestive—something like one or more birds suddenly dying while the owner inadvertently burned something while using a nonstick cooking item. A necropsy can confirm (or refute) such assumptions. Not all birds that are candidates for necropsy examinations die suddenly. A thorough necropsy can also be beneficial in confirmation or refinement of the clinical diagnosis. Clinical pathology may identify an illness as renal or hepatic disease in the live patient. Necropsy can refine and better characterize the type of liver or renal disease, and if there are other organs involved as well. For example, serum protein electrophoresis may show chronic inflammation with a spike in gamma proteins. Such a change can be related to fungal infections like aspergillosis, malaria infections, and sometimes even chronic issues like pododermatitis (bumblefoot). In penguins and birds of prey, differentiating these conditions is important for both individual management and flock management. Identifying comorbidities is another important role for necropsy examinations. It may be clear and evident that a young bird has died from a bacterial infection, but histologic review of the bursa or spleen may identify underlying circovirus or polyoma viral agents that lead to the fatal concern. Such cases are ones where the findings from a dead bird can impact decisions that affect the remaining living birds in an aviary.

Necropsy examinations provide important opportunities for training for practitioners and staff. Consider the opportunities they afford clinicians, technicians, and students. Regular internal examinations on deceased patients create a familiarity with anatomy that is difficult to obtain in any other manner. Regularly examining the internal viscera of various bird species has a direct and significant impact on clinical interventions such as radiology, endoscopy, advanced imaging such as computed tomography (CT) examinations, and surgery. Necropsy examinations provide opportunities to consider anatomy in relation to imaging results. Necropsies should be performed in a manner that helps to improve tissue handling; a valuable opportunity for the clinician with which to develop and hone their skills for the living patients with similar potential pathology suspected to be present. Approaches for interventions including endoscopy, surgical access to the coelomic cavities, and vascular access can be practiced or visualized during a necropsy examination. Suture skills can be perfected.

BOX 4.1 SELECTED REASONS TO PERFORM AN AVIAN NECROPSY

Patient Focused:

1. Determine the cause of death
2. Confirm or expand on the clinical diagnosis
3. Identify comorbidities (concurrent conditions)

Professional Focused:

4. Improve the accuracy of clinical diagnoses
5. Evaluate the effectiveness or medical and surgical interventions
6. Improve knowledge of anatomy

Owner Focused:

7. Obtain documentation for legal or forensic cases
8. Identify emerging diseases/flock issues
9. Screen for zoonotic disease issues
10. Identify and evaluate disease trends and management systems

FIGURE 4.1 At the base of the heart, there is a bulbous dilation of the trachea, the syringeal bulla, at the syrinx in the adult duck *(Anas platyrhynchos)*. The pericardium is mottled with urate deposits.

Even surgical techniques can be practiced without the interference of active bleeding. Every necropsy affords the clinician an opportunity to become better acquainted with the three-dimensional anatomy and anatomical pathology of birds. Anatomical variations such as the syrinx of ducks, the elongated gall bladder of toucans and toucanets, and even the grinding pads and stones found in the ventriculus of the Nicobar pigeon *(Caloenas nicobarica)* can be appreciated and their existence confirmed on necropsy examination (Figures 4.1–4.3).

Occasionally, patients do not respond to case management as expected. In these cases, a necropsy provides information on disease severity, which may explain the response to therapy. For example, birds affected by air sacculitis and/or pneumonia due to aspergillosis commonly require long-term treatment. When these infections are especially severe (Figure 4.4), death can result from tracheal occlusions (Figure 4.5) even if the air sac damage is resolving (see also Section 6: The Respiratory System, and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).

What value can an examination on a dead bird provide to remaining household birds or to the owner/caregiver? If

FIGURE 4.2 The naturally elongated gallbladder of a toucanet (*Aracari* spp.). The mottled appearance to the liver is due to a bacterial hepatitis, but the gallbladder is normal.

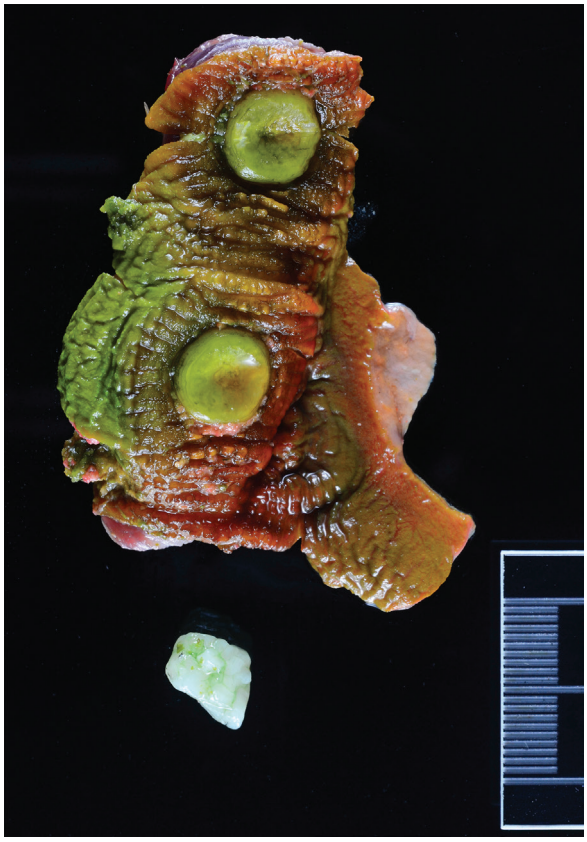

FIGURE 4.3 The ventricular mucosa and grinding stone from a Nicobar pigeon *(Caloenas nicobarica)*. The pads within the koilin are a normal feature in this species. The stone assists in grinding food. (Photo courtesy Disease Investigations, San Diego Zoo.)

infectious disease is a possibility, cohort animals can be treated or managed in ways to reduce the spread of infection. Often, these necropsies include cultures and cytologies collected at the time of necropsy. A case of enteritis or hepatitis could be due to a variety of bacterial or viral pathogens. A simple gross examination will not identify the culprit to a

FIGURE 4.4 Severe clavicular air sacculitis due to aspergillosis in a Magellanic penguin *(Spheniscus magellanicus)*. The clavicular air sac has a thick film of fungus and inflammation. The thoracic air sac has multifocal distribution of fungal plaques.

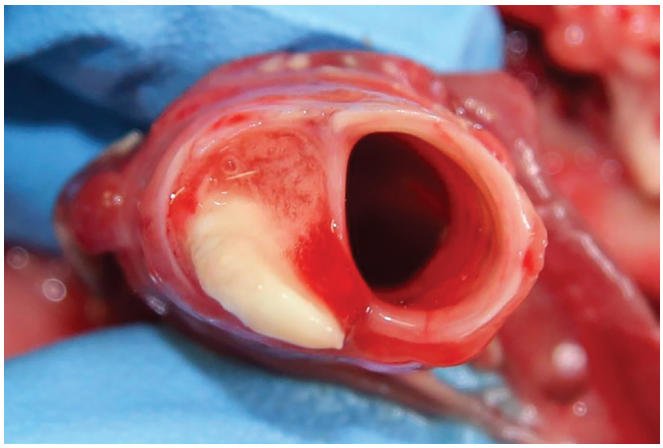

FIGURE 4.5 Cross section of the trachea of a penguin, showing complete occlusion of one of the tracheal lumens. Partial occlusion also occurs.

level of value in addressing the health of poor nutritional condition and contact animals. As a case example, a relatively new bird to a collection died suddenly while being treated for gram-negative enteritis based on fecal cytology. Necropsy with cytologies could show that this bird had a much more concerning coinfection with *Chlamydia psittaci* resulting in classical signs of poor nutritional condition, hepatitis, splenic enlargement with necrosis, enteritis and air sacculitis. As such, the necropsy cytology, resulted in the entire collection being treated for chlamydiosis and prevented a simple infection from becoming a disaster. Similarly, the necropsy results could lead to the owner being diagnosed and treated by their physician as well. Therefore, enhanced diagnostics from the necropsy can be useful to allow quick resolution of a disease and help prevent a large outbreak with spread of the disease to other birds, animals and/or humans.

Zoonotic conditions like chlamydiosis are well known to avian practitioners (see Chapter 18 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Obviously, screening for *Chlamydia* spp. on post-mortem examinations is indicated. In these cases, a positive finding suggests a need to screen or treat cohort birds and people. However, chlamydiosis is not the only zoonotic condition of concern. Other infectious agents such as influenza, West Nile virus (see Chapter 16), *Escherichia coli*, *Salmonella*, *Campylobacter* (see Chapter 17), cryptosporidia (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease), and *Giardia* (see Chapter 23) can impact multiple birds and owners.[1] When these agents are identified, further screening of live birds is indicated for direct treatment. Additionally, owners should be advised to consult their physician if they have concerns about zoonoses.

Unusual mortality events occur in collections and wildlife populations. The typical scenario is that one or two birds die, and then suddenly, lots of birds become sick and/or die. At this time, the clinician can be faced with desperate phone calls from one or more clients. In free-ranging birds, etiologies are often environmental, infectious, or toxic. Emaciation events due to fish population declines are not uncommon in seabirds like puffins (*Fratercula* spp.) and fulmars (*Fulmarus* spp.).[2] "Wrecks" due to migration during bad weather (where hundreds or thousands of birds can be found dead and dying because of uncontrolled landings), as well as massive die-offs due to infectious diseases like salmonellosis, West Nile virus, and avian influenza, or intoxications like avian botulism or ingestion of Avitrol (4-aminopyridine)[3,4] are all well documented. In these cases, it is not uncommon for the clinician to be presented with birds in various stages of decomposition. To best manage this, two or three of the best-preserved (freshest) specimens should be selected for further examination and sample collection while the rest of the carcasses are frozen for later evaluation, if needed. In rare cases, complete documentation of findings in all birds will be valuable.

A published report of lories and lorikeets (Loriinae) with salmonellosis causing an unusual mortality event in a zoo follows this pattern to a tee. First, two birds died. Then over the next 10 days, eight more birds died. Necropsy examinations identified hepatitis and splenitis, bacterial emboli, and enteritis indicative of overwhelming bacterial septicemia. *Salmonella typhimurium*, with the same antibiotic sensitivity pattern, was isolated from four birds. The same pathogen was isolated from a cohort snake and the environment, but not the food preparation areas. The follow-up of removing snakes that likely shed the agent into the environment was important in outbreak control.[5]

In private collections, conditions such as weather extremes and infectious disease concerns like psittacine herpesvirus-1 (Pacheco disease), paramyxovirus-1 and -3, avian polyoma virus in young birds, and chlamydiosis are common agents of unusual mortality events (see Chapter 18, Chapter 41, and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2 Infectious Disease). Toxic conditions like polytetrafluoroethylene (PTFE—Teflon) toxicosis and toxic plant ingestion are sadly still seen in both pet bird and breeder bird collections (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 18, Advancements in Diagnosis and Management of Toxicologic Problems).[6] Some infectious diseases that normally impact only individual birds like aspergillosis can present as unusual mortality events if predisposing conditions affect a large number at the same time. For example, if polar penguins are exposed to warm temperatures, they will often break out with aspergillosis as a colony issue within a few days to weeks. The goal of the necropsy examination in unusual mortality events is to determine both the cause of death and the predisposing conditions or

events that led to the deaths. In doing so, the necropsy is highly relevant to the remaining living birds.

A great example of the value in unusual mortality investigations is an event involving a collection of breeding psittacines in southern California that died from heat exhaustion. While these birds were acclimated to hot temperatures, a mix of high temperatures and reduced aviary shade resulted in seven adult birds dying over a 2-day period. Presumptive concerns were for an infectious disease or a toxicosis. The necropsy examinations showed high internal body temperatures and tissue congestion with nothing more. The environmental history and lack of lesions suggesting other typical causes for sudden death were key to the diagnosis. Shade clothes and sprinklers were installed and the remaining 55 adult birds in this collection survived continued temperature extremes.

Necropsy examinations are not only to determine the ultimate cause of death but also to determine the pathogenesis of disease to address primary problems. For example, many birds that die from acute visceral gout (and presumptive hyperuricemia) have predisposing renal amyloidosis, which may have resulted from chronic inflammation due to initiating conditions such as self-mutilation of pododermatitis (bumblefoot, see also Chapter 33; Figure 4.6). Management changes to reduce the incidence and severity of the initiating concern in the population can reduce or delay deaths.

Not only do thorough necropsy examinations consider how the story of the animal's illness and death evolved, but they also screen for concurrent health conditions that may impact other birds in the household or the collection. For example, nutritional issues such as vitamin A deficiency (identified histologically by squamous metaplasia of glands such as the esophageal glands) or vitamin D deficiency (identified both grossly and histologically by soft, bendable bones with disorganized cellular arrangement) may be present in birds that die for a completely unrelated issue. Regardless, managing these conditions in the remaining birds will elevate the overall health of the birds in the home or collection. Incidental viral inclusions can be identified histologically indicating viral presence in the bird or home or collection. Finding indication of the presence of agents such as avian polyomavirus or avian bornavirus (see Chapter 14 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease) can have an impact on management and/or vaccination considerations and future management decisions for a flock. Parasitic conditions (both internal and external) can be identified via necropsy examinations, and treated accordingly in the remaining live birds (see Chapter 9). While these infections may be incidental, they do reflect health management and may suggest a need for screening or treatment in cohort birds, or changes in management strategies and philosophy (see also Section 4: Infectious Disease Prevention).

FIGURE 4.6 Bilateral ventral hyperkeratosis and ulceration (pododermatitis, bumblefoot) in a gentoo penguin *(Pygoscelis papua)*.

BOX 4.2 ORGAN SYSTEMS AND THEIR REPRESENTATIVE TISSUES

Skin: skin, feathers, conjunctiva, uropygial gland
Nervous: brain, pituitary gland, spinal cord, sciatic nerve, crop or proventricular wall
Cardiovascular: heart, heart valves, major vessels
Respiratory: nares, sinuses, trachea, larynx, air sacs, lungs, pneumatic bones
Gastrointestinal: oral cavity/tongue, crop, esophagus, proventriculus, ventriculus, pancreas, duodenum, jejunum, ileum, ceca, colon, cloaca, vent, liver, gall bladder, Meckel diverticulum
Renal: Kidneys, ureters
Hematopoietic: spleen, thymus, bursa, bone marrow
Endocrine: thyroids, parathyroids, adrenal glands
Reproductive: ovaries, testes, oviduct (multiple levels), phallus
Musculoskeletal: skeletal muscle, bone, joint
Special sense: eye (globe), ears

There are certain cases where you may want to refer to a necropsy examination instead of performing it yourself. Legal cases associated with animal abuse, injury, or death, and concerns over malpractice are unfortunately common. These examinations, their write-up, and subsequent follow-up are often extensive. Working closely with an avian pathologist who can perform or suggest board-certified specialists for these types of forensic examinations is very valuable. Options for board-certified avian pathologists include state diagnostic laboratories and a few commercial pathology services. If you must complete the examination, you must focus on thorough, detailed documentation and extensive tissue collection. Box 4.2 lists sampling for extensive histopathology. The table is designed to assist as a reminder for day-to-day examinations. The list can be used as a check off list to identify what samples are collected and which are submitted for histopathology. In cases with legal concerns, collecting as many of the listed organs as is feasible is recommended. If you are aware of (or suspect) legal issues related to a case that you cannot refer to for some reason, it will be valuable to identify an hourly rate upfront for follow-on work after the necropsy is completed.

LOGISTICS: ASKING, SCHEDULING, AND CHARGING FOR NECROPSY EXAMINATIONS

Many veterinarians feel awkward asking owners about a necropsy. Hesitancy can result from unease with adding to the bill for a patient that has died or worries that a necropsy will provide information that was not obtained or uncovered during live animal care. Occasionally, owners are uncomfortable

with the carcass being cut open. The death of a bird can be an emotional time. Neverteless, the multiple levels of value from necropsy examinations should help to overcome these hurdles. Just as it may once have been difficult to suggest interventions like biopsies and advanced imaging, post-mortem examinations should be considered a regular part of complete standard of care provided to avian patients. Given that avian practitioners are often working with wildlife, multiple-bird households and collections, and new pet owners, the necropsy may indeed be the most valuable diagnostic investigation to offer. Post-mortem findings can be critical to managing contact birds, avian collections, and even humans.

First, set expectations ahead of the death of a bird. Many practices use new pet/new client onboarding to present information of the diagnostic opportunities for the practice. Sure, you may want to tout your new digital radiographic imaging, surgical equipment, or advanced imaging that is available. Why not also include a paragraph about complete examinations including necropsies so that clients understand that this is a diagnostic service that your practice provides? Explaining the value of a necropsy is much easier when it is a discussion about a distant future event in the face of a healthy and thriving pet. Necropsy examination results can provide a sense of closure. It can reassure the client and clinician that efforts were well spent. Most importantly, it can provide information that may benefit remaining birds or sometimes even people at home. If owners are concerned about desecration to the body, reassure them that a cosmetic examination can be performed with a single, long incision that is subsequently sutured closed. With all of this value, and all of these solutions, does it not make sense to recommend a necropsy?

Once you define a necropsy examination as an examination, scheduling becomes easier. Do not try to sneak a peek during your lunch break. Doing so shortchanges you, the examination itself, and your lunch hour. You are charging for the procedure; schedule it as you would any other procedure. Time in the schedule for necropsies should be scheduled just like it is for surgeries. Many clinicians prefer to perform necropsy examinations at the end of the day to manage potential spread of disease. Fair enough. If you save the last 30 minutes to an hour of the daily schedule for necropsy examinations, you will have time to do the job well.

Like surgeries, you need to charge for both the procedure itself and for tests—your time and knowledge have a value (see also Chapter 1 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 24, Practice Management and Risk Management). After working hard to treat a bird, death is an unwanted result. If you view it as a failure, you will miss opportunities to enhance your abilities and to provide the top level of care. You will miss an opportunity to understand more fully what happened in the case. Necropsy examinations can be billed as surgeries—there may be a cost based on time or a flat fee based on the procedure itself. If the necropsy also includes cytologic evaluations, cultures, and molecular diagnostics, these should be charged at clinical examination rates. Once a necropsy is incorporated into care as though it were a standard examination, it becomes a standard examination.

Occasionally, you will have a strong reason to perform a necropsy, but a client who is not willing to pay for the service. Some clients will provide permission but only if the examination is at no cost to them. The next step comes down to your investment in yourself. Will you perform the examination without pay? If yes, will you let the owner know what you find? These are difficult questions that need to be based in the philosophy of the practice. This is a great time to establish a theoretical "personal investment account." Your time is free to you—but we all only get so many hours in a day. Are you willing and able to invest some of your time to better understand this case? Post-mortem examinations often need follow-up like tissue histology, cultures, and cytologies. These evaluations have real costs associated with them. Before progressing with a necropsy, it must be determined who will pay for these costs. By keeping track of the costs associated with these educational opportunities, they become more like small professional workshops. Do not expect your diagnostic laboratory to underwrite these evaluations. They usually will not. But your pathologist may be willing to discuss your gross findings and images to help with interpretation. We will explore this further in the section How to Get the Most from Your Pathologist. No matter how or why you approach a necropsy, first and foremost, *get permission in writing from the owner*. Informed consent is required for post-mortem evaluations, just as it is for any procedure for a living patient.

GETTING THE MOST OUT OF A NECROPSY

The techniques of a necropsy examination are well described and often included in the vet school curriculum.[7] Rather than focusing on these techniques, this section provides a few tips that will make your necropsy examination more satisfying and successful.

A necropsy should always be performed in a specific area that is well lit, removed from the general patient traffic, and regularly cleaned and sanitized. Many practices have a small necropsy area in a storeroom near cadaver freezers. These areas, while remote from living patients, are often poorly lit and not pleasant to work in. Alternatives must be identified. If a necropsy examination is analogous to a surgical procedure, the area should be comparable. An isolation area treatment or examination room works well. In many practices, a corner of the regular treatment room is used. In any case, the area should be designated as the necropsy area and stocked with tools and supplies to reflect the work. There should be a counter or cabinet containing tools and supplies as well as materials to record notes—either paper or a computer or tablet terminal.

Basic necropsy tools should not be derived from tools that are considered too dull to serve in surgical packs. The tools that are considered essential for performing an avian necropsy are few. A basic inventory is listed in Box 4.3.

Having a good sterile set or two will make it much easier to perform necropsy examinations. Consider having specific

BOX 4.3 STANDARD NECROPSY TOOLS

Small Birds	Medium-to-Large Birds
1. Iris scissors	1. Poultry shears
2. Jewelers' forceps	2. Scissors
3. Iris forceps	3. Scalpel blade and handle
4. Magnification	4. Thumb forceps

Modified from Schmidt R: Forensic necropsy. In Speer BL, editor: *Current Therapy in Avian Medicine and Surgery*, St. Louis, 2016, Elsevier, pp 769–775.

necropsy examination packs to assure that the tools you need are all set out before the examination. Adequate forms, writing utensils, or access to a computer terminal to enter data should be readily available in the necropsy area. In addition to the tools for necropsy, the area should have adequate cleaning supplies and bags (and labels) for carcasses after the examination.

No tubes, bags, or swabs should leave the necropsy area without a proper label. Every label should have the patient identification (ID), the organ/contents, and the date. This rule will save you hours of confusion, investigation, and possible sadness. You may think you will remember later what went into that tube. You likely will not. A downside of performing necropsies on the fly or as the last examination of the day is the tendency to shortcut steps. Labeling is not a worthwhile shortcut.

Necropsy is about more than collecting tissues in formalin for histology. Tissues and fluids should also be collected and frozen for potential follow-on examinations such as microbiology and toxicology. Recording notes soon after the examination is important. As with surgical notes, the nuances of the procedure can easily be forgotten. Necropsy notes should include both what was seen and what was collected. It is often helpful to review the necropsy images to confirm that all of the important findings are recorded.

TRICKS TO SIMPLIFY THE NECROPSY PROCESS

Although we are all taught the basics of a necropsy in vet school, multiple avian necropsy protocols are available in the literature. However, there are a few simple tricks that will make the job easier and improve results. These tricks are generally not highlighted in the standard "how to" documents. In addition to the standard avian necropsy, evaluations on eggs and babies are slightly different. Information on those examinations can be found in the following section: Examinations of Eggs, Embryos, and Babies or Nestlings.

Standard tool packs or an image of the standard tools and supplies for the examination should be readily available in the necropsy area. Placing a copy of Figure 4.7 in the area gives a simple visual reminder of the complete setup. Many sections of the examination can be performed by support staff. Training a technician in normal avian anatomy will permit the clinician to evaluate the carcass, perform the initial examination, and indicate the tissue collection and sampling plan. The educated technician can finish the examination. Establishing a necropsy workflow plan like this is like managing clinical examinations. The trade-off for this sort of time management is that the ancillary benefits like tissue handling and surgical approach experience are not realized by the veterinarian.

Imaging may be helpful in evaluating a carcass prior to the direct examination of the body. Consider the value of radiographs in documenting injuries such as fractures and metal foreign bodies and directing where to search for items. If ultrasound or CT technology is available to your practice, images can be helpful, not only for evaluating patients but also for developing interpretive skills in this area. A necropsy examination provides a rare opportunity to check your answers in real time.

Because the feathers of birds can contaminate the internal tissues, control is critical to necropsy success. Feathers can be plucked from the carcass to provide a clean skin surface. Alternatives to plucking include wetting the feather coat with water and a small amount of dish soap to permit separating the feathers along feather tracks and reducing the number of downy and semiplume feathers floating about during the examination. The addition of soap helps to control the natural oils and powder down on the feathers that would otherwise repel the water. If neither plucking nor wetting is a realistic option, the body incision site can be managed with a layer of K-Y or ultrasound jelly to separate feathers from the incision area. In a cosmetic necropsy, the jelly can later be removed

FIGURE 4.7 Basic tools for a necropsy examination. Using sharp, dedicated tools will simply improve the experience of the necropsy. Have materials for sample collection, labeling, and taking notes. Not pictured is a camera, a critical tool to ensure that important findings are adequately captured.

with water and the feather coat blown dry with a hair drier to reduce incision visibility.

A picture is worth a thousand words. To get the most out of necropsy images, they need to document lesions and capture all the important findings in your examination. Having an assistant take images during your examination eliminates the need to glove and unglove repeatedly throughout the procedure. Take images with and without size markers. Take images with a wide angle and a close-up perspective. Images can (and should) be deleted so that you have an accurate but not overly extensive bank of images from each necropsy. However, if there is any possibility of a legal issue related to the case, save all images—you can always pare the number down in the future. In the end, you want to capture any identifying features, bands, tags, scars, or injuries. Weigh and photograph all patients prior to the examination to record the patient condition—both nutritional and post-mortem. Nutritional condition is often best captured after feathers have been removed or wetted to better expose the keel. Necropsy images may include a ruler for scale and should regularly have a marker of the patient ID to assure that images can be linked back to the patient. The scale/ruler should be at the margin of the image, not in the center covering tissues. In gross images (such as the whole coelomic cavities), the organs can be used for relative size indicators. If a ruler is not readily available, a known-sized object such as a pen or a coin can serve as size markers. As a rule, it is helpful to take images of lesions in situ and then of the affected organ or organ system alone. If images might be used for presentations or publications, think about how they best illustrate the lesion of interest. Often, including an image of a lesion as seen helps with the clinical correlates for radiographs or palpation. A second image showing the inside of a change then clarifies the finding. In Figure 4.8, a ventricular foreign body is imaged as seen on first examination and then after the ventriculus has been opened. A smooth, neutral background is a good start for compositions. While image background can now be manipulated with processing software, reducing background distractions and glare makes medical images easier to work with in the long run.

You will get most out of images without distractions like blood, feathers, fingers, or foreign objects. However, if coelomic cavities are full of blood, obtain an image of it before removing the offending material. When the cause of death is something like an aortic rupture, the coelomic cavity accumulation of blood tells the story. Similarly, peritonitis from omphalitis is a messy presentation. Before cleaning up the opened intestinal peritoneal cavity, consider what the findings are showing you. If tissue needs to be retracted to better show a deep lesion, use the necropsy forceps or scissors as a retractor. If you must have hands in your image, try to be sure that they are sporting clean gloves. Performing necropsy examinations on a table with integral plumbing makes spraying away blood or intestinal content much easier. Paper towels can be used to blot organs to remove excess blood or debris. Images of the intestinal mucosa should have as much ingesta and blood removed as is feasible.

If clinical radiographs identified pathology, a whole-body image or image of the affected site dissected that illustrates the change is often very helpful. For example, air sac thickening is a common change in cases of air sacculitis from aspergillosis. Post-mortem images of the air sac wall help to illustrate the changes identified on clinical imaging (Figure 4.4).

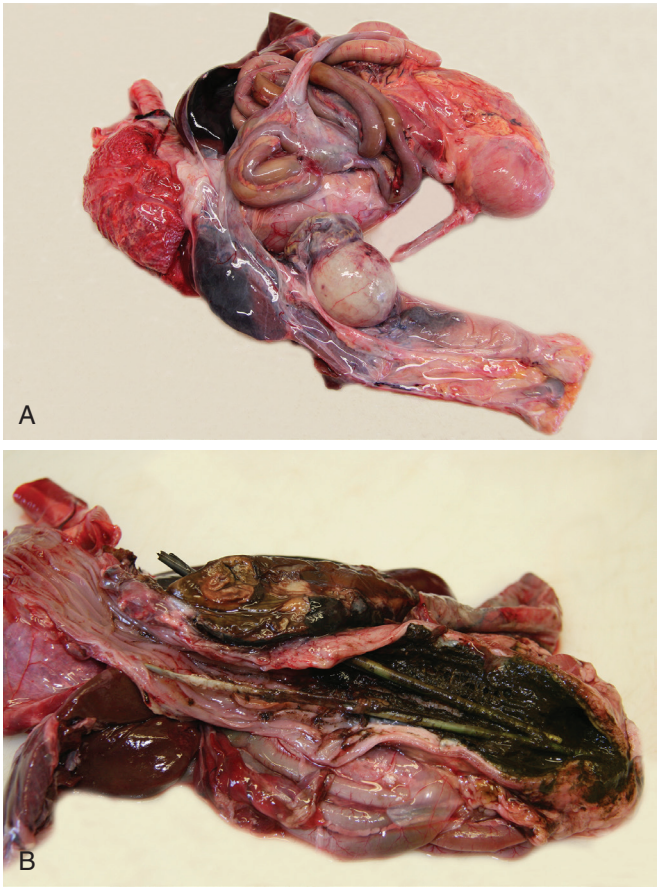

FIGURE 4.8 (A) Viscera from an Adelie penguin *(Pygoscelis adeliae)* demonstrate a linear protrusion from the ventriculus. (B) On cut section, there are feather shafts coursing through the ventricular wall. Inflammation is closely associated with the intestinal peritoneal cavity location of the shafts.

Certain organs are easiest to evaluate at early in the examination or with a specific approach. Upon opening the coelomic cavities, examination of the gonads and adrenals is easiest if performed early in the gross examination. The author recommends collecting the adrenals, gonad, and cranial kidney in one small section. The spleen in some birds can be very small and difficult to locate unless enlarged. In these species, identifying the spleen early in the coelomic examination is essential to organ identification. For example, penguins have a notoriously small spleen. In this species group, the author recommends opening the intestinal peritoneal cavity and reflecting the proventriculus and ventriculus to the left to identify the gastrosplenic region as the first step in the gross examination of the coelomic cavities. If the spleen is very easy to identify in penguins, it is enlarged. In young birds, locating and examining the bursa and thymus should be an early part of the examination to assure that these elusive organs are not forgotten. The thyroids and parathyroids are generally small. They are easily located along the great vessels at the base of the heart when the sternum is first reflected (Figure 4.9). Because they can be more difficult to identify once the heart has been removed, these organs should be identified and sampled prior to removal of the heart.

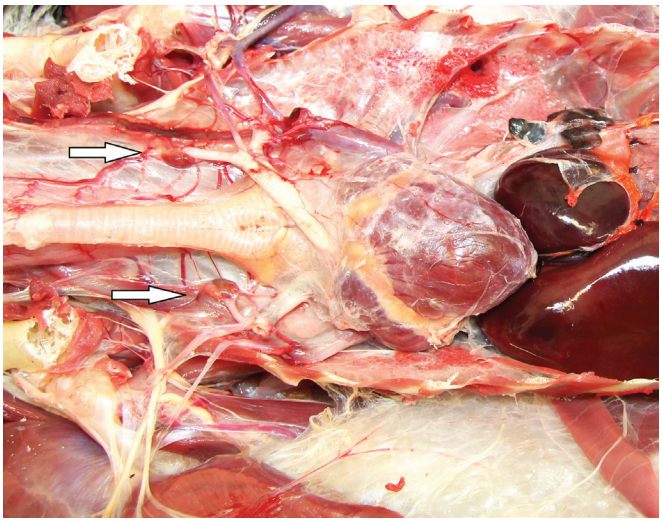

FIGURE 4.9 Thyroids from a California brown pelican *(Pelecanus occidentalis)*. The organs *(arrows)* are easiest to identify before the heart is removed.

The isthmus between the proventriculus and ventriculus is a common site for ulceration, neoplastic proliferation, and growth of some bacteria and fungi. It is therefore better to submit the proventriculus and ventriculus as a unit rather than as two separate samples to facilitate review of the isthmus. Sinuses are the final area where knowing a trick can make necropsy sampling more productive. In passerines, the best approach to sinus evaluation is to slice the head longitudinally and place the half head (brain included) directly into formalin. In psittacine and larger birds, the best sinus exposure is accomplished by a cross-sectional cut at or just behind the nares to expose the bony structures of the sinus and associated soft tissues. This cut is especially helpful in evaluating cockatiels *(Nymphicus hollandicus)* with clinical lockjaw (see Chapter 31 and Chapter 41). Small tissue samples have a way of getting lost in the formalin. Just as you might do with a biopsy, place small tissue fragments into a cassette to keep them more easily identifiable.

A necropsy examination may include sampling for microbiology. Collecting sterile swabs of organs and lesions is not difficult. If the organ of interest is exposed in a clean manner, direct collection with a needle or swab is feasible. When contamination is a concern, one additional step can make a big difference in getting pure cultures. A small spatula and a crème brûlée torch (Figure 4.7) provide a quick and simple way to sear tissue surfaces. Those preferring not to acquire veterinary tools at the cooking store can use a propane torch for the same purpose. The spatula is flamed with the torch until hot. The hot flat surface is pressed against the tissue to kill surface contaminants in a small section. For sampling soft solid organs like the liver and lungs, swabs can be directly plunged into the tissue in the seared area. For tougher organs like the heart and intestines, a scalpel blade can be used to cut the surface so that a swab can be introduced in a sterile manner.

A shortcut to get quick answers from a necropsy is sometimes tissue preps for cytology. Tissues such as lung, liver, kidney, and spleen can routinely be blotted to remove excess blood and touched to a slide surface (Figure 4.10). One

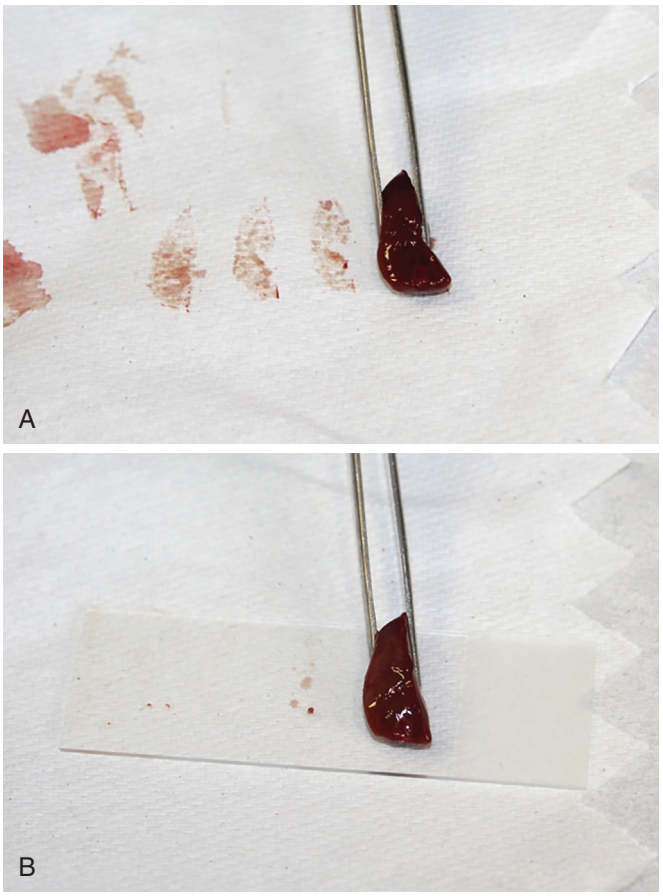

FIGURE 4.10 Touch preps for cytology. (A) Blotting tissue until very little blood remains. (B) Simple touch to a glass slide for cytology. By preparing slides with liver, lung, kidney, and spleen, each slide represents four major organ systems for a quick microscopic examination.

slide can be used for the entire organ set. If three slides are produced (each with the set of four organs), these can be stained with a modified Wright stain (Diff-Quick), Gram stain, and acid-fast or Giemsa stain (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 13 Advances in Clinical Pathology and Diagnostic Medicine). Some protozoal infections such as coccidiosis and atoxoplasmosis are better identified with these cytologies than with histologic review (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Often, when infectious agents are a concern, the speedy early results can direct therapy for the remaining collection while histopathology and bacteriology are pending.

WHAT TO COLLECT

Collecting tissues in a necropsy examination is a complicated decision. The first goal is to determine the cause of death. An important secondary goal is to get an idea of the holistic condition of the animal. These secondary, concurrent, or predisposing concerns are often where necropsy results can guide management efforts. The simplest solution is to collect everything. But reality jumps in all too often. Tissues may be collected to be cultured, frozen for later screening by

molecular or toxicologic evaluations, or fixed in formalin for histology. The amount of information gleaned from a necropsy is often related to the tissues collected for screening. Because necropsy examinations on hand-fed babies and eggs are different from routine necropsies, they will be separately addressed in the next section: Examinations of Eggs, Embryos, and Babies or Nestlings (see also Section 9: Embryology, Neonatology and Pediatrics).

Tissue preparations for ancillary testing beyond the examination and histology include cytologies, fluid analysis, and collection of tissues for molecular screening, toxicology, viral culture, microbiology, gamete rescue, and fibroblast or stem cell culture. Cytologies and fluid analysis rely on freshly collected (not frozen) tissues. Toxicology is usually performed on the liver, kidney, or adipose or gastrointestinal content. Brain tissue can be diagnostic if exposure to pesticides is a possibility. Microbiology materials depend on the clinical and gross findings. Typical sites for culture include the intestinal peritoneal cavity, liver, lung, air sacs, spleen, and intestines. Numerous samples can be collected for fibroblast culture and molecular archiving. In most cases, skin and/or adipose is the preferred sample. Molecular screening for infectious agents is often performed on the liver, kidney, spleen, heart, brain, and intestines. Some avian species have specific species survival programs run by zoos. (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 23, Conservation of Avian Species). A few owners and breeders support these projects and will request specific organs collected for archiving.

The most difficult necropsies are those with no specific gross findings. The tissues that are most collected for these cases are heart, lung, liver, kidney, spleen, and intestines. Please consider adding the brain to this list. While the basic set is often diagnostic, the questions often unresolved include histologic changes that might be present in the brain. Brain tissue can be collected cosmetically. The skin can be reflected to expose the dorsal surface of the skull. A window is cut through the skull cap, the brain is removed, and the skull cap and skin are replaced. The skin can then be sutured closed.

Even cases where the cause of death is identified benefit from a wide tissue review. Decisions on which tissues to submit for histology should be based on the pricing program at your diagnostic laboratory. Some laboratories charge a flat fee for a "whole-bird" necropsy set of tissues for histologic evaluation. If this is the case with your laboratory, the "more is more" philosophy of tissue collection should apply. Box 4.2 presents the full tissue collection list. Some laboratories charge per tissue. If this is the case, fewer tissues for evaluation may be selected—but unanswered questions may remain after histologic review. A solution to dealing with the "less is more" billing system is to collect a complete set of tissues, submit only the tissues critically needed for histology, and archive the additional formalin-fixed tissues. If histology suggests a need for more materials, they will be at hand. Admittedly, this tactic requires more time upfront on the part of the clinician. Some doctors deal with this challenge by performing a cursory examination and having students or technicians drive the thorough sampling plan. The time to collect additional materials is during the necropsy of the fresh carcass. Collecting tissues from a frozen carcass is less than optimal. One final diagnostic laboratory pricing scheme is a charge for grouped numbers of tissues—for example, one to four (small), five to seven (medium), and eight to ten (large). If this is the billing style of your diagnostic laboratory, you can maximize the histologic review by selecting the higher number of tissues from each grouping—for example, in this case, four, seven, and ten, respectively.

EXAMINATIONS OF EGGS, EMBRYOS, AND BABIES OR NESTLINGS

Veterinarians are often requested by aviculturists to investigate cases of reproductive failure. Knowledge of normal reproductive rates and an ability to perform an egg evaluation/embryo necropsy can provide tremendous value in this arena.

Population-level data on fertility and hatchability are essential for proper interpretation of any hatching failure. A useful rule of thumb for species with good incubation parameters is that roughly 80% of the total eggs laid should be fertile and hatch. Of those that fail to hatch, about half should be infertile and half embryo mortalities (see Section 9: Embryology, Neonatology and Pediatrics). Any changes to hatching success above background levels indicate a problem that warrants investigation.

Nutritional deficiencies and imbalances and almost any disease in breeding birds can significantly affect fertility and hatchability of eggs. Suggestive history for nutritional problems includes high or increased infertility, poor hatchability, thin eggshells, and egg binding in females, as well as poor plumage and poor bone quality in chicks. Evaluation of the breeder diet should include a review of the main diet and supplements.

Incubation issues can and often do result in embryonic mortality. Parameters that can result in failed embryonic development or hatch include temperature (dry bulb temp), humidity (wet bulb temp), incubator ventilation, and egg rotation frequency and manner (see also Chapter 40). Determining the stage of embryo development at which death occurred (and comparing that to the number of days of incubation) enables evaluation of developmental progress and facilitates formation of a differential diagnosis. If the embryo stage is retarded in relation to the days of incubation, it could indicate that the incubation temperature is too low.

Most embryos are nearly fully developed at the time of death. In these cases, the first step is to evaluate embryo position to evaluate potential hatching success. The embryo assumes the proper pip position 2 to 3 days before hatching. The normal position for hatching is head under the right wing, with the body oriented so that the beak is pointed toward the lower slope of the air cell. If the head is over the right wing, this is not typically a mortal malposition. Common malpositions associated with mortality include head under the left wing rotation away from the air cell, leg over the head, upside down (head away from the air cell), and head between the legs[8] (see Chapter 40).

Once the egg is opened, culture the yolk for bacterial pathogens. Yolk sac and umbilical infections are common, but post-mortem interval is important to rule out contamination. Infections can come from the maternal oviduct, the egg surface at laying or during incubation. Embryos do not produce much inflammatory response until very late in incubation.

For this reason, cultures without white blood cell reaction can still indicate pathogens. Changes such as necrosis may be the extent of the inflammatory change.

The embryo may have malformations. These can result from genetic or toxic issues with parents but can also reflect incubation issues early in development. Inbreeding is a common concern. In these instances, an overall evaluation of reproductive success and flock management may be needed to fully evaluate these findings.[8]

Mortalities are often recognized in nestlings and fledglings in a breeding collection (see Section 9: Embryology, Neonatology and Pediatrics). Necropsy evaluations in young birds should have a thorough history including brooder temperatures, hand-feeding records, and cohort health concerns. Necropsies should start with an assessment of nutritional condition and hydration as these are common issues with hand-fed babies. If a yolk sac is present, culture upon opening the intestinal peritoneal cavity is recommended. While yolk sac absorption varies by species (altricial species tend to resorb their yolk sacs more rapidly than precocial species), any yolk sac remaining after 13 days posthatch should be diagnosed as yolk sac retention.[8] Additional cultures and/or cytology of the mouth, crop, and intestines should be considered. Aspiration of formula is a common concern. Diagnosis is often seen with formula present within air sacs. The subacute condition typically results in a mixed bacterial infection that can lead to sepsis. Because terminal regurgitation can lead to formula at the larynx and in the proximal trachea, findings of formula limited to this region should be noted but not considered diagnostic until all other etiologies are ruled out.

Congenital malformations may be present that do not result in embryonic mortality but do cause death in hand-fed chicks. Cardiac malformations are the most common issue in the author's experience. For this reason, close examination of the heart is strongly recommended in neonatal bird necropsies (Figure 4.11). Ascites, either in fluid or gel form, can be the first finding suggestive of cardiac issues. Beyond cardiac concerns, leg and beak deformities can arise from management and nutritional issues. These conditions are often not fatal, but their recognition can suggest broader management issues worthy of investigation in the nursery (see Section 9: Embryology, Neonatology and Pediatrics).

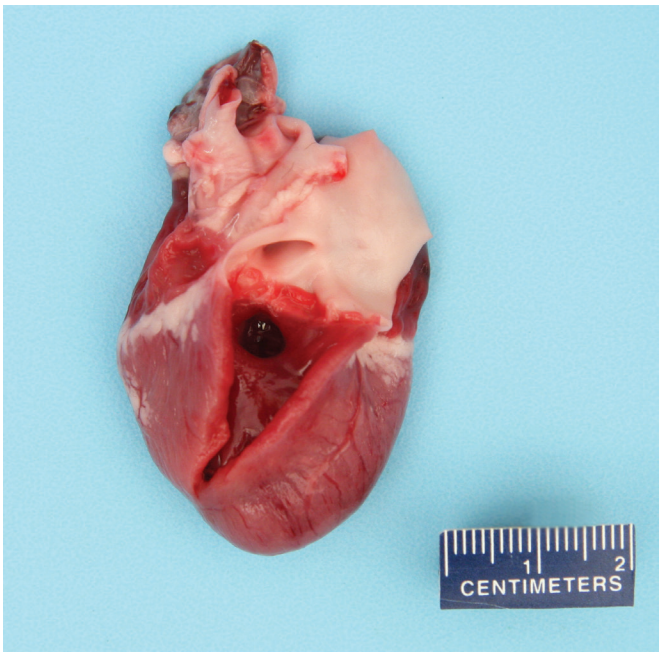

FIGURE 4.11 Subaortic ventricular septal defect in a neonatal Adelie penguin *(Pygoscelis adeliae)*.

Infectious diseases can rapidly cause mortality in many hand-fed birds. Primary viral concerns of psittacine and passerine babies include avian polyoma virus, circovirus, and avian adenovirus (see Section 9 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Avipox infections predominate in the immune-incompetent neonates (see Chapter 15). These infections are often more of a clinical nuisance than a cause of fatality, but they certainly represent a condition of neonatal concern. *Candida albicans* can proliferate and result in clinical disease. It is the most common fungal infection in the young bird and can result in thickening of the crop mucosa associated with delayed crop emptying or crop stasis (see Chapter 41). Associated with this condition, the crop contents often coagulate and present with a sour or fetid odor associated with overgrowth of yeast and bacteria. Bacterial sepsis is a major concern in baby birds. The incompletely developed immune system and immunosuppressive viruses make bacterial infections a more serious concern in neonates compared to adults. Common portals of entry include the umbilicus and yolk sac (omphalitis), as well as the gastrointestinal and respiratory tracts. The agents of greatest concern are like those in adult birds. They include *E. coli*, *Klebsiella*, *Salmonella* spp., *Pseudomonas* spp., and *Chlamydia* spp. (see Chapter 41). "Lockjaw syndrome" is a specific clinical entity in neonatal cockatiels. The condition is generally associated with infection by *Bordetella avium*, but a variety of bacterial agents have been isolated from cases. Some reported cases have had *Chlamydia psittaci* as a coinfection associated with *B. avium*. The lesions in this condition include rhinitis, sinusitis, and fibrosis of the prokinetic musculature in all terminal cases of lockjaw (see Chapter 31 and 41).[9]

HOW TO GET THE MOST FROM YOUR PATHOLOGIST

Selecting an avian pathologist is no small task. Done well, you will have a partner interested in your cases and your professional success. Most board-certified pathologists can do a very good job describing lesions in avian tissues. The value of an avian pathologist is in their specific knowledge relative to the diseases of birds and appropriate management. The avian pathologist understands your questions as a clinician and can rank lesions as to their significance in the "big picture" facing you and your client. Thankfully, good avian pathologists can be found at state and university diagnostic laboratories, in exotic animal pathology businesses, and even in large standard commercial laboratories. Once you have found one, be sure to ask for them when you send in samples. How can you find this magical pathologist?

Be on the lookout for pathologists who present at avian and exotic animal veterinary meetings or who present avian material at zoo and wildlife meetings. Look for their names on publications or in the membership roster of organizations like the Association of Avian Veterinarians (AAV), Wildlife

Disease Association (WDA), and the American (or European) Association of Zoo Veterinarians (AAZV or EAZV). Ask other avian clinicians who they use and trust with their histology. Important characteristics are that the pathologist can address questions you present either in writing with a case submission or on the phone call. They should be able to provide results in a timely manner. They should be able to direct you as needed with follow-up diagnostics, therapeutics, or management.

You can directly impact the quality of your pathology reports with the information you provide/share with your pathologist. Provide clinical pathology information (titers, culture results, etc.) when it reflects topics you would like addressed. For example, if bornavirus molecular diagnostic testing results were positive on the patient, and you submit organs like the proventriculus, ventriculus, adrenal, and brain, the pathologist should be looking at those organs specifically to identify lesions of mononuclear inflammation. (see Chapter 14 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). This should happen even if the cause of death is unrelated. If a previous biopsy has been performed, providing those results can help to guide the pathologist—you are not swaying them; you are helping them to provide context for their findings. Case material for necropsy submissions should include information about the individual, the flock or collection, the working diagnosis, gross findings, and specific questions you want to know the answers to from your report. With this degree of background information, the pathologist can create a more holistic evaluation of the tissues and the case. They can tell you what they know and share information about diagnostic limitations based on the tissue available.

Beyond single-case evaluations, having a good relationship with your pathologist means that they can help you with integrated investigations. If you are interested in cases of a specific neoplasia or infectious disease, your pathologist should be able to work with you through their database. By working with a single laboratory or a specific pathologist, you get the added value of their database as a resource for you and your practice. Most avian pathologists are delighted to work with you on presentations and publications related to important or interesting findings. Pathologists can assist with collaborations on study design and even identify additional clinicians with related interests. In short, a good pathologist is a great resource.

TALKING THE SAME LANGUAGE

It will be easier for you to write more like a pathologist than to convince your pathologist to write more like a clinician. Capturing gross findings without overinterpreting takes a little practice. But once you have established a routine for descriptive terms you will be able to comfortably describe what you see in a manner that will be very clear to the pathologist. The first step in every necropsy is to examine the patient as a whole and to evaluate each organ system. After observing the tissues, you can identify any abnormalities. Occasionally, special features like smell will be important. The most employed descriptive terms are for visually identified lesions. They should include five features:

1. Location and distribution: This can be the region in an organ such as a focal hemorrhage in the liver or it can describe the section of the organ such as thickening of the mucosa of the crop due to candidiasis. Typical terms include focal, multifocal, locally extensive, and diffuse.
2. Size and extent: Size can be an actual measure (length or weight) or a comparative statement like "the right kidney is twice the size of the left." Extent describes the portion of the organ or tissue that is affected.
3. Shape, demarcation, and contour: Shape is typically something like round, irregular, square, or pinpoint. Contour describes if a lesion is raised or depressed. Raised lesions usually indicate something added, like inflammatory cells or neoplasia. Something depressed usually indicates loss from necrosis or atrophy.
4. Color: Certain colors suggest different processes of the pathology. Red to purple often suggests hemorrhage or congestion. White or gray is often seen with necrosis or white blood cell infiltration. White is also seen in urate and calcium deposits, lipid, bone, fibrosis, and scarring. Yellow can be seen due to bile (icterus), degeneration of adipose (Figure 4.12), or associated with yolk. Black suggests melanin. Often, organs such as the gonads can be displaying natural melanosis. Other areas of normal pigmentation include the thyroid, oral mucosa, crop, and the meninges. Pathologic black changes can arise due to melanomas (Figure 4.13), excessive inhaled carbon, or in some cases trematode migrations and pigment deposition in the liver and spleen secondary to malaria infections. Green is common in some fungal infections. In addition to colors, pathologists often describe modifiers for distribution like linear, mottled, or stippled.
5. Texture: This describes how the organ feels and what the surface looks like. Typical words are soft (like your cheek), firm (like your nose), and hard (like a bone). Shiny tissues are usually wet. Crumbly tissues are usually dry. Surfaces can be regular or irregular, rough, or smooth. Tissues expanded with little bubbles are said to have crepitus. A gritty texture suggests mineralization. Fluids can be watery, viscous, gelatinous, creamy, or clotted.

Your description should be such that you can picture the case findings from words used in your gross report. You can either describe things system by system. Or, more typically,

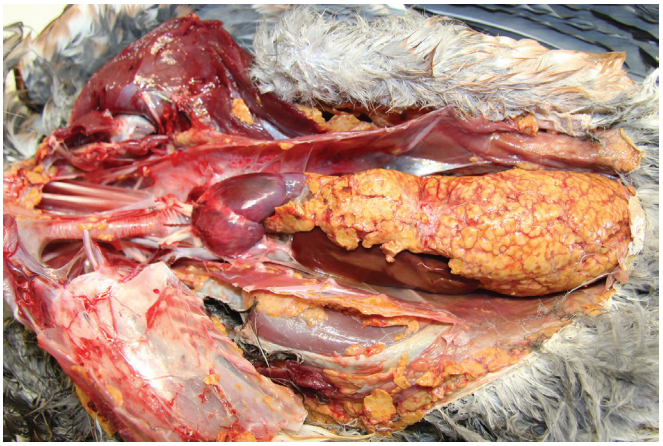

FIGURE 4.12 Degeneration of adipose in a nestling great blue heron chick *(Ardea herodias)*. Steatitis in this species is associated with pronounced accumulation of hard, yellow fat.

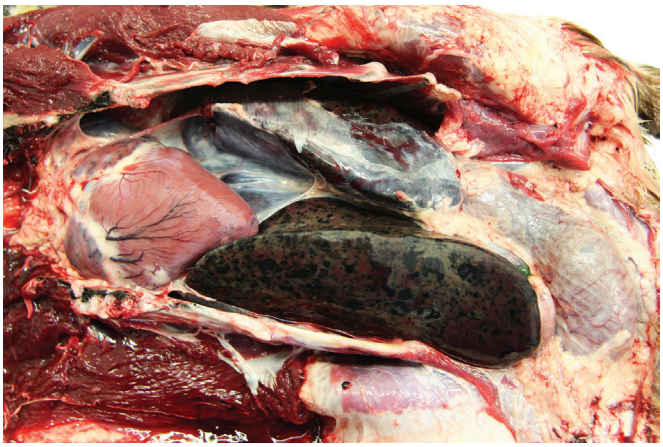

FIGURE 4.13 Hepatic melanoma in a Humboldt penguin *(Spheniscus humboldti)*. The extensive black pigment in the liver represents metastatic melanoma cells throughout the organ. The primary neoplasm was identified associated with skin.

describe the most important changes first and describe artifacts last, if at all. As you become more comfortable with necropsy examinations, you will learn what changes are artifacts and what are real. If you cannot decide, describe them. Pathologists can sort out what they mean based on histology. Typical artifact changes in avian patients are the product of decomposition. These include bile staining from the gall bladder on the liver, intestines, and even the muscle and skin over the abdominal region, an overall redness to intestines and intestinal content, dilation of the intestines, sloughing of the ventricular koilin, and congestion of the skull or meninges in the region of the cerebellum.

Getting your reports clear and concise for the pathologist is the first step in a common language for necropsies and pathology. Communication and transfer of information goes both ways. Proper interpretation of necropsy reports will increase the information you can glean from these documents. A necropsy report generally consists of three sections—description, diagnosis, and comments. To get more information inserted into the comment section, make sure to submit specific questions with your tissues. Questions can vary from "What is the change I saw in the kidney?" to "What should we do to manage the remaining household birds based on your findings?" A skilled pathologist can interpret results to answer your questions even if the histology findings are limited. Indeed, sometimes, negative findings are very helpful. Infectious diseases can be ruled out by a lack of changes in many cases. If additional tissues or special stains might address questions left unanswered, these too may be presented in the comments section.

Within the diagnosis section, there are multiple ways to present findings. Typically, the most important changes are noted as the first diagnoses. Down the line, significance becomes less. Generally, the cause of death is the first diagnosis. However, if the cause of death was known clinically but not shared on the histopathology submission form, the first diagnosis will only reflect the histopathology findings and not the entirety of available case information. This is not a shortcoming of the histopathology report, but it can sometimes be modified to fit your system as desired. It is a good idea to discuss how you prefer these reports to reflect the post-mortem findings.

The tissue description section will have specific descriptions of all abnormalities examined. A review of this section confirms which tissues were reviewed and where lesions were (and were not). It is important to remember that the diagnosis and description terminology is flexible. There are many ways to say the same thing. For example, "acute necrotizing hepatitis" and "acute hepatic necrosis with heterophilic infiltrates" can both serve as a diagnosis for similar histologic changes in the liver. The histologic descriptions can help you to better understand the variations in morphologic diagnoses.

WHAT TO DO WITH NECROPSY/ PATHOLOGY RESULTS

As with all laboratory results, the necropsy report is entered or attached to the individual patient's record—be it paper or electronic. But this should not be the end of what happens with this information. Avian veterinarians are unique in that many of our clients have collections of birds. Individual results provide a snapshot view of the collection at any time. Having a paper or digital folder for these clients in addition to individual records allows the clinician to keep track of "collection"-based results. Many practitioners have such folders to file flock-screening results and treatments. If the necropsy had ancillary testing, say cultures or PCR, the results should be filed in both the individual bird file as well as in the flock file. Also, into this file, should go the photos collected during the necropsy examination. Data management is where using a single pathologist from a single laboratory has tremendous value. Reference laboratories generally track submissions and diagnoses. Preparing a matrix of cases to address questions about facilities, species, and even specific diagnoses is only a simple search.

Some veterinarians use a variety of services for clinical and post-mortem examinations. When this is the case, the client should be encouraged to develop a matrix of mortalities to allow the same sort of evaluation that you can provide including cases that you have not seen.

If a case has a specifically good illustrating image from the gross or histologic examination, these images should get labeled and stored in yet another folder. I like to call this folder the "Good Pix" folder. Images here can be sorted by etiology or affected organ system. They should be well labeled as to bird species, identification, organ system, and diagnosis. This folder is where you can go for images for presentations and publications and to produce illustrations for client information. If a necropsy image specifically relates to a clinical image such as the live bird, a radiographic image, or an endoscopic view, including this image in the Good Pix folder enhances the value of the necropsy images. Indeed, the Good Pix folder can serve as an indexed repository for all images from clinical examinations, clinical pathology, imaging, and necropsy examinations. The index for this folder should be a spreadsheet that captures the bird species, identification, image organ system (or whole body), description, and diagnosis.

In addition to data and results from a necropsy, there is fair chance you will also have residual samples either frozen or in

formalin. Having these on hand is helpful, but keeping them forever is not. All stored or retained samples should be clearly labeled with a case and specimen ID and the date collected. This should be logged onto a simple spreadsheet. A monthly review and sample management (read tossing) will keep this archive under control while allowing you to hold onto samples that might prove useful in the future.

CONCLUSIONS

There are many reasons for viewing the necropsy as a standard examination in avian medicine. Working in concert with an avian pathologist, you can advance your abilities and expand your practice in a manner that adds not only value but also satisfaction.

CHAPTER 5

Pharmacologic Intervention

Lisa A. Tell • Krysta L. Martin • Emily D. Richards • Jennifer L. Davis • Zhoumeng Lin • Barbara A. Byrne • Lauren V. Powers

Visit eBooks.Health.Elsevier.com for a complete set of references.

Avian medicine encompasses treatment of a broad range of species across a variety of sectors, so it is no surprise that while some overarching principles of treatment may be similar, other considerations vary widely. Differing sectors include companion exotics, zoological institutions, backyard or commercial poultry and game birds, free-ranging, and hobby/sport species just to name a few. In some cases, the therapeutic focus might be on treating an individual patient or commercial flock, while in other situations release of the patient into a free-ranging environment might impact the treatment plan since the bird might be hunted and consumed by humans. Additionally, in some cases veterinarians might have to consider broader economic impacts and consequences of treating avian patients. For example, with a commercial flock, choosing to treat with a medication may drastically alter the return on investment and affect the treatment course, while simultaneously necessitating being mindful of any potential impacts on human food safety. As new research is published and therapies are discovered, practitioners need to evaluate relevant findings and establish an optimal therapeutic plan for their patients. The aim of this chapter is to provide a comprehensive overview for practitioners considering pharmacologic intervention for treating avian patients. Fundamental guidelines that are foundational to developing and monitoring a treatment plan will be covered, in addition to a review of general pharmacologic principles, pharmacokinetic modeling approaches, and interpretation of antimicrobial results. Lastly, useful resources are provided for current and future use.

EVALUATING DRUG THERAPY OPTIONS

Lisa A. Tell, Krysta L. Martin, Emily D. Richards

Visit eBooks.Health.Elsevier.com for a complete set of references.

Therapeutic intervention for an ill avian patient can be challenging due to limited scientific data that are bird specific. As with any other patient, thorough husbandry and medical assessment of the individual or flock and documenting problem and differential diagnosis lists are essential. Subjective and objective physical examination findings, pertinent husbandry practices, past medical history, clinical pathology, microbiology, and/or imaging results are all critical for identifying medical conditions needing to be addressed with treatment. Determining if clinical signs could be resolved with management or nutritional changes is essential for avian patients. Avian patients commonly have husbandry and management issues; therefore even if clinical pathology results suggest treatment, the disease condition might be secondary. For example, avian patients might have a gram-negative bacterial enteritis where contaminated food or water might be the source of the problem versus a true primary bacterial pathogen. Committing to a detailed assessment before instituting pharmacologic intervention could help avoid repeated and unnecessary treatment. In addition, identifying the exact medical condition that warrants treatment will help narrow the proposed medication list. If treating the bird is instigated, monitoring treatment outcome, whether symptom solution or restoration of clinical pathology laboratory values, is essential.

If pharmacologic therapy is warranted, a starting point for determining specific drug options would be drug formularies that have been compiled specifically for avian patients. Drug formularies for avian patients can be found in the "Resources for Practitioners" table at the end of this chapter. When choosing a therapeutic regimen based on a formulary listing, it is important to critically review references, check for evidence-based practices (Veterinary Information Network[1] is a commonly used resource in the United States), and confirm the applicability of the planned treatment regimens for the specific medical condition and

case. A drug therapy plan is complete when the practitioner has decided on the medication, dose to be administered, route of administration, frequency of administration, treatment duration, therapeutic monitoring, and how treatment success will be defined.

When a drug therapy plan is being constructed, best practice questions to consider include the following:

- *What nonpharmacological interventions can be utilized as an alternative?*

  While medications are often the first line of defense for "treatment," nonpharmacological interventions should be prioritized and could be a more favorable alternative without compromising the patient's health. Nonpharmacologic options minimize unnecessary medication use, especially with antimicrobials, and prevent adverse reactions. Even simple approaches, such as isolating sick patients, preventing the spread of disease, changing the food/water more frequently, or evaluating where the food/water bowls are relative to where the bird perches, can minimize or eliminate the need for antibiotic treatment. In some cases, establishing protocols for treating patients in multibird or multianimal homes is helpful since separating treated from nontreated animals might be warranted, especially to avoid cross-contamination through coprophagia. Further details on nonpharmacological interventions will be discussed later in this chapter.

- *What patient factors should be considered?*

  There are many patient factors that can affect selection of a medication, including breed/species, age, general health, renal/hepatic function, temperament/behavior, and reproductive status. Some breeds or species are more sensitive to certain drugs than others and should be avoided. For example, bone marrow toxicosis following fenbendazole treatment has been documented in Columbiformes, storks, and vultures, thus other anthelmintics should be considered.[2–4] Some drugs may have deleterious effects on certain age groups, such as fluoroquinolones causing cartilage damage in some young animals. The general health or concurrent issues of a patient may also play a role in drug selection. If a particular drug is known to exacerbate or have additive effects to current issues (such as a side effect of vomiting in a patient already presenting for regurgitation), risk versus benefits of the drug should be evaluated. The reproductive status of the patient may also be of value when determining what medication to prescribe.

- *Is the treated bird a food animal species or does it have the potential to produce food products for human consumption?*

  This is a vital question to answer prior to treating a bird because of the regulations and prohibitions related to medication use in food-producing animals. In some countries, there are specific drugs and drug classes that are prohibited from use in food-producing animals (Table 5.1).[5–8] This is due to the concern for drug residues being present in food products intended for human consumption. Additionally, in certain countries, such as the United States and Europe, if a drug is used in an extra-label manner in a food-producing animal, scientific data documenting drug residue depletion are required in order to establish an extended withdrawal interval. If such data do not exist, other medications have to be considered. If an animal has already been treated and there are no scientific data to support a withdrawal interval, the animal cannot enter the human food chain. Withholding animals for extended periods following treatment or having them condemned following illegal drug use poses economic losses for producers.

- *Will the proposed medication treat the disease or alleviate clinical signs?*

  It is important to utilize medications that will be effective, but equally critical is selection of antibiotics with a narrow killing spectrum to mitigate antimicrobial resistance. Drug selection based on culture and susceptibility is the gold standard. Best practice recommendations for using susceptibility results to guide therapeutic selection are discussed later in this chapter and in Chapter 7.

  One must also consider if the selected medication will be effective mechanistically and/or reach the site of action or infection at appropriate concentrations. These concepts are especially important for antimicrobials. For skin infections, consider topical therapy as drug concentrations at the infection site will likely be higher compared to systemic administration. With avian patients, it is also important to consider ingestion of a topical medication and secondary disruption of the gastrointestinal (GI) flora. Caseous abscesses can be challenging to resolve, since antibiotic penetration will be limited, and therefore surgical debridement should be performed prior to treatment. When therapeutic concentrations of medications need to be achieved in the central nervous system, it is imperative to determine if the medication's properties will allow it to cross the blood-brain barrier. Generally, drugs that are small, lipid soluble, unionized, along with low plasma protein binding are more likely to cross the blood-brain barrier.[9,10] For example, aspergillosis typically originates in the avian respiratory tract and the antifungal agent, itraconazole, is commonly prescribed.[11,12] However, if the infection disseminates to the central nervous system, treatment with itraconazole is not ideal since poor blood-brain barrier penetration has been documented.[10,13]

- *What will be the route of administration?*

  There are many ways medications can be delivered to avian patients—orally (via medicated water, medicated feed, or direct administration to oral cavity or ingluvies), intravascular, extravascular (intramuscular [IM], subcutaneous [SC], intracoelomic [IC]), inhalation, topically, ophthalmic, and so on. This is an important aspect to consider for avian patients, but especially imperative for medications that are concentration dependent to be therapeutic (see also Chapter 7). A classic example would be concentration-dependent antimicrobials like fluoroquinolones. If therapeutic concentrations cannot be achieved, it is likely that the infection will not resolve, but there is also increased potential for antibiotic resistance.

  For drugs proposed to be administered by intravascular or extravascular route to the caudal portion of a bird's body, one should assume that the drug will pass through the kidneys first via the renal portal system before being delivered to the rest of the body. This is especially important for renally excreted drugs. The renal portal

TABLE 5.1

Drugs Prohibited From Use in Food-Producing Animals in Various Countries

A

Drug Classes Prohibited From Extra-Label Drug Use

Fluoroquinolones (all avian species)
Indexed drugs (all avian species)
Medicated feeds (specific to chickens and turkeys)
Cephalosporins (specific to chickens and turkeys)

Drugs Prohibited From Use Entirely

Chloramphenicol (all avian species)
Clenbuterol (all avian species)
Diethylstilbestrol (all avian species)
Nitroimidazoles (dimetridazole, ipronidazole, metronidazole, etc.) (all avian species)
Nitrofurans (furazolidone, nitrofurazone, etc.) (all avian species)
Glycopeptides (all avian species)
Gentian violet (all avian species)
Adamantane and neuraminidase inhibitors (specific to chickens, turkeys, and ducks)

B

Carbadox
Chloramphenicol
Clenbuterol (except for tocolysis as per approved label)
Diethylstilbestrol (hexoestrol, dienoestrol, etc.)
Fluoroquinolones
Nitrofurans (furazolidone, nitrofurazone, etc.)
Nitroimidazoles (except dimetridazole as per approved label)
Phenylbutazone
Salbutamol
Thyrostats (thiouracil, etc.)

C

Thyrostatic substances
Stilbenes (stilbene derivatives, their salts, and esters)
Oestradiol-17β and ester-like derivatives
Beta-agonists (with derogations)

D

Chloramphenicol (or its salts or derivatives)
5-Nitrofuran compounds
Diethylstilbestrol (or other stilbene compounds)
Clenbuterol (or its salts or derivatives)
5-Nitroimidazole compounds

A: Drugs prohibited by the US Food and Drug Administration—avian specific.[5]
B: Drugs prohibited by the Australian Pesticides and Veterinary Medicines Authority.[6]
C: Drugs prohibited by the European Union.[7]
D: Drugs prohibited by Health Canada.[8]

system could eliminate the drug before it circulates to other parts of the body, which could lead to treatment failure. In some cases, the effect of the renal portal system on drug concentration may not necessarily be clinically significant, but it is still important to evaluate the literature before choosing to administer renally excreted drugs to the caudal half of the body. In addition, administering nephrotoxic drugs to the caudal portion of a bird's body is contraindicated.

For oral medication delivery via medicated water or feed, it is necessary to estimate the amount of food and water the patient consumes to calculate the necessary concentration of medicated feed or water so that the patient receives the proper dose. In sick patients, consumed amounts are likely to be decreased compared to healthy birds. Using average consumption estimates based on healthy individuals has the potential to result in underdosing and treatment failure. Additionally, medication delivery via feed or water is likely to provide a sustained drug concentration but at a lower maximum concentration, as the consumption of the medicated feed or water is continuous throughout the day versus a one-time event. Therefore, drug administration via medicated feed or water might not be appropriate for concentration-dependent medications. Another point to consider with orally administered drugs is the potential for crop retention. In most poultry species, GI absorption occurs in the small intestines.[14] This is likely true for most other avian species as well. Depending on the feeding system utilized or GI diseases, crop retention may occur, thus delaying the passage of orally administered medications to the small intestine and delaying absorption.[15]

If there are a several medication options for oral administration, consider whether administration with food or without food is necessary. For some medications, absorption may be better when administered with food, while others have better absorption when the patient is fasted. For example, voriconazole and doxycycline have been shown to have increased absorption when administered to fasted patients.[16,17] Because there are limited data for avian species regarding the effect of food on oral bioavailability of medications, effects of prandial state for other species and/or medications should be considered when treating birds, but further studies are necessary to guide definitive practices for birds. Information regarding optimal prandial states when taking medications can be found in the package insert and full details about the medication are outlined in the prescribing information handout. Alternatively, this information may also be found in a comprehensive veterinary drug information reference such as Plumb's Veterinary Drug Handbook.[18]

Reviewing the drug's mechanism of action, published pharmacokinetic data for the species to be treated or a related class of birds, and deciding on a route of administration are important before initiating therapy. With any treatment plan, administration compliance is key

for successful therapy. While the veterinarian may prefer a specific route of administration due to a specific drug's properties and treatment effectiveness, it is important to consider the client's or caregiver's ability and willingness to administer the medication(s) compliantly, especially in situations where there are multiple options for drug selection.

- *If an antibiotic is required, does it have time-dependent or concentration-dependent pharmacodynamics?*

  Ideally, antibiotic selection should be based on culture and sensitivity. When choosing a medication, it is important to know if the pharmacodynamics are time dependent or concentration dependent (see also Chapter 7). Efficacy of time-dependent antibiotics depends on the percentage of the dosing interval that an antibiotic is above the minimum inhibitory concentration (MIC), while concentration-dependent antibiotics target a serum/plasma/tissue concentration that is above the MIC. It is important to evaluate the literature to ensure that the pharmacokinetics of the desired drug, dose, and route of administration provides antibiotic concentrations in the serum/plasma/tissue or at the desired treatment site adequately, with respect to time or concentration above the MIC. These characteristics will impact the frequency of drug administration, so it is important to evaluate the pharmacokinetic literature for scientific guidance on how often to dose the medication to maintain concentrations above MIC. Such practices will help ensure treatment efficacy and help prevent the development of antimicrobial resistance. Knowing administration frequency may also impact the drug choice as some antibiotics require more frequent dosing compared to others. Typically, frequency of drug administration and treatment compliance are inversely related.

- *Does the patient have concomitant medical conditions or coadministered medications that can affect this drug?*

  It is always important to evaluate a patient's current medication list for potential drug interactions. If data do not exist for the species and drugs of interest, look to similar species, for potential or documented interactions as guidance. Plumb's Veterinary Drug Handbook[18] offers potential drug interactions based on data from small animals and humans. While this resource does not specifically focus on avian species, it does provide guidelines that should be considered when establishing a treatment plan. If veterinary-specific drug information is not available, the use of a human drug resource can be used to gain insight into potential drug-drug or drug-disease interactions. Some human drug information resources include Clinical Pharmacology, Lexicomp, and Micromedex.[19–21] Additional resources can be found in the "Resources for Practitioners" table at the end of this chapter.

  In addition to drug-drug interactions, evaluate the patient's medical status to reduce the incidence of drug-disease interactions. For example, patients with renal compromise should not receive drugs that have a relatively low threshold for being nephrotoxic or medications that are metabolized by the liver might accumulate in patients with hepatic disease.

- *Do the benefits of a chosen treatment outweigh the potential side effects or complications?*

  After the previously mentioned considerations have been addressed, it is vital to critically evaluate potential negative consequences that can occur from treating the patient with a particular medication. This could include negative consequences in terms of side effects directly related to the medication or economic losses if the bird or their by-products cannot enter the human food chain if a prohibited drug is administered. With any treatment, it is important to ensure that therapeutic benefits and desired outcomes for the patient, owner, producer, etc., outweigh the potential negative consequences.

REVIEW OF PHARMACOKINETICS AND PHARMACODYNAMICS

Jennifer L. Davis, Lisa A. Tell

Visit eBooks.Health.Elsevier.com for a complete set of references.

Drug administration in avian medicine requires selection of safe and effective dosage regimens. Unfortunately, in avian practice, this information is often limited or not available and therapy is further complicated by variability within and between avian species. However, a basic understanding of fundamental concepts associated with drug administration to birds[1] and the pharmacokinetics and pharmacodynamics of drugs in avian species will enable the clinician to optimize therapy while minimizing the risk of adverse drug effects.

Pharmacokinetics describes the effect the body has on a drug, including drug absorption, distribution, metabolism, and elimination. Pharmacodynamics, in contrast, describes the effect a drug has on the body and may be affected by an individual bird's or subspecies of bird's pharmacogenetic profile. This information, when available, can be applied to avian patients to determine dosage regimens in healthy animals and optimize treatment of diseased animals.

From a practitioner's standpoint, pharmacokinetic studies that detail drug absorption, distribution, metabolism, and elimination might seem esoteric but understanding these fundamental key components is essential for successful application in clinical practice.

DRUG ABSORPTION

A drug must get to the site of action at an effective concentration for a sufficient period of time in order to exert a therapeutic effect. This requires absorption into the system circulation, which is affected by the route of administration. The route by which a drug is administered also has economic and feasibility concerns, particularly in avian

medicine where treatment can be for an individual bird or a flock.

Oral Drug Administration

This is a common route of drug administration in birds, especially if patients are to be sent home and treated by the owner. Compared to mammals, there are several anatomic differences in avian species that might affect drug absorption via this route. One of these differences is the presence of a crop in several avian species, such as some birds in the Galliformes, Psittaciformes, Columbiformes, and Accipitriformes orders.[2] The crop is an expanded area of the cervical esophagus used to store food and, by extension, orally administered medications.[3] As little absorption occurs in the crop itself in most species, this can result in a more rapid or delayed drug absorption, depending on transit time through the crop. Crop-emptying rate is dependent on fill; therefore birds fasted prior to drug administration might have rapid drug absorption. Sick birds that are anorexic may also have faster crop-emptying times. However, avian patients with diseases that slow crop emptying and young hand-fed birds being gavaged with commercial liquid food products might have delays in drug absorption. Animals on dry feeds have slower crop emptying compared to those on wet feeds. For chickens (broilers in particular) crop emptying can be delayed up to 19 hours or more depending on the amount of food ingested.[1] The pH of the crop is neutral to acidic, varying with the species of bird and the presence and type of feed. This pH variability can affect drug absorption by resulting in drug degradation, precipitation, or increased solubility of the dosage form in the crop itself.[4] The crop may also contain a normal bacterial flora (e.g., *Lactobacillus* sp.) that can break down some drugs (e.g., macrolides) prior to absorption.[4]

After leaving the crop, orally administered drugs will move to the proventriculus and ventriculus or "gizzard." These two chambers are somewhat equivalent to the mammalian "stomach." In carnivorous and piscivorous birds, the proventriculus can store food due to the presence of multiple extensible folds.[5] In some species of birds (such as granivorous species), the ventriculus will have a high mineral content (including calcium and magnesium) due to the presence of grit and may therefore chelate certain drugs like fluoroquinolones or tetracyclines. This grit, however, can help with the grinding and dissolution of solid dosage forms such as tablets. The efficiency of grinding may depend on the diet of the individual species; carnivorous and piscivorous birds have a poorly differentiated gizzard compared to other birds. The low pH of the proventriculus/ventriculus can also degrade some acid-labile drugs (e.g., penicillin and erythromycin). Ingesta mixes back and forth between the proventriculus and the ventriculus to optimize mechanical and enzymatic digestion.[5] There is also reflux of ingesta between the duodenum and ventriculus. This retrograde movement of ingesta (and drug) may further delay absorption, as many drugs are absorbed in the small intestine. The remainder of the GI tract is relatively short in most birds, compared to mammals, particularly with respect to the large intestine. The cecum, however, may be well developed in species such as ducks, chickens, and ratites. Although the large intestines are typically not a common site for drug absorption, carrier-mediated absorption or permeability of lipophilic drugs can occur at this site, and therefore these anatomical differences may have an effect on overall absorption as well as elimination throughout the GI tract.

Administration of solid oral dosage forms has issues related to dissolution, as discussed previously, but also has issues related to stress on the bird being treated, and this method is not amenable to dosing large numbers of birds from a practical standpoint. Direct oral administration of solutions and suspensions decreases the issues with dissolution, but drugs may precipitate out of solution at the varying pH in the upper GI tract. Aspiration following regurgitation of drugs in liquid form may also occur.[1,6] For the treatment of large flocks of birds, this method is also not practical; therefore more commonly dosing is done via medicated water or feed.

Administration of drug in water or feed has the advantage of being a low-stress method suitable for treatment of multiple birds. However, this is also a disadvantage, as it may expose normal, healthy birds to medications that are not necessary. For antibiotics, this can lead to the development of resistant bacteria. Additionally, it is not possible to determine how much drug an individual bird receives. Sick animals tend to have a decrease in feed and water intake and may therefore not get the required dosage. Drugs in water and feed may also change the taste of either, resulting in aversive behaviors. Day length and ambient temperature can affect consumption. To increase drug exposure, medication of both feed and water simultaneously can be performed. In birds intended for food in the United States, many feeds medicated with antimicrobials are regulated under the Veterinary Feed Directive (VFD) and any administration requires the oversight of a veterinarian. Extra-label use of VFD drugs is prohibited. However, in order to address the lack of approved medicated feeds for minor avian species (such as chukar, quail, pheasants, etc.), the US Food and Drug Administration (FDA) codified a compliance policy guide[7] that allows inspectors to have regulatory discretion when a veterinarian writes a VFD for minor avian species.

Medicated water and feed result in ingestion of smaller quantities of drug more frequently throughout the day. These administration routes are optimal for treatment of large numbers of birds but are also used for cases where handling and restraint of individual patients is not possible. In some cases, sick birds will reduce the amount of food or water ingested; in extreme cases some birds will not drink medicated water. Additionally, absorption of drugs in medicated feed may be further delayed due to storage of drug in the crop or proventriculus. Drugs administered via medicated feed or water have the potential for decreased absorption and subsequently lower plasma concentrations compared to direct oral administration. This is an important consideration when a maximal drug concentration or a percentage of time above MIC is being targeted to ensure treatment efficacy.

Parenteral Drug Administration

Parenteral drug administration will overcome many of the issues associated with oral drug administration. Intravenous (IV) administration bypasses the absorption phase and delivers 100% of the drug directly to the systemic circulation. However, this route is technically the most difficult, particularly in avian species. The subcutaneous and intramuscular routes are technically less difficult but can have specific disadvantages.[6] Subcutaneous drug administration is most commonly performed in the inguinal, axillary, or interscapular regions. This route of administration can have decreased absorption in

dehydrated birds. Intramuscular drug administration is most commonly performed in the pectoral muscles, mid-keel region. Injections into the cranial pectoral muscle are more likely to result in hemorrhage. Repeated injections in the pectoral muscle, particularly with irritating substances, can eventually lead to muscle necrosis and atrophy. This can have long-term effects on the bird's ability to fly and also result in carcass rejection in animals intended for food. From a welfare standpoint, repeated intramuscular injections can also be painful, especially if the vehicle is viscous or administration of large volumes is required. Other factors to consider with intramuscular injections include differences in myoglobin concentrations in muscle fibers and the degree of muscle vascularization. These differences can be substantial between flighted and nonflighted birds and might influence drug pharmacokinetics, but no definitive studies have been published to date. In general, intramuscular injections administered in the thigh muscles are not advised in birds. Drugs administered at this site may be absorbed first into the external iliac vein, and then into the renal portal vein, where it is delivered to and immediately excreted via the kidneys. This can result in a renal "first-pass" effect and potentially decreased amounts of drug reaching the systemic circulation via this route of administration, particularly water-soluble drugs that undergo minimal metabolism such as gentamicin.[8,9]

Drug Administration via Inhalation

Nebulization has been commonly used in avian medicine to administer medications directly to the upper respiratory tract, pulmonary parenchyma, and air sac membranes. Experimental studies have shown that nebulization is not an efficacious method for delivering medications to the avian respiratory tract given the challenge of getting enough particle sizes that are also small enough for distribution to the air sac membranes and pulmonary parenchyma.[10] Direct tracheal delivery via ventilation[11] and using a commercial atomizer[12] has been experimentally shown to successfully deliver 0.5 μm particles of amphotericin B, but further work remains to be performed before such techniques can be applied clinically. Systemic absorption of drugs originally delivered directly to the avian respiratory tract is unknown and will most likely depend on the physiochemical properties of the medication. However, therapeutic drug concentrations of some antibiotics may persist locally in the lungs and air sac membranes for 4 to 6 hours after administration.[13] Drug persistence can also be impacted by the presence or absence of ciliated epithelium that would functionally remove inhaled particles. The distribution of ciliated epithelium in the upper airway of birds is similar to mammals but is sparse in the lower respiratory tract where pulmonary macrophages dominate. For the air sac membranes, ciliated epithelium is present at the ostia,[2] but not in the distal portions of the air sac membranes where drug removal would be minimal. Birds only utilize a small percentage of their respiratory tract when at rest, therefore drug absorption or distribution from the lung parenchyma might be influenced by the degree of activity and flight.

Pharmacokinetic Parameters Associated With Absorption

The fraction of drug absorbed after administration is represented by bioavailability (F%). Bioavailability is calculated by comparing the area under the curve (AUC) concentration versus time curves generated from plasma concentration data collected over a period of time. Because IV administration of a drug is presumed to have 100% absorption, the AUC of the IV dose is compared to the AUC via other routes of administration to get absolute bioavailability. When IV dosing is not feasible, due to lack of formulations, toxicity, or other factors, two extravascular routes of administration can be compared to calculate a relative bioavailability. Reasons for low bioavailability include incomplete absorption from the GI tract or injection site, instability of the drug in the vehicle, or first-pass metabolism (hepatic or renal in birds).[14,15]

Both the rate and extent of absorption affect bioavailability. The rate of absorption is represented by the absorption rate constant (k_a) or the time to maximum concentration (T_{max}). The extent of absorption includes AUC estimation and is also assessed using the maximum plasma concentration achieved (C_{max}).

DRUG DISTRIBUTION

Drug distribution is a key factor to evaluate when trying to extrapolate drug dosing regimens from mammals to birds or from birds to birds. Once a drug reaches the systemic circulation, it must be distributed from the central (blood) compartment to the peripheral tissues to exert an effect at the site of action. Distribution to organs of metabolism and elimination is also required for drug to be cleared from the body. There are multiple factors affecting a drug's ability to exit the plasma and therefore distribute to the site of action. All other factors remaining equal, well-perfused tissues take up a drug much more rapidly than do poorly perfused tissues. For tissues of greater mass (such as muscle), more drug-binding sites are present, which increase the capacity of that tissue for the drug. These two factors are dependent on each other and the ratio of blood flow to tissue mass is used to categorize drugs as either high or low-distribution drugs. For example, the brain has a high perfusion rate, but a relatively small tissue mass, resulting in a higher ratio. Not all drugs will distribute to the brain, however, due to the presence of protective barriers at this site that prevent drug diffusion between cells (paracellular). Only drugs that can diffuse through cells (transcellular) or those that have tissue-specific transport across the membrane will reach therapeutic concentration in these protected sites. Other sites in avian species with these protective barriers include the eye and atria (equivalent to mammalian alveoli). A drug's ability to diffuse transcellularly is dependent on its physicochemical characteristics: small weight, lipophilic drugs that are unionized at physiologic pH will cross membranes and typically have a higher distribution. Protein-bound drugs are too large to pass through or between cells and therefore have limited distribution. Protein binding is a property of the drug, but also the species to which the drug is administered. Proteins such as albumin, the main protein that binds weak acids, have species-specific affinities and a number of binding sites.[16] P-glycoprotein efflux pumps present at protective barriers pump drugs back out of cells, resulting in decreased drug diffusion into these sites. These pumps may be present in other organs, including the liver and GI tract, and may prevent drug absorption from and distribution into those sites.

Pharmacokinetic Parameters Associated With Distribution

The volume of distribution (Vd) is a theoretical proportionality constant relating the mass of drug in the body (dose) to the concentration measured in a sample (usually the plasma):

$$Vd = Dose/Concentration$$

It should be referred to as the "apparent" Vd because it represents a theoretical volume not any actual physiologic or anatomic space or volume. Low-Vd drugs remain in the blood vasculature and extracellular fluids whereas high-Vd drugs also distribute into the intracellular and transcellular fluid compartments. Drugs with a high Vd may have higher and more persistent tissue concentrations compared to plasma concentrations.

Since plasma concentrations are determined by absorption, Vd is typically only calculated for an IV dose, where absorption is 100%. If Vd is reported for extravascular routes of administration, it should be reported as Vd/F, or Vd relative to bioavailability. However, if bioavailability is low following extravascular administration, the Vd will be falsely elevated. Once the Vd for a specific drug is known for a specific species, this information can be used to design a dose that will result in the desired plasma concentration using the following equation (which is a modification of the previous equation):

$$Dose = Vd \times Concentration$$

DRUG METABOLISM AND ELIMINATION

Metabolism

Compared to mammals, information regarding drug metabolism is limited in birds with the majority of the literature focused on poultry species. Drug metabolism is the chemical alteration (biotransformation) of drugs by the body, and is most often accomplished by the liver, although other organs can play a role, including the lungs, kidney, and GI epithelium. There are two primary phases in drug metabolism. Phase I reactions are carried out by the cytochrome P450 (CYP450) enzyme system and include oxidation, reduction, or hydrolysis reactions. The purpose of these reactions is to add polar groups or remove nonpolar groups from the drug compound so that the drug is either directly excreted by biliary or renal processes or moved on to phase II reactions. Phase II reactions are conjugation reactions that couple a parent drug or its metabolite to a polar endogenous substrate (glucuronic acid, acetic acid, an amino acid, or an organic substrate such as sulfate). Phase II products are larger and more polar than the parent drugs, which restricts their distribution, and thus activity, in the body and allow for biliary or renal excretion/secretion. Biotransformation generally results in a metabolite with reduced pharmacological activity and effectively blocks drug effects. However, in some cases, the metabolite has enhanced activity compared to the parent drug. This phenomenon can be manipulated in the drug manufacturing process where a drug with enhanced stability and absorption is then cleaved in the body to an active form. These drugs are referred to as prodrugs.

Drug metabolism is not always a static process, since induction or inhibition of metabolism can occur, mainly due to changes in production of phase I CYP450 enzymes. This may occur as a result of administration of the drug itself (autoinduction or autoinhibition) or secondary to coadministration of a second drug that inhibits or induces the same CYP450 isoenzyme. There are limited data for avian species, and species differences may occur. For example, voriconazole, a triazole antifungal agent, is known to induce its own metabolism with multiple doses in humans and some avian species (e.g., grey parrots [*Psittacus erithacus*]), but multiple doses do not result in alterations in metabolism in horses.[17–19] In the case of enzymatic autoinduction or autoinhibition, single-dose studies might not reflect the pharmacokinetics of multiple dosing; therefore multiple-dose studies are essential. Diet, age, gender, and health, particularly with regard to liver disease, can also have an effect on drug metabolism and subsequent elimination.

Both phases I and II metabolic pathways have been shown to occur in avian species. Results of mRNA expression tests suggest CYP2C genes may have an important role in xenobiotic metabolism in chickens. The CYP2C45 gene was the most highly expressed isoform in chicken liver, while the CYP2C23b gene was the most highly induced by phenobarbital.[14] Responses to three separate classes of inducers of CYP450 are conserved in chickens and mammals, and CYP2R1 and CYP2U1 are fully conserved between avian and mammalian species, which reflect their essential functions in the metabolism of endogenous compounds.[20,21] Piscivorous birds show lower hepatic microsomal CYP450 activity relative to omnivorous or herbivorous terrestrial birds. For phase II metabolism, conjugation pathways present in mammals are also present in birds; however, only birds and reptiles form ornithine conjugates.[4]

Drug metabolism varies not only between species but also within species. The greatest source of variability between species relates to isoenzyme makeup of both cytochrome and noncytochrome enzyme systems, and in the availability of substrates for conjugation. Within a species, there are groups of individuals classified as ultrarapid or poor metabolizers of certain drug classes. The study of this phenomenon is called pharmacogenomics. Polymorphisms are well documented with certain reactions in humans and rats; however, very little information is available in avian or other veterinary species. Polymorphisms in CYP450 are speculated to be behind the severe toxicity seen in vultures exposed to nonsteroidal antiinflammatory drugs such as diclofenac and ketoprofen.[22] Drug metabolism can be influenced by disease processes and reproductive status as well as body composition, gender, age, and light cycles as has been reported for major veterinary species,[23] but these influences have not been well elucidated for avian species.

Drug-metabolizing enzymes obey classic Michaelis-Menten enzyme kinetics and may therefore display saturation with exposure to high drug concentrations, leading to zero-order (nonlinear) pharmacokinetics. This results in a constant rate of drug elimination, independent of dose, meaning the eliminated fraction of the administered dose has a relative decrease at higher doses. This can result in an enhancement of drug effect, or even toxicity, at high doses. Voriconazole is an example of a medication used in avian medicine to treat aspergillosis that has zero-order kinetics.[24]

ELIMINATION

Like mammals, the kidneys are the main route for drug elimination for birds. Renal elimination occurs passively through

glomerular filtration or actively through tubular secretion. Drug can also be passively reabsorbed in the kidney; therefore, net renal elimination of a drug will be the sum of all these processes.

Glomerular filtration is a relatively low-efficiency process and is restricted to protein-unbound drugs dissolved in plasma water. Renal clearance of a drug by passive diffusion is approximately one-sixth the corresponding value of renal blood flow. Tubular secretion is an active, carrier-mediated process that is relatively specific for organic acids and bases and is also remarkably rapid and efficient; the renal clearance of a drug excreted by active secretion approaches the value of renal blood flow. Protein binding does not restrict secretion because affinity for the active transport systems is greater than affinity for the protein. Tubular secretion is a saturable process. The final determinant of a drug's renal disposition is the mechanism of passive tubular reabsorption, which is dependent upon urine flow rate and pH, as well as lipid solubility of the nonionized drug. At low urine flow rates, as in states of dehydration, there is greater time for drug molecules to diffuse from the tubular fluid back into the blood.

There are numerous unique characteristics of a bird's renal system that may affect drug elimination.[8] The avian kidney consists of three lobular divisions (cranial, middle, caudal), each of which has cortical and medullary regions. The nephrons located in the more superficial, cortical area are simple nephrons, like those found in reptiles. These reptilian nephrons make up most of the nephrons in the bird, although mammalian-like nephrons may make up to 10% to 30% of the nephrons found in different bird species, the concentration of which depends on the bird's environment. In general, glomerular filtration rates in birds are lower than in mammals of similar body weights, and it is intermittent in birds whereas it is constant in mammals.[24,25] This may result in more variable drug elimination by glomerular filtration in birds, particularly in gallinaceous birds that have a more marked intermittent filtration compared to Passeriformes. Less is known about tubular secretion and reabsorption in avian species compared to mammals. The avian renal system is less efficient at concentrating urine and therefore may be less capable of tubular reabsorption. Urine pH, which can also affect tubular reabsorption, varies in female birds between 4.7 and 8 and is affected by egg-laying status; in male birds the pH is more stable and approximately 6.4.[26] The renal portal system and its role in excreting drug prior to absorption have been discussed previously.

Hepatobiliary excretion can also be a major route of drug elimination for some drugs and many metabolites, particularly lipophilic anionic drugs with larger molecular weights. The molecular weight cutoff for biliary excretion may vary by species, with 375 to 400, 394, and 475 Da reported for rats, dogs, and humans, respectively.[27,28] Assuming a similar range for the cutoff in birds, this may include drugs such as azithromycin and doxycycline. This process is relatively slow compared to renal excretion. Bile is an excretory product continuously produced by hepatocytes, stored in the gall bladder, and then secreted through the common bile duct into the duodenum. Not all birds have gall bladders (i.e., pigeons, most parrots, ostriches); therefore bile storage does not occur.[2]

Hepatobiliary excretion is an active process, utilizing p-glycoprotein efflux pump transporters, and is therefore saturable and competitive. Diffusion of drugs passively into the bile is not of major significance.

Compounds secreted in bile have a high degree of polarity, inhibiting reabsorption in the small intestines, and drugs are therefore subsequently excreted in feces. In some instances, however, drugs are metabolized by the intestinal microflora back to parent drug and are then eligible for reabsorption back into the systemic circulation. This process is termed enterohepatic recirculation and may result in greater overall exposure to the drug (increased bioavailability).

Pharmacokinetic Parameters Associated With Metabolism and Elimination

Clearance

Clearance is defined as the volume of blood cleared of a substance (drug) per unit time and is typically adjusted for body weight (volume/time/kg). Most reported clearance rates are the sum of the individual organ clearances, resulting in the total body clearance (Cl) of the drug from the animal:

$$\text{Total body clearance} = Cl_{Renal} + Cl_{Hepatic} + Cl_{Other}$$

Although other organs may function as eliminating systems (i.e., lung), the kidney and liver play the major role. In mammals, sweat glands can function as an eliminating system but birds do not have sweat glands.[2] The liver also has a metabolic role in drug elimination. Specific renal and hepatic drug clearance can be determined by measuring drug concentrations separately in urine and feces. However, the unique excretory system of the bird results in "hepatorenal" drug elimination, as it is not possible to separate out the different renal or biliary drug excretion without invasive testing methods. The individual contribution of the kidneys versus the liver in avian species is not often known.

Total body clearance can be calculated using the equation:

$$Cl = \text{Dose}/AUC$$

Similar to the volume of distribution, since this equation uses a measure of drug absorption, AUC, clearance can only be predicted accurately following IV administration. Clearance from extravascular administration should be reported as Cl/F and may not be accurate.

Half-life

The elimination half-life of a drug is a hybrid parameter that is related to the primary drug parameters of volume of distribution and clearance.

$$\text{Elimination half-life} = (0.693 \times Vd)/Cl$$

The plasma elimination half-life is defined as the time it takes for plasma drug concentration to decrease by 50% of the previous value. Since some drugs distribute outside of the plasma, a plasma elimination half-life does not necessarily represent the time it takes to eliminate 50% of the drug from the body. In first-order (nonsaturable) kinetics, the elimination half-life is a fixed value and is independent of the drug concentration. In zero-order (saturable) kinetics, the half-life value changes when plasma drug concentrations reach the point of saturation.

Half-life becomes very useful in the creation of multiple-dose regimens and is used to predict the time to steady-state concentration, the time when the rate of drug input is equal to the rate of drug elimination. It takes approximately four to

five drug half-lives to reach a steady state. For predicting withdrawal intervals following drug administration in animals intended for food, half-life can be used as well. For drugs with first-order kinetics, 99.9% of the drug is eliminated after 10 half-lives. This means that for most drugs, plasma concentrations will be below the tolerance (or maximum residue limit). However, this is not useful unless plasma concentrations and tissue or egg concentrations are parallel, which only occurs with drugs that have a small volume of distribution. For drugs with a large volume of distribution, tissue or egg half-lives cannot be applied using this rule.

PHARMACOKINETICS OF DRUGS IN EGGS

The principles of absorption and distribution can be applied to drugs that reach the matrices of eggs (egg yolk and white) of treated animals. Distribution of drugs to and within the egg will depend on physiochemical characteristics of the medication[29] and the composition of egg components, which might differ between avian species. Drug distribution to eggs and within the egg is of concern, as exposure of the developing egg to drugs can lead to toxic effects in the oocyte, as well as potential drug residues in eggs used for human consumption. When discussing the kinetics in eggs, it is important to consider the different components of the egg, as each one may have different kinetic properties. The yolk consists primarily of lipoproteins, whereas the egg white (albumen) is made up of water-soluble proteins (albumins) and the shell is mainly made of calcium carbonate. Each of these matrices will therefore absorb, bind, and eliminate drugs at different rates. A comprehensive review of drug residues studies summarizes these differences.[30]

In theory, lipophilic drugs would distribute more to the egg yolk and water-soluble drugs to the egg white. Additionally, drugs that chelate to calcium may bind to the shell components.[29] This does not often correlate to drug concentrations in vivo, however. Relatively lipophilic drugs such as sulfonamides, enrofloxacin, and doxycycline/minocycline reach higher concentrations in egg whites than in the egg yolk. Other studies have attempted to correlate drug distribution within the egg with other physicochemical properties. The drug acid-based dissociation constant (pKa) has also been investigated to try and discern its role in the differential distribution of drugs into egg yolks and whites. The pH of the yolk and egg white are approximately 6 and 7.6, respectively. This difference in pH can lead to differences in drug ionization based on drug pKa. However, no direct correlation has been found with drug pKa alone.

Traditional pharmacokinetic modeling techniques have not been successful in predicting or explaining drug kinetics in eggs. Newer research has centered on physiologically based pharmacokinetic (PBPK) models.[31] Most avian PBPK models have focused on meat products, but models focusing on the reproductive tract have the potential for predicting drug kinetics in egg yolks and whites.[32,33] These models incorporate plasma drug concentrations in the female and the physiology of egg development into the equations as each component forms at different rates and stages of egg development.[34] Drug absorption and subsequent concentrations reached in eggs are a function of the drug concentration in the plasma of the female bird. This is thought to be a passive diffusion into the egg, and therefore nonsaturable. As previously described, direct oral administration or injection will result in higher plasma concentrations in the bird, and therefore higher concentrations in the egg matrices, compared to medicated water and feed. The duration of exposure also plays a role in drug absorption into the eggs and is linked to the stage of egg production. Prolonged exposure can be either from repeated dosing or from environmental exposure and drug recycling from excreted waste.[35] Drug disposition into egg yolks occurs mainly during the rapid growth phase, which lasts 8 to 10 days prior to ovulation in a nonlinear fashion, taking 8 to 10 days to reach equilibrium. Egg white formation is much more rapid than yolk formation, occurring over an 8- to 10-hour period after ovulation, with albumen deposition occurring in the first 2 to 3 hours. Drug deposition therefore occurs first in the egg whites and reaches equilibrium more rapidly (within 2–3 days).[36]

Incorporating the rate of egg component formation into the equation along with the plasma concentration to which the egg is exposed allows for approximate simulation of drug concentration in eggs.[34] Further refinement of the model incorporates both pKa and protein binding of the drug.[36] In this model, lipophilicity had little effect, confirming previous studies. However, the drugs for which the PBPK models have been applied are all moderately lipophilic. Highly lipophilic drugs, such as chloramphenicol, are known to reach higher concentrations in yolks versus egg whites.[37] Moreover, they persist in eggs for an extended period, particularly following multiple dose exposures. This is likely due to persistence of these drugs in the tissue of the female bird (which could include ovarian tissue) and therefore extended exposure in the forming eggs.

These models currently have some limitations. They assume passive transfer of drug into the egg, without the potential for active/facilitated transport.[36] They also assume uniform egg production, number of oocytes in the fast-growing stage, egg weight, and proportional weights of egg yolk and albumen.[34] Additionally, any factors that affect drug pharmacokinetics in the female can also affect the extent and rate of drug deposition in the eggs.

There is little-to-no drug metabolism or elimination from nonfertilized eggs. "Clearance" of drugs from eggs is therefore expressed as number of days a drug is detected in eggs following administration to the female. This information can be used to determine egg withholding times for eggs sold or used for human consumption.

OVERVIEW OF MODELING OPTIONS: ESTABLISHING AND OPTIMIZING AVIAN DOSING REGIMEN

Zhoumeng Lin, Lisa A. Tell

Visit eBooks.Health.Elsevier.com for a complete set of references.

Before administering a new medication that has never been used in birds, some baseline pharmacokinetic parameters should be estimated, even if it is in a domestic poultry species, to help provide insight regarding therapeutic targets and relative safety. To establish and optimize dosing regimens, PK modeling is the gold standard. PK modeling is a subdiscipline of pharmacology that studies the characteristics of absorption, distribution, metabolism, and excretion of drugs and their metabolites in the body using mathematical equations. The basic principles behind PK modeling have been summarized by JE Riviere and is an excellent review of the fundamental core concepts.[1] PK models play an important role in optimizing dosing regimens as they can relate the administered external dose to the internal dose (e.g., plasma or tissue dose metric), which can be further correlated with the efficacy of a drug to establish pharmacokinetic/pharmacodynamic (PK/PD) relationship. Due to increasing antimicrobial resistance and the shortage of new antibiotics in veterinary medicine, the use of PK models in dosing regimen optimization of antibiotics to improve clinical outcomes of infections is becoming increasingly important.[2,3]

There are different PK modeling and analysis methods that have been used with varying degrees of frequency and for different sectors of birds. Depending on the assumption of a specific method, PK analysis methods can be separated into classical PK (i.e., noncompartmental and compartmental approaches) and PBPK methods. Depending on whether the method considers population variability, PK analysis methods can be distinguished between individual and population approaches. Classical PK methods are typically individual approaches, whereas population approaches include population PK (PopPK) and population PBPK (PopPBPK) methods. This section will outline the three modeling approaches that have been used in avian medicine. Application of modeling techniques to guide dosing protocols will also be discussed.

CLASSIC PHARMACOKINETIC MODELING (NONCOMPARTMENTAL AND COMPARTMENTAL)

The simplest classical PK method is noncompartmental analysis (NCA). Compared to classical compartmental PK methods, NCA is unique and versatile as it does not rely on an assumption of compartmental models to the data, but just connects the observed individual concentrations by linear interpolation to calculate accurate results and the results are also acceptable for bioequivalence studies. NCA is mainly used to estimate area under the curve (AUC) of the plasma or blood concentration versus time plot that represents the kinetic profile of a drug upon administration. In general, NCA is a useful first step of PK analysis to explore available data and calculate regular PK measures, such as clearance, volume of distribution, AUC, and C_{max}. NCA is the most used modeling method to estimate basic PK parameters for drugs used in avian medicine.[4–6]

Classical compartmental PK models can be divided into one- or single-compartmental and multiple (two-, three-, and so on) compartmental models (Figure 5.1). Compartmental

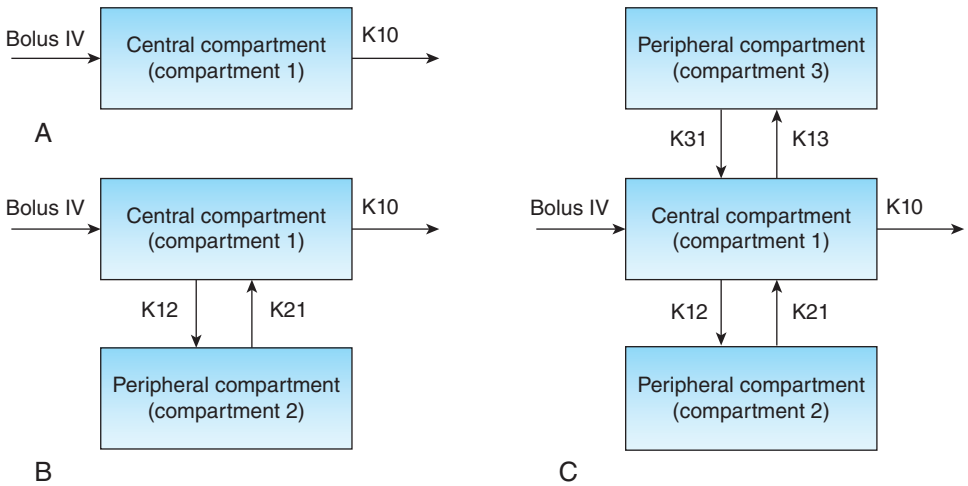

FIGURE 5.1 Schematics of common compartmental pharmacokinetic models following an IV bolus administration of a drug. (A) One-compartmental model; (B) two-compartmental model; (C) three-compartmental model. The unit of rate constants is typically per hour or per minute. *IV*, Intravenous; *K10*, elimination rate constant; *K12*, transfer rate constant from compartment 1 to compartment 2; *K13*, transfer rate constant from compartment 1 to compartment 3; *K21*, transfer rate constant from compartment 2 to compartment 1; *K31*, transfer rate constant from compartment 3 to compartment 1. The unit of rate constants is typically per hour or per minute.

PK methods assume that upon administration a drug is introduced into a central compartment, distributed throughout the central compartment for a one-compartmental model or between the central and one or more peripheral compartments for multicompartmental models, followed by elimination via metabolism and/or excretion from the central compartment.[7]

The simplest compartmental PK model is the one-compartmental PK model with IV bolus injection and first-order elimination. This model assumes that the entire body is a single kinetically homogeneous unit and upon injection a drug gets distributed throughout the body instantaneously, reaches equilibrium between the blood and tissues rapidly. In multicompartmental models, it is assumed that the body is composed of heterogeneous groups of tissues each with a different degree of blood flow and affinity for a drug and therefore different rates of distribution or elimination. The central compartment represents a combination of blood and highly perfused tissues (e.g., liver, lungs, and kidneys) that equilibrate with the blood rapidly, whereas the peripheral compartment comprises poorly perfused tissues (e.g., muscle, skin, and adipose) that equilibrate with the blood slowly. Compared to NCA, the advantage of a compartmental PK model is the ability to simulate or predict the concentration at any time following a specific exposure scenario where some PK data points are available and were used to fit the compartmental PK model. Compartmental modeling has been used to estimate PK parameters for avian species but given the study design and data-driven limitations this method has fallen out of favor. Classical compartmental modeling is less optimal for nondomestic avian species and small birds (limited blood volume) due to the need for numerous sampling times to accurately reflect drug distribution and elimination to/from various compartments.

While both NCA and compartmental PK models have merits, the common drawback of these classical PK methods is that they are data-driven empirical methods and thus have limited extrapolation capability. It is also important to note that in classical compartmental PK models, a compartment represents a virtual compartment that does not correspond to a physiological organ or tissue; thus the volume of a PK compartment is termed apparent volume of distribution rather than a physiological volume. This is a key distinction between compartmental PK and PBPK model that will be introduced further in the following sections.

PHYSIOLOGICALLY BASED PHARMACOKINETIC MODELING

PBPK Modeling and analysis is a computational simulation method that describes the absorption, distribution, metabolism, and excretion of a substance in the body based on the interrelationships among key physiological, biochemical, and physicochemical determinants using mathematical equations.[8,9] In a PBPK model, each compartment corresponds to a specific organ or tissue or a group of tissues; thus the volume of each compartment has a specific physiological meaning. PBPK models are a mechanism-based method and many species- and chemical-specific parameters can be incorporated into the model. As such, PBPK models are generally more complex and robust than classical compartmental PK models. The advantages of PBPK models include the great extrapolation capability across species, administration doses, routes, and duration, and the ability to predict concentrations of a chemical in the target organ at any time following different exposure scenarios. The shortcoming of PBPK models is that they are generally more complex, have more parameters, require more data to calibrate or validate, and are computationally more intensive. For birds, PBPK models have been developed most commonly for chemicals for domestic avian species[10–20] since the physiological parameter values (cardiac output, regional blood flow for organs/tissues, organ/tissue weights, etc.) needed to build the model can be obtained from terminal experiments and/or carcasses. In contrast, these physiological parameters are difficult to obtain for nondomestic species as a reasonable number of study subjects are needed, invasive methods are necessary for obtaining the physiological data necessary for building the model, and organ weights are obtained from healthy animal carcasses.

POPULATION-BASED PHARMACOKINETIC MODELING

The abovementioned classical compartmental PK and PBPK methods are individual approaches or deterministic methods as each model parameter has a fixed value, and the variability of model parameters within a population is not considered. Once population variability is considered, these PK and PBPK methods become population approaches and are termed PopPK and PopPBPK models, respectively.

PopPK methods analyze concentration-time datasets for a drug within a population as a whole. Traditionally, PopPK parameters were estimated by a standard two-stage "individual" approach, which fits PK data of each individual separately with a compartmental model and then combines individual parameter estimates to generate mean (population) parameters and standard deviations.[21,22] However, this traditional approach does not describe nor explain the types of population variability. This issue can be well addressed by more sophisticated PopPK methods that involve the development of nonlinear mixed-effects (NLME) models. These models are termed "nonlinear" because nonlinear kinetic equations are used and "mixed effects" implies the consideration of both fixed (for parameters that have the same values for every subject) and random (for parameters whose values are subject specific) effects. PopPK models can generate more types of results than classical compartmental PK models, including mean PopPK parameters (e.g., volume of distribution), variability between subjects (interindividual or between-subject variability, BSV), and explanations of observed variability by covariates (e.g., individual characteristics such as age, body weight, or sex), as well as residual variability (e.g., experimental uncertainty or variability). A PopPK approach is more applicable to nondomestic avian species versus a PopPBPK approach since only time versus concentration and covariate data are needed for a PopPK approach. For reasons that were mentioned previously, a PopPBPK approach is more applicable to domestic avian species.

APPLICATION OF PHARMACOKINETIC MODELING METHODS TO GUIDE DOSING REGIMEN

Classical PK, PBPK, and PopPK methods can all be used to guide dosing designs. While classical noncompartmental and compartmental PK methods are relatively simple, they are sufficient to calculate essential PK parameters, such as AUC and C_{max} following a specific dosing regimen. These parameters are useful to design an improved dosing strategy. The adequacy of different dosing regimens of antibiotics can be evaluated by different PK/PD indices (e.g., AUC/MIC, C_{max}/MIC, and time > MIC) that represent the relationship between a PK measure of exposure to the antibiotic (e.g., AUC and C_{max}) and a PD measure of bacterial susceptibility to the drug (usually the MIC).[21] For example, cephalosporins are time-dependent antibiotics and the PK/PD index of T > MIC (i.e., the percentage of a time period where the unbound drug concentration exceeds the minimum inhibitory concentration) is the best predictor of clinical success of this class of drugs.[23] Previous studies have shown that the optimal duration of T > MIC should be at least 50% of the dosage interval.[23,24] Based on this information, a recent study showed that an extra-label use of intramuscular injection of cefquinome in black swans at 2 mg/kg every 24 hours, the dose typically used in labeled species, would not be an appropriate dosing regimen in black swans to treat *Escherichia coli* as the probability of attaining T > MIC of at least 50% of the dosage interval was not attained[25]; this recommendation was based on Monte Carlo simulated data for classical PK analysis.[25] Note that while classical PK methods are useful to guide dosing, their usefulness is limited to the dose level at which PK data were collected, and it cannot be used to evaluate the appropriateness of other dosing regimens at other dose levels. While linear extrapolation can be done, this is usually of high uncertainty as it is not supported by empirical data or PK mechanisms.

Compared to classical PK methods, PopPK methods are more versatile and have various clinical applications, such as dosing evaluation/optimization of antibiotics, setting clinical breakpoints, and therapeutic drug monitoring.[21] Another strength is that PopPK methods can analyze sparse datasets from a population of animals, thereby reducing the number of samples needed for each animal thus mitigating the stress from frequent sampling on animals.[26] To develop a reliable and robust PopPK model for a particular drug in a certain species, available relevant data from a diverse source, including from different studies using different dosing regimens from different laboratories, can be included. Provided that the quality of data is acceptable (usually the richer the data are), the more robust the PopPK model is. Also, a reliable PopPK model usually undergoes an extensive validation process using different methods, such as objective functions based on likelihood (e.g., Akaike Information Criterion [AIC]), graphical comparisons, bootstrapping to estimate parameter precision, and simulation-based diagnostics (e.g., Visual Predictive Check [VPC]), as well as external validation when a new dataset becomes available after the model has been developed.[27,28] As a result, the inference range of the PopPK model is usually wider as it includes multiple datasets in the development process. Therefore, PopPK models can be used to run simulations of different dosing regimens (e.g., the same dose level with different dosing intervals, and different dose levels with same dosing interval) and predict the probabilities of target attainment (PTA) of specific PK/PD targets of different dosing regimens and a range of MICs.[29,30] These results can be used to design the optimal therapeutic regimen to treat an infectious disease against a particular bacterial agent with a certain MIC.

PopPK methods have been increasingly used to guide dosing designs in avian medicine.[26,31–34] In a recent study, a sparse-sampling design was used to collect plasma samples (one to four samples each animal) from California brown pelicans *(Pelecanus occidentalis californicus)* after a single intramuscular injection of danofloxacin at 15 mg/kg (27.45–55.95 mg each animal depending on body weight), and a PopPK model with NLME modeling was developed to characterize the PK properties of the animal population.[26] Since typical therapeutic targets for fluoroquinolones are a C_{max} greater than or equal to 10× the MIC or AUC greater than or equal to 100× the MIC,[35] this study showed that the typical value for AUC in the studied population (13.75 μg/mL × hour) was sufficient for bacteria with MIC values less than or equal to 0.12 μg/mL, and the typical C_{max} value (2.5 μg/mL) from this study was sufficient for bacteria with MIC values less than or equal to 0.25 μg/mL.[26] Based on these results, the authors concluded that the danofloxacin dose used in this study produced plasma drug concentrations that would meet traditional therapeutic targets for bacteria with MIC values less than or equal to 0.25 μg/mL in pelicans.[26]

While the PopPK method is useful to guide dosing, it is still a data-driven empirical method and thus is limited in usefulness to extrapolate beyond the inference range of the experimental data, although the range is typically wider as data from many sources with different study designs can be integrated during model development. Specifically, PopPK methods cannot be used to extrapolate across species or between different subpopulations of the same species of animals as population- and species-specific physiological information is not incorporated in the PopPK model. This issue can be ideally addressed by PBPK models.

PBPK models have many applications, including dose optimization, bioequivalence analysis, drug-drug interaction studies, drug residue predictions, food safety, and risk assessment.[36,37] In human medicine, PBPK models are useful to guide dosing special subpopulations, such as neonates, children, and pregnant women.[38–40] Typically, a PBPK model in healthy adults is developed first as there are usually more data available in adults than other age groups, and then age-specific physiological information is incorporated into the model to extrapolate it to a special subpopulation to guide dosing designs. For example, in a recent study a full PBPK model of oxycodone following IV and oral administration was developed in adults, and then was extrapolated to children by incorporating age-appropriate anatomy and physiology, such as protein binding, clearance, metabolic enzyme expression and activities, as well as metabolic rates, and this model was validated with available clinical PK datasets.[40] According to this age-dependent PBPK model, the authors found that different IV dose regimens should be given to children of different age groups compared to a standard 0.1 mg/kg in adults, and a progressive increasing dose level with age growth following oral administration is recommended for children. This approach of using PBPK models to guide dosing for subpopulations of birds has not been studied to date but holds promise for evaluating subpopulations such as breed cohort production classes.

In the field of veterinary medicine, there are several PBPK models for different chemicals in different avian species, including chickens, turkeys, pheasants, and quail.[10–20] However, these models were developed and mainly applied to predict chemical residues in poultry meat products for food safety and risk assessment. None of these models has been reported to guide dosing designs. A review of published physiological parameters for birds has been published and can serve as the basis for developing generic PBPK models for common avian species.[41] The use of PBPK models to guide dosing and drug residue avoidance in veterinary medicine, including in avian species, has not been explored and remains a gap in the application of PBPK models.

PHARMACOLOGICAL INTERVENTION: INTERPRETATION OF ANTIMICROBIAL SUSCEPTIBILITY RESULTS

Barbara A. Byrne

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Antimicrobial therapy is the cornerstone of treating infectious diseases in avian species. Antimicrobials should only be used when there is evidence of an infection and ideally based on culture and susceptibility results. However, sometimes collection of a suitable sample is not possible; in these cases, one should use historical and regional susceptibility data reflecting the likely organisms for the anatomical location of the infection for empirical antimicrobial selection. In either case, response to therapy should be monitored and duration of treatment be limited as much as possible. Culture and susceptibility results, when carried out carefully, help to guide therapy through identification of causative organisms and provide in vitro measurements of the MIC in the case of broth dilution methods or zone diameter in disk diffusion that are then used for interpretation to predict in vivo efficacy.

PREANALYTICAL CONSIDERATIONS

Preanalytical considerations for culture and susceptibility testing include selection of the appropriate sample and conditions for sample storage and transport to the laboratory. These variables can impact interpretation and testing of isolates obtained. Ideally, a sterile site should be sampled that reflects the disease condition and sufficient material should be collected to allow detection of pathogens.

Isolation of pathogens from sterile sites, particularly when only one or two bacterial species are detected, likely reflects true infection rather than contamination if care was taken during sampling and transport to the laboratory. When multiple bacterial species are detected from a sample, it can be difficult to determine which, if any, are causative. In these cases, resampling may be more appropriate than susceptibility testing of all isolates. Interpretation of culture results from nonsterile sites is more challenging. If flora normally found in that site are isolated, it is difficult to distinguish whether they are causing disease or merely reflecting normal colonization. For example, isolation of streptococci or staphylococci from the nares or choanae could be considered normal flora and it would be difficult to determine if they were responsible for disease at that site or in the lower respiratory tract. Cytological findings such as the Gram stain and hematologic stains to distinguish heterophils can be helpful to determine the contribution of specific pathogens to a disease process when sampling sites with normal flora. For example, observation of bacteria and inflammation on cytology, especially if bacteria are found intracellularly, likely indicates the presence of an infection for a sterile site. The laboratory must determine which isolates to test or not test for antimicrobial susceptibility and which to consider as normal flora based on clinical signs, cytological findings, suspected condition, avian species, age, and other signalments. Optimization of sampling helps in this process.

Specimen size and storage conditions can also affect culture results. Small samples taken from normally sterile sites with few bacteria or fungi may not be adequate to detect pathogens. In general, as large a sample as can be safely collected is best. Swabs can be useful for sample collection in many avian species but if larger samples are available, they would be preferred. If anaerobic culture is desired, the swab or small (<1 mL) sample should be placed in prereduced transport medium that maintains the anaerobic environment. These media generally maintain aerobic, facultative anaerobic, and anaerobic bacteria, so a single swab, tissue, or fluid sample should be adequate for testing. However, if one or more enrichment steps are required, such as for isolation of *Salmonella* or other enteric organisms from a colonized site such as feces, more than one swab should be submitted.

Freezing of samples is not recommended as this will decrease the number of organisms in the sample and fastidious bacteria may be lost altogether. Fungi are highly susceptible to freezing so samples intended for fungal culture should never be frozen.

Samples should be placed in a sterile container for transport to the laboratory. If samples are small, for example, a drop or two of fluid or tissue less than 0.5 cm,[1] the sample should be placed in a transport medium or a small amount of sterile water or saline should be added to maintain moisture during transport. Samples should be kept cool and shipped overnight, if possible, to the laboratory following local transportation guidelines.

The laboratory should be notified as to the suspected class(es) of pathogens since many may require specialized media to isolate. For example, both fungi and *Mycoplasma* require specific medium formulations and culture conditions for optimal isolation and the laboratory can utilize them if informed. Likewise, specific pathogens or samples from certain anatomic locations may require specialized medium or culture conditions.

SUSCEPTIBILITY TESTING

Once a culture yields one or more isolates, the laboratory has the responsibility to select the most appropriate isolates, considered causative, for susceptibility testing based on the information provided by the submitting veterinarian. Similarly, the laboratory must carry out proper testing with appropriate routine quality control testing when reporting susceptibility results.

Methods for susceptibility testing can vary between laboratories and some laboratories may use multiple techniques depending on the antimicrobial drug tested. Common methods for susceptibility testing include disk diffusion (also known as Kirby-Bauer testing), broth dilution or microdilution, and MIC gradient strips. Each method has both pros and cons and each laboratory must determine the best fit for their circumstances (Table 5.2).

In disk diffusion testing, a paper disk saturated with a standard amount of antimicrobial is placed on a standardized lawn of bacteria on Mueller-Hinton agar. The agar is then incubated up to 24 hours and the zone of inhibition is measured (Figure 5.2A). The zone diameter determines the interpretation of the isolate as susceptible, intermediately susceptible, or resistant. Disk diffusion testing does not require any specialized equipment or training and can be performed by most microbiology laboratories. It is also relatively inexpensive, and several different antimicrobials can be tested on a single agar plate depending on the plate diameter. New or different antimicrobial drugs can be incorporated easily. Although the results can be interpreted as susceptible, intermediate, or resistant, this test does not determine an MIC, so it cannot be used to refine therapy. Also, if zone diameter interpretations are not available for a particular drug:microorganism combination, it is difficult to extrapolate to estimate if a therapy would be effective. Slow-growing or some fastidious bacteria cannot be tested using this method.

For the broth dilution method, a standard number of bacteria is suspended in Mueller-Hinton broth and added to tubes (dilution) or wells (microdilution in a 96-well plate) containing different concentrations of antimicrobial drug reflecting expected plasma or tissue levels. The tube or plate is covered, incubated, and then examined for growth (Figure 5.2B). The lowest concentration of drug that inhibits visible growth of bacteria (or 80% of growth in the case of potentiated sulfa drugs) is the MIC. Advantages of the broth dilution method include the ability to determine an MIC and to test more fastidious organisms. The disadvantages of this technique are that more specialized equipment and training are needed, and it is more expensive to run. There are several commercially available panels that have set concentrations and antimicrobial drugs. Flexibility would require the creation of custom panels or in-house test development.

The MIC gradient strip also utilizes Mueller-Hinton agar inoculated with a standard number of bacteria. However, for

TABLE 5.2

Advantages and Disadvantages of Different Susceptibility Testing Methodologies

	Disk Diffusion (Kirby-Bauer)	Broth Dilution (Broth Microdilution)	Minimum Inhibitory Concentration Strips
Advantages	Inexpensive	A minimum inhibitory concentration value is generated to refine therapy	Can be used for slow-growing or some fastidious bacteria
	No specialized equipment or training necessary	Can be used for slow-growing or some fastidious bacteria	No specialized equipment or training necessary
	Easy to perform	Can test multiple antimicrobial agents on a single 96-well plate	Easy to perform
	Can test multiple antimicrobial agents on a single agar plate	Several commercially available panels available	Can test multiple antimicrobial agents on a single agar plate
	New or different antimicrobial drugs can be easily incorporated		New or different antimicrobial drugs can be easily incorporated
Disadvantages	No minimum inhibitory concentration value generated to refine therapy	More expensive to perform than disk diffusion or minimum inhibitory concentration strip method	More expensive to perform than disk diffusion
	Cannot be used for slow-growing or some fastidious bacteria	Some fastidious organisms cannot be tested	Some fastidious organisms cannot be tested
		Hard to modify commercially available panels for new or different antimicrobial drugs	

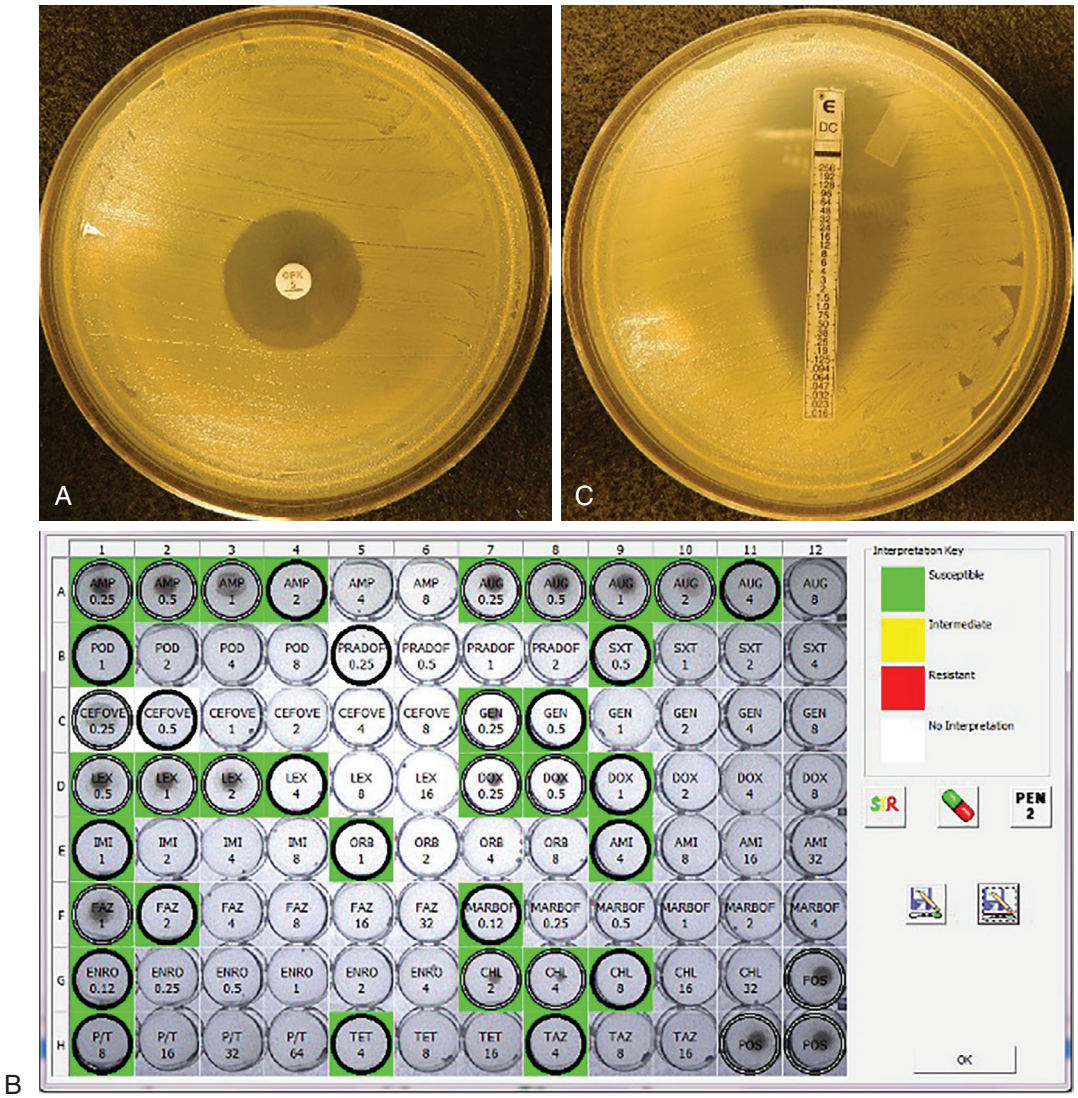

FIGURE 5.2 Examples of antimicrobial susceptibility tests. (A) Disk diffusion—*Staphylococcus aureus* tested for susceptibility to ofloxacin. The zone of inhibition is 24 cm. (B) Broth microdilution—canine *Escherichia coli* isolate showing inhibition of growth at different concentrations (numbers in μg/mL) of drug. *Green* indicates concentrations where the organism is considered susceptible to the agent. *Dark areas* within wells indicate bacterial growth. There are several antimicrobial drugs for which there is no interpretation (*no color*). (C) Minimum inhibitory concentration strip—doxycycline and *S. aureus* showing a minimum inhibitory concentration of 0.125 micrograms/mL.

this testing a strip impregnated with a gradient of antimicrobial is placed on the lawn and the agar incubated. The region where the bacterial growth contacts the strip determines the MIC (Figure 5.2C). Similar to the disk diffusion method, testing using an MIC strip is relatively easy to perform, and multiple strips can be tested on a single agar. It has the added advantage of providing an MIC. However, it is more expensive to perform than disk diffusion.

When testing is performed in a standardized manner using appropriate controls, medium, and incubation conditions according to methodology described by the manufacturer and the Clinical and Laboratories Standards Institute (CLSI)[2] or European Committee on Antimicrobial Susceptibility Testing, results can generally be compared between laboratories. Keep in mind that the MIC value may vary by a 2-fold dilution for the same isolate tested on different days.

INTERPRETATION OF SUSCEPTIBILITY RESULTS

Once a diameter of inhibition or an MIC is obtained an interpretation of these results can be made. In the context of this chapter, interpretation is a clinical interpretation reflecting whether an MIC or inhibitory zone diameter is likely to predict clinical efficacy. The three most common interpretive categories for antimicrobials used in veterinary medicine are susceptible, intermediate, and resistant. Categorization or interpretation of a zone diameter or an MIC is dependent on a

breakpoint or cutoff value. Interpretation of susceptible is "a category defined by a breakpoint that implies that isolates with an MIC at or below or a zone diameter at or above the susceptibility breakpoint are inhibited by the usually achievable concentrations of antimicrobial agent when the dosage recommended to treat the site of infection is used, resulting in likely clinical efficacy."[3] Intermediate is "a category defined by a breakpoint that includes isolates with MICs or zone diameters within the intermediate range that approach usually attainable blood and tissue levels and for which response rates may be lower than for susceptible isolates."[3] Finally, resistant is "a category defined by a breakpoint that implies that isolates with an MIC at or above or a zone diameter at or below the resistant breakpoint are not inhibited by the usually achievable concentration of the agent with normal dosage schedules and/or that demonstrate MICs or zone diameters that fall in the range in which specific microbial resistance mechanisms are likely, and clinical efficacy of the agent against the isolate has not been reliably shown in isolates with similar phenotypes."[3]

Breakpoints are determined using several criteria. The first is the pharmacokinetics (PK) of the drug at specific dosages, routes of administration, and animal species. The drug must achieve levels capable of inhibiting or killing bacteria at the site of the infection. The second is the pharmacodynamic (PD) relationship between a particular drug and pathogen where there is an antimicrobial effect on the pathogen over time. The relationship between PK and PD determines the outcome of therapy. The third input into determining the breakpoint is the epidemiological cutoff value (ECV). The ECV is determined by looking at the distribution of the MICs in a population of bacteria. Often this distribution frequency will fall into a bimodal distribution with some of the population with low MICs and some having higher MICs (Figure 5.3). The bacteria with higher MICs are presumed or proven to have acquired a resistance determinant to the drug whereas those with lower MICs have not. The drug concentration(s) between these two modes is(are) considered the ECV.

Antimicrobial drugs can be categorized by their PK/PD relationship. For example, beta-lactam drug effects on a microorganism depend on the time the drug is above the MIC and they are said to have "time-dependent" antimicrobial activity. For time-dependent inhibition the concentration of drug should exceed the MIC for at least 50% of the dosing interval.[3] On the other hand, drugs such as aminoglycosides or fluoroquinolones are considered "concentration dependent" where the maximum concentration above the MIC (C_{max}:MIC ratio) or the area under the concentration curve over 24 hours (AUC_{24}):MIC ratio determines clinical outcome. Concentration-dependent drugs such as aminoglycosides should have a C_{max}:MIC ratio of 8 to 10 whereas fluoroquinolone activity can be predicted by the 8- to 10-fold C_{max}:MIC ratio or AUC_{24}:MIC ratio of 100 to 125.[3]

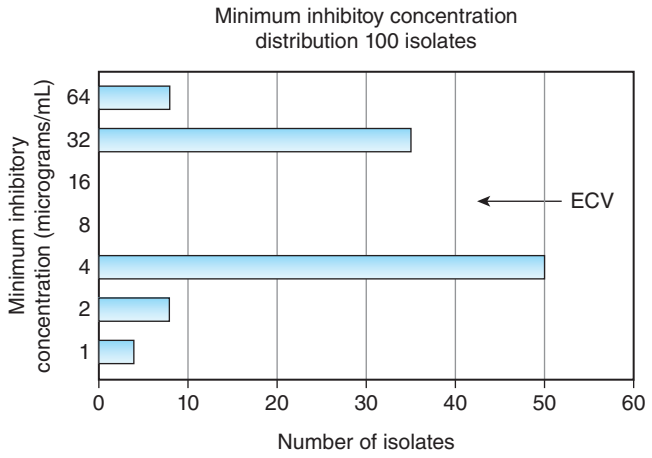

FIGURE 5.3 Theoretical example of the distribution of minimum inhibitory concentrations of 100 isolates. *ECV,* Epidemiological cutoff value.

Breakpoints are made for specific hosts (e.g., dog), drug:bug combinations (e.g., amoxicillin/clavulanic acid: *E. coli*), and often sites of infection (e.g., urine). In early CLSI publications with breakpoints, distinctions were not always made based on the site of infection, whereas now, they are more limited in scope where a breakpoint might be available for interpretation of an MIC from *Pasteurella multocida* isolated from the respiratory tract of cattle but not for an isolate from the urine. When a breakpoint is not available for one or more of these criteria, an interpretation cannot be made and may appear as "no interpretation" in a susceptibility report. Unfortunately, no interpretation categorization is now fairly common in veterinary medicine, particularly for isolates from avian species or for drugs used in an extra-label manner.

An MIC categorized as "susceptible" implies that clinical efficacy is likely when using that drug, provided that the drug reaches the site of infection. There are several reasons why an antimicrobial drug may not be as effective as predicted by a breakpoint. These include the presence of pus or necrotic debris that may bind drugs like aminoglycosides. A low tissue pH can decrease the activity of macrolides and fluoroquinolones. The presence of a surgical implant or other foreign material such as an IV or urinary catheter may provide a surface for biofilm formation by bacteria that prevents penetration of the antimicrobial agent to the organism. Decreased blood supply or the presence of a capsule in chronic infections may result in decreased concentration at the site of infection. Each of these is a consideration when planning antimicrobial therapy.

Extrapolations beyond established breakpoints should be approached cautiously. However, if a breakpoint is not available, a limited informed estimation of efficacy may be made. If there are data or breakpoints available for similar bacteria in the same host species these might be used. Unfortunately, the only avian breakpoint published in the current CLSI guidelines VET08 document is for enrofloxacin and *E. coli* in poultry.[1] However, in the United States, this drug was withdrawn for use in poultry in 2008. Still, some antimicrobial susceptibility software will report isolates as susceptible or resistant based on extrapolation from other veterinary species or humans. A general strategy is to first utilize breakpoints for related bacteria in the host species, then same bacteria in similar host species, then unrelated bacteria in the host species, and finally PK/PD relationships along with the measured MIC. Because so few breakpoints are established for any avian drug:bug combinations, one must have knowledge about the PK and PD in their avian species of interest to utilize MICs found in a susceptibility report.

Some bacteria will have intrinsic resistance to specific antimicrobial drugs or classes. For example, *Enterococcus* spp. are intrinsically resistant to cephalosporins, aminoglycosides (except high-level aminoglycoside concentrations), clindamycin, fluoroquinolones, and trimethoprim-sulfa. However, in some cases, the isolate will have a low MIC and appear susceptible in vivo.[1] The laboratory should elect to not report these results for drugs to which the organism has intrinsic resistance to avoid this pitfall and inappropriate use of antimicrobials.

COMPONENTS OF A SUSCEPTIBILITY REPORT

An antimicrobial susceptibility report will have several components including organism(s) tested, drugs reported, MIC in μg/mL, interpretation of the results when available, and any comments regarding the isolate or interpretation. Most laboratories will report the MIC when available, but in general do not report the zone diameter when disk diffusion is used. An example of a susceptibility report can be found in Figure 5.4. Generally, a report includes information regarding the animal identification, species, and owner. The report itself will detail the types of bacteria isolated and their relative amount(s) (e.g., 1+, 2+, etc., corresponding to the area of streaking where colonies are identified). Some reports will provide guidance as to drug dosages used for interpretation. The <= or ≤ symbol before the MIC indicates that there was no growth in the lowest concentration of drug tested and the > sign means that there was growth at the highest concentration of drug tested. Since the laboratory only tests concentrations that surround levels (and breakpoints) found in the blood or tissue of the host animal, a greater than symbol demonstrates that the bacterium was not inhibited at concentrations exceeding those found in the animal and it would be unlikely to be efficacious even if no interpretation can be provided. The less than or equal to symbol is more difficult to utilize unless you know something about the expected drug concentrations at the site of infection (drug distribution), duration of concentration above the MIC, and/or the AUC_{24} or C_{max}. If these are known, then the appropriate PK/PD indices can be calculated to estimate clinical efficacy.

	E. coli hemolytic		
Amoxi/Clav	Suscept		4.00
Ampicillin	Suscept		2.00
Cefazolin	Suscept		2.00
Cefovecin	No Int P		0.50

Tetracycline	Suscept	<=	4.00
Trim/Sulpham	Suscept	<=	0.50

FIGURE 5.4 Example of a susceptibility report of *Escherichia coli* isolated from an avian wound. The numbers represent the minimum inhibitory concentrations measured for this isolate in μg/mL. No Int P is no interpretation published, meaning that a breakpoint for that drug:bug combination has not been determined and susceptibility interpretation cannot be assigned. There are interpretations for many drugs based on host species other than avian, many of these drugs would be considered extra-label use or illegal to use in poultry.

WHAT IF YOU DO NOT HAVE CULTURE AND SUSCEPTIBILITY RESULTS?

Not uncommonly, clinical situations or economics do not allow the veterinarian to collect a sample for culture and susceptibility testing. In these cases, historical susceptibility testing results can be utilized. An antibiogram is a summary of susceptibility of organisms to specific antimicrobial drugs. It can be stratified as to animal host, anatomical location of the infection, and type of clinic. It is useful to compile an antibiogram using testing from the same hospital, or regional data if available. Ideally, information from the hospital where the animal is seen should be used for compiling. However, a single practice, particularly those seeing pet birds of many species, may not generate enough data to prepare an appropriate antibiogram. In these situations, regional data from a microbiology laboratory or compilation of results from multiple area practices can be used. If regional information is unavailable, then published studies reflecting regional or even national geographic regions can be utilized. However, one should keep in mind that these broad national data may not reflect regional antimicrobial resistance trends or practice types.

Antibiograms should be compiled at least annually utilizing clinical isolates rather than surveillance isolates,[4] although if insufficient data are available, several years can be used and a minimum of 30 isolates should be included. They should include only antimicrobial drugs routinely reported for a bacterial species and they should not utilize duplicate data; only data from the first instance of a bacterial species from a patient should be included. Isolates designated as intermediate should not be included in the percent susceptible category. The antibiogram should include information about the percentage of staphylococci that are methicillin resistant. If possible, supplemental information on the antibiogram by practice type can be useful as isolates from referral institutions may demonstrate increased resistance when compared to general practice.

ANTIMICROBIAL STEWARDSHIP

Antimicrobial resistance is a global health concern that can be attributed to overuse and misuse of antimicrobials,[5] in the human and veterinary world alike. Antimicrobial stewardship is an effort to optimize antimicrobial prescribing in such a way to improve overall outcomes while minimizing adverse consequences by considering antimicrobial, patient, and bacterial factors (see Chapter 6). In addition to minimizing antimicrobial resistance, antimicrobial stewardship is essential given the lack of novel antimicrobial development and potential for zoonotic diseases. In human medicine, the focus is using the right drug at the right dose for the right duration.[6] However, antimicrobial stewardship in veterinary species emphasizes the prevention of infection, judicious use of antimicrobials, and preventing the emergence of resistance to drugs considered important for use in human medicine.[7,8] Although human and veterinary strategies are implemented differently, it is important to recognize that both have similar goals: to use antimicrobial drugs

only when needed, to have the best outcome, and to limit harm, including development of resistant organisms.

In the United States, implementation of antimicrobial stewardship in the veterinary setting has historically led to a separation between companion animals and those that produce food for human consumption. The US Food and Drug Administration (FDA) has been taking measures to improve judicious use, such as requiring a defined duration of use on antimicrobial drug labels and requiring resistance risk evaluation of all new drugs since 2003. More recently there has been a strong push to advance progress by requiring veterinarian oversight of antimicrobials considered important in human medicine when used in livestock, which has led to reductions in the amount of antimicrobials used.[9,10] Although these regulations have been successful in limiting antimicrobial use in livestock, it may not go far enough, which is why the FDA has a 5-year target for this policy to include antimicrobials used in companion animals.[11]

Regardless of the type of animal being treated, there is a responsibility of veterinarians to limit antimicrobial drug use to situations when there is a high suspicion for or proven infection and to only use prophylactic antimicrobial regimens in cases where there is a proven historical benefit rather than purely for growth promotion. According to the Centers for Disease Control and Prevention (CDC), the *Core Elements of Antibiotic Stewardship* outlined for human medicine require practitioner commitment to implementing policies aimed at optimizing antibiotic prescribing, assessing the outcome and modifying as needed, and monitoring prescribing practices and access resources to stay up to date on prescribing practices.[12] In veterinary medicine, the International Society for Companion Animal Infectious Diseases (ISCAID) publishes guidelines for treating common infectious diseases.[13] Even though the current guidelines do not include recommendations for birds, they contain useful concepts that can be applied to avian medicine.

One aspect of optimal prescribing relies heavily on culture and susceptibility testing because these results drive the most appropriate drug selection with the highest likelihood of treatment success. Important considerations for culture and susceptibility testing include proper sample selection, judicious susceptibility testing, and interpretation of results to ensure they are consistent with the overall clinical picture. If culture and susceptibility testing are not options, before prescribing empiric antimicrobial treatment one must consider other reasons for observed physical examination findings and changes in clinical pathology. For example, an inflammatory leukogram might reflect a primary infection but rather inflammation secondary to a noninfectious process. Empiric antimicrobial therapy can delay diagnosis of the underlying process, confound further diagnostics, and promote resistance. These factors are components of risk assessment when employing empiric therapy.

To have an effective stewardship program, key elements revolve around culture and susceptibility testing, use of an appropriate antimicrobial drug at the correct dose for the shortest duration as possible, monitoring of outcomes, and de-escalation of therapy as appropriate. Additional resources regarding antimicrobial stewardship goals and implementation strategies can be found in the "Resources for Practitioners" table at the end of this chapter.

CONSIDERATIONS WHEN PHARMACOKINETIC OR TREATMENT DATA DO NOT EXIST

Jennifer L. Davis

Visit eBooks.Health.Elsevier.com for a complete set of references.

Given the large number of avian species and the paucity of pharmacokinetic data in these species, the practitioner is often unable to find published doses of drugs for a particular patient. This results in the need to interpolate or extrapolate information available in other species to that patient. Figure 5.5 depicts a pyramid approach for estimating a medication dose for avian patients utilizing different types of available data. Data available for nonavian species must be used with extreme caution, as mammalian species metabolize and eliminate drugs in a very different manner compared to birds. However, there are drugs considered "well-behaved" from a pharmacokinetic standpoint. This typically means that the drug exhibits linear kinetics over a range of doses, is not overly lipophilic, has low to moderate protein binding, undergoes minimal hepatic metabolism, and is eliminated by the kidneys using glomerular filtration. These drugs are most amenable to across and within species extrapolations. The pharmacodynamic effects also need to be similar across species. Fortunately, this means that several antibiotics are amenable to extrapolation across multiple species, as they are well-behaved and the pharmacodynamic effects relate to the concentration needed to affect the microbe being treated (MIC) at the site of infection rather than any specific receptor interaction in the animal, which may be species specific.[1] Examples of drugs that were determined to be well-behaved across veterinary and laboratory species include tetracycline, oxytetracycline, chlortetracycline, erythromycin, diazepam, prednisolone, cephapirin, ampicillin, gentamicin, apramycin, and carbenicillin.[1]

Determination of whether or not a drug is well-behaved can be done by researching available literature to determine if it demonstrates first-order kinetics, the presence of active or toxic metabolites, and knowledge of common elimination routes.

Options for finding dose information involve searching the literature as well as both domestic and foreign drug databases to discover data regarding pharmacokinetics, safety, and efficacy of the drug in the avian species of interest. If this is not available, data from other avian species, or lastly, data in mammalian species can be used. Literature should be evaluated preferentially as well. If meta-analysis or systematic reviews are available, they should be considered to have the highest quality of information, followed by randomized controlled trials, case-control studies, case reports or series, and lastly, anecdotal evidence. The drug approval process provides a vast

amount of information on efficacy, toxicity, or safety, and also pharmacokinetics, which may include dose escalation data and an assessment of linearity. Both domestic and foreign drug databases should be searched for this information as countries often have different drugs available for use. Additionally, even if the drug is not approved in an avian species, examination of approval documents may reveal preapproval clinical testing in avian species and be a useful source of information.

MULTIPLE DOSE REGIMENS

If data are reported in the literature, they are typically based on the administration of a single dose only, and to healthy animals only. However, clinical use usually involves multiple drug administrations to sick animals. For drugs that exhibit linear kinetics, multiple-dose regimens can be predicted from single-dose data. The two main parameters to adjust for a multiple dosage regimen are the drug dose and the frequency of drug administration (tau [τ] or the time interval between doses). Doubling the dose will produce higher plasma drug concentrations that are detectable for an additional half-life of the drug. Using a dose interval that is short compared to the time required for drug elimination will result in accumulation of the drug in the plasma; therefore extending the dose interval will change the degree of accumulation. The drug accumulation ratio (AR) can be calculated based on the equation:

$$AR = 1/(1 - e^{-k\tau})$$

where k is the elimination rate constant, determined by single-dose studies.

The principle of superposition assumes that early doses of drug do not affect the pharmacokinetics of subsequent doses.[2] Therefore, each dose can be considered as an independent event, and the sum of all these dosing events provides the total concentration of drug in circulation. This information can then be used to generate a concentration-time curve of any dosing regimen by calculating the total drug concentration in the body (C_{Total}) using the concentration from each individual dosing event. You can generalize this equation as the following:

$$Cn(t') = C_1(t) + C_1(t) \times [(1 - e^{-(n-1)\beta\tau})/e^{-\beta\tau} \times e^{-\beta\tau'}]$$

where t′ is the time after administration of the nth dose, t is the time after administration of the first dose, n is the number of doses, and β is the elimination rate constant. This equation relates to one-compartment, IV data. Also, if only plasma data are available, it may not accurately represent tissue concentrations. Drugs with a large Vd may have persistence and accumulation in tissues that are not reflected in the plasma.

ALLOMETRIC SCALING

Allometry is the study of size and its consequences. Allometric scaling is a method that predicts pharmacokinetic data for a drug in one species through interpolation or extrapolation from data available in other species.[3] This is possible because most pharmacokinetic parameters depend upon physiologic functions (heart rate, glomerular filtration rate [GFR], etc.) that are ultimately relatable to basal metabolic rate (BMR). Allometric scaling assumes that BMR is related to size, with larger animals having slower metabolic rates. Therefore, the equation used to mathematically define allometric scaling for a given pharmacokinetic parameter (Y) is:

$$Y = a \times BW^b$$

where a is the allometric coefficient, BW is body weight, and b is the exponent of the equation. Data can be log transformed to stabilize variance and minimize deviations from the regression line.

In order to obtain the best results from allometric scaling, interspecies comparisons should be done on animals with similar physiology that are closely related in aspects other than size, and data should be available from three or more species over three orders of magnitude in size (some smaller, some larger).[3] Therefore, when considering using allometric scaling for a specific avian species, data from other avian species over a range of weights are preferred and mammalian data are useful only for a limited number of drugs.[4] Differences in diet can also influence drug metabolism and renal elimination; therefore the best result within avian species would be obtained with birds within the same dietary group (e.g., piscivorous vs herbivorous).

Clearance is the most common parameter subjected to simple allometric scaling and is appropriate for drugs that are renally excreted by filtration (nonsaturable). These would be considered well-behaved drugs with linear kinetics over a range of doses. Drugs that are highly metabolized in the liver, particularly those with a low hepatic extraction ratio, do not scale as well due to the heterogeneity of metabolic capacity between species. Volume of distribution can also scale but is best for drugs that are confined to the plasma and extracellular space, as the volume of total body water and extracellular fluid scale with weight, whereas other fluid volumes may not. Increases in body weight typically lead to decreases in fluid volumes. Clearance and volume of distribution are both primary pharmacokinetic parameters and are affected by dose administered and absorption. Therefore, IV data must be available. Half-life is a hybrid parameter involving both Cl and Vd and not directly correlated to physiologic processes. It is sometimes used in allometric scaling and may be a more robust parameter as it is less sensitive to occasional differences in individual parameters caused by nonphysiologic reasons (e.g., laboratory variations).[1]

Both Cl and Vd can be affected by protein binding and using pharmacokinetic data derived from the unbound fraction of drug can help increase correlations between species, particularly for drugs with high hepatic extraction ratios.[3] The percentage of plasma protein binding of drugs can be a source of variability between species. There are several other factors to account for when considering using allometric scaling for dose determination. Pharmacogenetic differences in drug metabolism, saturation of metabolism or elimination processes (nonlinear kinetics), differences in urine pH, drug-induced alterations in physiologic processes (e.g., drugs that alter heart rate or renal blood flow and fluid balance), and the presence of species-specific drug transporters all influence (typically decrease) the usability of allometric scaling.

There are little published data regarding the use of allometric scaling to predict doses for avian species. Riviere et al.[1] examined allometric scaling of 44 drugs across mammalian (including laboratory animals) and avian species. A very limited number of drugs scaled across all species using half-life as the tested pharmacokinetic parameter, including ampicillin, apramycin, erythromycin, oxytetracycline, and tetracycline. Subsequent papers by this group removed avian species from analyses due to the difficulty of finding drugs that would scale based on the high degree of physiologic variation between mammals and birds.

The predictive power of allometric scaling increases when only data from avian species are included.[5] Analysis of commonly used antibacterial drugs in birds showed a significant correlation with body weight for Cl, Vd, and, in some cases, elimination half-life for fluoroquinolones, penicillins, aminoglycosides, potentiated sulfonamides, tetracyclines, and florfenicol.[6] This study looked at several avian species; however, they represented a relatively small variation in size from quail and pigeon to turkeys. Another study looked at the validity of scaling the chemotherapeutic drug carboplatin in avian species from different orders (parakeets, pigeons, chickens, ducks).[7] A significant correlation was found between body weight and elimination half-life in that study.

In summary, data from the literature can be used to determine drug doses for avian species in some instances. Well-behaved drugs that follow first-order, linear kinetics are most amenable to extrapolation across species. Drugs with nonlinear kinetics are harder to predict, particularly with multiple-dose regimens. If these drugs must be used in the absence of species-specific data, close and careful monitoring of patients is required, as well as a knowledge of the inherent toxicity associated with that drug in other species.

ALTERNATIVES TO PHARMACOLOGICAL TREATMENT

Emily D. Richards, Lisa A. Tell

Visit eBooks.Health.Elsevier.com for a complete set of references.

Because the majority of the current literature and regulations regarding drug use in food-producing animals focuses on the reduction of antimicrobial medication, this section also focuses on alternatives to antimicrobial medication use; however, the concept of using medication therapy only when necessary should ideally be applied to any situation, regardless of medication class.

A useful resource describing ways to reduce antimicrobial use in animals is from the European Medicines Agency and European Food Safety Authority, which describes in detail nonpharmacological interventions and alternative therapies that can be utilized on a flock scale.[1] Nonpharmacological interventions include optimizing husbandry and maintaining biosecurity. These can be accomplished through adequate light and heat sources, providing nutritional feed, allowing for adequate space and a clean environment (regular and proper disinfection, removal of fecal material), as well as maintaining adequate protections from transmitting pathogens from one bird to another (especially between farms or homes).

In poultry, current practices of utilizing alternatives to antimicrobials with strong scientific evidence center around the use of pre- and probiotics, organic acids, in-feed enzymes, and vaccines.[2] Other options utilized in poultry species, with some scientific evidence supporting efficacy, include phytochemicals, immune modulators, antimicrobial peptides, and bacteriophages.[2] An important consideration for these methods is the timing and duration of use, as some are only efficacious if used prior to exposure while others can be utilized continuously.[2]

COMPOUNDING CONSIDERATIONS FOR AVIAN PATIENTS

Krysta L. Martin, Lauren V. Powers, Emily D. Richards, Lisa A. Tell

Visit eBooks.Health.Elsevier.com for a complete set of references.

According to the US Food and Drug Administration (FDA), compounding is the term used for "any manipulation of a drug formulation to produce a dosage form other than that manipulated and provided for in the directions for use on the approved drug product." Practically, compounding is the combining, mixing, or altering of ingredients to create a medication that is tailored to the needs of an individual patient. Oftentimes, compounded products lack safety, efficacy, and food residue data that are required for commercially approved products. Due to this lack of data, the potential exists for treatment failure and adverse reactions in treated animals or consumers of their food products. Before deciding to use a compounded product, it is important to consider your governmental regulations regarding compounding, especially for use in avian species that are food producing such as chickens and turkeys, regardless of their intended use. Although compounding may provide cost savings in some situations, compounded products should be reserved as a last line of therapy due to lack of supporting data, compared to commercially available products.

In nonproduction avian medicine, there is a shortage of FDA-approved veterinary products for avian species. Due to this, drugs are often utilized in an extra-label manner, including the use of compounded medications. Compounding allows the preparation of medication specific to the needs of the patient, such as preparation of liquid formulations, which are often times preferred for oral administration; ability to choose flavoring to increase palatability and compliance; and preparation at a concentration that is suitable given the patient's body weight.

Below are aspects to consider when utilizing compounded medications for avian patients.

1. It is important to consider whether or not the patient is a food-producing animal species or has the potential to become a food-producing animal. This is also a concern when treating wildlife where the fate of the animal is unknown or in backyard operations where antimicrobial resistance is still a potential and human exposure is a risk. Food-producing animal species tend to have stricter governmental regulations in regard to drug use in order to protect human health and avoid violative drug residues from entering the human food chain. In the United States, estimating a recommended withdrawal interval following extra-label drug use in food-producing animals is only possible if scientific data are available.[1] Since pharmacokinetic data are scarce for compounded medications, veterinarians need to consider the possibility that estimation of a withdrawal interval recommendation might not be possible following use of a compounded medication in a food-producing animal. Furthermore, if a withdrawal interval cannot be estimated, it would be best practice for the veterinarian to document the recommendation that the animal and its edible by-products never enter the human food chain.
2. When deciding to use a compounded product from an outsourced pharmacy (i.e., the veterinarian is not preparing the product in-house), it is important to use a reputable compounding pharmacy that is utilizing best compounding practices. In the United States, the *United States Pharmacopeia* (USP) establishes guidelines for best practices for both sterile and nonsterile compounding.[2] These guidelines discuss formulations, preparation techniques, storage and handling of ingredients and products, as well as establishing a beyond-use date (BUD). Veterinarians should be familiar with these guidelines when preparing compounded medications in-house, and ensure that an outsourced pharmacy follows these industry standards.
3. It is recommended that the "recipe" (or "formula") used to prepare a compounded medication has been evaluated at a minimum for potency and stability. This is to help ensure that the final product contains the desired drug concentration and will be stable for a given period of time. As a gold standard, every batch of compounded medication should be tested for potency and stability, since variability between batches is expected. However, even though interbatch variability is expected, it is likely cost and time prohibitive to test each individual batch for potency and stability; therefore, using a standard formulation that has been tested for stability and potency is the next best practice to provide for a minimum consistency between batches.
4. The source of the active ingredient is also important to consider. It is recommended that the prescribing veterinarian ask about this if the compounding is being outsourced to a pharmacy. There are generally two sources from which to obtain the active ingredient to compound from: a commercially available finished product (e.g., tablet, capsule) or a "bulk powder," or raw chemical, also known as the active pharmaceutical ingredient (API). APIs lack excipients, which can be beneficial in situations where excipients of a commercially available product have been known to cause adverse reactions in the intended patient or species. Due to the differences in purity, compounding from bulk powder runs the risk of the drug concentration differing from a commercial product. This is problematic when there is a small margin of safety between the therapeutic dose and a toxic dose. Additionally, dosing errors can occur due to potential differences in the salt forms between commercially available products and an API. For example, metronidazole is commercially formulated as the base form (~171 g/mol) and the hydrochloride salt (~207 g/mol)—both are known to be bitter, which is why the more palatable metronidazole benzoate salt form (~275 g/mol) API is preferred for compounding. However, due to the increased molecular weight

of the benzoate form, a 1.6 times dose increase is required when using the benzoate salt form in order to administer an accurate metronidazole dose.[3] Some compounding pharmacies will account for these differences in their formulations and the compounded metronidazole benzoate concentration will be listed on the label as equivalent to metronidazole hydrochloride. Although this example refers specifically to a medication that has regulatory concerns for some birds in certain countries, this concept applies to many other medications. Referring to compounding governmental regulations is necessary to confirm that use of bulk powder is permissible. Preferentially compounding from bulk powder rather than a commercially available product has been utilized to aid in cost savings, but this is not considered the best practice, and may even be considered illegal in some countries. Ideally the commercial product should be utilized as the source of active ingredient unless there are studies to show pharmacokinetics and benefit of using bulk powder. A prime example of the importance of knowing the supportive data for use of a compounded product involves the use of compounded itraconazole from bulk powder. Multiple studies in various species, including some avian species, have shown compounded itraconazole from bulk powder may not be well absorbed and therefore unable to reach therapeutic concentrations,[4–6] causing treatment failure. Unfortunately, in the United States, there are no set regulations that require a compounder to disclose up front the source of the active ingredient in the compounded preparation; however, they should provide this information upon request.

Compounded products play an important role in treating avian species as there are limited commercially approved products. The overarching message is that just because a compounded product can be prepared at the concentration/formulation/combination desired, it does not mean that it should be or that it will be effective, safe, and/or stable. Reviewing the literature on compounded formulations, pharmacokinetic data on compounded products, governmental regulations, and best compounding practices should not be overlooked in the best interest of the patient.

MONITORING ESTABLISHED TREATMENT PLAN

Krysta L. Martin, Emily D. Richards, Lisa A. Tell

Visit eBooks.Health.Elsevier.com for a complete set of references.

Once a treatment plan has been established and initiated, it is important to monitor the patient through the entire treatment course and illness resolution. By doing so, compliance as well as treatment effectiveness and drug safety can be evaluated. Being familiar with the characteristics of the drug(s) chosen for treatment, such as how it is metabolized, where the site of action is, and common side effects will help guide monitoring. For drugs that have a renal site of action, a downstream effect by the kidneys, or are known to be nephrotoxic (i.e., aminoglycosides), practitioners may consider checking renal biochemical parameters during treatment, especially if the patient already has some renal compromise. Renal dysfunction prior to treatment may even warrant consideration to dose adjust compared to patients with no impairment. Having knowledge that a drug might increase renal function biochemical parameters or liver enzyme activities, justifies recommendations for clients to monitor for renal or hepatic disease clinical signs, and could alter the treatment course or justify supportive care, such as addition of fluids to ensure proper hydration and support renal function.

Published resources (ideally referred or authored by experts in the field) detailing information about veterinary drugs are helpful with gathering information about key characteristics and side effects of commonly used medications. Examples of some resources can be found in the "Resources for Practitioners" table at the end of this chapter. For all medications, it is important to be aware of common side effects as well as less frequent or serious side effects that may require further evaluation. The occurrence of common side effects does not always require modification of treatment selection or plans, but serious side effects warrant further investigation. Not only is it important for the practitioner to be aware of potential complications, but it is also necessary to relay this information to the client/caregiver as they will be responsible for monitoring and observing for clinical signs of adverse side effects. If information available regarding drug side effects is not specific for the species being treated, look for information in a related species. If necessary, keep broadening the search even if you have to use an unrelated species to provide general guidance for advising the client.

In addition to monitoring for potential negative side effects of the medication(s), monitoring clinical signs, symptoms, and clinical pathology laboratory values for improvement is recommended to evaluate if treatment goals are being met. Depending on the length of the prescribed treatment course, evaluating the effectiveness of the therapeutic plan prior to completion and potentially multiple times during the treatment is optimal. This will allow necessary changes to be made sooner than later, which would achieve meeting therapeutic goals sooner and minimizing deleterious patient effects.

When monitoring an antimicrobial treatment plan, if the patient obtains the desired response and the antimicrobial(s) is/are confirmed to be susceptible, treatment de-escalation could be considered. For example, if two antibiotics (one with broad and one with narrow spectrum) are prescribed for initial treatment until culture and sensitivity results become available; if the cultured organism is found to be sensitive to both antibiotics, then reducing treatment to just the narrow spectrum antibiotic might be warranted. If the desired response is not obtained, but the antimicrobial is confirmed to be susceptible, evaluation if pharmacodynamic properties of the antimicrobial are being maximized would be important. For example, determining if a time-dependent antimicrobial is prescribed in a manner that provides sufficient time above MIC. Additionally, one should

also consider whether the drug is reaching the site of action or assessing if another problem, that was not previously identified, is contributing to treatment failure. If the desired response is not obtained and the antimicrobial is confirmed to be resistant, then the therapeutic plan should be changed.

In certain situations, such as when drugs have a narrow therapeutic window, meaning there is little difference between the drug being effective and toxic, therapeutic drug monitoring (TDM) should be considered. TDM is the clinical practice of measuring blood/serum/plasma drug concentrations at specific time points during treatment in order to optimize drug dosage, frequency of administration, and to maintain therapeutic efficacy and safety. Ideally, TDM is used after the patient has achieved a steady-state concentration, which is generally time equivalent to three to five elimination half-lives.[1] In addition to TDM being useful for drugs with a narrow therapeutic window, TDM can also help identify therapeutic failure due to client noncompliance or a poorly prepared or ineffective compounded medication.[1,2] While TDM is not as commonly used in veterinary medicine as it is in human medicine, it has been used in animal patients for monitoring medications such as anticonvulsants (e.g., phenobarbital, bromide), antimicrobials (e.g., aminoglycosides), cardioactive drugs (e.g., digoxin, theophylline), immunosuppressive medications (e.g., cyclosporine), and thyroid supplementation.[1] In veterinary medicine, and particular avian medicine, there are multiple challenges with utilizing TDM. The biggest limitation is a lack of confirmed therapeutic concentrations for various drugs and species and unknown targeted concentrations for which above and below pose increased risks for severe side effects or treatment failure, respectively. Population pharmacokinetic studies are required to have this range defined, which are often lacking in avian medicine. Other challenges are limited availability of validated assays for the species of interest and analytical methods with minimum sample volumes that are small enough for avian patients. These considerations are important to allow proper interpretation of results. For more information and details regarding TDM refer to the "Resources for Practitioners" table for helpful references.

CHAPTER 6

Antimicrobial Agents

Isabelle Langlois • Ingeborg M. van Geijlswijk • Christal G. Pollock

Visit eBooks.Health.Elsevier.com for a complete set of references.

The use of antimicrobial drugs made a wide range of life-threatening infections readily treatable in the 20th century. Unfortunately, any use of antimicrobial drugs can contribute to the emergence and spread of resistance. Today, antimicrobial resistance is recognized as one of the greatest global public health challenges of our time. Antimicrobial stewardship programs describe responsible measures that can help mitigate the public health crisis of antimicrobial resistance while preserving the effectiveness of available antimicrobial agents.

CORE ELEMENTS OF ANTIMICROBIAL STEWARDSHIP

Christal G. Pollock

THE "WONDER DRUG" ERA

Returning to his lab after summer vacation in 1928, Scottish microbiologist Sir Alexander Fleming noticed that dots of mold had somehow found their way into a petri dish in which he was growing *Staphylococcus* spp. Surrounding the mold was a halo in which the bacteria had died. Fleming's research on the antibacterial effects of this *Penicillium* mold was largely forgotten until the beginning of World War II when investigators at Oxford University took up this work.[1] Penicillin, the extract from this mold, was used to combat infections during the war, saving the lives of untold numbers of servicemen (Figure 6.1).[2]

Although penicillin was considered remarkable, the dawn of the "wonder drug" era technically began between 1941 and 1945 with the discovery of the first aminoglycoside, streptomycin.[3] Between 1945 and 1955, a variety of antimicrobial drugs were discovered, including bacitracin, chloramphenicol, erythromycin, neomycin, nitrofurans, polymyxin, streptogramins, and tetracyclines.[3] These antimicrobial drugs transformed both human and animal health, making a wide range of life-threatening infections readily treatable.[3]

ANTIMICROBIAL RESISTANCE CRISIS

Antimicrobial resistance mechanisms are defense strategies that microbes develop, or randomly evolve during erroneous DNA replications which are automatically selected during exposure to antibiotics, to help them survive and avoid the inhibitory or killing effects of antimicrobials.[4,5] Resistance was already recognized by Fleming in the late 1940s but became clinically important between 1961 and 1965 with the advent of methicillin and other penicillinase-resistant penicillins.[3] Increasing resistance was observed when methicillin-resistant *Staphylococcus aureus* (MRSA) emerged in human medicine between 1986 and 1990.[3] Vancomycin-resistant enterococci then surfaced in humans between 1991 and 1995 and penicillin-resistant *Streptococcus* between 1996 and 2000.[3] Between 2005 and 2010, methicillin-resistant *Staphylococcus pseudintermedius* and MRSA began to emerge in animals.[3] However, even in 30,000-year-old permafrost samples containing ancient DNA, genes encoding for resistance to beta-lactams, tetracyclines, and glycopeptide antibiotics were identified, showing that natural antimicrobials were already selected for genetic resistance information.[6]

Antimicrobial resistance is now recognized as one of the greatest global public health challenges of our time.[4,5,7,8] Rising levels of antimicrobial resistance pose serious dangers to patients, population health, food security, the environment, and economic stability worldwide.[4,9] Resistance has been found in human and veterinary communities and agriculture in every US state and every country across the globe.[4] The threat of antimicrobial resistance is most dire for natural and synthetic antibacterial antimicrobial agents, but the efficacy of antifungals, antiparasitics, and antivirals is also threatened.[7,8]

The world may now be entering a "post-antibiotic era".[3,10] We now live in a time when people around the world die from untreatable infections because of the emergence and spread of antimicrobial resistance.[4,8] A committee commissioned by the UK Prime Minister in 2014 concluded that worldwide human deaths due to antimicrobial resistance had already reached 700,000 people per year and deaths were estimated to eventually rise to 10 million annually.[7,11] In addition to increasing morbidity and mortality, resistant infections also add significant costs to healthcare systems.[7]

MECHANISMS OF ANTIMICROBIAL RESISTANCE

There are multiple mechanisms of antimicrobial resistance.[3,7] Any use of antimicrobial drugs, in people, veterinary medicine, or agriculture, can contribute to the development or selection of antimicrobial resistance,[7,11,12] particularly in common human enteric pathogens or commensals like *Salmonella* spp., *Campylobacter* spp., *Enterococcus* spp., and *Escherichia coli*.[7,11,13] Microorganisms faced with antimicrobial selection pressure enhance their

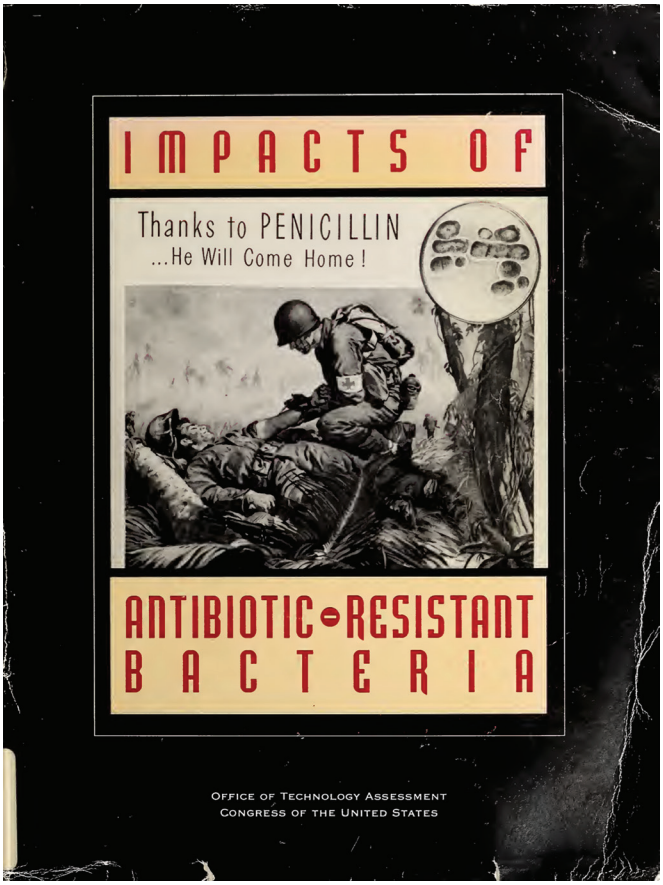

FIGURE 6.1 A century ago, clinicians had few effective medicines to treat infectious diseases. Penicillin became the foundation of a new era in treatment, but over time bacteria have demonstrated the ability to "fight back," and some antibacterial drugs are no longer effective against infectious diseases they defeated only a few years ago. Today, an understanding of antimicrobial resistance and antimicrobial stewardship is imperative to ensure most antimicrobials retain their efficacy (US Congress, Office of Technology Assessment).[10] (Original source: Life magazine advertisement, August 14, 1944. Image source: Wikimedia Commons via United States Congress, Office of Technology Assessment.)

fitness by acquiring, selecting, and expressing resistance genes and then share those genes via plasmid exchange with other microorganisms.[7,13] There is also concern that exposure to heavy metals and biocides, such as disinfectants and antiseptics in animals and environmental niches, may co-select for resistance to antimicrobials.[7,14] Furthermore, wherever antimicrobials are used, a resistant subpopulation may already be present, and selection pressure will allow these resistant microorganisms to increase in number.[13] Therefore, reservoirs of resistance exist within humans, animals, the local environments of hospitals, farms, and aquaculture environments, as well as water, soil, wildlife, and many other ecological niches, due to pollution by sewage, pharmaceutical industry waste, and manure runoff from farms (Figure 6.2).[7,15–17]

This is a true One Health issue.[8,11,18] Bacteria and their genes move relatively easily within and between humans, animals, and the environment.[6] There is evidence indicating human-to-animal transfer of resistance, particularly in horses and household pets, but also in livestock.[13,19–22] This problem is exemplified by the occurrence of human hospital-associated and community-associated MRSA infections in animals, particularly in domestic pets.[8,11,18] Resistant bacteria can also be transferred from animals to humans. Although in general one could safely state that antimicrobial use in companion animal practice is much lower than that in farm animals, the close relationship between treated animals and humans increases the risk of transfer of resistance and infection.[11,23]

ANTIMICROBIAL RESISTANCE IN VETERINARY MEDICINE

Veterinarians have come under increasing scrutiny for their antimicrobial prescribing practices.[11,12] Emergence of resistance among livestock and companion animals, and the risk of its transfer to humans, is an issue of increasing concern.[11]

Large-scale use of antimicrobials was widely adopted during the intensification and scaling-up of agriculture that occurred post–World War II.[7] By 1950, there was widespread, largely empirical, and preventive use of antimicrobials in animals, particularly food animals.[3] This practice is still considered necessary for efficient food production in some circles. In the veterinary/agricultural sectors, most antimicrobials were authorized for use before there was any systematic evaluation of the potential adverse effects on antimicrobial resistance.[7] In the United States, veterinary oversight has only been required since 2017 for the use of medically important antimicrobials in the feed and drinking water of food animals for treatment, control, or prevention of infection.[11] Globally, not all antimicrobial drug use in food animals is under veterinary prescription, despite repeated recommendations by the World Health Organization (WHO) and other responsible organizations.[3]

ANTIMICROBIAL RESISTANCE IN BIRDS

Detection of antimicrobial-resistant pathogens in birds is an important concern in the animal-human-ecosystem interface of One Health.[24–26] Among avian species, domestic chickens have been found to have the most antimicrobial resistance. This finding may partially reflect the large number of studies that have focused on antibacterial therapy in chickens, as well as the risk for resistance associated with intensive farming practices.[27–29] Multidrug-resistant bacteria and antibacterial-resistant genes have been isolated from live poultry (Table 6.1), as well as chicken carcasses and chicken meat.[27–29]

Wild birds, which inhabit a wide variety of environments and can migrate large distances, are also important reservoirs and vectors for antimicrobial resistance in the environment (Table 6.1).[37,118,121] Birds of prey are important indicators for the presence of multidrug-resistant bacteria within the ecosystem because of their predatory and/or scavenging behavior.[38,40,122,124] Urban pigeons (*Columba livia domestica*) are also an important reservoir of pathogenic and multidrug-resistant bacteria, as their close association with humans can facilitate the transfer of zoonotic disease.[26,76,78,79,81–84] Genes encoding for antimicrobial resistance have also been found in aquatic birds in diverse locations all over the world, from penguins in Antarctica to ducks in a wastewater treatment plant in Australia.[118] Bacteria resistant to beta-lactam and tetracycline drugs are also commonly found in the gut microbiome of birds, especially in scavenging and aquatic species, such as waterfowl, gulls, and waders,[45,51,52,55,59,68,118] and resistant bacteria have also

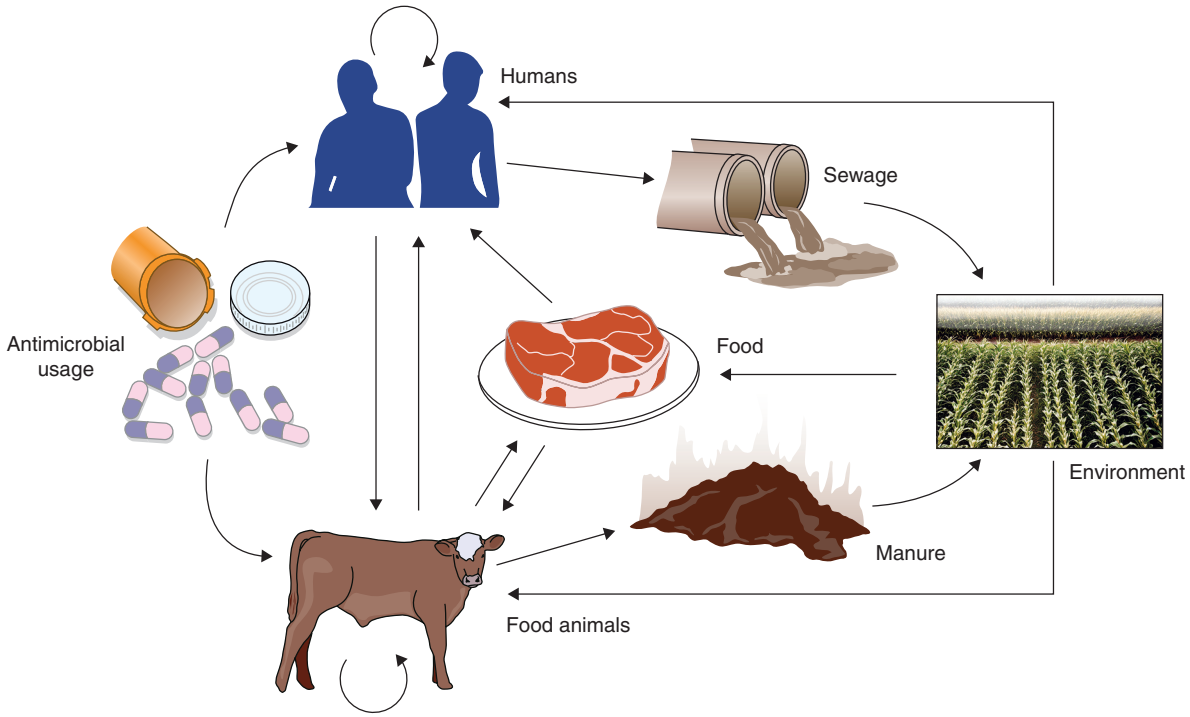

FIGURE 6.2 Diagrammatic representation of the routes of transmission of antimicrobial resistance between farm animals, the environment, and humans. (From Woolhouse ME, Ward MJ: Microbiology. Sources of antimicrobial resistance *Science* 341:1460–1461, 2013. doi: 10.1126/science.1243444.)[19]

even been isolated from songbirds that visit garden feeders.[125] Close contact with these birds, their feces, other bodily fluids, or soiled bedding material puts animal health care workers at risk for exposure to organisms with antimicrobial resistance.[121] It is imperative that workers practice sensible personal hygiene precautions when feeding or handling birds.[125]

Although the possibility of water contamination by bird feces is considered an important risk factor for the transmission of resistant bacteria,[51] exposure of migratory birds to swine waste or human waste (even if it goes through sewage treatment) is an important method for exposure and dispersal of a multidrug-resistant bacteria and resistance genes into waterways and other environmental sources.[44,45,51,118,121,126]

WHAT IS ANTIMICROBIAL STEWARDSHIP?

Antimicrobial stewardship describes responsible measures that can help mitigate the public health crisis of antimicrobial resistance while preserving the effectiveness of available antimicrobial agents.[11,24] Antimicrobial stewardship programs have been principally developed, implemented, and studied in human hospitals, but most global and national action plans to reduce antimicrobial resistance have also called for implementation of antimicrobial stewardship programs in veterinary practices.[11,12,25,26,127]

Additionally, legislative measures can support selective use of important antimicrobials. In the European Union, as a consequence of the new Veterinary Medicines Regulation (EU) 2019/6, implementing regulation (EU) 2022/1255 designating antimicrobials or groups of antimicrobials reserved for treatment of certain infections in humans has come into force on 9 February 2023. Eighteen substances/groups of substances of antibacterial drugs, 18 antiviral substances, and 1 antiprotozoal substance are specified in an Annex, which can be revised when necessary. The use in animals of medicinal products for human use that contain any of the antimicrobials or groups of antimicrobials listed in the Annex is prohibited.

No single intervention can address the problem of antimicrobial resistance. Instead a combination of interventions and approaches are used that have the potential to impact the antimicrobial resistance crisis.[3] The collective actions involved in antimicrobial stewardship have been conceptualized in a variety of ways: as a set of coordinated interventions, a strategy or program, or even as a philosophy or ethic.[26,121] Regardless of what it is called, antimicrobial stewardship requires a multifaceted approach that includes policies, guidelines, surveillance, prevalence reports, education, and audit of prescribing practices (Table 6.2).[26]

Stewardship programs typically entail a variety of strategies to prevent and control common diseases.[5,11,13,25,38] After all, if the incidence of disease can be reduced, the pressure to use antimicrobials can be similarly reduced.[13,25] When disease does occur, avoid the use of empirical antimicrobial agents whenever possible.[11] Early, appropriate diagnostic testing is an important substitute for the empirical use of antimicrobials.[13] When the use of antimicrobials cannot be circumvented, use an evidence-based approach to optimize antimicrobial selection, dosing, route, and duration of therapy (see Chapter 5). This approach will maximize clinical cure while minimizing conditions that select for resistant strains of microorganisms.[25,26,121] In some regions of the world, veterinary prescription and use of certain antimicrobial classes

ANTIMICROBIAL RESISTANCE				
Phenotype	**Enzymes**	**Genotype**	**Comments**	**Ref**
PEN, TET, C, ERY, STR, CLI, FUS, OXC, FOX		mecA	*S. aureus* was identified in 32 samples (34.8%) from nestlings from two landfill-associated and two natural habitat colonies. Prevalence was higher in nestlings from landfills (55.8%). Three birds from landfill colonies carried MRSA	75
STR (>50%), AMP (40%), AX (37%), ERY, TET			35 strains were isolated: *Campylobacter jejuni* (27), *Campylobacter coli* (8)	76
AX, CEPH, CRO, FEP	bla_{CTX-M}	CTX-M-15		66
AMP (87.5%), CRO (62.5%), CIP (62.5%), STR (56%), TET (56%), SXT (56%), C (18.7%), GM (6%)		CTX-M-15 (25%)	Resistant *E. coli* detected in 9.8% of pigeons	65
AMK (36.8%), AMP (7.8%)		CTX-M-15	*E. coli* detected at an overall rate of 12.1%; resistance to ≥1 of abx in 37.9% Four CTX-M-15–producing strains from four different birds	77
AMK (24%), GM (23.6%), AMP (22.8%), TET (17%), AX (16.9%)			A relatively higher proportion of isolates from pigeon feces (67%) were AR than those from roof-harvested rainwater (53%) The most abundant resistance phenotype: AK-GM-CIP-TET (6.8%)	78
		CTX-M-2 CTX-M-8		79
STR, TET, SU, CIP		*qnrA, qnrB, qnrC, qnrS, qnrD*	*E. coli* isolates were found in 203 samples. AR was recorded in 3 isolates. No ESBL-producing *E. coli* isolates were detected	80
	$bla_{CTX-M-1}$ group ESBL			34
	$bla_{CTX-M-15}$	CTX, TEM-1 *tet(A), tet(B) strA, strB,* class I integron *drfA17-aadA5*		47
		CTX-M-8	The frequency of MDR *E. coli* in captive pigeons was relatively high	81
TET, AX				82
TET (20%), GM (9%), ERY (9%), AMP (3%), VAN (3%)		*tetM, tetK, tetL, tetO, ermB* *vanA, vanC1, ant(4′)-Ia, aac(6′)aph(2), aph(3″)-IIIa, pbp5*	A total of 143 enterococci were isolated: *E. faecalis* ($n = 36$), *E. faecium* (27), *E. durans* (19), *E. hirae* (17), *E. mundtii* (17), *E. gallinarum* (12), *E. casseliflavus* (12), *E. columbae* (3). Resistance to abx (1–4) was detected in 45 isolates (31%)	80
AX, AMC CEPH, FF, F, CO				66
AX, AMC, KF, FF, F, CO				66
STR, AX, AMC, AMP, CAZ	bla_{TEM-1}	Class1 integron	Samples were collected from 50 freshly dead squabs, 40 freshly dead adults, 60 diseased adults, and 100 apparently healthy adults Class1 integron were characterized in 70% of squab isolates, 42.9% in adults, and 14.3% in the pigeon environment	83
TET			Resistance was detected in one bird	74
OXY, quinolones, MET (5%)			Beta-hemolytic coagulase-positive staphylococci	82
		sulI (30%), *sulII, tet(Q)* (13%–17%) TEM (4%) *tet(A), catI, qnrS*	The average of antimicrobial resistance genes detected per pigeon was 2	84

	Chicken (C)	Algeria	124 isolates	*E. coli* (feces)
	Chicken (C)	China (Shandong)	1	*E. coli, Cronobacter sakazakii*
	Chicken (C)	France (Marseille)	28 birds, 2 isolates	*H. alvei* (feces)
	Chicken (C)	Egypt	100	*K. pneumoniae* (feces, necropsy)
	Chicken (C)	France (Marseille)	28 birds, 1 isolate	*P. auruginosa* (feces)
	Chicken (C)	France (Marseille)	28 birds, 1 isolate	*Providencia alcalifaciens* (feces)
	Chicken (C)	Argentina (Entre Ríos)	657 birds, 4 isolates	*Salmonella* spp. (cloacal swab)
	Chicken (C)	Germany (Bavaria)	799 swabs, 800 eggs	*Salmonella* spp., *Campylobacter* spp., *E. coli* (cloacal swabs, egg contents, and shells)
	Chicken (C)	Algeria	503	Bacteria not isolated (feces)
	Red-legged partridge (*Alectoris rufa*) (F)	Spain	127	*Enterococcus* spp. (cloacal/rectal samples)

ANTIMICROBIAL RESISTANCE				
Phenotype	**Enzymes**	**Genotype**	**Comments**	**Ref**
ERY			Prevalence of ERY resistance among *Campylobacter* strains isolated from broiler chickens has been reported at 10% or lower	88
ERY			Macrolide use (single or multiple treatments with medicated water containing TY 0.53 g/L) did not qualify for ERY-resistant mutations in treated birds TY in feed at a growth-promoting dose (0.05 g/kg feed) caused ERY-resistant mutants to emerge after prolonged exposure to abx	92
TET, AMP, SXT, NA		CTX-M	Free range chickens	52
STR (65%), SU (51%), TRI (40%), SPT, TET, neomycin		TEM-52, SHV-2 CTX-M-1	Enterobacteriaceae (mostly *E. coli*) were identified in 10% of feces from healthy chickens. Resistance to at least 1 abx was observed in 113 isolates	29
CTX (100%), cefquinome (100%), CTF (98.7%), DC (97.4%), TET (97.4%), NA (97.4%), KM (96.2%), FLO (93.6%), ENR (89.7), CIP (83%), STR (83%), GM (78%), FF (78%), LEV (74%), CO (73%), MEM (47%), AMK (34.6%)		*mcr-1*	Isolates were collected from diseased chickens showing signs of diarrhea. About 53 isolates (67.9%) harbored *mcr-1*	93
AX, AMC, CRO, FEP, STX, GM	bla_{TEM-1}	TEM-1	*E. coli* was isolated from 25% of birds. MDR bacteria were also isolated	66
DC (97%), SU (94.9%), ENR (92%), AMP (89.7%), ofloxacin (84.6%), FLO (82%), SPT (61.5%), TET, SXT			About 92 avian pathogenic *E. coli* (APEC) isolates were recovered from broiler chickens with clinical signs and lesions of colibacillosis	94
CBP		*mcr-1* NDM-9	CBP-resistant *C. sakazakii* and *mcr-1* in *E. coli* were present in the same "diseased" chicken	95
AX, AMC, CEPH, CO				66
CBP		*kpc* OXA-48 NDM	*K. pneumoniae* was isolated from 35% from broilers with signs of respiratory disease. Fifteen of these isolates were CBP-resistant	96
AX, CEPH, CRO, F, STX	*bla*TEM	TEM-1		66
F, CO				66
ERY			Four serovars were isolated (*Salmonella ser.* Lille, *S. ser.* Newport, *S. ser.* Enteritidis, and *S. ser.* Rissen)	97
SPT			Laying hens were evaluated in both organic and conventional flocks *E. coli* from organic layers showed significant lower resistance rates All tested *Salmonella* ($n = 23$) proved to be resistant to SPT	98
		TEM ($n = 128$, 25.4%) SHV-128 ($n = 83$, 16.5%) CTX-M ($n = 46$, 9%) OXA-58		99
TET (66%), ERY (46%), KM (22.9%), STR (11.5%), GM (9.4%), VAN			Incidence of VRE-i isolates identified in red-legged partridges: 7.9%	39

TABLE 6.1

Select Reports of Antimicrobial Resistance in Birds—cont'd

Order/Family	Species	Geographic Location	Animals or Samples	ARB Isolated (Source)
	Cattle egret (*Bubulcus ibis*) Hooded crow (*Corvus cornix*) Rock pigeon (*Columba livia*) Laughing dove (*Spilopelia senegalensis*)	Egypt (Giza, Cairo, El-Sharkia, El-Ismailia, Port Said)	20 each	*E. coli, K. pneumoniae* (feces)
	Raptors, waterbirds, and passerines (F)	Italy (Sicily)		*E. coli, Proteus mirabilis, P. vulgaris, Citrobacter freundii, E. cloacae, K. oxytoca, Salmonella typhimurium, Escherichia vulneris, Enterobacter amnigenus* biogroup 2, *Salmonella* Duesseldorf, *H. alvei*
	Raptors (F)	Spain (Catalonia)	663	*E. coli* (35%), *P. aeruginosa* (7%), *Staphylococcus* spp. (5%)
	Three mountain caracaras (*Phalcoboenus megalopterus*) Four Egyptian vultures (*Neophron percnopterus*) Two red-headed vultures (*Sarcogyps calvus*) Two Eurasian eagle-owls (*Bubo bubo*) Three snowy owls (*Bubo scandiacus*) (C)	Italy (Verona)		*E. coli* (14), *Klebsiella* spp. (7), *Proteus* spp. (6), *Staphylococcus* spp. (6) as well as *Escherichia fergusonii. S. odorifera, Citrobacter youngae, Providencia stuartii, Raoultella ornithinolytica* (cloacal swabs)
	Herons, egrets, cormorants	Israel	47 isolates	*Vibrio cholerae* serogroups O1 and O139
	Two mountain caracaras (*Phalcoboenus megalopterus*) Two Eurasian eagle-owls (*Bubo bubo*) Three snowy owls (*Bubo scandiacus*) (C)	Italy (Verona)		Coagulase-negative *Staphylococcus* spp., *S. aureus* (conjunctival swabs)

Antimicrobial Resistance Phenotypes

AMC, Amoxicillin/clavulanic acid; *AMK*, amikacin; *AMP*, ampicillin; *APC*, aminobenzyl-penicillin; *ATM*, aztreonam; *AX*, amoxicillin; *BC*, bacitracin; *CAR*, carbenicillin; *CAZ*, ceftazidime; *CBP*, carbapenem; *CEF*, cefadroxil; *CEPH*, cephalothin; *C*, chloramphenicol; *CLI*, clindamycin; *CIP*, ciprofloxacin; *CO*, colistin; *CPD*, cefpodoxime; *CRO*, ceftriaxone; *CTF*, ceftiofur; *CTX*, cefotaxime; *CVN*, cefovecin; *DC*, doxycycline; *ENR*, enrofloxacin; *ERY*, erythromycin; *ETP*, ertapenem; *F*, nitrofurantoin; *FEP*, cefepime; *FF*, fosfomycin; *FLO*, florfenicol; *FOX*, cefoxitin; *FUS*, fusidic acid; *GM*, gentamicin; *IPM*, imipenem; *KM*, kanamycin; *KZ*, cefazolin; *LCM*, lincomycin; *LEV*, levofloxacin; *MEM*, meropenem; *MET*, methicillin; *MRB*, marbofloxacin; *NA*, nalidixic acid; *OXA*, oxacillin; *OXY*, oxytetracycline; *PEN*, penicillin; *PIP*, piperacillin; *PO*, polymyxin; *SA*, sulfadimethoxine; *SM*, dihydrostreptomycin; *SPT*, spectinomycin; *STR*, streptomycin; SU, sulfonamide, sulfamethoxazole; *SXT*, sulfamethoxazole/trimethoprim; *SZL*, sulfathiazole; *TB*, tobramycin; *TC*, oxytetracycline; *TEC*, teicoplanin; *TEM*, temocillin; *TET*, tetracycline; *TIC*, ticarcillin; *TGC*, tigecycline; *TM*, tobramycin; *TRI*, trimethoprim; *TY*, tylosin; *VAN*, vancomycin.

Antimicrobial Resistance Genotypes

aac(3)-II, aac(3)-IV, aadA1, aadA2, aadA5, aminoglycoside resistance genes; *aac(6)-Ib-cr*, associated with multidrug resistance plasmids; *AmpC*, class C beta-lactamase; *bla*, beta-lactamase; *CTX-M*, producing ESBL; *ESBL*, extended-spectrum beta-lactamase; *SBL*, serine β-lactamase; *SHV*: class A beta-lactamase; *TEM*, class A beta-lactamase; *pAmpC*, plasmid-encoded class C beta-lactamase.

Comments

abx, antibiotic; *ARB*, antibiotic-resistant bacteria; *ARG*, antibiotic resistance gene; *C*, captive; *F*, free-ranging; *MDR*, multidrug-resistant (at least three classes of antibiotics); *MRSA*, methicillin-resistant *Staphylococcus aureus*; *MSSA*, methicillin-susceptible *Staphylococcus aureus*; *VIM*, Verona integron-encoded; *MBL*, metallo-β-lactamase; *VRE-i*, vancomycin-resistant enterococci with intrinsic resistance.

ANTIMICROBIAL RESISTANCE				
Phenotype	**Enzymes**	**Genotype**	**Comments**	**Ref**
CO, PO		*mcr-1, mcr-2*	Isolates from 4 taxa grouped together as "resident birds": *E. coli* (12 isolates), *K. pneumoniae* (4 isolates), *K. oxytoca* (1 isolate), *P. aeruginosa* (1 isolate) The prevalence of *mcr-1* in resident birds was 10.4% while the prevalence of *mcr-2* was 1.4%	51
STX, STR, AMC, AMP, TET			Isolates showed significant frequencies of AR. MDR also occurred. The most frequently displayed resistances were to SXT. There were also significant levels of resistance to STR, AMC, AMP were found. Lower levels of AR to TET were shown	121
CLI, AMP, TET, ENR, SXT, CXM			Retrospective study evaluating 108 abx sensitivity profiles: >50% of isolates (34 different bacterial species) demonstrated resistance. Among *E. coli* strains, 71% (27/38) presented MDR	24
SXT, PEN, AMP, A, AMC, CEF, KZ, OXY, DC, STR, KM, GM, AMK, ERY, TY, LCM, CLI, ENR, CIP, MRB, CVN			Gram-positive bacteria were isolated from 3 Strigiformes and 3 Falconiformes; gram-negative bacteria were cultured from all birds. All isolates were MDR	122
SXT (44%), azithromycin (22%), DC (11%)			The percentage of AR was highest in birds when compared to isolates from chironomids or fish	123
A, KZ, GM, TY, CIP, MRB, PEN, AMP, LCM, C, ERY, SXT, STR, OXY, ENR			Seven out of 14 birds (50%) had positive culture. The most common bacteria isolated was *S. xylosus* ($n = 4$), while *S. chromogenes, S. lentus,* and *S. aureus* were only isolated once	122

TABLE 6.2

Core Principles of Judicious Use of Antimicrobial Agents[7,12,16,28]

Category	Principles	
Pretreatment	Disease prevention	Reduce the incidence of infection through proper animal care and husbandry, including appropriate biosecurity measures, effective sanitation, hygiene, infection prevention measures, and health monitoring.[6,12]
	Professional intervention	Over-the-counter access is contrary to the basic concepts of prudent and effective antimicrobial use and could presumably increase the risk of resistance.[13] Ensure that the use of antimicrobials meets all the requirements of a valid veterinarian–client–patient relationship.[12,13] Use flock surveillance programs and educational programs that promote responsible and prudent use of antimicrobial agents.[12]
	Alternatives to antimicrobial agents	Efficacious, evidence-based alternatives to antimicrobial agents can be an important adjunct to good husbandry practices.[12] For example, curettage of focal granulomas or local therapy with biocides or antimicrobial drugs may be effective in some cases.
Diagnosis	Accurate diagnosis	Use antimicrobials only after a general or preliminary diagnosis has been made, which indicates that antimicrobial therapy is appropriate.[5] Avoid antimicrobial therapy for nonseptic inflammatory conditions and uncomplicated viral infections, even when mucoid discharge is thick, yellow, or green.[5,13,26] Also remember that it is uncommon for many infections to develop without a predisposing condition. Therefore, repeated treatment with antimicrobials without attention to the underlying cause can ultimately be futile clinically while also increasing the risk of antimicrobial resistance.[13]
Therapeutic objective and plan	Develop outcome objectives and an implementation plan, including consideration of therapeutic choices, supportive therapy, host, environment, infectious agent, and other factors.[9]	
Drug selection	Justification of antimicrobial use	Antimicrobials should not be used to compensate for or mask poor farm or veterinary practices.[12] Use informed professional judgment balancing the potential benefits for animals, humans, and the environment against the risks, particularly the risk of antimicrobial resistance selection.[12]
	Guidelines for antimicrobial use	Consult disease- and species-specific guidelines to inform antimicrobial selection and use (Tables 6.10A–E). Although antimicrobials must be prescribed in accordance with existing laws and regulations,[12] there is a common misconception that using antimicrobial agents according to label recommendations is equivalent to prudent use of antimicrobial agents.[16] This is not true. The label dose, dosing interval, and indications are not always consistent with current principles for responsible antimicrobial use, particularly for some older drugs like penicillin.[16]
	Critically important antimicrobial agents	Antimicrobial agents should be used only after careful review and reasonable justification; however, there is a particular concern regarding the use of agents of special importance to human (and veterinary!) medicine (Table 6.3).[12]
	Culture and sensitivity testing	When clinically relevant, use culture and antimicrobial sensitivity testing to guide the selection of antimicrobials, especially when initial treatment has failed.[5,12] Selective reporting of sensitivity testing is another form of stewardship intervention designed to restrict inappropriate or unnecessary antimicrobial use.[29]
	Spectrum of activity	Whenever appropriate, select narrow-spectrum antimicrobials, as opposed to broad-spectrum antimicrobials.[12] Never hesitate to transition a patient to a more targeted antimicrobial for longer-term therapy based on culture and sensitivity test results, additional diagnostic information, and/or clinical progression.[16,33]
	Extra-label (off-label) therapy	Confine extra-label therapy to cases in which medications used according to label instructions were ineffective or unavailable and where there is scientific evidence.[12]
Drug use	Dosage regimens	Where possible, optimize regimens for therapeutic antimicrobial use following current pharmacokinetic and pharmacodynamic guidance.[12] Suboptimal dosing can lead to resistance.[33]
	Duration of treatment	As the duration of patient exposure to antimicrobials increases, the likelihood of selection and colonization with resistant organisms also rises.[28] Therefore, minimize exposure to antimicrobials by treating for only as long as needed to meet the therapeutic objective.[5,12] Higher doses for shorter periods of time are generally preferable.[31] Never continue antimicrobials once there is clinical and microbiological evidence that an infection has been eliminated or once an alternate diagnosis has been made.[16] Timely planned therapy evaluation is a prerogative for adequate stop or switch decisions. It is a common misconception that there is a need to complete a minimum duration of an antimicrobial drug to prevent the emergence of resistance.[13] There is no prescribed minimum duration of administration of an antimicrobial drug.[16]

TABLE 6.2

Core Principles of Judicious Use of Antimicrobial Agents—cont'd

Category	Principles	
	Labeling and instructions	The veterinarian should provide written instructions on drug use, with clear details on the method of administration, dose rate, frequency and duration of treatment, as well as precautions and withholding period.[12]
	Target animals	Limit antimicrobial treatment to ill or at-risk animals, treating the fewest animals possible.[5,12]
		The prudence of treating moribund birds with antimicrobial drugs must be questioned. Antimicrobial drugs, especially those of critical importance to human health (Table 6.3), should never be used without reasonable expectation that they will favorably impact the outcome.[16]
		Patients that require invasive therapies and intensive care are at increased risk for developing difficult-to-treat, resistant infections. Veterinarians must take every precaution to reduce the risk of infection in these animals.[16]
	Record keeping	Maintain accurate records of therapy and outcome to allow therapeutic regimens to be evaluated.[5,12]
	Compliance	Confirm that drug use instructions are accurately followed.[12]
Post treatment activities	Environmental contamination	Avoid antimicrobial contamination of the environment whenever possible.[5,12] Unused medication should never be disposed of in the sink or garbage. Instead medication should be returned to the veterinary office. Many communities also offer drug take-back programs, and some pharmacies and hospitals also have permanent disposal sites.
	Continuous evaluation	Continually monitor and evaluate veterinary prescribing practices as well as the effectiveness of the antimicrobial selection program.[12,15] Participate in benchmarking initiatives whenever available.[127]
		Interventions directed at driving behavioral change include practitioner education, reinforcing factors, such as audits and feedback, as well as enabling factors like decision support.[15]

are also restricted or banned based on residue or antimicrobial resistance concerns.[11] The outcome of therapy must also be continually evaluated.[5,25] Although these coordinated interventions are designed to improve and measure the appropriate use of antimicrobials, antimicrobial stewardship cannot target individual prescriptions alone because stressing the judicious use of antimicrobials does not explicitly consider the need to balance individual and societal needs.[3,26,40]

RESISTANCE TO RESPONSIBLE ANTIMICROBIAL STEWARDSHIP

There are many challenges to improving antimicrobial stewardship, including lack of awareness for the need for all prescribers and users to be good antimicrobial stewards, lack of controls on antimicrobial availability in many countries, pressures on prescribers to use antimicrobials even when they are unnecessary, and lack of oversight.[7] There are many online resources available that are intended to guide and assist clinicians (Table 6.3).

CLIENT EDUCATION

One of the prime challenges that veterinarians face are demands for antimicrobial therapy from clients, as owners may immediately assume that "every debilitated bird requires antibiotics".[7] Although this can be a difficult conversation, often the first and most crucial step is to educate owners about the concepts of antimicrobial resistance and responsible antimicrobial stewardship. Whenever possible, disseminate this information before a problem arises. Just as it is valuable to have a valid veterinarian-client-patient relationship before a problem arises, it is also extremely helpful for the owner to understand these concepts before a cherished companion animal becomes ill. Websites that target consumers, such as "Antibiotics and You", can be particularly helpful in explaining these concepts in layman's terms (Table 6.3).

Counseling clients and producers on the importance of diagnostic testing can be another major challenge for veterinary health professionals.[13] It sometimes helps to emphasize that the time and money spent on diagnostic testing can potentially reduce morbidity, mortality, and even overall treatment costs.[13]

When antimicrobial agents are prescribed, encourage and ensure that directions are accurately followed.[11] Provide clearly written instructions on drug use, with clear details on the method of administration, dose rate, frequency, and duration of treatment, as well as precautions and withholding period.[11] When antimicrobial drug therapy is discontinued, encourage clients to return unused antimicrobial drugs for disposal.[13] The educated consumer will have a clear understanding of why holding onto leftover antimicrobials "just in case" is a poor idea or why disposing of drugs by flushing them potentially contaminates the environment with antimicrobials.[5,11]

ANTIMICROBIAL DRUG SELECTION AND USE

Isabelle Langlois

The goal of antimicrobial therapy is to assist the defense mechanisms of the avian host to contain and eliminate the

World Health Organization (WHO) List of Medically Important Antimicrobials World Organization for Animal Health (OIE) List of Antimicrobial Agents of Veterinary Importance	The first WHO *f*es, most recently in 2018. Antimicrobial classes used in human medicine are categorized into three groups: critically important, highly important, and important. Antimicrobials used in food-producing animals have also been listed and categorized by the OIE as critically important, highly important, and important together with the animal species to which they are applied, the indications for their use, and whether they are essential or have few alternatives.	https://www.who.int/publications/i/item/9789241515528 https://www.woah.org/app/uploads/2021/06/a-oie-list-antimicrobials-june2021.pdf

invading infectious agent. This action is facilitated when the therapeutic concentration of the selected drug is rapidly reached at the site of infection and maintained for sufficient length of time. Of course, the selective toxicity of the drug for the offending pathogen should occur prior to any toxic effect of the drug on the avian host. Selection of the most appropriate drug will also depend on the severity of illness, availability of pharmacokinetic and pharmacodynamic data in the treated species, cost of the drug, and routes of administration that can be accomplished by the owner or the veterinary hospital staff.

ANTIMICROBIALS ACCORDING TO THEIR IMPORTANCE IN HUMAN MEDICINE

The WHO has developed criteria to rank antimicrobials according to their importance in human medicine,[128] and several countries have drawn inspiration from this.[129–131] Table 6.4 categorizes antimicrobials according to their importance in human medicine. Several antimicrobial classes are commonly used in avian species. At first, the relative importance of antimicrobials was determined for use in developing risk management strategies related to antimicrobial use in food production animals.[128,132]

TABLE 6.4

Classification of Antimicrobial Drugs According to Their Importance in Human Medicine (WHO: https://www.who.int/publications/i/item/9789241515528)[128]

Because multidrug-resistance is mostly observed in bacterial pathogens, this list primarily focuses on antibacterial drugs.

Category I: Very High Importance (Critically Important Antimicrobials)	Category II: High Importance (Highly Important Antimicrobials)
◆ Essential for the treatment of serious infections ◆ Limited or no availability of alternative antimicrobials for effective treatment in case of emergence of resistance to these agents ◆ Aminoglycosides (except topical agents) ◆ Carbapenems (imipenem) ◆ Cephalosporins (third and fourth generation) ◆ Fluoroquinolones (enrofloxacin) ◆ Glycopeptides (vancomycin) ◆ Glycylcyclines (tigecycline) ◆ Macrolides and ketolides (azithromycin) ◆ Lipopeptides ◆ Monobactams ◆ Oxazolidinones ◆ Penicillins with penicillin-beta-lactamase inhibitors (amoxicillin/clavulanic acid) ◆ Phosphonic acid derivatives (fosfomycin) ◆ Polymyxin (colistin, polymyxin B) ◆ Therapeutic agents for *Mycobacterium* spp. (ethambutol, isoniazid, pyrazinamide, rifampicin)	◆ Used to treat a variety of infections, including serious infections, and for which alternatives are generally available ◆ Microorganisms resistant to drugs of this category are generally susceptible to Category I drugs ◆ Amphenicols (chloramphenicol, florfenicol) ◆ Cephalosporins (first and second generation) ◆ Fusidic acid ◆ Lincosamides (lincomycin, clindamycin) ◆ Penicillins ◆ Quinolones (except fluoroquinolones) ◆ Streptogramins (virginiamycin) ◆ Sulfonamides (sulfamethoxazole) ± trimethoprim ◆ Tetracyclines
Category III: Medium Importance (Important Antimicrobials)	**Category IV: Low Importance**
◆ Used for the treatment of infections for which alternatives are generally available ◆ Infections caused by microorganisms resistant to these drugs are generally susceptible to Category I or II drugs ◆ Aminocyclitols (streptomycin) ◆ Aminoglycosides (topical agents) ◆ Bacitracin ◆ Nitrofuran derivatives ◆ Nitroimidazoles (metronidazole) ◆ Pleuromutilins	Antimicrobials in this category are currently not used in human medicine ◆ Flavophospholipols (bambermycin) ◆ Ionophores (monensin) ◆ Amprolium

Later, it was expanded to companion animals,[13,133] and as such, this classification may also be used for avian species, knowing that ultimately the One Health concept applies in all spheres of veterinary medicine to minimize the risk of transmission of resistance to the human population. As previously stated, the correlations between antimicrobial usage in human and animals, and prevalence of resistance in each group, respectively, is well-documented.[132,134,135]

PRINCIPLES OF ANTIMICROBIAL SELECTION

The avian veterinarian's first choice for an antimicrobial drug should be an approved veterinary product, used in an on-label or, if need be, an extra-label manner. A drug that has been shown to be efficacious and is categorized as being of lower importance in human medicine should be prioritized unless medical requirements dictate otherwise. For situations in which extra-label drug use (ELDU) might result in the use of a drug of lower importance to human medicine, ELDU may in fact be preferable to on-label use of a drug of higher importance to human medicine.

Optimal antimicrobial therapy is based on identifying the microorganism involved and—in case of bacterial infections—culture and sensitivity testing to help select the most appropriate drug (Table 6.5; see also Chapter 5). Cytology (e.g., Gram stain) of an appropriately collected sample may provide insight as to a pathogen involved while awaiting culture results.[139,140] Gram-negative bacterial infections are most common in several species groups such as Psittacidae (*E. coli*, *Klebsiella* spp.) and Columbidae (*Salmonella* spp.). Knowing gram-negative bacteria readily acquire resistance genes,[141] the need to submit a sample for culture and sensitivity testing must be emphasized when they appear to be involved in the disease process. Gram-positive bacterial infections (*Staphylococcus aureus*, *Enterococcus* spp.) are seen less frequently in psittacine birds. However, in Passeriformes, *Enterococcus faecalis* is a major pathogen of the respiratory system, and *Streptococcus gallolyticus* causes septicemia in pigeons. Gram stain coloration may also help provide precise and prompt diagnoses if a mycotic organism is involved, as fungal cultures may take a few weeks.

Empirical antimicrobial treatment is appropriate in two clinical situations: life-threatening infection and mild infection managed on an outpatient basis.[139] Birds often hide clinical

TABLE 6.5

Pharmacokinetic/Pharmacodynamic Indices and Mechanism of Action of Select Antibacterial Agents[136–138]

Antibacterial Class	Representative Antibacterial Drugs	Mechanism of Action	Spectrum	"Cidal" or "Static"	Predictive PK/PD Parameter
Aminoglycosides	Gentamicin, amikacin, neomycin, spectinomycin	Protein synthesis inhibitor	Some gram positives, most gram negatives including *Pseudomonas*	Bactericidal	C_{max}/MIC
Beta-lactams	Penicillins, cephalosporins, carbapenems	Cell wall synthesis inhibitor	Many gram positives and negatives, most anaerobes	Bactericidal	Time > MIC
Glycopeptides	Vancomycin	Cell wall synthesis inhibitor	*Clostridium*, coagulase-negative staphylococci, beta-hemolytic streptococci, MRSA	Bactericidal (slowly)	Time > MIC, C_{max}/MIC
Fluoroquinolones	Enrofloxacin, ciprofloxacin, danofloxacin, marbofloxacin, pradofloxacin	DNA replication/transcription inhibitor	Most aerobic gram negatives, some gram positives, *Chlamydia*, *Mycoplasma*, *Mycobacterium*, *Campylobacter*	Bactericidal	AUC/MIC, C_{max}/MIC
Macrolides/azalides/lincosamides	Erythromycin, clarithromycin, azithromycin, clindamycin	Protein synthesis inhibitor	Many gram positives, most *Chlamydia*, *Mycoplasma*, *Campylobacter*, *Mycobacterium*	Bacteriostatic	AUC/MIC
Tetracyclines	Oxytetracycline, chlortetracycline, doxycycline, minocycline	Protein synthesis inhibitor	Many gram positives, some Gram negatives (except *Pseudomonas*), *Mycoplasma*, *Chlamydia*, anaerobes	Bacteriostatic	Time > MIC
Trimethoprim-sulfonamides	Sulfadimethoxine, sulfamethazine	Folic acid synthesis inhibitor	Many gram positives and negatives (except *Pseudomonas*)	Bactericidal	AUC/MIC

AUC/MIC, Area under the curve to MIC ratio; *C_{max}/MIC*, peak plasma concentration to MIC ratio; *T > MIC*, time above MIC; *MRSA*, methicillin-resistant *Staphylococcus aureus; PD,* pharmacodynamic; *PK,* pharmacokinetic.

signs of illness; therefore, they often present at an advanced critical stage of disease. In the later situation, if infection recurs or fails to respond to initial antimicrobial selection or if the clinical situation involves many animals presenting the same clinical signs, appropriate samples for culture and sensitivity testing should be obtained.[139,142]

Successful antimicrobial therapy requires reducing pathogen numbers to reach a point where host defenses are effective. The distinction between bactericidal-fungicidal-virucidal and bacteriostatic-fungistatic-virustatic agents appears to be clear using in vitro techniques but can be inconsistent for a particular drug against all microorganisms.[143] The supposed superiority of bactericidal-fungicidal-virucidal agents over bacteriostatic-fungistatic-virustatic agents is of little clinical relevance when treating the vast majority of infections, especially in patients with uncomplicated infections and competent immune system.[143] Bactericidal-fungicidal-virucidal drugs may be preferred for life-threatening infections, infections of vital tissues (central nervous system, cardiovascular, and bones), and in immunocompromised individuals.[139] If sensitivity testing has been performed, avian practitioners should use an antimicrobial drug to which the microorganism is susceptible regardless of whether it is bacteriostatic-fungistatic-virustatic or bactericidal-fungicidal-virucidal (Table 6.5).[144]

Narrow-spectrum drugs may be preferred to broad-spectrum antimicrobials when appropriate to decrease the likelihood of interfering with commensal microbial flora[139] while minimizing the selection of resistant organisms.[142] The narrower the spectrum, the less likely resistance might develop. Table 6.6 presents the examples of antimicrobial drugs classified according to their spectrum of activity.

Generally, drug combinations should be considered for their synergistic effects where individual agents have failed,[145] or when the identified clinical condition of the patient dictates such therapeutic approach, and their efficacy is established. The most important exception to this rule is the combination of sulfonamides with trimethoprim, as in these combinations, sulfonamides are much more potent (potentiated), and therefore lower doses are needed with less toxicity. Further, the inhibition of two sequential steps in folic acid production leaves less room for resistance due to escape routes. Combining antimicrobial agents may have disadvantages: (1) a bacteriostatic-fungistatic-virustatic drug may neutralize bactericidal-fungicidal-virucidal effects of another agent; (2) additive or synergistic toxicity may occur; and (3) superinfection may occur after destroying normal microbial flora.[139] Clinical indications for the use of antimicrobial combinations are presented in Table 6.7.

TABLE 6.6

List of Antimicrobial Drugs Used in Avian Medicine According to Their Spectrum of Activity

Spectrum of Activity	Examples of Antimicrobial Drugs
Narrow	Metronidazole
	Aminoglycosides (gentamicin)
Moderate	Macrolides (azithromycin)
	Lincosamides (clindamycin)
Broad	Amoxicillin ± clavulanic acid
	Cephalosporins
	Tetracyclines (doxycycline)
	Potentiated sulfonamides (trimethoprim-sulfamethoxazole)
	Fluoroquinolones (enrofloxacin)

Modified from Battersby I: Using antibiotics responsibly in companion animals, *In Pract* 36(3):106, 2014.

When applicable, local administration of the antimicrobial should be considered, as this method of delivery has the potential to achieve higher and more persistent drug concentration than systemic administration at the site of infection. When using antimicrobials for local delivery, ensure that the antimicrobial directed against the causative agent and vehicle are suited for this use and do not have a detrimental effect on the tissue while being compatible with the delivery system used.[146]

LOCAL ADMINISTRATION OF ANTIMICROBIALS IN AVIAN PATIENTS

In avian patients, local administration of antimicrobials may include local application or instillation, direct intralesional local delivery, nebulization, and regional perfusions. Topical hydrosoluble creams may be used sparingly on the skin to treat localized infections, such as dermatitis.[146] Topical ointment or drops may be preferred to treat eye infection. Antimicrobial ophthalmic preparations (ointments and drops) may be instilled intranasally to treat nasal infections,[146,147] in addition to their classical use to treat eye infection. Powdered and aerosolized antimicrobials may be useful to treat ectoparasites.[147]

Direct intralesional administration of antimicrobials may be achieved using antibiotic-impregnated beads.

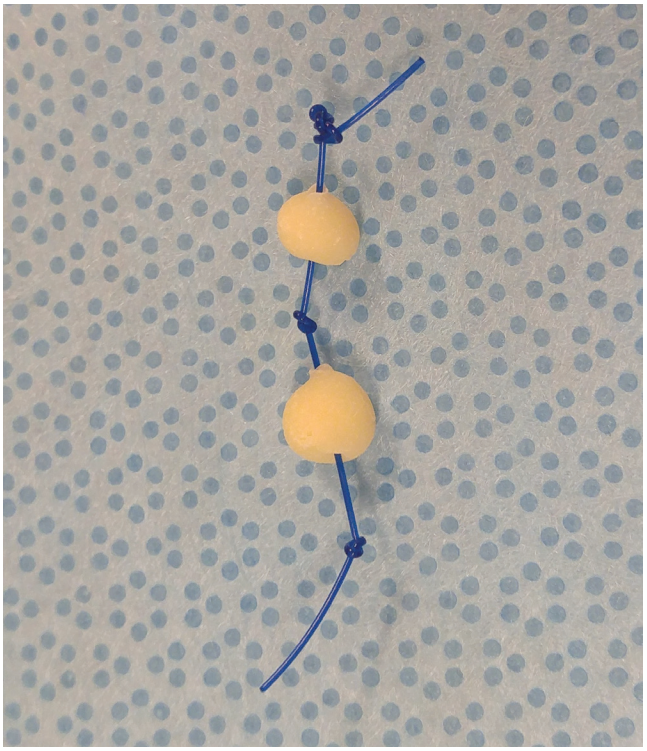

FIGURE 6.3 Beads fashioned around a piece of nonabsorbable suture material so that they are strung together to facilitate removal from the infection site. (Photo courtesy of Zoological Medicine Service, Université de Montréal.)

Antibiotic-impregnated polymethyl methacrylate (AIPMMA) beads are most often used in avian osteomyelitis and soft tissue infections.[148,149] Available authorized medicinal products like cement and beads containing gentamicin, tobramycin, and clindamycin may be used.[150] There is rapid release during the first 24 hours after implantation followed by prolonged sustained release that can last for weeks.[150] The antibacterial drug concentrations achieved at the site of infection are far above the minimal inhibitory concentrations (MICs) for most common bacterial pathogens,[151] without relying on vascular supply and tissue integrity. Beads can be fashioned around a piece of nonabsorbable suture material so that they are strung together, making it easier to remove them from the infection site (Figure 6.3).[146] Antibacterial drug–impregnated

TABLE 6.7

Clinical Indications for the Use of Antimicrobial Combinations[139,145]

Indications	Rationale
Antimicrobial synergism beneficial in other species with similar conditions	◆ Combination of antimicrobial agents has proved superior to monotherapy in other species (i.e., treatment of endocarditis in humans). ◆ Patients with impaired host defenses as synergistic combinations are advantageous in such patient.
Polymicrobial infections	One agent cannot address all the pathogens causing the infection.
Decrease the emergence of resistant isolates	Microorganisms that may develop resistance by various mechanism will have less chance of doing so if treated with multiple antimicrobials (e.g., *Mycobacterium* spp.).
Decrease dose-related toxicity	Combined therapy may allow dosage reduction of a toxic drug.

calcium sulfate beads were used in conjunction with regional limb perfusion (see later) in a Pekin duck (*Anas platyrhynchos domesticus*) to treat septic tenosynovitis and osteoarthritis.[152] Clinical use of calcium sulfate beads in veterinary medicine was first reported in 2008 with a case series of six dogs with osteomyelitis.[153] Other reported uses include the management of deep surgical site infection associated with orthopedic surgery and local carboplatin delivery.[154,155] In human medicine, they have been used in the treatment of osteomyelitis in the long bones, arthroplasty, periprosthetic joint infection, and open fractures.[156] Calcium sulfate is a bioresorbable material. Therefore, a second procedure is not required for removal as opposed to AIPMMA beads.[153,156] Pharmacokinetic studies have shown its superiority as 100% of its loaded antibacterial drugs are released, compared to around 10% in AIPMMA, which results in much higher concentrations for an extended period.[156] Finally, this biomaterial allows the use of a larger range of antimicrobials because setting occurs at room temperature. Complications reported with the use of calcium sulfate beads in human medicine include aseptic wound drainage, infection reoccurrence, transient hypercalcemia, and heterotropic ossification.[156]

The administration of antimicrobial agents by nebulization may be used as an adjunct to systemic administration in severe avian respiratory disease (see Chapter 5 and Appendix 1). Nebulization time is typically 15 to 30 minutes and frequency varies from one to three times daily. Administration is mostly performed without handling, in a closed cage or induction chamber, thus reducing stress for the patient (Figure 6.4). Nebulization enables to reach diseased tissue with poorly perfused respiratory structures such as the avian air sacs.[157] Pharmacokinetic studies of nebulized drugs have been published in various species[158–162] and have confirmed reduced systemic absorption with short-lasting low plasma concentrations.[159,160] Effective nebulization depends on the particle size. Use of a nebulizer generating microspheres smaller than 3 μm is recommended.[163,164] In pigeons, with an increasing time of exposure to aerosolized particles, the degree of particle deposition into the respiratory system is maximized, until a balance is reached with approximately uniform particle distribution to each of the air sacs.[165] However, nebulization had to be performed for at least 2 hours in this study to result in readily observable deposition of the 1.0 μm fluorescent microspheres in the air sacs.[165] The suspending agent for drug nebulization influences drug deposition. A study showed that saline resulted in more diffusion into the air sacs compared to propylene glycol, with some air sac diffusion being detectable after only 30 minutes of nebulization.[166] The addition of dimethyl sulfoxide (DMSO) to a nebulized solution of tylosin was shown to result in higher concentrations in lung and air sac tissues.[161] Overall, when using a lipophilic agent, current nebulization session time may be suboptimal and may need to be adapted according to the patient's clinical progress.

FIGURE 6.4 Nebulization of birds is readily performed using an acrylic box and human nebulizer. Dependent on the drug that is nebulized, a compressor or ultrasonic nebulizer can be used. Nebulization should always be performed in a well-ventilated room with as little human presence as possible to minimize exposure. (Photo courtesy Yvonne van Zeeland.)

Intravenous regional limb perfusion (IVRLP) and intraosseous regional limb perfusion (IORLP) appear to be safe and effective for local antimicrobial administration in avian patients with severe pododermatitis or osteomyelitis involving multiple joints of the distal extremities (Figure 6.5; see also Chapter 33). This method may be used as an alternative or adjunctive therapeutic option. In a chicken model, the mean plasma and synovial fluid ceftiofur concentrations exceeded the therapeutic threshold for most common bacterial pathogens (>1.0 μg/mL).[167] The mean synovial fluid ceftiofur concentration for the IVRLP group was significantly greater than that for the IORLP, making intravenous administration preferable. Clinically, the therapeutic use of amikacin along with flunixin meglumine administered through IVRLP yielded dramatic improvement of mobility and a noticeable decrease in the swelling of the right foot of the chicken suffering from cellulitis.[168] Also in chickens, regional limb perfusion of amikacin at high doses produced no discernable renal pathology in healthy euhydrated chickens.[169] IVRLP using ampicillin/sulbactam has also been used successfully in brown pelicans (*Pelecanus occidentalis*) presented for rehabilitation. Birds were released 3 to 4 weeks after initial perfusion therapy with no observed adverse effects.[170]

Recently, a simple novel surgical method (n = 8) involving custom-made drains to resolve septic arthritis of the intertarsal and interphalangeal joints in ducks has been presented.[171] Drains were regularly flushed with dilute 2.5% chlorhexidine solution, and seven of the eight ducks enrolled in the study received concurrent antibacterial treatment. Approximately a year post-surgery, 75% of the ducks had no detectable limp (25% were lost to follow-up). According to these authors' experiences, systemic and regional treatment with antibacterial drugs may slow the progression or stop early cases of septic arthritis in waterfowl, while successful treatment of chronic septic arthritis is difficult at best.

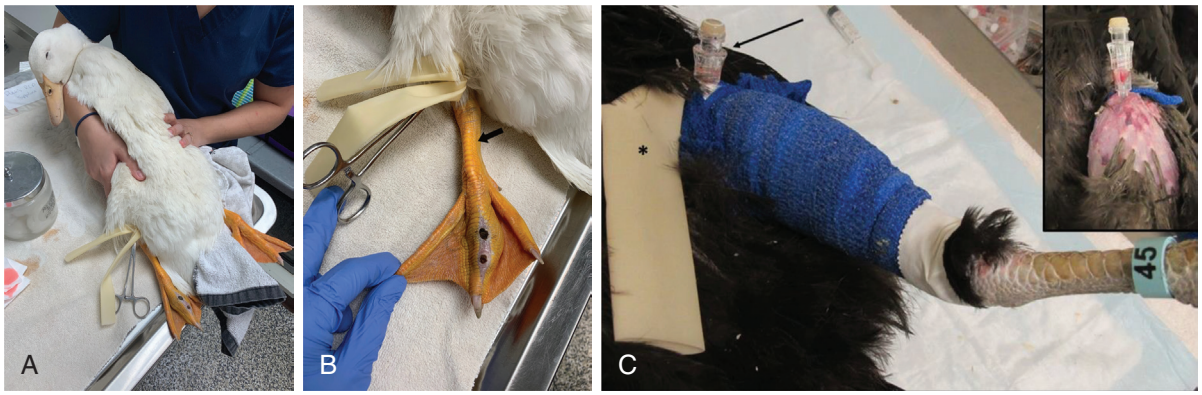

FIGURE 6.5 Regional limb perfusion (RLP) allows for the delivery of high concentrations of antimicrobial drugs into the synovium and osseous and soft tissue structures of the distal limbs in birds. For the procedure, a Penrose drain, which is used as a tourniquet, is positioned around the leg at mid-tibiotarsal level and secured with hemostat (A). Following disinfection of the skin, a 25-G butterfly catheter is aseptically placed in the medial metatarsal vein *(arrow)* to administer the drugs (B). Once the catheter is flushed with a small amount of sterile saline solution, the catheter is removed, and a bandage is placed over the injection site. To optimize perfusion of the drug into the distal tissues, the tourniquet is left in place for 10 minutes. To prevent hematoma formation, it is recommended to leave the bandage in place until after the tourniquet is removed. Aside from intravenous regional limb perfusion (IVRLP), the intraosseous route (intraosseous regional limb perfusion; IORLP) is also feasible. For this purpose, an intraosseous catheter is placed in the proximal aspect of the tibiotarsal bone. The procedure follows similar steps as those described for IVRLP, except for placement of the tourniquet, which should be positioned at mid-femoral level to allow for optimal perfusion of the distal extremities (C). IMPROVED PRESCRIBING

Isabelle Langlois, Ingeborg M. van Geijlswijk

Antimicrobials are regularly prescribed in avian practice, and it is not uncommon for avian veterinarians to prescribe them without having first documented an infection. As such, the prescription of antimicrobials is not always appropriate. Table 6.8 presents a list of tips to improve prescribing habits in avian medicine.

KEEP IN MIND THE ONE HEALTH CONCEPT

The problem of emerging multiresistant bacteria is well recognized in human medicine.[172] *S. aureus*, a major human pathogen, possesses virulence factors and the ability to acquire resistance to most antibacterial drugs. Clinical use of methicillin has led to the appearance of MRSA and the past few decades have witnessed the existence of new MRSA.[172,173] Some of these new clones can invade community settings and infect

TABLE 6.8

Tips to "Be Wise" When Prescribing Antimicrobials to Avian Patients[139,142,175]

B	Build practice policies	◆ Practice policies for empirical prescribing (while awaiting culture and/or other test results) and prophylactic use. ◆ Optimize therapy while taking into consideration the One Health concept.
E	Encourage/evaluate culture and sensitivity testing	◆ Culture and sensitivity testing are always indicated and essential when empirical dosing has failed.
W	Weigh pros and cons of delivery methods	◆ Use of topical preparation or loco-regional administration reduce selection pressure on commensal flora.
I	Inform yourself	◆ Consider which microorganisms are likely to be involved (viral, fungal, bacterial, gram positive, gram negative, aerobic/anaerobic). ◆ Assess the distribution and the penetration in relation to the clinical presentation. ◆ Search for recent pharmacokinetic/pharmacodynamics studies in a closely related species. ◆ Identify any potential side effects and how to ensure their early detection.
S	Select proper spectrum	◆ Narrow-spectrum antimicrobials have fewer side effects on the patient's microbiome.
E	Educate your clients	◆ Repeated culture may be indicated to confirm resolution of the infection. ◆ Dispose of remaining medication appropriately.

people without predisposing factors. This trend continues with the buildup of the MRSA reservoir in companion and production animals.[172] Shared population of MRSA can infect both humans and companion animals without undergoing host adaptation.[174,175] Furthermore, some clones of human origin have adapted to new animal hosts by losing useless virulence factor or acquiring new mobile genetic elements.[173]

There is a correlation between close contact with humans and increased risk of colonization of pets with *S. aureus*. This has been demonstrated in pet birds.[176] In a study to characterize *Staphylococcus* spp. isolated from commensal cutaneous microflora of privately owned birds and birds from a sanctuary for unwanted psittacines in the American desert southwest, companion birds were twice as likely to have positive results for staphylococci than sanctuary birds (71% vs 35%), and the species of staphylococci isolated from captive parrot were more commonly isolated from people.[177] Intimate contact between pets and their owners creates favorable conditions for MRSA transmission.[173] Concordantly, the owners of pets are more often colonized by MRSA than the general population.[178] Moreover, cases of MRSA infection in avian species have been documented.[114,180,181] Therefore, it is crucial that avian veterinarians adopt a responsible and unified approach to usage of antibacterial drugs (see also Chapter 7). Responsible prescribing of antibacterial drugs is also part of the strategy to minimize nosocomial multiresistant bacterial infection in veterinary facilities.

ESTABLISH PRESCRIBING PRACTICE POLICIES

Veterinary prescribing guidelines have been developed for many fields of veterinary medicine with the objective to confer benefits to animal and public health while preserving and maintaining the therapeutic efficacy of antimicrobials.[13,182] While contributing to educate veterinarians on the prudent use of antimicrobials, these guidelines do not provide specific directions regarding appropriate use of specific antimicrobials in a specific clinical situation. The development of individual practice policies regarding specific use of antimicrobials is likely to be more effective,[183] despite not being available in most practices.[184] Development of an antimicrobial policy was recently developed in a zoological medicine service after internal analysis revealed most antimicrobial prescriptions were not indicated or inappropriate.[185]

Charts that display strategies for selecting antimicrobials for common avian clinical conditions based on the organ system involved are tailored to assist veterinarians improve prescribing of antimicrobials in outpatient settings and inpatient care (Tables 6.10A-E). In addition, avian practices should develop a prescribing policy that includes a list of conditions for which antimicrobials are unnecessary and clinical situations for which antimicrobial prophylaxis is required. Studies in veterinary medicine have shown that establishing practice policies has a positive impact on prescribing habits, leading to a reduction in the frequency of antibacterial prescribing, such as fluoroquinolones, over the years.[175]

ANTIMICROBIAL SELECTION

As mentioned in the previous section, selection of antimicrobials should ideally be based on a definitive diagnosis of the microorganism involved and, in case of a bacterial pathogen, results from culture and sensitivity testing (see also Chapter 5). If this is not possible, then consider the most likely pathogens involved and the ability of the drug to achieve adequate tissue concentration at the infection site (Tables 6.10A-E). Beware that granuloma formation, commonly associated with subchronic and chronic infection in birds, inhibits drug penetration. Therefore, lipophilic drugs may be preferred and local treatment (debridement), when possible, will improve drug tissue penetration.

SELECT PROPER DOSE, FREQUENCY, AND ROUTE OF ADMINISTRATION

It is vital to use antimicrobials at an appropriate dose.[13] However, choosing a dose can be challenging as formularies often list a wide range of dosages, and pharmacokinetics of antimicrobials may not be available in the species treated or a closely related species. It is important to keep in mind that selection of resistant mutants takes place in concentration ranges above the MIC, when the wild types can no longer survive, but mutants can (Figure 6.6).[186] For some (but not all) antimicrobials, concentrations are achievable that also inhibit these mutants, as long as the dosing is high enough to exceed this mutant preventive concentration (MPC). During the period of the dosing interval that concentrations are between MPC and MIC, resistant mutants are selected; this concentration range is called the mutant selection window (MSW).[187] This mutant selection mechanism will also take place in the microbiota of the patient! Furthermore, published pharmacokinetic data represent mean data obtained from a limited number of healthy birds, while the immune status of the patient may influence therapeutic outcome. Dosages may also have to be modified in neonates and in animals with impaired liver or kidney function. Nevertheless, basic pharmacodynamic data of antimicrobials can be considered when selecting a dosing regimen. Concentration-dependent antimicrobial agents such as fluoroquinolones and aminoglycosides may be administered parenterally once daily if high peak concentrations are achieved, whereas time-dependent antimicrobials such as beta-lactams, sulfonamides, tetracycline, and macrolides must be given more frequently to maintain plasma concentration above the target plasma concentration. Of note, penicillins and cephalosporins have short duration of action in birds compared to mammals and must be administered orally at least three to four times daily.[188]

The frequency and route of administration of a drug are key elements to consider when choosing an antimicrobial regimen in an avian patient. The clinical status of the patient and its familiarity with human handling must be taken into consideration. In critical patients and those not familiar with human handling, a treatment regimen that can be administered with minimal handling through a vascular access or with longer dosage interval is preferred.

DETERMINE PROPER DURATION OF TREATMENT

Generally, the duration of treatment should be as short as possible. In human medicine, several studies have suggested that shortening duration of antimicrobial treatment may be helpful to limit the emergence of resistance, without negatively affecting clinical outcome.[189] Hence, there has been a shift toward much shorter courses of antimicrobial therapy.

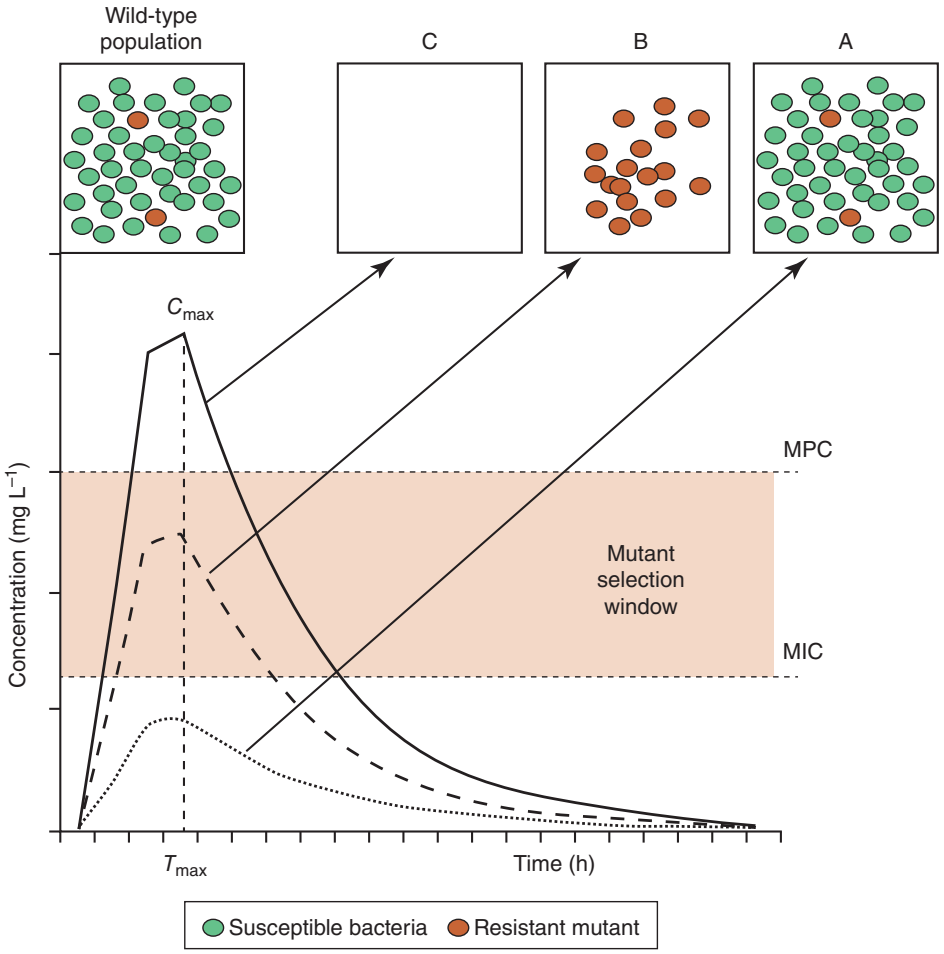

FIGURE 6.6 Mutant selection window (MSW) and mutant prevention concentration (MPC). The figure illustrates three different situations where an antimicrobial drug is administered. *Curves* represent the pharmacokinetics (concentration over time) of the antimicrobial agent and *square boxes* represent the bacterial population. (A) The pharmacokinetic curve is below the MIC; thus, no selection of a resistant mutant subpopulation within the wild-type population is expected. (B) The pharmacokinetic curve is mainly within the MSW; therefore, the resistant mutant subpopulation within the wild-type population can be selectable. (C) The pharmacokinetic curve surpasses the MPC; thus, the susceptible microorganisms are inhibited and selection of a resistant mutant subpopulation is potentially avoided. (From Canton et al: 2011, FEMS,[186] with permission.)

For example, septic arthritis in children is treated for 10 days, as there is no difference in outcome between a 10-day and a 30-day course of antibiotics.[190] In veterinary medicine, a prospective study in 47 dogs with uncomplicated pneumonia provides preliminary data (dogs not randomized, bacterial pneumonia not confirmed in all cases) following the same trend. There were no significant differences in radiographic resolution and relapse rates between dogs treated with a short course of antibacterial drugs (<14 days) compared to those treated with a longer course (>14 days).[191] The American College of Veterinary Internal Medicine (ACVIM) Consensus Statement on antimicrobial use in animals advises that antimicrobials should never be continued once there is clinical and microbiological evidence that an infection has been eliminated.[13] In avian medicine, the data to determine the shortest effective period of therapy are very limited. In 2010, a 21-day course of either doxycycline (35 mg/kg q24h) or azithromycin (40 mg/kg q48h) was effective in eliminating *Chlamydia psittaci* infection in experimentally inoculated cockatiels.[192] Historically, the recommended treatment period for chlamydiosis was 45 days, except in budgerigars, where 30 days of treatment can be effective.[193] Until further studies in avian species are performed comparing different treatment durations of the same antimicrobial agent for a specific condition, selection of the shortest treatment duration will remain challenging.

The clinical experience of avian veterinarians with diverse infections is helpful in assessing response to treatment. Indirect monitoring techniques can be used to evaluate the drug's efficacy such as repeated physical examination, complete blood count (CBC), plasma biochemical analysis, and repeated culture and sensitivity testing.[194] Direct therapeutic drug monitoring

can involve establishing or maintaining a patient within a therapeutic window to decrease the risk of adverse effects and ensure efficacy, or calculating a dosing interval.[194] However, in the absence of species-specific therapeutic intervals and therapeutic windows, direct methods are rarely used in avian medicine.

ANALYZE THERAPEUTIC FAILURE

Therapeutic failure when using antimicrobials has many causes. Table 6.9 presents a list of potential reasons avian practitioners may consider in understanding why undesirable results occurred. Antimicrobial therapy alone is no substitute for an integrated approach to the patient in the event of an infection. Appropriate management of the infection site by debriding ischemic tissue, removing foreign material, blood clots or fluid pockets, and/or flushing out caseous exudate should be performed when applicable.

Figure 6.7 provides a flowchart in which most of the above-discussed concepts have been integrated to help assist avian veterinarians in using antimicrobial agents judiciously until evidence-based treatment guidelines become available for common infections seen in birds.

TABLE 6.9

Potential Causes of Antimicrobial Therapeutic Failure[139,142]

Causes Related to the Pathogen	Causes Related to the Antimicrobial	Causes Related to the Patient
◆ Incorrect diagnosis (e.g., viral disease misdiagnosed as bacterial infection) ◆ Inaccurate results of laboratory tests ◆ Antimicrobial resistance ◆ Metabolic state of the pathogen (biofilm)	◆ Inappropriate dose, frequency, and route of administration ◆ Inadequate antimicrobial selection ◆ Poor diffusion at the target tissue (e.g., cross the blood-brain barrier) ◆ Poor performance inactivity of the selected drug at the site of infection (e.g., abscess)	◆ Underlying neoplastic process ◆ Presence of foreign material (foreign body, necrotic tissue) ◆ Depressed host immunity (concurrent debilitating illness, severe, and/or chronic malnutrition) ◆ Owner compliance

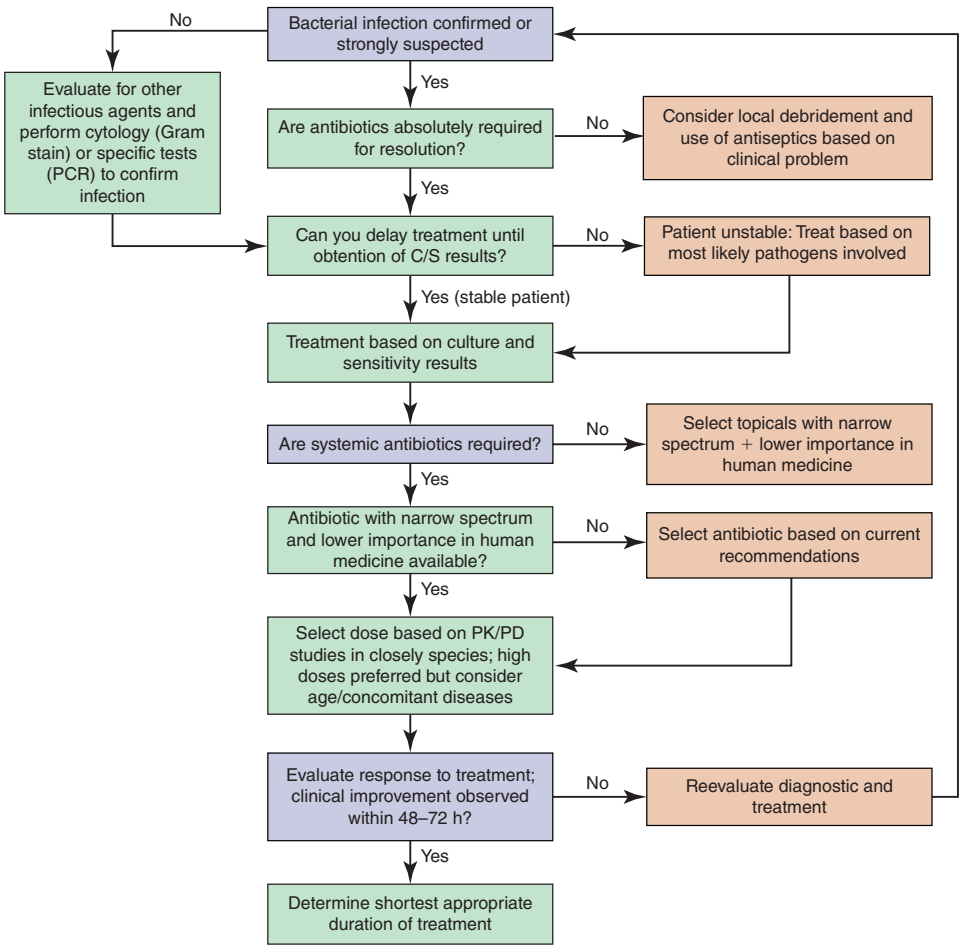

FIGURE 6.7 Flowchart for judicious use of antimicrobial drugs in avian medicine. *C/S*, Culture/sensitivity; *PCR*, polymerase chain reaction; *PK/PD*, pharmacokinetics/pharmacodynamics.

COMPOUNDING AND EXTRA-LABEL DRUG USE (SEE ALSO CHAPTER 5)

Ingeborg M. van Geijlswijk

Only a few veterinary medicinal products (VMPs) are authorized for birds; even in production animals, the number of antimicrobial VMPs (AVMPs) is limited. And even when AVMPs are available, most of the time the formulation and packages are not suitable for pet avian patients. Drinking water medication is common in food-producing animals, but the ill pet bird might refrain from drinking, and for that reason this route of administration is not preferred. Individual administration by the owner is preferably oral, and a potion is preferred over tablets for several reasons, above all the dosing accuracy. Due to large dosing differences between cats/dogs and birds for beta-lactam antibiotics, broadly available potions of amoxicillin for companion animals are suitable for use in (much smaller) birds, when needed with other excipients like taste correction with fruity aromas. When dosing regimens are more comparable (e.g., metronidazole 50 mg/kg/24 hours), the strength of the potion for cats/dogs may be too high to allow (accurate) dosing in small birds, or additives for disguising taste (e.g., poultry liver) might be unfavorable. For some antimicrobials, human medicinal products are available with a suitable concentration and formulation, for example, in case of metronidazole (Flagyl 40 mg/mL, which contains metronidazole as benzoate to prevent dissolution and metallic taste), TMS (Co-trimoxazole 48 mg/mL), and azithromycin (Azithromycin 40 mg/mL). Some products for drinking water, like tylosin 100%, can be compounded into capsules by a pharmacist, enabling the owner to make an ad hoc solution at a favorable concentration. Note that it is important to realize that for oral use the tartrate ester of tylosin is applied, while tylosin in most injectables is not suitable for oral use due to a much lower bioavailability.

For other substances, most importantly doxycycline, compounding might be necessary in the absence of commercial formulations (see also Chapter 5). Major questions in relation to compounding of antimicrobials and other drugs are as follows:

1) What volume is acceptable to administer (which determines the concentration)?
2) In which solvent is the active substance stable for at least one treatment course (e.g., water or oily solvents), or should it be formulated in a suspension to prevent degradation (e.g., doxycycline)?
3) Is the taste acceptable, is adding a taste excipient necessary and sufficient, or is it necessary to formulate a suspension for this reason (e.g., metronidazole)?

Another aspect is the exposure of the professional to the antimicrobial drug while compounding it and the safety of the patient owner during administration. Exposure to antimicrobials should be reduced to a minimum for all that have nothing to gain. For this reason, breaking or crushing of tablets is to be avoided at all times, unless performed by a professional with adequate personal protection. In EU member states, the Annex of Regulation (EU) 2022/1255 should be consulted to check whether the chosen antimicrobial is not reserved for treatment of infections in humans.

TREATMENT OF COMMON ILLNESSES

Table 6.10A: Psittaciformes—Isabelle Langlois;

Table 6.10D: Columbiformes—Christal Pollock;
Table 6.10E: Anseriformes—Christal Pollock;

TABLE 6.10A

Recommendations for Judicious Antimicrobial Use in Psittaciformes[139,142,157,188,189,193]

	Body Systems				
	Integument			**Respiratory**	
Common conditions	Dermatitis/folliculitis	Bite wound	Beak/skin trauma	Rhinitis/sinusitis	Tracheitis, pneumonia, airsacculitis
Cytology and culture	Cytology: imprint smear, skin scraping, tape strips Culture: swab, skin biopsy	Deep culture if evolution is unfavorable	Imprint smear Culture if systemic signs are present or evolution is unfavorable	Choanal swab, nasal flush, sinusal wash Sample collected by biopsy in chronic cases	Patient stability may interfere w/ investigations Tracheal lavage, lung/air sac imprint from biopsy sample, lung/air sac biopsy
Most likely pathogens	*Staphylococcus*, *Enterobacter*, *E. coli*	Aerobes Anaerobes	Variable pending origin and location of lesion	Aerobic gram-negative bacteria (*E. coli, Klebsiella,* etc.) *Chlamydia psittaci*	*Aspergillus* spp. Aerobic gram-negative bacteria (*E. coli, Klebsiella,* etc.) *Chlamydia psittaci*
Empirical antimicrobial suggestions	Avoid empirical choice when possible TMS or Amox/Clav	Amox/Clav (stable patient) Consider first-generation cephalosporin and amikacin or cefotaxime or piperacillin (septic shock)	TMS Consider addition of antifungal drug (fluconazole) with beak lesion	Consider local treatment with ophthalmic preparation (tobramycin) Gram-negative infection: TMS Chlamydiosis: doxycycline	Aspergillosis: itraconazole (use low dose in Grey parrots) or terbinafine with amphotericin B nebulization Aerobic gram negative: parenteral TMS or enrofloxacin or cefotaxime Chlamydiosis: doxycycline
Comments	Consider topical therapy with antiseptic solution, dressings, antibacterial cream Treat until recheck evaluation confirms clinical resolution	Always combine with topical therapy Proper wound care (cleansing, debridement, irrigation) reduces infection more than antibiotics (see Chapter 36) Cat bite, deep puncture wound, severe crushing injury; systemic therapy indicated (see Chapter 36)	Proper wound care (cleansing, debridement, irrigation, closure if indicated) is often sufficient, especially if granulation is ongoing (see Chapter 36) Restore beak function using prosthetic or surgical reduction if indicated (see Chapter 31)	Perform nasal/sinusal flush to remove debris in the initial phase of treatment (see Chapter 27 and 28) If *C. psittaci* is likely, perform specific tests (see Chapter 18); adjust treatment duration based on shortest documented course in the species Further diagnostic tests indicated if recurrence or suboptimal response to treatment	Treat for 1 month post-resolution of clinical signs or documented lesions for Aspergillosis (see Chapter 8) If *C. psittaci* is likely, perform specific tests (see Chapter 18); adjust treatment duration based on shortest documented course in the affected species

Amox/Clav, Amoxicillin/clavulanate; *TMS*, trimethoprim-sulfonamides.

Ophthalmic	Gastrointestinal			Reproductive	Orthopedic	Multisystemic
Conjunctivitis, keratitis, uveitis	Ingluvitis	Proventriculitis, ventriculitis	Enteritis, cloacitis	Salpingitis	Septic arthritis, osteomyelitis	Septicemia, multiple organ infection
Conjunctival swab	Crop swab or wash	Fecal sample for direct smear evaluation Proventricular wash for cytology and culture	Fecal sample	Oviductal sample collected through cloacoscopy may be considered	Fine-needle aspirate of affected joint for cytology and culture Bone biopsy for impression smear, culture, histopathology	Patient stability may interfere with investigations Cytology and culture may be performed on fine-needle aspirate, biopsy of various organs
Various bacteria *Chlamydia psittaci*	*Candida albicans* Aerobic gram-negative bacteria (*E. coli, Klebsiella,* etc.)	*Macrorhabdus ornithogaster*	Aerobic gram-negative bacteria (*E. coli, Klebsiella,* etc.) Anaerobic bacteria (*Clostridium*)	Aerobic gram-negative bacteria (*E. coli* most common)	*Staphylococcus* spp. *Streptococcus* spp.	Aerobic gram-negative bacteria (*E. coli, Klebsiella,* etc.) *Coxiella*-like bacteria *Chlamydia psittaci* *Mycobacterium avium* and *M. genavense*
Tobramycin or gentamicin Chlamydiosis: tetracycline topically and doxycycline systemically	Candidiasis: nystatin Gram-negative infection: TMS	Amphotericin B orally for 1 month	Gram-negative infection: TMS or chloramphenicol Anaerobic bacteria: clindamycin	Amox/Clav or TMS or enrofloxacin (severe cases)	Septic arthritis: clindamycin or first-generation cephalosporin or Amox/Clav Osteomyelitis: clindamycin pending culture	Gram-negative infection: enrofloxacin or cefotaxime Coxiella-like: doxycycline and enrofloxacin Chlamydiosis: doxycycline Consider pros and cons of treating mycobacteriosis; if treatment is elected, ensure to use multiple drugs concurrently to prevent the emergence of resistance
Clean eye(s) with eyewash solution twice daily in the initial phase of treatment If *C. psittaci* is likely, perform specific tests (see Chapter 18); adjust doxycycline treatment duration based on shortest documented course in the affected species	Nystatin requires direct contact with *Candida* spp.; if fungal hyphae are seen suggesting deep tissue infection, prefer fluconazole	May not be possible to clear *Macrorhabdus* infection in all birds (see Chapter 2, Infectious Disease in Current Therapy in Avian Medicine and Surgery, Vol. 1) Improve husbandry practices Consider adding sodium benzoate to the drinking water (anecdotally successful; still experi-mental)	*Clostridium* spp. are difficult to isolate and cultivate; diagnosis often relies on cytology	TMS has poor diffusion in granuloma; consider alternative if suspected Check for retained or ruptured egg Salpingectomy may be required (see Chapter 21, Surgery in Current Therapy in Avian Medicine and Surgery, Vol. 1)	*Mycobacterium* spp. rarely cause osteomyelitis (see Chapter 2, Infectious Disease in Current Therapy in Avian Medicine and Surgery, Vol. 1)	Consider specific diagnostic tests for chlamydiosis, *Coxiella*-like bacteria, mycobacteriosis and aspergillosis (see Chapter 18, and Chapter 2, Infectious Disease in Current Therapy in Avian Medicine and Surgery, Vol. 1) Prefer IV/IO administration to rapidly achieve high plasma and tissue concentrations

TABLE 6.10B

Recommendations for Judicious Antimicrobial Use in Passeriformes[125,195–209]

	Body Systems						
	Integument		**Respiratory**			**Ophthalmic**	
Common conditions	Dermatitis, proliferative skin lesions	Cat bite wounds	Rhinitis/ sinusitis	Tracheitis	Pneumonia, airsacculitis	Panophthalmia, iridocyclitis	Conjunctivitis, blepharitis, keratitis
Cytology and culture	Cytology: imprint smear, skin scraping, tape preparation	Deep culture if progression is unfavorable	Cytology: choanal swab, nasal flush, sinus flush	Patient stability may interfere with antemortem diagnostic testing	Patient stability may interfere with antemortem diagnostic testing		Conjunctival swab
	Culture: swab, skin biopsy		Culture: Collect sample via biopsy in chronic cases	Diagnostic necropsy to collect samples or demonstrate the presence of parasites	Lung/air sac imprint, biopsy sample for cytology/culture: include acid-fast staining		
					Diagnostic necropsy to collect samples or demonstrate the presence of mites within the air sacs	Diagnostic necropsy to collect samples or demonstrate the presence of parasites	
Most likely pathogens	*Staphylococcus aureus, S. epidermidis, Streptococcus* spp.	*Pasteurella multocida,* anaerobes	*Staphylococcus* spp., *Streptococcus* spp., *E. coli*, and other Enterobacteriaceae, *Chlamydia psittaci*	*Enterococcus faecalis*	*Enterococcus faecalis, Pseudomonas, Staphylococcus* spp., *Streptococcus* spp., *Mycoplasma gallisepticum* (C/F), *Mycobacterium* spp. (RHS),	*Yersinia pseudotuberculosis*	*Staphylococcus* spp., *Streptococcus* spp., *E. coli* and other Enterobacteriaceae, *Mycoplasma gallisepticum* (HF), *Chlamydia psittaci*
	Knemidokoptes pilae (F)		*Trichomonas* spp.	*Sternostoma tracheacolum* (F/C)	*Sternostoma tracheacolum* (F/C), *Toxoplasma gondii*	*Toxoplasma gondii*	*Toxoplasma gondii*
	Microsporum gallinae, Trichophyton spp.				*Aspergillus fumigatus* (M, F)		

	Gastrointestinal				Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
	Oropharyngeal plaques, stomatitis	Ingluvitis, esophagitis	Proventriculitis, ventriculitis	Enteritis	Septic arthritis	Multiple organ infection, septicemia	Encephalitis
	Oral swab, wet mount and Gram stain cytology	Crop wash or swab, wet mount and Gram stain cytology	Fresh fecal sample for wet mount or Gram stain cytology Proventricular wash for cytology and culture	Fresh fecal sample for fecal wet mount, flotation, cytology, including acid-fast stain Impression smears of several organs to demonstrate *Atoxoplasma*	Fine-needle aspirate of affected joint for cytology and culture	Patient stability may interfere with investigations Impression smears of several organs to demonstrate *Atoxoplasma*	*Atoxoplasma, Toxoplasma*: Impression smears to demonstrate *Atoxoplasma*
		Aerobic culture		Aerobic culture		Aerobic fecal or tissue culture: fecal excretion of *Salmonella* spp. is intermittent and therefore serial sampling of feces from individual birds is recommended	
				Diagnostic necropsy to collect samples		Diagnostic necropsy to collect samples	Diagnostic necropsy to collect samples
		Salmonella typhimurium		*E. coli* and other Enterobacteriaceae (C/F), *Pseudomonas, Salmonella typhimurium, Yersinia pseudotuberculosis, Campylobacter fetus var jejuni* (TF, E), *Mycobacterium avium* (RHS), *M. intracellulare, M. genavense*	*Staphylococcus* spp., *Streptococcus* spp., *Mycobacterium* spp.	*Salmonella typhimurium*, *Pasteurella multocida* (see cat bite wounds), *Yersinia pseudotuberculosis*, *E. coli* (F/E/N), *Erysipelothrix rhusiopathiae*, *Listeria monocytogenes* (C), *Mycobacterium avium* complex, *Chlamydia psittaci*	
	Trichomonas gallinae	*Trichomonas gallinae*		*Atoxoplasma* (C/F/M), *Cochlosoma* (BF), *Isospora* spp. (C), *Cryptosporidium spp.* (GF)		Atoxoplasma (gf) (FL)	*Toxoplasma gondii*, *Atoxoplasma*, (*Trichomonas* spp.)
	Candida albicans	*Candida albicans* (F)	*Macrorhabdus ornithogaster*

TABLE 6.10B

Recommendations for Judicious Antimicrobial Use in Passeriformes—cont'd

	Body Systems						
	Integument		**Respiratory**			**Ophthalmic**	
Common conditions	Dermatitis, proliferative skin lesions	Cat bite wounds	Rhinitis/ sinusitis	Tracheitis	Pneumonia, airsacculitis	Panophthalmia, iridocyclitis	Conjunctivitis, blepharitis, keratitis
Empirical antimicrobial suggestions	*Knemidokoptes:* macrocyclic lactones, pyrethrins (see Chapter 9)			*Sternostoma:* macrocylic lactones (see Chapter 9)	*Sternostoma:* macrocylic lactones (see Chapter 9)		
	TMS, doxycycline	Stable patient: TMS, Amox/Clav	TMS, water-soluble doxycyciline, Amox/Clav	TMS, water-soluble doxycycline	TMS, water-soluble doxycycline	TMS, doxycycline	TMS, water-soluble doxycycline
	Topical, dilute povidone-iodine solution	Sepsis: 1st generation cephalosporin and amikacin or cefotaxime or piperacillin	Amox/Clav	*Enterococcus:* later gen cephalosporin injectables			Mycoplasmosis: tylosin, tetracyclines, topical ophthalmic aminoglycosides
							Tobramycin or gentamicin
			Chlamydiosis: doxycycline	Chlamydiosis: doxycycline		Chlamydiosis: doxycycline	
	Dermatophytosis: nystatin, imidazoles, triazoles				Aspergillosis: triazole or terbinafine with amphotericin B nebulization		

	Gastrointestinal				Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
	Oropharyngeal plaques, stomatitis	Ingluvitis, esophagitis	Proventriculitis, ventriculitis	Enteritis	Septic arthritis	Multiple organ infection, septicemia	Encephalitis
	Trichomoniasis: nitroimidazoles (see Chapter 9)	Trichomoniasis: nitroimidazoles (see Chapter 9)		Cochlosomosis: nitroimidazoles (see Chapter 9)			
				Atoxoplasmosis: sulfachlorpyridazine, toltrazuril, diclazuril			Atoxoplasmosis: sulfachlorpyrazine or toltrazuril in the drinking water
				Coccidiosis: sulfachlorpyridazine, toltrazuril, or amprolium in the water, oral TMS, sulfadimethoxine			
				Cryptosporidiosis: Treatment may be attempted with paromomycin, azithromycin, roxithromycin			
		TMS		TMS, water-soluble doxycycline	Septic arthritis: Clindamycin or 1st generation cephalosporin or Amox/Clav	Gram-neg: fluoroquinolones or advanced-spectrum penicillin or cephalosporins	
				Campylobacteriosis: erythromycin			
					Chlamydiosis: doxycycline	Chlamydiosis: doxycycline	Chlamydiosis: doxycycline
	Candidiasis: Nystatin	Candidiasis: Nystatin	Macrorhabdus: amphotericin B (nystatin, fluconazole)				

Continued

TABLE 6.10B

Recommendations for Judicious Antimicrobial Use in Passeriformes—cont'd

	Body Systems						
	Integument		**Respiratory**			**Ophthalmic**	
Common conditions	Dermatitis, proliferative skin lesions	Cat bite wounds	Rhinitis/ sinusitis	Tracheitis	Pneumonia, airsacculitis	Panophthalmia, iridocyclitis	Conjunctivitis, blepharitis, keratitis
Comments	Dermatomycosis: HS, American robin blue tit bullfinch	Always combine with topical therapy	Perform nasal/ sinus flush to remove debris in the initial phase of treatment (see Chapters 27 and 28)	*Sternostoma:* an antemortem diagnosis can sometimes be made by transillumination of the trachea (see Chapters 27 and 28)			Clean eye(s) with eyewash solution twice daily in the initial phase of treatment
	Poxvirus is an important DDX (see Chapter 15) Treatment is primarily supportive, although surgical debulking of cutaneous masses may speed healing	Cat bite, deep puncture wound, severe crushing injury; systemic therapy indicated					Mycoplasma: treated birds remained culture or PCR+ for up to 6 months after Rx was ended. Treated birds may become asymptomatic carriers. Clinically affected birds should be euthanized or kept in strict quarantine (see Chapter 2, Infectious Disease in Current Therapy in Avian Medicine and Surgery, Vol. 1)

Amox/Clav, Amoxicillin and clavulanate; *BF*, Bengalese or society finch (*Lonchura striata*); *C*, canaries (*Serinus canaria*); *E*, Estrildidae (Gouldian finches, munias, mannikins, firefinches, parrotfinches, waxbills); *F*, finches; *gf*, greenfinch, goldfinch; *GIT*, gastrointestinal tract; *HF*, house finches (*Haemorhous mexicanus*); *M*, mynah birds (*Acridotheres tristis*); *RHS*, red-hooded siskins (*Spinus cucullatus*);TMS, trimethoprim-sulfonamides.

Gastrointestinal				Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
Oropharyngeal plaques, stomatitis	Ingluvitis, esophagitis	Proventriculitis, ventriculitis	Enteritis	Septic arthritis	Multiple organ infection, septicemia	Encephalitis
Candidiasis: nystatin requires direct contact with *Candida* spp. The presence of fungal hyphae suggests deep tissue infection; therefore, consider fluconazole. Correct predisposing factors.			Some reports of toxicity with metronidazole or dimetronidazole in some finch species, like owl finches		Salmonellosis, mycobacteriosis: Consider euthanasia *Salmonella* spp. can often be recovered from the feces even after prolonged and apparently effective treatment	Atoxoplasma: disinfection and prevention of fecal contamination are important methods to reduce transmission; however, oocysts are stable for months to years. Bali mynah most seriously impacted
			Enterobacteriaceae: neomycin and spectinomycin were historically used because they are effective and are not absorbed from the GIT			

TABLE 6.10C

Recommendations for Judicious Antimicrobial Use in Falconiformes/Strigiformes[24,210–223]

	Body Systems			
	Integument	**Respiratory**		**Ophthalmic**
Common conditions	Pododermatitis	Tracheitis	Pneumonia, airsacculitis	Conjunctivitis, keratitis
Cytology and culture	Cytology: impression smear Culture: swab, biopsy	Fresh fecal sample for direct smear, flotation; microscopic examination of oral swabs Tracheal lavage if clinical status allows	Lung/air sac imprints or squash preparations from biopsy sample, lung/air sac biopsy, if clinical status allows	Conjunctival swab
Most likely pathogens	*Staphylococcus* spp., mainly *S. aureus, Escherichia coli*	*Trichomonas gallinae* *E. coli* *Aspergillus* spp.	*Serratospiculum* spp. *E. coli, Pseudomonas aeruginosa* *Aspergillus* spp.	*Staphylococcus hyicus, S. intermedius, (Chlamydia buteonis)*
Empirical antimicrobial suggestions	See comments below		Serratospiculosis: IVM, FBZ Aspergillosis: amphotericin B, azoles (clotrimazole, enilconazole, itraconazole, ketoconazole, voriconazole), terbinafine	Tetracycline, erythromycin
Comments	Resistance is of concern; therefore base abx choice on C/S whenever possible. In addition to systemic abx, management can include direct intralesional antibiotic delivery, surgical debridement, and postoperative protective foot casting. Also, modify husbandry and perches as needed (see Chapter 33)		Falcons (*S. seurati* in tropical countries; *S. amaculata* in North America Chapter 2	

abx, Antibiotic; *FBZ*, fenbendazole; *IVM*, ivermectin

Gastrointestinal				Musculoskeletal	Multisystemic Infection, Septicemia
Oropharyngeal plaques, stomatitis	Ingluvitis	Proventriculitis, ventriculitis	Enteritis	Septic arthritis	Septicemia, multiple organ infection
Oropharyngeal swab for wet mount cytology, Gram stain cytology	Crop swab, crop wash for wet mount cytology, Gram stain cytology	Fresh fecal sample for direct smear, flotation	Fresh fecal sample for direct smear, flotation	Fine-needle aspirate of affected joint for cytology and culture	Fine-needle aspirate, biopsy of various organs for cytology and culture
		Proventricular wash for cytology and culture		Bone biopsy for impression smear, culture, histopathology	Blood culture
Trichomonas gallinae	*Trichomonas gallinae*	*Porrocaecum* spp., *Contracaecum* spp.	*Porrocaecum* spp., *Contracaecum* spp.	*Trichomonas gallinae*	*Serratospiculum* spp.
Capillaria	*Capillaria*	*Capillaria*	*Capillaria, Eimeria* spp., *Caryospora* spp.		
E. coli, Pseudomonas aeruginosa	*Candida* spp.			*S. aureus, S. hyicus*	*Pseudomonas aeruginosa*, *E. coli*, *Mycobacterium avium* complex
Trichomoniasis: metronidazole, carnidazole	Trichomoniasis: metronidazole, carnidazole	Nematodiasis: IVM, Drontal Plus (praziquantel + pyrantel pamoate + febantel)	Coccidiosis: sulfadimethoxine, toltrazuril	See comments below	
Trichomoniasis: poor prognosis for severe cases however, successful treatment has been reported with metronidazole × 3–7 days followed by surgical removal of granulomas (see Chapter 22)	Trichomoniasis: birds of prey can develop disease by feeding on infected prey, particularly rock pigeons (*Columba livia*) and mourning doves (*Zenaida macroura*; see Chapter 22)	*Contracaecum* spp. are particularly common in fish-eating birds			

TABLE 6.10D

Recommendations for Judicious Antimicrobial Use in Columbiformes[224–240]

	Body Systems					
	Integument		**Respiratory**		**Ophthalmic**	
Common conditions	Proliferative skin lesions	Dermatitis	Rhinitis/ sinusitis	Tracheitis, pneumonia, airsacculitis	Panophthalmia, iridocyclitis	Conjunctivitis, blepharitis, keratitis
Cytology and culture	Cytology: imprint smear, skin scraping, tape preparation Culture: swab, skin biopsy	Cytology: imprint smear, skin scraping, tape strips Culture: swab, skin biopsy	Cytology: choanal swab, nasal flush, sinus flush Culture: Collect sample via biopsy in chronic cases	Patient stability may interfere with antemortem diagnostic testing	Fine-needle aspirate for cytology and culture	Conjunctival swab
Most likely pathogens	*Knemidokoptes mutans*	*Dermanyssus gallinae, Ornithonyssus sylviarum* *Candida albicans*	*Trichomonas gallinae*	*Sarcocystis calchasi*		

Gastrointestinal				Reproductive	Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
Oropharyngeal plaques, stomatitis	Ingluvitis	Proventriculitis, ventriculitis	Enteritis	Oophoritis, orchitis	Septic arthritis	Multiple organ infection, septicemia	Encephalitis meningitis
Oral swab, wet mount, and Gram stain cytology	Crop wash or swab, wet mount, and Gram stain cytology Aerobic culture	Fresh fecal sample for wet mount or Gram stain cytology Proventricular wash Dlagnostic necropsy: include proventricular/ventricular scraping	Fresh fecal samples, cloacal swabs, or intestinal contents from very fresh cadavers: wet mount cytology, flotation, direct microscopic examination using Giemsa and acid-fast stains	Biopsy samples can be collected via laparoscopy but diagnosis is typically made at necropsy	Arthrocentesis of swollen joints for cytology and culture	Patient stability may interfere with investigations; however, cytology and culture can be performed on fine-needle aspirate or biopsy of various organs, particularly the liver and spleen Blood culture Diagnostic necropsy: collect fresh tissue samples from lungs, liver, intestines, heart, spleen, kidney	Collection of CSF by lumbar puncture is virtually impossible in birds. Instead, fluid is aspirated from the subarachnoid space or fourth ventricle. The presence of venous sinuses makes hemorrhage and death a significant risk of this procedure Diagnostic necropsy to collect samples
	Aerobic culture	Proventricular wash for cytology and culture	Aerobic and anaerobic cultures: pooling feces over 5 days may be useful because *Salmonella* spp. are shed intermittently				
		Diagnostic necropsy: include proventricular/ventricular scraping	Diagnostic necropsy: include intestinal scraping				
Trichomonas gallinae	*Trichomonas gallinae*	*Trichomonas gallinae* *Tetrameres* spp., *Dispharynx* spp.	*Capillaria obsignata, C. caudinflata* *Hexamita columbae* (*Spironucleus columbae*), *Eimeria columbarum, E. labbaena, Isospora* spp., *Ascaridia columbae, Ornithostrongylus* spp.				*Sarcocystis calchasi*
Candida albicans	*Candida albicans*

TABLE 6.10D

Recommendations for Judicious Antimicrobial Use in Columbiformes—cont'd

	Body Systems					
	Integument		**Respiratory**		**Ophthalmic**	
		Salmonella typhimurium var. Copenhagen (paratyphoid) *S. arizonae, S pullorum*	*Pasteurella* spp., *Mycoplasma* spp., *Chlamydia psittaci*	*Mycoplasma* spp.	*Salmonella typhimurium* var. Copenhagen *S. arizonae, S pullorum, Chlamydia psittaci*	*Pasteurella multocida, Hemophilus gallinarum, Chlamydia psittaci, Mycoplasma* spp.
Empirical antimicrobial suggestions	Knemidokoptes: IVM, moxidectin, pyrethrin-based products	Ectoparasites: IVM	Trichomoniasis: carnidazole, ronidazole, metronidazole (Dimetridazole has a low margin of safety)			
		Candidiasis: nystatin, (fluconazole)				
			Chlamydiosis: Doxycycline can be given to individual birds, or chlortetracycline-medicated feed or oxytetracycline-medicated water can be used (see Chapter 18)	Chlamydiosis: doxycycline		Chlamydiosis: doxycycline
		TMS, Amox/Clav, ±florfenicol	TMS, tetracyclines, amoxicillin		TMS, Amox/Clav, ±florfenicol	

Gastrointestinal			Reproductive	Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
		Salmonella typhimurium var. Copenhagen *E. coli, Klebsiella, Chlamydia psittaci, C. perfringens*	*Salmonella typhimurium* var. Copenhagen	*Salmonella typhimurium* var. Copenhagen *Streptococcus gallolyticus, Pasteurella multocida*	*Salmonella typhimurium* var. Copenhagen *E. coli, Streptococcus gallolyticus, Streptococcus bovis, Klebsiella, Yersinia pseudotuberculosis, Pasteurella multocida, M. avium* complex, *S. arizonae, S pullorum, Chlamydia psittaci*	*Salmonella typhimurium* var. Copenhagen *Streptococcus gallolyticus, S. arizonae, S pullorum*
	Nematodiasis: IVM, FBZ (see caution below)	Nematodiasis: IVM, FBZ; pyrantel pamoate is better for ascarids				
	CAUTION: Most reported cases of benzimidazole toxicosis in birds are in Columbiformes: bone marrow suppression, direct GIT damage					Sarcocystosis: amprolium, sulfamethazine, chlortetracycline was ineffective in chickens
		Coccidiosis: amprolium, toltrazuril, clazuril, sulfas				
Candidiasis: nystatin, (fluconazole)	Candidiasis: nystatin (fluconazole)					
		Chlamydiosis: doxycycline			Chlamydiosis: doxycycline	
		TMS, Amox/Clav, ±florfenicol	TMS, Amox/Clav, ±florfenicol	TMS, amoxicillin, Amox/Clav, ±florfenicol	TMS, Amox/Clav, ±florfenicol	TMS, Amox/Clav, ±florfenicol

Continued

TABLE 6.10D

Recommendations for Judicious Antimicrobial Use in Columbiformes—cont'd

	Body Systems			
	Integument		**Respiratory**	**Ophthalmic**
Comments	Poxvirus is also an important DDX (see Chapter 15).	Debridement of severe trichomoniasis lesions may be indicated	Avoid intramuscular injections in racing pigeons	
		Sinus flushing of abx Consider euthanasia for paratyphoid (Salmonella typhimurium var. Copenhagen): Salmonella spp. can often be recovered from the feces even after prolonged and apparently effective treatment.		

ABX, Antibiotics; *IVM*, ivermectin; *TMS*, trimethoprim-sulfonamides.

TABLE 6.10E

Recommendations for Judicious Antimicrobial Use in Anseriformes[241–247]

	Body Systems			
	Integument	**Respiratory**		**Ophthalmic**
Common conditions	Pododermatitis	Rhinitis/sinusitis	Tracheitis, pneumonia, airsacculitis	Conjunctivitis, keratitis, uveitis
Cytology and culture	Cytology: impression smear	Cytology, culture: pharyngeal swabs, nasal flush, sinus flush, sinus aspirate	Lung/air sac imprint from biopsy sample, lung/air sac biopsy if clinical status allows Tracheal lavage if clinical status allows	Conjunctival swab

Gastrointestinal			Reproductive	Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
	Nematodiasis: prevents exposure via foraging to intermediate hosts, like pill bugs	Dimetridazole has a low margin of safety and can be toxic (see Chapter 9)				
		Recommend wire flooring and regular cleaning of the loft. Vitamin B supplementation after therapy is also beneficial because sulfas reduce thiamine absorption				*Sarcocystis:* trapping opossums and relocating birds to clean, new premises may reduce flock mortality (see Chapter 2, Infectious Disease in Current Therapy in Avian Medicine and Surgery, Vol. 1)
		There is evidence of growing resistance to sulfas and amprolium (see Chapter 9)				

	Gastrointestinal		Reproductive	Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
Proventriculitis, ventriculitis	Enteritis	Cloacitis, phallic prolapse	Salpingitis	Septic arthritis, osteomyelitis	Multiorgan infection, septicemia	Encephalitis, meningitis, myelitis
Fresh fecal sample for direct smear evaluation, flotation	Fresh fecal sample for direct smear evaluation, flotation, acid-fast stain	Cytology: impression smear	Samples can potentially be collected via cloacoscopy	Fine-needle aspirate of affected joint for cytology and culture	Fine-needle aspirate, biopsy of various organs for cytology and culture	Biopsy for impression smear, culture, histopathology

Continued

TABLE 6.10E

Recommendations for Judicious Antimicrobial Use in Anseriformes—cont'd

	Body Systems			
	Integument	**Respiratory**		**Ophthalmic**
	Culture: swab, biopsy	Collect sample via biopsy in chronic cases		
Most likely pathogens	*Staphylococcus, Enterobacter, E. coli*	*Riemerella anatipestifer, Hemophilus* spp., *Pasteurella* spp., *E. coli, Pseudomonas* spp., *Erysipelothrix rhusiopathiae, Mycobacterium* spp., *Mycoplasma* spp., *Chlamydia psittaci*	*Riemerella anatipestifer, Pasteurella multocida, Pseudomonas* spp., *Aeromonas hydrophila, Mycoplasma* spp., *(Mycobacterium avium)*	*Riemerella anatipestifer, Pasteurella multocida, Chlamydia psittaci*
		Theromyzon spp.	*Cytodites nudus,* Cyathostoma	*Theromyzon* spp.
			Syngamus trachea, Cyathostoma, Theromyzon spp. *Aspergillus fumigatus*	
Empirical antimicrobial suggestions	TMS, Amox/Clav	Mycoplasmosis: tylosin, tetracyclines, lincomycin, and spectinomycin, valnemulin, tiamulin, tyvalosin	TMS, sulfaquinoxaline, chloramphenicol, florfenicol, penicillin and streptomycin, or sulfaquinoxaline	Tobramycin, gentamicin
		R. anatipestifer: Amox/Clav, cefotaxime, cefuroxime sodium		Chlamydiosis: doxycycline
		Chlamydiosis: doxycycline		

	Gastrointestinal		Reproductive	Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
Proventricular wash for cytology and culture		Culture: swab, biopsy		Bone biopsy for impression smear, culture, histopathology	Blood culture	*Eimeria* truncata can be found in the urine
Riemerella anatipestifer	*Riemerella anatipestifer, Pasteurella multocida, E. coli, Hemophilus* spp., *Pseudomonas* spp., *Aeromonas hydrophila, Salmonella* spp., (*Mycobacterium avium*)	*Neisseria* spp., *Mycoplasma* spp.	*Riemerella anatipestifer, Mycoplasma* spp.	*Riemerella anatipestifer, Pasteurella multocida, Yersinia pseudotuberculosis, Actinobacillus, E. coli, Erysipelothrix rhusiopathiae, Mycoplasma synoviae, (Mycobacterium avium)*	*Riemerella anatipestifer, Pasteurella multocida, E. coli, Actinobacillus, Pseudomonas* spp., *Aeromonas hydrophila, Erysipelothrix rhusiopathiae*	*Riemerella anatipestifer, Salmonella* spp.
Echinuria, Tetrameres, Eustrongyloides, Amidostomum spp., *Epomidostomum* spp.	*Cryptosporidium avium,* coccidiosis, (acanthocephalans)	*Cryptosporidium avium*				*Eimeria truncata*
					Aspergillus fumigatus (young birds can die peracutely)	
TMS, sulfaquinoxaline, chloramphenicol, florfenicol, penicillin and streptomycin, or sulfaquinoxaline	TMS, sulfaquinoxaline, chloramphenicol, florfenicol, penicillin and streptomycin, or sulfaquinoxaline	Mycoplasmosis: tylosin, tetracyclines, lincomycin, and spectinomycin, valnemulin, tiamulin, tyvalosin	Amxo/Clav, TMS, enrofloxacin (severe cases)	Septic arthritis: clindamycin or first-generation cephalosporin or Amox/Clav	TMS, sulfaquinoxaline, chloramphenicol, florfenicol, penicillin and streptomycin, or sulfaquinoxaline	TMS, sulfaquinoxaline, chloramphenicol, florfenicol, penicillin and streptomycin, or sulfaquinoxaline
			Check for retained or ruptured egg(s), salpingectomy may be required	Osteomyelitis: clindamycin, pending culture	*R. anatipestifer*: Amox/Clav, cefotaxime, cefuroxime sodium	*R. anatipestifer*: Amox/Clav, cefotaxime, cefuroxime sodium
				Pasteurella multocida: beta-lactam antibiotics, oxytetracycline	*Pasteurella multocida*: beta-lactam antibiotics, oxytetracycline or enrofloxacin Recommend euthanasia for *Mycobacterium* spp.	

Continued

TABLE 6.10E

Recommendations for Judicious Antimicrobial Use in Anseriformes—cont'd

Body Systems			
Integument	**Respiratory**	**Ophthalmic**	
	Syngamus: IVM, thiabendazole		
	Aspergillosis: azole drug, amphotericin B		
Comments			
Mycoplasmosis: Antibiotic therapy does not eliminate the organism, but it can resolve clinical signs. It is equally important to assess and treat any underlying stressors. Consider euthanasia for the well-being of the flock (see Chapter 20)			
	Cyathostoma: Treatment with IVM was unsuccessful in a Hawaiian goose *Syngamus:* It is possible to retrieve the worms endoscopically		

IVM, Ivermectin; *TMS*, trimethoprim-sulfonamides.

	Gastrointestinal	Reproductive	Musculoskeletal	Multisystemic Infection, Septicemia	Neurologic
	Nematodiasis: IVM, FBZ; pyrantel pamoate is better for ascarids				*Eimeria truncata:* sulfonamides
		TMS has poor diffusion in granuloma; consider alternative if suspected.	Pasteurellosis: The organism is easily destroyed by common disinfectants, sunlight, drying, and heat. Therefore, good sanitation practices are an important part of disease prevention and control Mycoplasmosis: Surgical intervention may be necessary but the prognosis is guarded. It is also important to move the bird to softer ground or grass. Antimicrobial treatment does *not* eliminate *Mycoplasma* spp. (see Chapter 20)	*Riemerella anatipestifer*: The management of disease relies upon prompt removal and incineration of carcasses as well as cleaning the environment Free-ranging swans and geese seem to be predisposed to *Pseudomonas* and *Aeromonas* infections, particularly during the summer months

CHAPTER 7

Antibacterial Drugs

Isabelle Langlois • Ingeborg M. van Geijlswijk • Christal G. Pollock

CULTURE RESULTS AND INTERPRETATION

Isabelle Langlois

Laboratories used by veterinary practices should be able to provide information regarding the pathogen's identification and susceptibility within 48 hours of receiving the collected sample. Laboratory results may be misleading for several reasons, summarized in Box 7.1. Laboratories may use selective culture media to enhance the growth of pathogens or inhibit the growth of contaminants, for example, cefsulodin-irgasan-novobiocin (CIN) agar for the selection of *Yersinia* spp. or brilliant green agar (BGA) for the selection of *Salmonella* spp. This might be helpful in a selection of samples and potential pathogens.

Knowledge of commensal microbial flora of avian system is helpful in interpreting culture results. The most frequently identified bacterial organisms isolated from the skin of psittacine birds belongs to the genus *Staphylococcus*, followed by the genus *Corynebacterium*.[1] *Acinetobacter* spp., *Curtobacterium* spp., *Microbacterium* spp., and *Streptococcus* spp. are also commonly isolated. The normal gastrointestinal flora of healthy psittacine birds is predominately composed of gram-positive bacteria. This finding has been recently confirmed by a study investigating the level of agreement between results from Gram stain and bacterial culture from healthy Hispaniolan Amazon parrots *(Amazona ventralis)* fed a pelleted diet.[2] Most bacteria (97.2%) identified were gram-positive. Interestingly, gram-negative organisms were identified in 30% of birds on Gram stains, representing 3% to 15% of the observed bacterial population. *Escherichia coli* was the only gram-negative organism identified on culture. Agreement between results of Gram stain and culture was considered fair, with culture tending to underestimate the true diversity of bacteria colonizing the gastrointestinal tract. Clinical application of this study suggests that Gram stains may be of higher value than culture as screening tests for health assessment.[3] A parallel testing strategy may limit the likelihood of misclassifying the microbial flora of psittacine patients.

Scientific findings in one species may not be extrapolable to other species. Host bird species is the most important factor in determining microbial community composition, although sampling site, diet, and captivity status also contribute to gut bacterial communities.[4] As such, a study investigating gut microbiota in Asian herbivorous, long-distance migratory Anseriformes showed the dominant bacterial phyla across all samples were Firmicutes, Proteobacteria, and *Actinobacteria*, but significant variations were detected among different goose species and sampling sites.[5] In captive Falconiformes and Strigiformes, gram-negative bacteria were the most common isolates, and birds fed chicken had more varied gram-negative bacterial species and in greater numbers per fecal samples.[6] This outlines that interpretation of culture results must take into consideration the patient's species and diet.

ANTIBACTERIAL SUSCEPTIBILITY TESTING AND INTERPRETATION

Christal G. Pollock

Antibacterial susceptibility testing (AST) can be a powerful tool in the judicious selection of antibiotic therapy.[7] For individual patients, AST can assist in identifying the optimal antibiotic regimen by determining the susceptibility and resistance of a specific pathogen to a range of antibacterial agents.[7–11]

On a larger scale, AST can aid in the evaluation of treatment provided by hospitals or even national infectious disease control programs.[7] The data gathered can be used to create a cumulative antibiogram that indicates the proportion of bacterial isolates in a population susceptible (or resistant) to a specific drug.[12,13] A survey on antibiogram use in veterinary medicine showed antibiogram use to be almost systematic in poultry, frequent in pigs, and rare in both bovine and equine medicine.[14] Box 7.2 summarizes the clinical uses of antibiograms.

INDICATIONS

Empirical therapy continues to be an effective choice in simple infections or for known pathogens, such as beta-hemolytic *Streptococcus* spp., *Pasteurella* spp., and *Chlamydia* spp.[11,15,16] Susceptibility testing is used to guide drug choice for difficult-to-treat infections or for isolates that possess acquired resistance mechanisms, such as Enterobacteriaceae, *Pseudomonas* spp., *Staphylococcus* spp., and *Enterococcus* spp.[11,16] Special consideration should also be given to isolates retrieved from osteomyelitis, protected sites, like the eye, immunocompromised patients, or patients recently given antibiotics.[12,17] Even a single dose can be associated with emergent resistance.[12]

BOX 7.1 KEY ELEMENTS TO REMEMBER WHEN INTERPRETING CULTURE RESULTS

- A negative culture does not rule out infection. Failure to isolate the causative agents may be due to poor sample collection, poor sample transport (e.g., anaerobes transported in aerobic transport media), or additional/specific requirements for culture not routinely used by most laboratories (e.g., mycobacteria, Chlamydiales, *Mycoplasma* spp.).
- Identification of microbial agents does not necessarily implicate these organisms as the precipitating cause of the infection as they may be part of the normal flora or secondary invaders or contaminants.
- Bacterial organisms that are part of the normal avian microbiota in a normal physiologic state may also be opportunistic pathogens. Therefore, isolation of a commensal organism does not rule out infection.
- Bacteria isolated may represent local bacterial population in the bird's environment.

Modified from Langlois I: Medical causes of feather damaging behavior, *Vet Clin North Am Exot Anim Pract* 24(1):119–152, 2021.[86]

BOX 7.2 FUNCTION OF ANTIBIOGRAMS

Antibiograms are used to:
Assess local susceptibility rates
Monitor resistance trends over time
Guide selection of empiric antimicrobial treatment
Guide decisions about which antimicrobials are included in hospital formularies

From Wieczorkiewicz S, Sincak C: *The pharmacist's guide to antimicrobial therapy and stewardship*, ed 1, Bethesda, MA, 2016, American Society of Health-System Pharmacist Publications.[13]

SPECIMEN COLLECTION

A pure bacterial culture, containing approximately three to five well-isolated colonies of the organism causing infection, is needed for AST.[8,18] Therefore the clinician must submit samples that are representative of the disease process while minimizing contaminant growth. A surgical preparation should be performed before sample collection, whenever possible.[12] Blood, fluid, or tissue samples are preferable to swabs.[12] Consult your diagnostic laboratory for specific recommendations on appropriate specimen collection, handling, and transport.[16]

SUSCEPTIBILITY TEST TECHNIQUES

For all phenotypic AST, a standardized inoculum is prepared from well-isolated colonies taken from a bacterial culture.[7,8,12] A standard amount of the inoculum is then used to inoculate the testing media.[12] There are several methods available that can be divided into two distinct categories: diffusion and dilution based (see also Chapter 5).[8] Diffusion techniques are based on the inhibition of bacterial growth by an antibacterial agent diffusing through solid media from filter paper disks impregnated with various antibiotics (disk diffusion) or an elongated, absorbent strip containing a known gradient of antibiotic (Epsilometer or E-test) (Figure 7.1).[9,16,19] In dilution-based susceptibility testing, such as broth dilution or agar disk dilution, a standard concentration of the inoculum is combined with increasing concentrations of the antibiotic in a series of tubes or microdilution plates (Figure 7.1).[7,9]

Most veterinary laboratories use agar disk diffusion and/or the broth microdilution method.[7] Specific drug panels are used for each taxonomic group. There are also separate gram-negative and gram-positive panels for diagnostic and surveillance purposes.[7] Although some fastidious organisms, such as *Mycobacterium* spp., may be sent to specialized facilities, routine susceptibility testing is generally not performed for other difficult-to-grow organisms, such as obligate anaerobes and intracellular bacteria.[18]

The checkerboard assay allows laboratories to evaluate the activity of antibiotic combinations on pathogens (Figure 7.2).[7] Although not considered a standardized technique, this difficult and time-consuming assay can be used to evaluate synergy, indifference, or antagonism between two antibacterial agents when they are combined.[7]

ALTERNATIVE METHODOLOGIES

Alternative tests with the potential to reduce the standard processing time associated with AST (36 hours plus transport) include direct susceptibility testing by disk diffusion, polymerase chain reaction (PCR), matrix-assisted laser desorption ionization–time of flight, next-generation sequencing, and whole-genome sequencing.[7,20] Susceptibility tests using genotypic methods do not always require bacterial colonies from culture because resistance genes to certain antimicrobial drugs can be detected using molecular techniques.[8]

SUSCEPTIBILITY TEST RESULTS

Diagnostic laboratories frequently utilize "class testing," in which a particular drug is used to predict the susceptibility of other agents within the same antibiotic class.[7] For example, ampicillin, tetracycline, and clindamycin are routinely tested as the representatives for their respective antibacterial classes.[7] There are certain antibacterial agents, however, for which class testing cannot be performed, such as many macrolides, aminoglycosides, and some cephalosporins.[12]

QUANTITATIVE DATA

The lowest concentration of drug that inhibits visible growth of the organism is reported as the minimum inhibitory concentration (MIC),[8–11] which is expressed in milligrams or micrograms per milliliter.[12,13] A high MIC value means that more drug is needed to affect the organism's function or replication.[12,14] A low value means that less drug is needed to affect the organism.[16] MIC is currently the simplest and best measure we have of the antibacterial effect in vitro.[21]

For each organism-antibiotic pair, there is a particular cutoff MIC that defines susceptibility called the breakpoint (Figure 7.1).[10,12,16] Breakpoints or interpretative criteria differ not only based on organism-antibiotic pairs but also by the

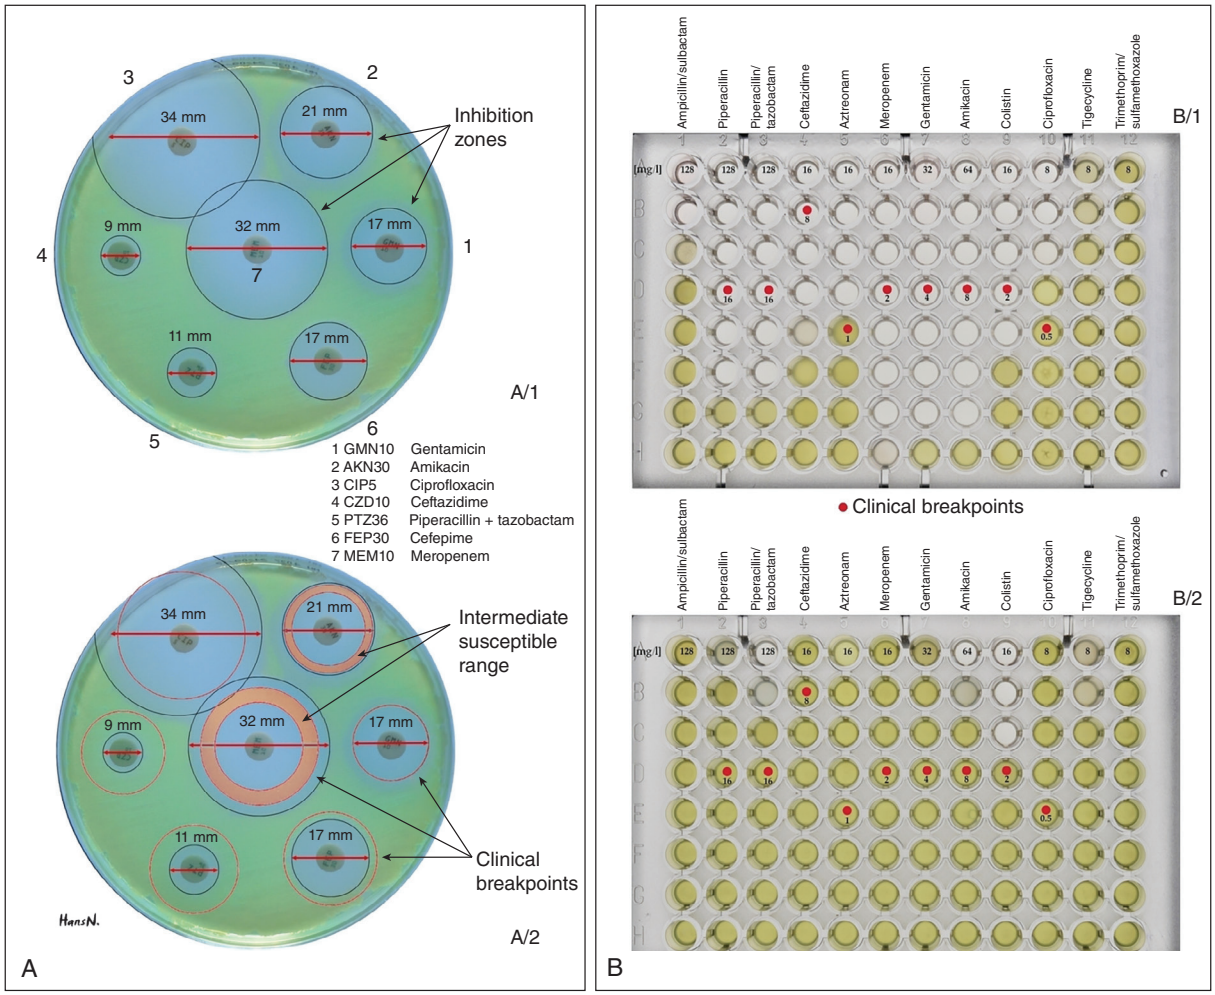

FIGURE 7.1 (A) Agar disk diffusion, also known as the Kirby-Bauer test. (B) Broth dilution using a microdilution plate. *Red dots* indicate clinical breakpoints. (Photo courtesy HansN via Wikimedia Commons.)

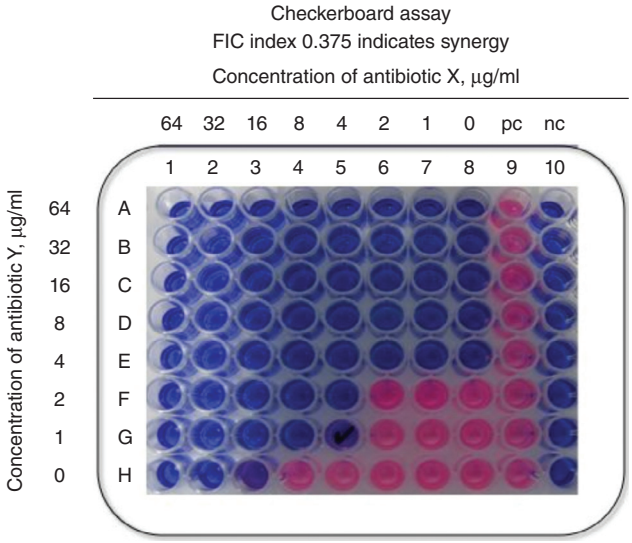

FIGURE 7.2 In the checkerboard assay, one antimicrobial agent is added vertically at two-fold dilutions to a 96-well plate while another agent is added horizontally to produce a "checkerboard" of various combined drug concentrations.[7] (Photo courtesy Dr. Marina Berditsch, IBG-2/IOC, KIT.)

site of infection.[10] Breakpoints are determined after careful and exhaustive review of pharmacodynamics (PD) and pharmacokinetics (PK), and they are regularly reviewed, particularly when mechanisms of bacterial resistance to a specific drug have been described.[12,16,21]

Initially, veterinary diagnostic laboratories had to rely heavily on human standards; however, the veterinary subcommittee of the Clinical and Laboratory Standards Institute has created a growing number of breakpoints for antibacterial agents in companion animal species, like dogs, cats, horses, cattle, and swine.[7,16] In chickens and turkeys, a veterinary-specific breakpoint has been identified for enrofloxacin.[7] Fortunately, similarities in PK and pathogen susceptibilities between humans and animals allow human breakpoints to be extrapolated for many drugs.[16]

QUALITATIVE DATA

Using available clinical breakpoints, an organism can also be categorized as susceptible ("S"), resistant ("R"), or intermediate ("I").[10] Susceptible is associated with a high probability of success following treatment and resistant is associated with a low probability of success.[9,13] Intermediate is a poorly defined range that is used when results fall into a buffer zone between susceptible and resistant strains.[10,16] Although successful therapy is possible in some circumstances, an intermediate result can mean that certain variables in the AST were not properly controlled (see the following section on Limitations of Susceptibility Testing).[10,16] Some isolates can also be reported as susceptible dose dependent ("S-DD"), which means the microbe may be susceptible to higher and/or more frequent dosing but is likely to be resistant to low doses (see the section on Integration of Pharmacokinetic/Pharmacodynamic Data).[10,13,16] If you are unclear about what information was used to determine "S"/"I"/"R" on your patient's report, clarify this point with your laboratory.[7]

LIMITATIONS OF SUSCEPTIBILITY TESTING

Pitfalls in susceptibility testing can occur at every stage of the AST process,[7,12,16] beginning with sampling, continuing through identification and testing, and concluding with interpretation and dose design.[12,18]

- Was the culture pure? Or does it consist of mixed colonies?[8]
- Was the microbe cultured truly a pathogen? Neither contaminants nor normal bacterial flora should be selected for AST.[7,17] This is why cytology often complements AST, since findings such as phagocytosis of the organism can be indicative of pathogenicity.[12]
- Was the isolate speciated? It is particularly important to speciate genera such as *Enterococcus*, *Streptococcus*, and *Staphylococcus* to identify the source of infection and/or determine proper treatment.[12]
- How was growth or absence of growth detected? Human observation versus computer-enhanced images or spectrophotometry can contribute to variability in results.[12]
- Are proper PK/PD data available? This crucial information is lacking for many antimicrobials used in companion birds, and extrapolation of data among different species is questionable, particularly for drugs that are orally administered and lipid soluble. Oral bioavailability can differ markedly among species.[12]

Another limitation of susceptibility testing is detection of acquired resistance that is rapidly induced by the presence of the drug.[12] This might be best exemplified by gram-negative organisms that produce extended-spectrum beta-lactamases.[12] These enzymes are induced at the site of infection by the presence of the drug and generally are not expressed by the isolate cultured in vitro.[12]

INTERPRETATION OF TEST RESULTS

Susceptibility testing measures the direct interactions between the antibacterial agent and the organism in vitro, but this is only one aspect of a very complicated clinical scenario.[21] Just because an antibiotic has the lowest MIC for a pathogen does not mean it is the best choice for an individual patient.[10] Susceptibility involves complex in vivo factors related to dose and dosing schedule, PK of the antibacterial in the individual, adequacy of host defenses, the site of infection, and other numerous factors that can influence the clinical outcome.[7,9,12,15,16,22] Therefore it is the job of the clinician to determine which "susceptible" drugs are most likely to achieve therapeutic success by considering a variety of drug, microbial, and host factors.[7,12,22]

INTEGRATION OF PHARMACOKINETIC/PHARMACODYNAMIC DATA

Breakpoints are related to achievable drug levels in target tissues.[7] Since drug concentrations vary in different body sites or fluids, PK studies are required to determine if therapeutic levels are reached in target tissues.[9]

The PD properties of an antibiotic refer to the manner in which the antibacterial drug exerts its effects on the target organism.[9,10] As previously stated, for most infections, outcomes using appropriate bacteriostatic or bactericidal drugs are similar; however, bactericidal antibiotics are preferred in immunocompromised patients and possibly those with osteomyelitis (see Table 6.5).[10] In these cases, it can be useful to know the lowest concentration of an antibacterial agent required to kill the organism or the minimal bactericidal concentration (MBC).[9] The MBC is determined by subculturing a small sample from the MIC assay onto growth medium and examining it for bacterial growth. Serial dilutions are made of the antimicrobial in bacterial growth media. After a standard incubation, the lowest concentration that has reduced the number of colonies by 99.9% is the MBC.[9] Bactericidal antibiotics usually have an MBC equal or similar to the MIC, whereas bacteriostatic antibiotics usually have an MBC significantly higher than the MIC (see Table 6.5).[9] While MIC testing is standard in most laboratories, MBC testing is more difficult to perform and is not routinely done in clinical practice.[10,16]

Antibiotics are also classified as either time or concentration dependent (Table 7.1). This information will help determine if it is better to administer a high dose of antibiotics all at once or achieve lower concentrations for a longer time. Table 7.2 illustrates the intersection of breakpoints, MIC, and PD data.[10]

TABLE 7.1

Concentration- Versus Time-Dependent Drugs[9,12,21–23]

Parameter	Concentration-Dependent Drugs[a]	Time-Dependent Drugs[b]
Examples	Fluoroquinolones,[c] aminoglycosides, metronidazole, doxycycline, vancomycin	Beta-lactams,[c] some macrolides, tetracyclines, trimethoprim-sulfa combinations, chloramphenicol, carbapenems, vancomycin, linezolid, lincosamides
Factor that increases drug efficacy	Drug concentration increases several-fold above the minimum inhibitory concentration (MIC) of a given pathogen[d]	Length of time that serum levels exceed the MIC of a given pathogen
Optimal dosing strategy	Use highest effective dose (without toxicity) at long dosing intervals	Frequent drug administration

[a]Also known as "dose dependent."
[b]Also known as "dose independent."
[c]Some fluoroquinolones, beta-lactams, tetracyclines, and glycopeptides possess characteristics of both time- and concentration-dependent classes.[12,23] Their best predictor of efficacy is the 24-hour area under the serum concentration versus time curve (AUC)/MIC ratio.
[d]It is not necessary or even beneficial to maintain drug levels above the MIC between doses, as it might increase toxicity.

TABLE 7.2

Examples of Antibiotic Susceptibility Breakpoints to *Escherichia coli*[10]

Antibiotics	Susceptible (Breakpoint)	Susceptible, Dose Dependent	Intermediate	Resistant
Ampicillin	≤8 mg/L		16 mg/L	≥32 mg/L
Cefepime	≤2 mg/L	4–8 mg/L		≥16 mg/L
Levofloxacin	≤2 mg/L		4 mg/L	≥8 mg/L
Trimethoprim/sulfamethoxazole	≤2/38 mg/L			≥4/76 mg/L

Breakpoints differ for various pathogen-antibiotic combinations. In this example, the breakpoint for levofloxacin against *E. coli* is 2 mg/L and 8 mg/L for ampicillin. If an isolate of *E. coli* from the patient's bloodstream is found to have an MIC of 1 mg/L for levofloxacin but 2 mg/L for ampicillin, it does not mean that levofloxacin is a better choice for that patient. Levofloxacin is a concentration-dependent drug typically dosed much less frequently than the time-dependent drug, ampicillin. The much higher concentration of ampicillin achieved in the body (due to higher doses) means that organisms with a higher MIC to ampicillin are still susceptible to this antimicrobial agent. In other words, the MIC values for levofloxacin and ampicillin are not directly comparable.[10]

The postantibiotic effect (PAE) is a period of suppressed bacterial growth seen after brief exposure of the organism to the antimicrobial.[12] The PAE is generally longer in vivo than in vitro.[23] Clinically, this translates to inhibited bacterial growth even though the drug is no longer present and thus is below the MIC of the infecting microbe.[12] The impact of the PAE on antimicrobial efficacy can be profound, particularly for concentration-dependent drugs.[12] It is the PAE that allows some drugs to be administered at long intervals despite short half-lives.[12] The mechanisms of action of the PAE are varied. For beta-lactams, it is the length of time the organism takes to synthesize new penicillin-binding proteins.[23] Beta-lactams only express PAE for gram-positive bacteria, with the exception of carbapenems which may also have a gram-negative PAE.[23] Antimicrobial drugs that inhibit DNA or protein synthesis, such as macrolides, fluoroquinolones, and aminoglycosides, tend to exert PAE against gram-negative bacteria.[23]

HOST FACTORS

The penetrability of host target tissue must also be considered.[9,12,16] If the target is a protected site, such as the central nervous system or eye, or perhaps a granuloma that cannot be accessed surgically, then a lipid-soluble drug is preferred (Box 7.3).[12] If there are no significant tissue barriers to penetrate and there is adequate blood supply, then a water-soluble antibacterial drug, such as beta-lactams or aminoglycosides, is recommended.[12,16]

Also consider the patient's clinical status.[12] A bactericidal drug is recommended if the patient is immunocompromised or severely debilitated (see Table 6.5).[12] If there is marked inflammation, a "susceptible" drug that accumulates in phagocytic heterophils, such as fluoroquinolones, macrolides, or lincosamides, should be considered.[12] Also consider the risk of altered drug disposition if the patient suffers from comorbidities.[9] For

instance, nephrotoxicity is a risk with the administration of aminoglycosides or sulfa drugs.

ANTIBACTERIAL PROPHYLAXIS

Isabelle Langlois, Ingeborg M. van Geijlswijk

Antibacterial prophylaxis consists of initiating antimicrobial chemotherapy in a patient considered to be at risk of infection in order to prevent an infection from developing. Patients considered at risk of infection include those undergoing surgical procedures or those with immunosuppression for a variety of reasons including cancer chemotherapy. When elected, antibacterial prophylaxis should have the smallest impact on the patient's microbiome and the microbiologic ecology of the hospital to prevent detrimental effect on the patient and work environment with increased risk of superinfection, development of bacterial resistance, additional cost of hospitalization, and increased incidence of adverse effects for the patient.[24]

PROPHYLACTIC ANTIBIOTIC USE IN THE SURGICAL PATIENT

Prophylactic use of antibacterial drugs is indicated when there is clearly an increased risk of infection or when infection would be catastrophic. The aim of antibacterial prophylaxis in the surgical patient is the reduction of microbial burden and the risk of intraoperative contamination such that normal host defenses can prevent infection.[25] The first, and of utmost importance, decisions avian clinician have to make regarding their surgical patient is whether or not antibacterial prophylaxis is indicated. Of course, antibacterial drug use does not replace proper surgical technique (atraumatic tissue handling, appropriate use of sutures, adequate hemostasis, elimination of dead space) and strict adhesion to aseptic techniques.[26,27]

Drug Selection

The drug selected must be present at the surgical site during the time of potential contamination.[28] Antibiotic prophylaxis should be selected based on expected microorganisms most likely to contaminate the surgical site and their anticipated resistance patterns as determined by recent laboratory data. These microorganisms are different in different species. While in mammals the main bacteria at the surgical site will consist of *Staphylococcus* spp. and *Streptococcus* spp. (which are covered by the surgical site infection [SSI] prophylactic antibiotic cefazolin), in reptiles *Pseudomonas* spp. are abundant, and in most avian species the feather microbiota were dominated by the phyla Proteobacteria, Actinobacteria, and Bacteroidetes.[29] These bacteria are known for producing antibiotics themselves.

Low incidence of adverse effects, available PK of the drug in the species of interest, PD indices of favorable outcome, and cost are other pertinent elements to consider. The use of newer broad-spectrum medication should be avoided in surgical prophylaxis to decrease the emergence of resistant isolates.[30] The goal is to use an antibiotic that is effective at least against 80% of the probable pathogens.[31] This recommendation remains a challenge with the increasing widespread resistance. Many bacterial isolates now have MIC approaching the threshold of susceptibility.[31] Therefore, the higher end of the dosing should be used, and for time-dependent drugs, intervals may need to be shortened.

Method of Administration

Intravenous or intraosseous prophylactic antibiotics should be given no earlier than 30 to 60 minutes prior to surgical incision, and they should ideally be discontinued at or within 24 hours of the end of the surgery.[26,31] The use of oral antibacterial drugs for prophylaxis may not be prudent since peak concentrations are likely to be lower due to bioavailability.[26] Surgical infection rates in dogs undergoing orthopedic implant surgery were similar when antibacterial prophylaxis was administered perioperatively over 3 hours or as a course continued for 6 days.[31] A study in small animals noted that individuals that received antibiotics without following the aforementioned protocol and those that received only postoperative antibiotics had a higher rate of infection than the group that did not receive any antibiotics.[32] This underscores that prophylactic antibiotics must be used correctly. However, a recent survey showed the use of perioperative antimicrobials in small animal surgery was suboptimal with respect to timing, duration, choice of antibiotic, and selection of surgical cases requiring prophylaxis.[33] Despite the absence of studies regarding prophylactic use of antibiotics in avian surgery, conclusions are likely to be similar. The administration of antibacterial drugs should be repeated intraoperatively if the surgical procedure lasts beyond two half-lives after the first dose.[30] This will ensure adequate drug concentration at the surgical site until wound closure is completed.

The use of prophylactic antibiotics postoperatively is not recommended by both the American Centers for Disease Control and Prevention (CDC) and the European Center for Disease Prevention and Control due to conflicting studies regarding their efficacy and their potential contribution to antibiotic resistance.[31] The administration of the first dose intravenously prior to surgery to obtain a quick efficacious peak at decreasing microbial population and a short course is key to minimizing emergent resistance.[34,35] Recent researches in dogs demonstrated prophylactic use of antibiotics postoperatively is beneficial in reducing SSI following clean procedures where a medical device was implanted.[36,37] Therefore, postoperative prophylactic antibiotics should be limited to this clinical situation with implants. A dosing regimen of 4 to 5 days is sufficient with proper dosing regimen, whereas dosing regimens extending to 10 days facilitate therapeutic failure due to emerging resistance.[34,35]

Factors Involved in the Development of a Surgical Site Infection

Numerous factors determine the likelihood of the development of SSI such as classification of type of wound, factors related to the nature of the procedure to be performed, and patient-related factors.[27]

Wound classification

Recommendations for antibacterial prophylaxis perioperatively in veterinary medicine are based on the classification scheme developed by the CDC.[38] Wounds are classified by degree of contamination to help predict the likelihood that infection will develop (Table 7.3). This scheme is helpful, but

TABLE 7.3

Surgical Wound Classification Based on Centers for Disease Control and Prevention Classification[38]

Classification	Description	Examples
Class 1: Clean	Nontraumatic, noninflamed operative wounds in which the respiratory, gastrointestinal, genitourinary, and oropharyngeal tracts are not entered	♦ Cutaneous mass excision ♦ Constricting toe syndrome surgical correction ♦ Reduction of closed fracture
Class 2: Clean-contaminated	Operative wounds in which the respiratory, gastrointestinal, or genitourinary tract is entered under controlled conditions without unusual contamination	♦ Ingluviotomy ♦ Proventriculotomy ♦ Salpingotomy ♦ Perforation of a surgical glove
Class 3: Contaminated	Open, fresh, accidental wounds; procedures in which gastrointestinal contents or infected oviductal content is spilled or a major break in aseptic technique occurs	♦ Skin laceration ♦ Proventricular spillage during proventriculotomy
Class 4: Dirty or infected	Old traumatic wounds with purulent discharge, devitalized tissue or foreign bodies; procedures in which a viscus is perforated or feces contamination occurs	♦ Chronic open fracture ♦ Abscess excision ♦ Septic coelomitis ♦ Ventral tail laceration

its accuracy in veterinary surgery may vary according to the procedure. Prophylactic antibiotics are not indicated for most clean procedures,[26,39] except if an implant (nonabsorbable suture, polypropylene mesh) is used.[26,31] In those circumstances, their use is seemingly warranted. Antibiotic prophylaxis is indicated for clean-contaminated and contaminated procedures.[31,32] Dirty wounds are considered to be infected. Therefore, in this clinical situation, antibacterial drugs are used therapeutically rather than prophylactically.

Procedure-related factors

Phagocytosis and humoral immunity are significantly diminished when tissue integrity is interrupted during surgery.[31] Therefore, inexperienced surgeons may create more tissue trauma leading to greater susceptibility to infection compared to experienced surgeons.[31] Total surgery time and total anesthesia time are well-established risk factors of SSI in small animals.[32,40,41] The proposed mechanism is by suppression of the immune system associated with a transient decrease in lymphocytes that has been correlated with the duration of the surgery.[31] The risk of infection for animals undergoing a 90-minute procedure is twice as high as that of animals undergoing a 60-minute procedure.[32] Of note, in small animals, anesthesia time is a risk factor for postoperative wound infection independent of the duration of surgery.[40] Therefore, efforts should be made to expedite avian patient preparation and postoperative diagnostic procedures such as radiography following orthopedic surgery, for example.

Patient-related factors

In human medicine, advancing age, obesity, chronic inflammation, depressed immune system, the use of braided/multifilament suture material, and severe concurrent illnesses are cited as risk factors for SSI.[25] Veterinary studies with sufficient statistical power to identify patient-related factors in the development of SSI are scant. A study showed that dogs suffering from hypotension during surgery were 27 times more likely to develop SSI potentially secondary to a decrease in oxygenated blood flow to the surgical site.[42] Some of these factors may also apply to birds and warrant antibiotic prophylaxis.

PROPHYLACTIC USE IN THE CANCER CHEMOTHERAPY PATIENT

Bacterial infection following cancer chemotherapy-induced neutropenia is a serious cause of morbidity and mortality both in human and veterinary patients. Comprehensive guidelines exist to assist human oncologists in prescribing antibacterial prophylaxis. Still, there is an ongoing debate among human oncologists as any decreased incidence in bacterial infections is countered by patient adverse effects and the development of antibiotic resistance. In veterinary medicine, there is a paucity of available resources.[43–45] This is even truer in avian medicine as oncology is in its infancy and there is no established standard of care. This section will review current knowledge in human and small animal veterinary medicine while providing insights on the prophylaxis practices described in the avian literature.

Potential Benefits of Antibacterial Prophylaxis

Control trials evaluating antibiotic prophylaxis in human cancer chemotherapy patients showed there was a statistically significant reduction in fever, microbiologically documented infections, and hospitalization, although there was no significant difference in mortality between the two groups.[46,47] Humans with neutropenia of great severity and duration seem to benefit from prophylactic therapy compared to humans with mild to moderate neutropenia.[48] In veterinary medicine, a recent double-blinded, placebo-controlled study in dogs with lymphoma (n = 39) or osteosarcoma (n = 34) showed administration of trimethoprim-sulfonamide (30 mg/kg PO q12h) for the first 14 days after the dogs' first doxorubicin chemotherapy to result in modest but significant reduction in nonhematologic toxicity (gastrointestinal toxicity, hospitalization, suspected infection).[49] Other veterinary studies have shown no beneficial evidence regarding the efficacy of antimicrobial prophylaxis.[50,51] Globally, the potential advantages of prophylactic therapy include a reduction in infection rate, a reduction in the time to onset of infection, and a reduction in the speed in which an incipient infection develops into

overwhelming sepsis.[24] Ultimately, these benefits may facilitate the home management of neutropenic animals, or heteropenic birds, and improve quality of life.

Potential Disadvantages of Antibacterial Prophylaxis

Antibacterial prophylaxis can exert a selection pressure on the composition and function within the gastrointestinal microbiome of an individual patient, which may result in the emergence of antibiotic-resistant strains. This undesirable effect is well documented in human literature but has yet to be evaluated in the veterinary field. Human studies show increasing reports of fluoroquinolone-resistant bacteria isolated from patients receiving chemotherapy prophylaxis.[52,53] Moreover, there is increasing evidence that disruption of the microbiome can ultimately alter the efficacy of chemotherapy. Mice treated with antibacterial drugs prior to chemotherapy showed decreased tumor necrosis, and mice with lymphoma showed reduced response to cyclophosphamide when receiving antibacterial drugs with gram-positive spectrum.[54,55] Adverse drug reactions and additional expense for the owner are other elements to consider.

Patients at Risk

In human medicine, antibacterial prophylaxis is indicated in patients most at risk of developing sepsis, such as patients with acute leukemias, those on high-dose chemotherapy, and those in the first cycle of chemotherapy.[56,57] In veterinary medicine, the latter was also demonstrated in dogs, with 48.7% of the dogs that became septic after receiving the drug for the first time and 71.8% that were in the induction phase when they became septic.[58] The presence of concomitant diseases (renal failure, heart conditions, etc.) renders human patients more likely to have septic complication.[59]

Timing for Initiating Antibacterial Prophylaxis

In febrile neutropenia cases, treatment with empirical antibiotics is recommended by both veterinary and human texts.[45] In patients that are not septic, starting prophylaxis at the time of chemotherapy protocol initiation is more common in human studies while administration of prophylaxis is more common on documentation of a neutropenia in veterinary patients.[45] Neutropenia is far more likely to occur in human chemotherapy protocols warranting the administration of prophylaxis in anticipation.[45]

The decision to give antibacterial and/or antifungal prophylaxis implies to determine what significant neutropenia is. For most chemotherapy drugs, the neutrophil nadir is at 5 to 7 days postadministration.[45] Therefore, complete blood count (CBC) is performed 1 week postchemotherapy. Heteropenia happens most commonly at approximately 1 week after chemotherapy in avian species as well and warrant weekly monitoring of blood cell counts.[60] According to the American Society of Clinical Oncology, antibacterial and antifungal prophylaxis are only recommended for patients expected to have an absolute neutrophil count (ANC) count of 0.1×10^9/L for >7 days, unless other factors increase risks for complications.[61] The Veterinary Cooperative Oncology Group provides a grading system based on the levels of neutropenia following chemotherapy administration in dogs and cats (Table 7.4).[62] This classification has been used to characterize heteropenia in birds.[63] According to this classification, veterinary patients with an ANC of below 0.5×10^9/L suffer from severe neutropenia. A grade 3 neutropenia ($<1 \times 10^9$/L) is generally considered clinically significant, especially if there is likely to be a decline in neutrophil numbers in the next 24 to 48 hours.[24]

Most veterinary texts therefore recommend antimicrobial prophylaxis in the asymptomatic patient whenever an ANC of ≤ 0.5 to 1.0×10^9/L is present or anticipated.[24,43] Bisson and colleagues recommend using an ANC cutoff 0.75×10^9/L to state prophylactic antimicrobial use is indicated.[45] Use should be considered if an ANC is 0.75 to 1.0×10^9/L with one or more risk factors (hematological malignancies, concomitant disease) and antimicrobial prophylaxis should not be used with an ANC $>1 \times 10^9$/L or with an ANC $>0.75 \times 10^9$/L with no risk factors.[45] These guidelines can be used to assist avian veterinarians in their decision process until research can provide a clearer answer on their application in birds. Routine prophylactic therapy during chemotherapy is not recommended if the owner can closely observe the animal for signs of illness and if the anticipated neutropenia is of short duration.[24] Chemotherapy has been performed successfully in avian patients without prophylactic use of antibiotics.[64,65] Among chemotherapeutic drugs, cyclophosphamide is known to cause significant heteropenia in Galliformes under experimental conditions.[66,67]

Duration of Administration

Most veterinary references advise a 3- to 7-day course of antimicrobials on documentation of neutropenia, although this recommendation is not supported by peer-reviewed literature.[43] If no infection is documented, Bisson and colleagues favor the administration of prophylactic antimicrobials until the ANC has increased back to the aforementioned original

TABLE 7.4

Grading Based on the Levels of Neutropenia Following Chemotherapy or Following Biological Antineoplastic Therapy in Dogs and Cats[62]

Grading	Absolute Neutrophil Count	Clinical Significance
1	1500/μL to lower limit of normal	Mild; observation; intervention not indicated
2	1000–1499/μL	Moderate; outpatient or noninvasive intervention indicated
3	500–999/μL	Severe or medically significant; hospitalization or prolongation of hospitalization indicated
4	<500/μL	Life-threatening; urgent intervention indicated

value used to initiate the therapy (0.75×10^9/L).[45] To monitor the ANC, measurement of CBC 3 days after starting antimicrobials should be performed. This approach appears to be most appropriate since there is no evidence that stopping antibiotic treatment early encourages antibiotic resistance, while taking antibiotics for a longer period than necessary increases the risk of resistance while contributing to antimicrobial overuse.[68]

Choice of Antibacterial Drugs

In humans and small mammals, prophylactic therapy is directed at the intestinal flora to reduce aerobic gram-negative organisms most often responsible for severe infections.[24,31] This principle probably applies to psittacine birds as well since their normal gastrointestinal flora is composed predominately of gram-positive bacteria and pathogenic bacteria are usually gram-negative.[1] The majority of infections occurring in cancer chemotherapy patients results from bacterial translocation from the patient's own gastrointestinal tract.[31,45] Prophylaxis should not be directed toward anaerobic bacterial population since this group contributes to prevent fungal overgrowth and colonization by exogenous organisms.

Extensive and unnecessary antibacterial coverage should be avoided. In human oncology, use of a single antibacterial is recommended unless there is a patient-specific indication.[59] In human medicine, the lack of adequate coverage for gram-positive bacteria when using quinolones has been investigated and showed that while bacteremia episodes were decreased, there was a significant increase in side effects in the patients receiving an additional drug compared to quinolones alone.[57] The most frequently used antibacterial for prophylaxis is levofloxacin, a second-generation fluoroquinolone, because they have minimal side effects, high concentration in feces, and little activity against anaerobic bacteria.[57] TMP-Sulfa (trimethoprim/sulfamethoxazole) have similar broad spectrum and spare anaerobic gastrointestinal flora, but they have been associated with more adverse effects than quinolones in humans.[57]

In small animal oncology, veterinary texts advise oral antibacterials similar to those used in humans such as enrofloxacin and TMP-Sulfa.[24,43] However, unlike TMP-sulfa, fluoroquinolones are listed by the World Health Organization as critically important for human medicine.[69] Therefore, prophylactic use of fluoroquinolones should be highly discouraged and veterinary clinicians have a key role to play in implementing this recommendation.

CHEMOTHERAPY PROPHYLAXIS IN AVIAN MEDICINE

Case reports describing the use of chemotherapy in different avian species have been described in the literature.[63–65,70–82] Among these, some describe the prophylactic use of antibiotics,[70,73,75,76,78,79] while others mention the use of antibiotics in an unspecified manner.[81] Table 7.5 provides a summary of cases for which antibiotic treatments were given prophylactically in association with chemotherapy.

Looking at the timing for prophylaxis administration, contrary to what is typically done in veterinary medicine, that is, to start antibiotic prophylaxis when neutropenia is documented, the administration of prophylaxis in birds is more in line with what is done in human medicine, that is, starting prophylaxis at the time of chemotherapy protocol initiation. The classification provided by the Veterinary Cooperative Oncology Group was not used and antibacterial prophylaxis was administered while absolute heterophil count (AHC) was within or superior to the reference interval for the affected bird in many cases.[73,74,78,80] When a clinically significant decrease in the AHC was identified, follow-up hematology was not performed to consider discontinuation of antibiotics.

The duration of administration of antibacterials was much longer in some cases than the typical a 3- to 7-day course of antibacterial drugs cited in small animal veterinary references when neutropenia is confirmed. In some birds, prophylaxis was started several days prior to chemotherapy,[78,79] and sometimes pursued weeks after chemotherapy is completed.[70]

Monotherapy with a fluoroquinolone or penicillin coupled with beta-lactamase inhibitors was mostly used. While monotherapy is in accordance with current human and veterinary recommendations for antibiotic prophylaxis in chemotherapy patients, the selection of antibiotics of very high importance in human medicine should be abandoned unless a culture and antibiotic susceptibility test supports its use with no other options. Further, penicillins are not ideal choices because they possess activity against anaerobic bacteria.[24] TMP-Sulfa is a commonly used antibiotic to treat bacterial gastrointestinal diseases in birds and should be considered to follow small animal recommendations.

Antifungal prophylaxis was used along with chemotherapy in some avian species known to be susceptible to aspergillosis.[70,76,78] While routine antifungal prophylaxis is not recommended in veterinary medicine,[24] this recommendation may not be appropriate in some avian species and merits further investigations. Along these lines, the use of antimicrobials may be considered in birds receiving corticosteroids. The hypothalamic-pituitary-adrenal system of pigeons was reported to react to exogenous glucocorticoids by early delayed feedback and to be more sensitive to suppression by glucocorticoids than that of mammals.[83] More recently, the safety or side effects of long-term oral steroid administration (prednisolone 1 mg/kg PO q24h for 29 days) were investigated in adult unknown sex Carneau pigeons *(Columba livia)*.[84] There was no evidence of infectious disease on gross or histologic postmortem examination. Overall, no adverse clinical, clinicopathologic, or histopathologic changes were noted in the treated birds compared to the control birds in this study. Along the same lines, a study in ring doves *(Streptopelia risoria)* suggested the presence of a melatonin-corticosterone coupling with the possibility that melatonin released in situations of stress counteracts the adverse effects of glucocorticoids on the organism.[85] Clinical acumen should be used in managing birds receiving corticosteroids in light of the aforementioned information.

The information presented here shows that prophylactic antibiotic administration to birds undergoing chemotherapy can be optimized. Current recommendations in veterinary and human medicine can be adapted to birds while awaiting research to provide answers as to their application and associated results.

TABLE 7.5

Antibacterial Prophylaxis in Avian Chemotherapy Patient

Species	Neoplasm	Chemotherapy	CBC	AHC	Prophylaxis
Mallard duck *(Anas platyrhynchos)*[70]	Sertoli cell tumor	◆ Carboplatin 15 mg/kg diluted in 25 ml 5% dextrose, q4–5 weeks for 4 doses	◆ 2 weeks after each carboplatin dose	◆ After first dose: 1.28 × 10^9/L ◆ After second dose: 0.84 × 10^9/L ◆ After third dose: 0.72 × 10^9/L	◆ Amoxicillin-clavulanic acid 125 mg/kg q12h initiated with chemotherapy and continued for 5 months postchemotherapy
Double yellow-headed Amazon parrot *(Amazona ochrocephala oratrix)*[74]	T-cell chronic lymphocytic leukemia	◆ Chlorambucil 2 mg/kg PO twice weekly for 40 days	◆ Every 1 week	◆ Remained within reference intervals (3.3–8.8 × 10^9/L)	◆ Amoxicillin-clavulanic acid 125 mg/kg q12h initiated with chemotherapy; duration not specified
Green-winged macaw *(Ara chloropterus)*[79]	Chronic lymphocytic leukemia	◆ Chlorambucil 1 mg/kg PO twice weekly with prednisone 1 mg/kg PO q24h (chlorambucil stopped at 6 weeks due to thrombocytopenia) Then 6 weeks later: ◆ Cyclophosphamide 5 mg/kg PO for 4 days q21d, then weekly for 29 weeks	◆ 1, 3, and 6 weeks post initiation of chemotherapy ◆ 7 and 16 days postcessation chlorambucil ◆ Every week after starting cyclophosphamide	◆ AHC above reference interval at 1 (45 × 10^9/L) and 3 (16.5 × 10^9/L) postinitiation of chlorambucil ◆ AHC not presented thereafter	◆ Enrofloxacin 10 mg/kg PO q12h began 5 weeks prior to chemotherapy; duration not specified
African penguin *(Spheniscus demersus)*[78]	Squamous cell carcinoma	◆ Intralesional cisplatin (0.2 mg/kg then 0.9 mg/kg) q7d for 3 doses	◆ Prior to second and third cisplatin injection	◆ AHC within reference intervals	◆ Prophylactic antibiotic (not specified) administered for 28 days prior to chemotherapy ◆ Enrofloxacin 10 mg/kg IM at first injection of cisplatin
Blue-and-gold macaw *(Ara ararauna)*[73]	Fibrosarcoma	◆ Radiation (40 Gy delivered over 22 days q48h) ◆ Intralesional cisplatin 0.3 mg/cm^3 of tissue	◆ Every week during treatment	◆ AHC above or within reference intervals	◆ Enrofloxacin 15 mg/kg PO q12h; duration not specified
Kori bustard *(Ardeotis kori)*[75]	Myxosarcoma	◆ Carboplatin (4.6 mg) impregnated, calcium-based matrix beads (12 beads) surgically placed locally Then 1 month later: ◆ Cyclophosphamide 10 mg/m^2 q24h and meloxicam 0.1 mg/kg q24h for 17 weeks	◆ At beads placement ◆ 1 month post beads placement	◆ AHC (1.7 × 10^9/L) at beads placement ◆ AHC within reference intervals 1 month post–beads placement	◆ Cefazolin 50 mg/kg IV at beads placement ◆ 30-day course of enrofloxacin 10 mg/kg PO q24h started with cyclophosphamide and meloxicam

AHC, Absolute heterophil count; *CBC*, complete blood count; *IM*, intramuscular; *IV*, intravenous; *PO*, per os.

CONCLUSION

Antibacterial drugs are a key treatment component for many bacterial diseases in veterinary and human medicine. Avian veterinarians need to be prudent, responsible, rational, and judicious in their antibacterial drug selection and use. They also need to educate owners to recruit them into partnership in this endeavor. Antibiotic resistance is affecting patient care. It is critical to implement ways to improve antibacterial uses in our daily practice to reduce antibiotic resistance selection and preserve the efficacy of antibacterial agents. Part of antimicrobial stewardship is timely therapy evaluation done within a couple of days, which can stimulate the owners of patients to therapy adherence and minimize the length of antibacterial treatment courses.

CHAPTER 8

Antifungal Drugs

Gunther Antonissen • An Martel • Dominik Fischer

Visit eBooks.Health.Elsevier.com for a complete set of references.

An antifungal drug is a pharmaceutical fungicide or fungistatic used to treat and prevent mycosis such as aspergillosis, macrorhabdosis, and candidiasis. The use of antifungals in birds is characterized by interspecies and interindividual variability in the pharmacokinetics, affecting drug efficacy and toxicity. Rational usage of antifungal drugs in avian species is much more than only selecting an appropriate dosage. Different factors such as the chemical structure, resistance, species-specific toxicity, antifungal drug formulation, and optimal route and frequency of administration should be considered.

MECHANISM OF ACTION

Three major groups of antifungals involved in the inhibition of synthesis or direct interaction with ergosterol are frequently used in avian practice: 1) polyene macrolide antibioitcs or polyenes; 2) azole derivatives; and 3) allylamines (Figure 8.1).

Polyene macrolide antibiotics or polyenes, including, amphotericin B, nystatin, and pimaricin (or natamycin), act primarily by binding to ergosterol, a sterol that resides on the cell membranes of fungi and acts to maintain membrane integrity. Following binding to ergosterole polyenes form pores in the plasma membrane, causing leakage of sodium, potassium, and hydrogen ions, which eventually leads to cell death (Figure 8.1). Polyenes have a broad antifungal spectrum, including a variety of yeasts (e.g., *Macrorhabdus ornithogaster*, *Candida* spp., *Rhodotorula* spp.) and molds (e.g., *Aspergillus* spp., *Mucor* spp., *Penicillium* spp.), and can be fungistatic or fungicidal, depending on the dosage.[1–4]

Azoles derivatives or azoles inhibit the enzyme cytochrome P450–dependent 14-α-sterol demethylase, a key enzyme in ergosterol biosynthesis (Figure 8.1). Consequently, exposed fungi become depleted of ergosterol and accumulate 14-α-methylated sterols. This causes disruption of membrane structure and function, thereby inhibiting fungal growth. Azoles are classified into two groups: the imidazoles which have two nitrogens in the azole ring (e.g., clotrimazole, miconazole, enilconazole, and ketoconazole), and triazoles which have three nitrogens in the azole ring (e.g., itraconazole, fluconazole, voriconazole, isavuconazole, and posaconazole).[5–8] The lower host toxicity of triazoles compared to imidazoles has correlated with their lower affinity for avian cytochrome P450 enzymes and their lesser propensity to inhibit avian sterol synthesis. Most azole antifungal agents have fungistatic and broad-spectrum activity against both yeasts and filamentous fungi. At doses used in birds, voriconazole can be fungicidal, but several days are needed to reach steady-state concentrations.[1–4]

Allylamines, such as terbinafine, inhibit the enzyme squalene epoxidase, which converts squalene to ergosterol (Figure 8.1). Inhibition of this enzyme causes squalene, a substance toxic to fungal cells, to accumulate intracellularly and leads to rapid cell death. Allylamines have fungicidal activity against dermatophytes, molds, and certain dimorphic fungi and fungistatic activity against yeasts.[1–4]

In addition to the antimicrobial agents affecting fungal sterols, inhibitors of the glucan synthesis, such as echinocandins (e.g., caspofungin, micafungin, and anidulafungin) also affect the integrity of the fungal cell wall (Figure 8.1). Echinocandins act as specific, noncompetitive inhibitors of the fungal β-(1,3)-glucan synthase complex, an essential component of the cell wall. Inhibition of the β-(1,3)-glucan synthesis leads to cytological and ultrastructural changes in fungi, osmotic instability, and cell death. Echinocandins exhibit fungicidal activities against *Candida* spp. but are fungistatic for *Aspergillus* spp.[4]

Finally, fluoropyrimidines such as 5-fluorocytosine have with inhibitory activity against many yeasts, and fungi, including *Candida* spp., *Cryptococcus neoformans*, and against *Aspergillus* spp. Following uptake by the susceptible fungal cells, 5-fluorocytosine is converted into 5-fluorouracil, which is further converted to metabolites that inhibit fungal RNA and DNA synthesis (Figure 8.1).[4]

Toxicity

The development of safe new antifungal therapies has been constrained by fungal organisms being eukaryotic pathogens that colonize a eukaryotic host, and the narrow range of physiologic differences between the host and the pathogen may represent hurdles to developing safe and wide-ranging antifungal agents. Furthermore, antifungal therapy is typically prolonged and can last several months.

In birds, drug distribution patterns differ between avian species due to anatomic and physiologic differences such as differences in crop and/or gastric pH between avian groups. This may result in species differences in antifungal drug toxicity.

Parenteral amphotericin B administration can induce a dose-dependent nephrotoxicity in mammals, as a result of renal vasoconstriction, reduced glomerular filtration rate, and direct toxic effect on the membranes of the renal tubule cells. Renal

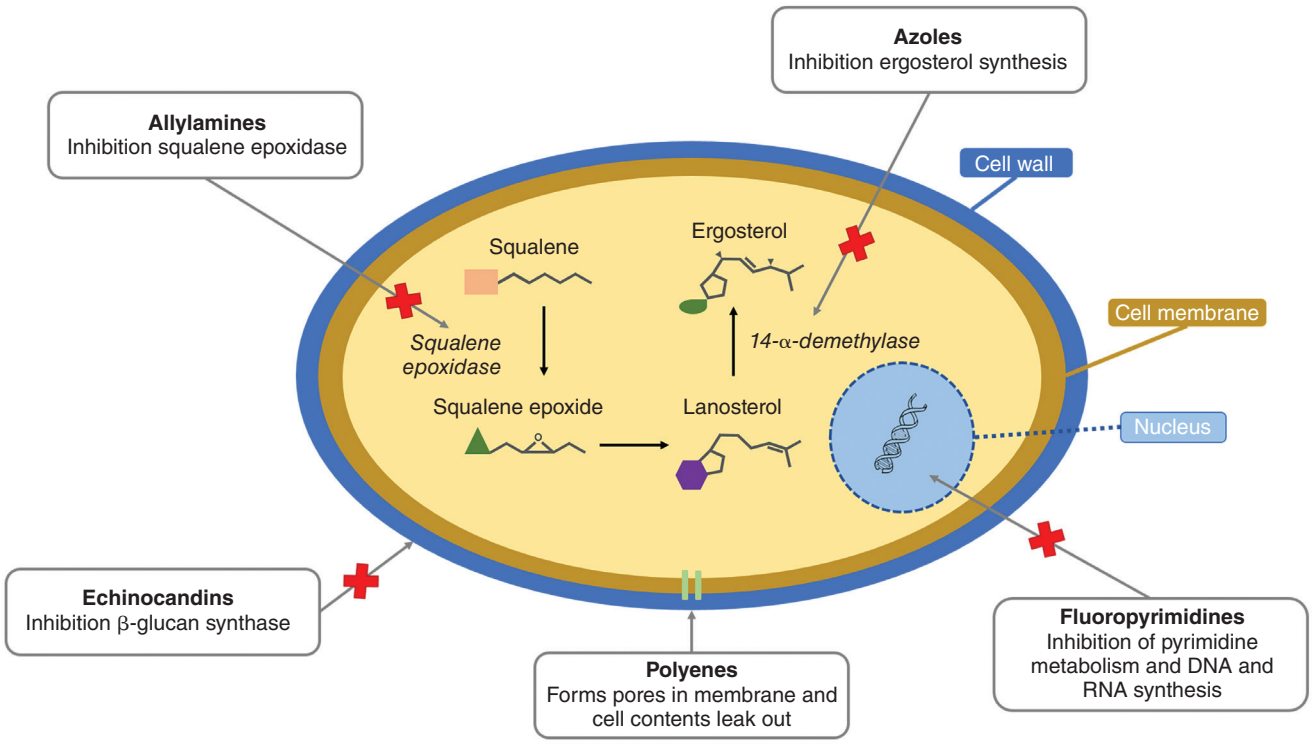

FIGURE 8.1 Mechanisms of action of the major classes of antifungal drugs.

toxicity is related to binding of the drug to the sterol-rich cell membranes in kidney tubules. In contrast to mammals, nephrotoxicity is lessened in birds due to their faster elimination rate. However, due to aforementioned risks, systemic use of amphotericin B deoxycholate should be limited and reserved for severe cases of aspergillosis. Lipid formulations of amphotericin B should be considered in settings in which azoles are contraindicated (e.g., in case of cardiac insufficiency) or not tolerated. Nystatin is poorly absorbed from the gastrointestinal tract, hence having limited-to-no side effects. However, when used parenterally, nystatin may cause high systemic toxicity and thus parenteral administration should be avoided. Therefore, nystatin is used primarily orally or topically to treat *Candida* infections of mucosa, skin, and the gastrointestinal tract. However, use of nystatin should be avoided if the gastrointestinal epithelium is not intact as systemic absorption might occur.[1,4]

The most commonly observed side effects associated with azole administration in avian patients are gastrointestinal signs, such as anorexia and vomiting, and liver dysfunction. Toxicity of azoles is associated with the drug-specific binding to the fungal cytochrome P450 enzyme instead of the vertebrate analog. In general, azoles are well tolerated in birds; however, remarkable species differences are observed. The apparent sensitivity to azoles experienced by different bird species might be explained by differences in the drug's pharmacokinetics. Although undocumented in avian species, genotypic polymorphism of cytochrome P450 isoenzyme CYP2C19 has been linked in humans with a variable sensitivity to voriconazole toxicity.[1,9,10] Currently, pharmacokinetic studies investigating the higher sensitivity to itraconazole toxicity of grey parrots *(Psittacus erithacus)* and Timneh parrots *(Psittacus timneh)* are still lacking. Grey parrots appear to be very sensitive to itraconazole and may exhibit adverse reactions, such as distinct anorexia and depression, at normal dosage levels. Anecdotally, similar adverse reactions have been seen in Senegal parrots *(Poicephalus senegalus)* and birds with impaired liver function. Anecdotally, drowsiness and apathy have also been reported in African fish eagles *(Haliaeetus vocifer)* following administration of 10 mg/kg itraconazole, but scientific evidence is lacking to confirm these observations. Nevertheless, it is advised to be cautious when using itraconazole in (potentially) sensitive species, ensuring not to exceed a dose of 5 mg/kg body weight (BW) in grey parrots, and carefully monitor for occurrence of adverse effects. If these are observed, treatment should be stopped immediately. However, it might be advisable to avoid use itraconazole in these species unless no alternative treatment is available.[1,2]

A prolonged elimination half-life of voriconazole has been observed in pigeons *(Columba livia domestica)* and African penguins *(Spheniscus demersus)*, which might potentially induce drug accumulation with extended dosing and toxicity.[11–13] Following oral administration of voriconazole (10 and 20 mg/kg BW q12h) to pigeons, Beernaert et al. observed hepatotoxicity, demonstrated by hepatomegaly and military hepatic necrosis and, on histology, vacuolization up to apoptosis of hepatocytes and heterophilic and lymphocytic infiltration.[11] Similarly, toxicity was observed in multiple penguin species after administering voriconazole (6.1–22.2 mg/kg BW q12-24h), resulting in clinical signs such as anorexia, lethargy, weakness, change in mentation, ataxia, paresis, apparent vision changes, seizure-like activity, and generalized seizures.[13] However, in most species, including grey parrots, voriconazole is generally characterized by a good tolerability when orally administered. Observed adverse effects during

treatment are slight and rare, and usually present as depression, hepatopathy, and polyuria. Similarly, limited adverse effects have been reported for fluconazole and posaconazole.

Of the imidazoles, enilconazole and clotrimazole rarely cause side effects when used topically. However, in humans it has been reported that clotrimazole induces edema, erythema, vesication, desquamation, pruritus, and urticarial after cutaneous application. Prudent use of ketoconazole is recommended since adverse liver, renal, gastrointestinal, and circulatory side effects have been reported following parenteral administration.[2] Furthermore, caution is advised when azoles are coadministered with drugs being potent cytochrome P450 inhibitors, such as midazolam, enrofloxacin, and clindamycin.[2,13]

The use of terbinafine is generally associated with limited side effects, such as mild gastrointestinal symptoms and hepatobiliary dysfunction. In red-tailed hawks *(Buteo jamaicensis)*, oral administration of a high-dose terbinafine (120 mg/kg BW) induced regurgitation.[14] Anecdotally, mild gastrointestinal toxicity and hepatobiliary dysfunction were observed in some psittacine species such as a grey parrot, a blue-fronted Amazon parrot *(Amazona aestiva)*, and a Senegal parrot *(Poicephalus senegalus)* following long-term administration of terbinafine (10–15 mg/kg BW q12h) alone or in combination with itraconazole or voriconazole (van Zeeland, personal communication). Likewise, regurgitation was anecdotally reported in macaws (*Ara* spp.) treated solely with either voriconazole or itraconazole (van Zeeland, personal communication).

No clinical studies are available describing the usage of echinocandins in avian patients; however, limited toxicity might be observed in humans, such as cardiovascular toxicity.

DRUG FORMULATION

Stability, solubility, absorption, and severe toxicity are among the major challenges of antifungal drugs compromising optimal treatment. Most of the polyene, allylamine, azole, and echinocandin derivatives are very slightly soluble in water and sparingly in organic solvents. Different formulations and drug delivery strategies have been developed to improve the antifungal pharmacokinetics with targeted delivery, rapidly followed by sustained release and prolonged retention of high drug concentration localized at the infection site.[1] To reduce the intrinsic toxicity and to enhance efficacy of amphotericin B, different lipid formulations have been developed, that is, amphotericin B lipid complex, liposomal amphotericin B, and amphotericin B colloidal dispersion. In budgerigars *(Melopsittacus undulatus)* and cockatiels, *(Nymphicus hollandicus)*, more than half of birds stopped shedding *M. ornithogaster* following treatment with amphotericin B colloidal dispersion via drinking water at 0.1 mg/mL for 28 days.[15] Nevertheless, in-depth information on the pharmacokinetics, pharmacodynamics, and clinical use of amphotericin B lipid formulations in birds is lacking. Based on *in vitro* and *in vivo* studies in rodents, dogs, and humans, lipid formulations of amphotericin B are suggested to generally have a slower onset of action since they require dissociation of free amphotericin from the lipid vehicle. The incorporation of amphotericin B into a lipid vesicle will enhance drug uptake by the liver and spleen and cause accumulation of the drug by the mononuclear phagocyte system at sites of capillary damage and inflammation.[1,4] Topical treatment of a deep infection with *Aspergillus fumigatus* of the pectoral muscle in a goliath heron *(Ardea goliath)* with liposomal amphotericin B (1.35 mg/kg q24h) (mixed with sterile, water-soluble, gelatin lubricant for more than 1 month) led to the complete resolution of the wound infection. No signs of nephrotoxicity were observed in this bird based on clinical examination and plasma uric acid levels.[16] Following intratracheal aerosol administration of a single dose (3 mg/kg BW) of liposomal amphotericin B to healthy mallard ducks *(Anas platyrhynchos)*, drug concentrations in pulmonary parenchyma exceeded the targeted minimal inhibitory concentration (MIC) for avian isolates of *Aspergillus* spp. of 1 μg/mL, while systemic levels of amphotericin B in plasma and kidney were low.[17] In human medicine, differences in pharmacokinetics and toxicity between conventional amphotericin B deoxycholate and lipid formulations are reflected in the recommended dosages: amphotericin B deoxycholate 0.25 to 1.5 mg/kg q24h, amphotericin B lipid complex 5 mg/kg BW q24h, liposomal amphotericin B 1 to 5 mg/kg BW q24h, and amphotericin B colloidal dispersion 3 to 5 mg/kg q24h.[18] Comparatively, the conventional amphotericin B deoxycholate is administered at a dose of 1 to 1.5 mg/kg BW q8h to birds.[1,19] Nanotechnology holds great promise to overcome the limitations of antifungal drug solubility and toxicity. Nanoparticles are characterized by their small particle size ranging from 1 to 1,000 nm and can be classified into phospholipid vesicles (e.g., liposomes), nonphospholipid vesicles, polymeric nanoparticles, polymeric micelles, solid lipid nanoparticles, nanostructured lipid carriers, nanoemulsions, and dendrimers. In falcons (*Falco* spp.), it was demonstrated that itraconazole-loaded nanostructured lipid carriers penetrate deeply in the lungs and air sacs, which is a prerequisite for pulmonary treatment of aspergillosis.[1,20] Innovative antifungal drug formulations are mostly only available as human-approved products. Because of the high cost of this type of product, attempts to use more cost-effective formulations in veterinary medicine, such as compounded formulations, have been attempted. However, these formulations are mostly characterized by a low systemic absorption; hence, their usage is not recommended.

DRUG RESISTANCE

Antifungal susceptibility testing may be helpful for monitoring therapy in avian species. Standardized in vitro antifungal susceptibility testing methods for yeast and molds have been developed by the Clinical and Laboratory Standards Institute (CLSI) and the European Committee on Antimicrobial Susceptibility Testing (EUCAST), whereby the MIC is considered as the lowest concentration giving rise to an inhibition of growth of 50% or more and referenced to a clinical breakpoint. Additionally, the minimal fungicidal concentration (MFC) is defined as the lowest concentration showing approximately 99.0% to 99.5% of killing activity. Acquired resistance of *A. fumigatus* strains, isolated from companion and wild birds, is reported for amphotericin B, itraconazole, voriconazole, and caspofungin.[21,22] Some isolates have been described with resistance to more than one antifungal drug (amphotericin + itraconazole, itraconazole + voriconazole, and caspofungin + amphotericin).[21,22] Although historically

used, significant resistance of *Candida albicans* to itraconazole has been reported.[23] Finally, also evidence of nystatin and of amphotericin B resistance in *M. ornithogaster* have been reported.[24]

Combined Antifungal Therapy

Treatment of fungal diseases is often complicated by poor response and high toxicity; therefore, double-drug combinations might be promising to enhance efficacy. Unfortunately, data on the effect of combining different types of antifungals in avian patients are lacking; however, data from human medicine demonstrate some interesting findings. *In vitro* studies have shown that combined use of antifungals can broaden the coverage, increase the fungicidal effect, and decrease the risk of development of resistance. Furthermore, combined agents can have synergistic activity with decreased toxicity. Nonetheless, different concentrations of each drug combination can be associated with results that range from antagonism to synergy, and host factors can greatly affect the clinical outcome. Synergy might occur by simultaneous inhibition of different fungal cell targets, for example, amphotericin B and echinocandins.[25] Similarly, a synergistic interaction between terbinafine and itraconazole has been observed *in vitro* for *A. fumigatus*, resulting in a reduced MIC and MFC. The synergistic effect of the combination terbinafine-itraconazole was even observed for an itraconazole-resistant *A. fumigatus* strain.[26] Amphotericin B and azoles damage the cell membrane, which might increase the uptake of other agents like 5-fluorocytosine. Since amphotericin B and azoles target the same site, simultaneous administration might result in an antagonistic interaction, where azoles prevent the synthesis of ergosterol, and render amphotericin B, which binds the ergosterol in the cell membrane, inactive. In avian medicine, the use of certain aerosolized disinfectants such as F10 (a blend of quaternary ammonium and biguanide compounds) (Health and Hygiene [Pty] Ltd, Johannesburg, South Africa) and lufenuron has been reported to enhance efficacy of inhalation therapy with azoles (e.g., enilconazole), but scientific studies on the safety and efficacy of these substances are lacking.[27] Anecdotally, the combination of nystatin and fluconazole increases drug efficiency and decreases the required volume to be administered for successful treatment of severe cases of gastrointestinal candidiasis compared to separate use of the substances. Likewise, the alternate combination of amphotericin B and nystatin (distributed across three to four time points) has been used successfully in birds with macrorhabdosis (van Zeeland, personal communication). Different routes of administration can also be combined, such as systemic triazole therapy (itraconazole or posaconazole) combined with inhalation therapy or topical intranasal clotrimazole or enilconazole.[25]

PRACTICAL GUIDELINES ON ADMINISTRATION AND TREATMENT

Drug administration and choice of drugs and additional measures taken to treat fungal infections depend mainly on the course and the severity of the disease. Depending on the drug formulation, antimycotic drugs need to be given regularly, i.e., once (SID, q24h) or twice (BID, q12h) daily, to achieve a systemic effect. In most cases, treatment needs to be continued for at least 21 to 28 days in milder cases, up to 3 to 4 months or even longer in severe cases, and a combination of several approaches is usually required. Antimycotic drugs may be administered orally, via nebulization, intratracheally, intramuscularly, subcutaneously, intravenously, and topically onto fungal lesions, for example, inside the air sac during endoscopic examination (Figure 8.2).[2] Consultation of pharmacokinetic studies is recommendable prior to making decisions on the use of particular antifungal agents and formulation of the drug in the individual avian patient.

Oral Therapy

Oral treatment with antifungal drugs is the most common route of drug delivery for systemic treatment of aspergillosis or microsporidia infections (e.g., *Encephalitozoon* spp. or *Enterocytozoon* spp.) as well as for the treatment of gastrointestinal yeast such as *Candida* spp. (most common *C. albicans* but also *C. parapsilosis*, *C. rugosa*, *C. krusei*, and *C. tropicalis*) and *M. ornithogaster*. Gastrointestinal yeast infections are usually treated with formulations that act locally and are not absorbed from the gastrointestinal tract.[28] For the treatment in passerines and psittacines, especially when dealing with treatment of a multi-bird aviary, powdered formulations of nystatin from small mammal medicine (e.g., RodiCare Nystatin, Alfavet, Neumünster, Germany) can be used and sprinkled over the food. Additionally, 28-day treatment regimens with amphotericin B via the drinkwater (alone or combined with individual oral treatment) have been described using a powder for the preparation of an infusion solution (amphotericin B 50 mg Pulver, Bristol-Myers Squibb GmbH & Co, KGaA, Monheim am Rhein, Germany) mixed at 0.1 mg/mL.[15] For the treatment of aspergillosis, oral formulations of azoles (mainly itraconazole and voriconazole) are most commonly used, which are absorbed from the gastrointestinal tract following oral administration. Oral suspensions are preferably dosed and administered using syringes. Because suspensions are not available for all antimycotic drugs, as an alternative, tablets can be dissolved in sterile water; however, demixing of these self-made drug solutions and unequal distribution of active ingredients must be considered. Microsporidia such as *Encephalitozoon* spp. (e.g., *E. hellem* or *E. cuniculi*) or *Enterocytozoon bieneusi*, which were initially regarded as protozoal parasites but are now recognized as fungi, require a different approach. These microsporidial organisms can be associated with renal, hepatic (e.g., granulomatous hepatitis), intestinal, and ocular infection, and are commonly treated with albendazole, sometimes combined with fumagillin, for a minimum duration of 4 weeks.[29] Medical training of the avian patient helps to facilitate (long-term) oral medication (see Chapter 46). When birds are trained to take medicine voluntarily from spoons or syringes, this is an immense advantage for targeted and stress-free treatment. To increase acceptance, drugs (suspensions, solutions, beats, or tablets) may be hidden in food (e.g., in mice for raptors), soaked up in treats or mixed with preferred porridge, meshed fruits, yogurt, or juice. Soaking of millets and grain feed with antifungal amphotericin B suspensions can provide a suitable option for treating avian gastric yeast and candidiasis. However, it should be kept in mind that any mixture of drugs carries a risk for altered resorption due to interaction of the drug and the carrier substance. Nevertheless, administration with food is usually more promising than mixing of drug solutions in the

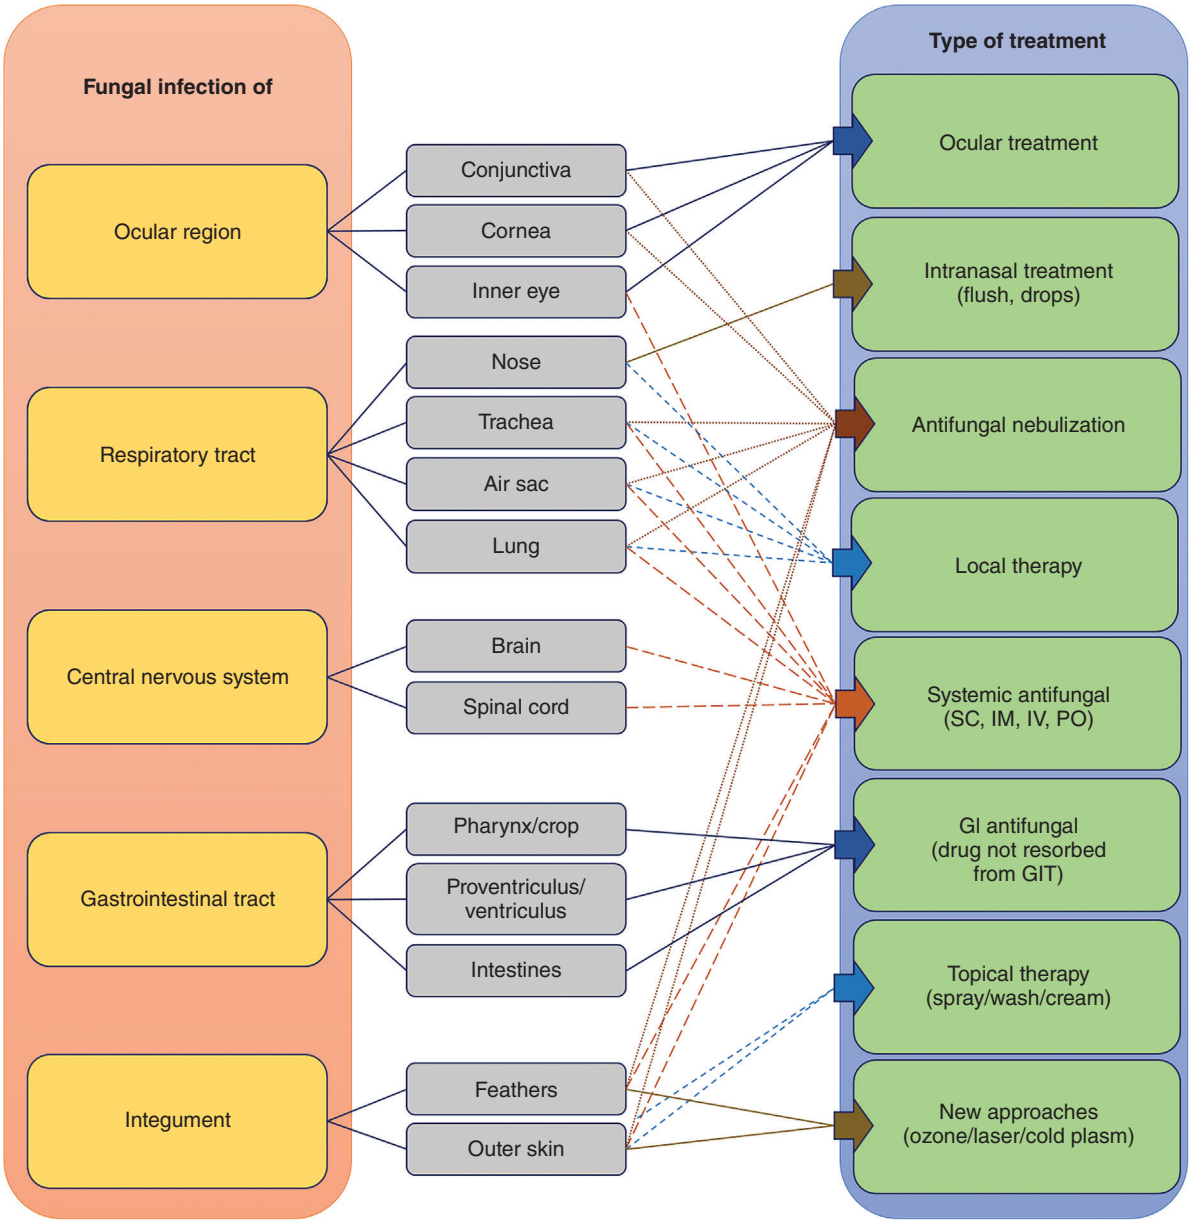

FIGURE 8.2 Antifungal treatment decision tree. *GI*, gastrointestinal; *GIT*, gastrointestinal tract; *IM*, intramuscular; *PO*, oral; *SC*, subcutaneous.

drinking water, unless specific formulations for the preparation of an infusion solution are used.[15] In other cases, demixing of drug solution may occur, as well as unequal or insufficient water uptake by individual birds, especially in case of xerophilic species that are adapted to deserts and hot climates such as budgerigars. Nevertheless, sodium benzoate at 500 to 1000 mg/L of drinking water has been suggested to successfully treat candidiasis in budgerigars.[30] Concerns have been raised with toxicity when using these high dosages, particularly in parent-fed nestlings or species that have higher fluid requirements than budgerigars. When birds do not ingest drugs with a small amount of food voluntarily and are not trained to drug administration, manual restraint is usually necessary to facilitate dropwise drug instillation, administration of tablets, or gavage/tube feeding. Independent from potential interactions with the food contents, bioavailability after oral administration may vary between avian species, dependent on the pH within the gastrointestinal tract, which needs to be considered by the veterinarian.

Inhalation Therapy

Inhalation therapy is preferably combined with oral medication, offering a valuable and 'stress-free' addition to the therapeutic regimen in the absence of major side effects.[31,32] Nebulization of antimycotic drugs (e.g., amphotericin B, terbinafine, or triazoles such as enilconazole and clotrimazole) has been regularly reported for the treatment of aspergillosis, despite the lack of antifungal drugs specifically designed or licensed for nebulization in veterinary or human medicine.[2] The antifungal medication is mixed with

saline solution and nebulized using a commercial inhalation device. Aerosol droplets produced should be sufficiently fine and respirable (droplet size smaller than 3–5 μm) to be able to enter parabronchial structures and atria. Ultrasonic nebulizers will generally suffice for hydrophilic substances; however, to accommodate the large lipophilic antifungal molecules, compressor nebulizers will often be required.[1] Fogging using a commercially available "smogger" unit has been used inside aviaries in the Middle East to treat a larger number of individuals at the same time.[27] Birds inhale the aerosolized antifungal agent via the respiratory route, enabling the drug to reach lesions in the upper respiratory tract, air sacs, and lungs; however, the timing of nebulization and the type of drug involved are important factors to consider (see also Chapters 5 and 6). Handling of birds and associated stress can be limited with inhalation therapy. Patients may be placed in specifically designed nebulization chambers or in transport boxes that are sealed off with towels or blankets to ensure concentrated delivery of aerosolized medication for at least 20 to 30 minutes (Figure 8.3).[27] From an occupational safety perspective, nebulization chambers/boxes should be placed in a well-ventilated room where no people are present for the duration of the nebulization process to minimize the human exposure to antifungal substances. It can be advantageous to the patient and overall success of the antifungal treatment if stress is minimized, e.g. by training the patient to voluntarily enter and stay inside the nebulization chambers, or by hooding a raptor and leaving it hooded while inside the nebulization box.

Parenteral Administration

In severe cases of systemic fungal infections, antifungal drugs may be administered parenterally via the subcutaneous, intramuscular, or intravenous route. Likewise, parenteral injections are an alternative administration route to oral medication in patients with vomitus or regurgitation or those with acute courses of aspergillosis or unusual localizations of fungal infections (e.g., in joints, bones, or the spinal cord). As with any oral drug delivery, medical training will facilitate stress-free medication in birds (Figure 8.4). Injectable solutions are available for amphotericin B, fluconazole, voriconazole, and posaconazole, but the therapeutic efficacy of fluconazole against *Aspergillus* spp. appears low.[2] Voriconazole has been used successfully in various species in recent years,[33–39] with relatively few side effects and larger clinical utility compared to amphotericin B. However, a faster onset of therapeutic action has been reported for amphotericin B compared to the triazole drugs. This might explain why this agent is often used for a limited time during the initial phases of aspergillosis treatment. For treatment of (potentially zoonotic) infections with *Cryptococcus neoformans*, which may result in ocular and nasal discharge, sinusitis, respiratory distress, CNS signs, and death (see Chapter 21), systemic therapy using fluconazole combined with amphotericin B or miconazole has been reported.[40–43] If central nervous system involvement is suspected, fluconazole is preferred due to its ability to cross the blood-brain barrier into cerebrospinal fluid.[43] For intravenous therapy, the installation of a peripheral venous catheter in the basilic or the tibiotarsal vein is recommended, as this allows parallel administration of fluids (intravenous drip infusion) and prevents phlebitis resulting from repeated venepuncture. Careful fixation and padding of the peripheral catheter using surgical suture material, appropriate adhesive tape, and bandage material are required in order to prevent inadvertent catheter removal by the patient.

FIGURE 8.4 Medical training facilitates stress-free oral and parenteral antifungal drug administration in trained birds. (*Left:* Courtesy Dr. Elisa Wüst. *Right:* Courtesy Clinic for Birds, Reptiles, Amphibians and Fish, JLU Giessen.)

Topical Treatment

Topical administration of antimycotic drugs directly to the fungal lesion is suggested in addition to nebulization for the treatment of fungal lesions inside the trachea or the syrinx. For this purpose, injectable solutions such as amphotericin B or voriconazole can be administered intratracheally (IT), using a (plastic) catheter that is inserted via the glottis into the trachea in an orthograde manner. Alternatively, if the glottis is not easily accessible (e.g., in small-sized birds), small-sized needles may be used for transtracheal drug delivery after thorough cleaning and disinfection of the injection site. As birds with tracheal aspergillosis usually suffer from inspiratory dyspnea caused by restricted airflow, the installation of an air sac cannula is an important step for emergency treatment of patients (see Chapter 29 and 34), while enabling respiration to be maintained despite of tracheal administration of liquid medicine, or while performing tracheoscopy or tracheal surgery. In some cases of tracheal aspergillosis, tracheal plugs can be removed in toto or in piecemeal fashion using biopsy forceps, cotton swabs, or suction catheters under visual guidance of an endoscope (see Chapter 30). Alternatively, if tracheal lesions are extensive, surgical tracheotomy and debridement may be required (see Chapter 29).

Topical treatment and surgery may be required for the treatment of air sac aspergillomas. Similar to the inratracheal route, injectable solutions may be instilled dropwise on top of lesions using plastic tubes or flexible injection needle instrumentation that are inserted via the incision (during surgical procedures) or working channel (during endoscopic procedures). Prior to instillation of the antifungal medication, initial (endo)surgical debridement of the fungal lesions is recommended. There are several endo surgical procedures described to access the air sacs using a single-, a double-, or a triple-entry technique (see Chapters 29 and 30).[44] Aside from using a biopsy or grasping forceps and/or endoscopic scissors to debulk the lesions, diode lasers have also been used successfully for endoscopic removal of aspergillomas. However, caution is warranted when using this equipment inside the well-ventilated air sacs due to the risk of burning. If thick, caseous encapsulated air sac lesions are too extensive to achieve endoscopic removal, classical surgical intervention via lateral laparotomy approach may be performed (see Chapter 29). Stabilization of the patient and initiation of medical treatment are commonly required, prior to initiating (endo)surgical intervention.

Topical antifungal treatment may be applied to the oropharyngeal mucous membranes in case of candidiasis, to the outer skin and feather follicles in case of fungal dermatitis and/or folliculitis, or to eyes or nose in case of ocular fungal infection, rhinitis, or sinusitis. Samour and Naldo applied miconazole gel to the mucous membranes of falcons to treat clinical candidiasis in the oral cavity and crop.[45] Fungal dermatitis, especially in the axillary and inguinal regions, and associated feather destructive behavior may be caused by more than 20 fungal species including *Aspergillus* spp., *Candida* spp., *Trichophyton* spp. (e.g., *T. gallinae*, *T. rubrum*, *T. simii*, and *T. megnini*), *Malassezia* spp., *Mucor* sp., *Microsporum gallinae*, *Microsporum gypseum*, *Cladosporium* spp., *Helminthosporium* spp., *Paecilomyces* spp., and *Rhodotorula mucilaginosa.* Targeted therapy of these infections includes topical antifungal treatment using nystatin, terbinafine, or azole creams (e.g., clotrimazole or bifonazole) in addition to the application of enilconazole washing solution or chlorhexidine-miconazole shampoo as established for dogs and cats. However, bathing of the entire body in a washing solution might be less advisable because it is usually stressful and may alter feather condition in birds. Thus gentle dapping the affected skin with soaked gauze swabs or lightly spraying the lesions with a spray flask are generally preferred for topical delivery of the drug. Topical spray disinfection using chlorhexidine, iodine, or F10 solution may also be helpful in the treatment of fungal skin lesions. The use of creams and ointments for topical treatment in birds is controversial. While creams can cover the skin lesions and ensure targeted delivery of the antifungal agent they also stick to the feathers, thereby altering their structure and function, and possibly result in feather destructive behavior (see Chapter 32). Especially oily and lipid-based products can mat the plumage and lead to excessive preening; hence, these should be avoided in birds. If using creams, these should be restricted to featherless areas or areas where feathers have been pre-emptively removed. In severe cases of dermatitis, topical treatment should be combined with systemic antifungal therapy (e.g., administration of azoles such as fluconazole) to increase antifungal action. Moreover,

surgical debridement of infected skin, including removal of crusts, excoriated skin, and surgical excision of damaged tissues may be required. The same applies for bumblefoot lesions from which fungal organisms such as *Aspergillus* spp. or *Candida* spp. may be isolated in rare cases, hence requiring topical and systemic antifungal therapy (see Chapter 33). Soft laser therapy and alternative treatment options from human medicine such as cold plasma therapy using atmospheric pressure plasma jet devices (Figure 8.5) or ozone (trioxygen) therapy (Figure 8.6) seem promising for the topical treatment of chronic wounds and fungal infections of the skin and accessible mucous membranes. These therapeutic options might offer an effective fungistatic to fungicide supplement to standard wound management in avian patients in the future, especially facing increasing antifungal drug resistance in recent years.

Ocular fungal infections including diseases of conjunctiva, cornea, and/or anterior eye chamber can be treated using antifungal eye drops. Since these are usually not commercially available, a pharmacist may prepare them on request. Similar formulations may be used for the treatment of fungal rhinitis and sinusitis in addition to inhalation therapy and systemic antifungal medication. However, nasal flushes using amphotericin B (intravenous formulation), enilconazole, or F10 SC solutions (Health and Hygiene, Florida Hills, South Africa) have been reported as beneficial addition to the treatment of fungal rhinitis and sinusitis.[27] In chronic or severe cases, surgical opening and thorough cleaning of the infraorbital sinus is required (see Chapter 29).[22] As some fungi such as *Aspergillus* spp. and *Exophiala (Cladosporium) werneckii* are known to be able to spread from the eye to the brain, ocular mycosis may carry a guarded prognosis.[46]

Supplemental Therapy

In addition to specific antimycotic therapy, elimination of predisposing factors (e.g., stress, suboptimal hygiene, husbandry deficiencies) and supportive treatment are required for effective treatment and prevention of relapses of fungal infections. Supportive treatment consists of supplementation of vitamins (especially vitamin A), support of liver function (e.g., by administration of silymarin/milk thistle), and fluid therapy. In inappetent patients, tube feeding and the addition of antiemetic drugs or antacids may be advised. Oral administration of thyme tea or sucralfate (25 mg/kg PO q8h) have been reported as supportive therapy in budgerigars suffering from macrorhabdosis. In case of respiratory fungal disease, oxygen supplementation will generally benefit the patient. Likewise, mucolytic drugs or bronchodilators might be beneficial additions to the treatment of respiratory fungal infections (see Chapter 28). As in most cases of fungal disease a bacterial coinfection cannot be ruled out, antibiotic therapy might be initiated parallel to initiating antifungal treatment. To manage disruption to the intestinal flora following antibiotic use, administration of probiotics may be considered. However, it should be taken into consideration that any of the aforementioned treatments, especially long-term antibiotic treatment, might lead to stress and immunosuppression (as do steroidal antiphlogistics), hence any additional treatment should be carefully assessed for its true need.[2]

Conclusion

To treat avian aspergillosis, the combined use of antifungal inhalation therapy (e.g., with enilconazole) with oral and/or parenteral medication (e.g., voriconazole) and supportive therapy, as needed, is advised.Therapeutic success needs to be monitored regularly, based on which treatment may be adjusted accordingly. Follow-up examinations should at least include a full clinical examinations, combined with imaging (especially endoscopy), hematology, blood chemistry, and measurement of oxygen saturation to allow for monitoring of clinical improvement in the patient's condition, anti-infective progress, and adequacy of respiratory function. In some avian species, specific tests such as the measurement of fungal antigens or specific antibodies are available besides plasma/serum electrophoresis and acute-phase protein determination.

(see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease, and Chapter 13, Advances in Clinical Pathology and Diagnostic Medicine). For emergency treatment, oxygen supplementation and air sac cannulation should be considered (see Chapters 28 and 29). In severe cases, surgical intervention may be necessary (see Chapter 29).[47,48]

Treatment of macrorhabdosis and candidiasis requires oral administration of amphotericin B and/or nystatin, administered over a period of 4 to 6 weeks twice daily (Table 8.1 ; see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). If antifungal resistance to amphotericin B is suspected, a therapy using voriconazole orally might be attempted. *Candida* spp. usually respond adequately to treatment using nystatin or nystatin-fluconazole mixtures; hence targeted therapy of candidiasis is mostly accomplished by orally administering these agents over a period of 7 to 10 days.

For the treatment of systemic fungal infections, parenteral formulations are available (Table 8.1).

Fungal infections of the skin, mucous membranes, the eye, the nose, and the sinus may be treated using topical antifungal medication (Table 8.1). In any case, fungal culture and sensitivity testing are advisable for diagnosis and targeted antifungal therapy.

TABLE 8.1

Overview of Antifungal Treatment Schedules[49,50]

TOPICAL OCULAR ANTIFUNGAL TREATMENT		
Amphotericin B *(polyene macrolide)*	0.025 mg/mL sterile water subconjunctival: q24h[51] 4% ointment: q24h[51]	Treatment of candidiasis of the third eyelid in ornamental ducks; often combined with systemic antifungal treatment
Fumagillin	1 drop (0.114 mg/mL in sterile water) q2–3h until 1 w post clinical signs[52]	Treatment of fungal and microsporidial keratoconjunctivitis in Amazon parrots (*Amazona* spp.); used in combination with oral albendazole; solution should be filtered prior to application
Miconazole *(azole derivative)*	2% cream: q24h × 7 d[52] IV solution: 1 drop q2h[52]	Most species; treatment of candidiasis of the third eyelid
Pimaricin/natamycin *(polyene macrolide)*	1 drop q2–8h × 14–21 d[53]	Gradually taper off after treatment
ANTIFUNGAL NEBULIZATION		
Amphotericin B *(polyene macrolide)*	0.1–1 mg/mL sterile water over 15–60 min, q6–24h[27,53–56] 10 mg/20 mL sterile water over 30 min, q12h[27]	Most species; minor systemic absorption with aerosol administration; may lead to hypokalemia, especially when given with corticosteroids; mix with sterile water due to risk of precipitation with electrolytic solutions and saline; low efficacy and possible weight loss in hummingbirds at 0.25 mg/mL × 15 min q12h; Falcons
Amphotericin B liposome *(polyene macrolide)*	1–4 mg/mL sterile water over 15–60 min, q12–24h; 7–10 mg/mL sterile water over 15 min, q12h[49]	Most species; mix with sterile water due to risk of precipitation with electrolyte and saline solutions
Clotrimazole *(azole derivative)*	10 mg/mL solution, e.g., with propylene glycol or polyethylene glycol over 30–60 min, q24h[49,53,54]	Most species; potentially toxic to psittacines at this dose; use in combination with systemic antifungals; in raptors, sometimes given over 3 d, followed by 2 d off and repeated for up to 4 months q8–12h[27]
Enilconazole *(azole derivative)*	0.2 mg/5 mL saline q12h × 21 d[53] 10 mg/mL saline or sterile water[53]	Most species; birds of prey are sometimes treated using a different regimen, i.e., 50 mg/25 mL saline × 30–45 min q8–12h[27] or 0.1 mL/kg in 5 mL sterile water × 30 min q24h 5 d on/2 d off[49]; in the authors' experience 10 mg/5 mL saline × 30 min q12h × 28 d is well accepted by most species
F10 *(blend of quaternary ammonium and biguanide compound)*	1:250 dilution over 30–45 min, q12h[27,57]	Dose given to raptors; in the authors' experience this dose is well tolerated in psittacines, also when combined with 10 mg/5 mL enilconazole[27,57]
Itraconazole *(azole derivative)*	1%–10% nanoparticulate suspension over 30 min, q24h[58,59]	Evaluated in Japanese quail *(Coturnix japonica)* in experimental aspergillosis, with 10% being most effective
Miconazole *(azole derivative)*	15 min q8h × 10 d[53]	Dose given to raptors to treat aspergillosis
Terbinafine *(allylamine)*	1 mg/mL in sterile water over 15 min; q12h[60]	Used in most species to treat aspergillosis; dose evaluated for Hispaniolan Amazon parrots *(Amazona ventralis)*; higher doses may be required to maintain therapeutic levels;[60] dosages used in raptors are similar but longer (30 min) and more frequent (q8–12h) intervals are advised; may also be used in combination with N-acetyl-L-cysteine[27]
Voriconazole *(azole derivative)*	10 mg/mL saline solution over 15–30 min, q8–12h[11,54]	Most species; low plasma concentration and low pulmonary drug concentration in pigeons *(Columba livia domestica)*

Continued

TABLE 8.1

Overview of Antifungal Treatment Schedules—cont'd

LOCAL THERAPY—TRACHEA, LUNG, AIR SAC, SINUSES OR NASAL CAVITY		
Amphotericin B *(polyene macrolide)*	1 mg/kg IT q8–12h × 3–12 d[49,61–63] 1 mg/kg IAS/IP inside fungal lesions[49,61–63] 0.05–1 mg/mL sterile water for nasal flush[49,61–63]	Most species including psittacines and raptors; dilute in sterile water or 5% glucose solution (e.g., 0.3–0.5 mL/kg BW) prior to administration; may cause tracheitis after IT administration; after initial IT therapy over 12 d may be continued q48h over 5 w
Clotrimazole *(azole derivative)*	nasal flush 10 mg/mL[49,64]	Effective against yeast and *Aspergillus*; used in most species for nasal flush;
	2 mg/kg IT q24h × 5 d[49,60]	In psittacines; applied to syringeal aspergilloma using catheter or endoscope working channel
Enilconazole *(azole derivative)*	1 mg/kg IT q24h of a 1:10 dilution with sterile water[49]	Treatment of aspergillosis in falcons (*Falco* spp.)
Miconazole *(azole derivative)*	5 mg/kg IT of a 10 mg/mL solution diluted with saline q12h × 5 d[49]	Treatment of aspergillosis in psittacines
Voriconazole *(azole derivative)*	12.5 mg/kg q24h[65]	Treatment of aspergillosis in raptors
SYSTEMIC ANTIFUNGAL TREATMENT—ORAL ADMINISTRATION		
Fluconazole *(azole derivative)*	10–20 mg/kg PO q24h × 30 d	Used in psittacines and pigeons *(Columba livia domestica)* to treat aspergillosis; doses ≥ 10 mg/kg might be toxic to budgerigars *(Melopsittacus undulatus)*;
	15 mg/kg PO q12h × 30 d[49]	Used in raptors to treat systemic mycoses—doses to treat candidiasis and GI fungal infections are much lower (see below)
Griseofulvin	10 mg/kg PO q12h × 21 d[49]	Used in pigeons *(Columba livia domestica)* to treat dermatophytosis;
	30–50 mg/kg q24h in drinking water[49]	Used in ostriches *(Struthio camelus)* to treat mycotic dermatitis
Itraconazole *(azole derivative)*	5–10 mg/kg q12–24h × 10–14 d[49] higher doses reported in: raptors: 15 mg/kg PO q12h × 4–6 w[66,67] penguins (Sphenisciformes): 20 mg/kg PO q24h[49,69]	Most species; first-choice drug for the treatment of aspergillosis, also used to treat candidiasis and dermatophytosis; treatment may be prolonged to 60 d in finches[67,68] and to 90 d in psittacines;[31,64] toxicity reported in grey parrots *(Psittacus erithacus)* at doses ≥ 5 mg/kg; anecdotal reports of drowsiness/apathy in African fish eagles *(Icthyophaga vocifer)*[49]
Ketoconazole *(azole derivative)*	15–30 mg/kg PO q8–24h × 7–14 d[49,64,67,70,71] 30 mg/kg q12h × 7–30 d[49,71]	Dose recommendations variable in avian species to treat aspergillosis and candidiasis; Dose used in most species; lower doses used in ratites: 5–10 mg/kg PO q24h; higher doses given to pigeons *(Columba livia domestica)*: 20–40 mg/kg PO q12h × 15–60 d; higher doses also used in raptors and toucans: 60 mg/kg PO q12h;
	200 mg/L drinking water[49,56,72]	Dose administered to canaries *(Serinus canaria)*, Gouldian finches *(Chloebia gouldiae)*, and hummingbirds (*Trochilus* spp.) to treat candidiasis
Terbinafine *(allylamine)*	10–30 mg/kg PO q12–24h[14,49,73,74] 15 mg/kg PO q24h (penguins)[73] 22 mg/kg PO q24h (raptors)[14]	Doses provided to most species to treat yeast and mold infection; limited action against *Aspergillus* spp. (questionable therapeutic potential), may be combined with itraconazole to increase effectivity; Higher dosages (60 m/kg PO q24h) given to Amazon parrots (*Amazona* spp.)[75] and common shelducks *(Tadorna tadorna)*;[76] Authors frequently have success using dosages of 15–20 mg/kg PO q12h × 30 d
Posaconazole *(azole derivative)*	12.5–20 mg/kg PO (falcons)[77]	Should be administered together with food or dissolved in corn oil

TABLE 8.1

Overview of Antifungal Treatment Schedules—cont'd

Voriconazole *(azole derivative)*	10–18 mg/kg PO q12h[11,19,21,49,65,78,79] or 20 mg/kg PO q24h × 21 d[80]	Used in most avian species to treat aspergillosis; efficacy against most yeasts; prolonged elimination half-life has been observed in pigeons *(Columba livia domestica)* and African penguins (*Spheniscus demersus*; Note: increased anecdotal reporting of toxicity in penguins); pigeons treated with low dose of 10 mg/kg PO q12h or 20 mg/kg PO q24h;[11,19,21] 20 mg/kg PO q8–12h has also been used in ducks;[81] doses in raptors vary from 10 mg/kg PO q8h (red-tailed hawks; *Buteo jamaicencis*) to 12.5 mg/kg PO q12h (falcons; *Falco* spp.);[65,82,83] Dose in parrots is 12–18 mg/kg PO q12h (Grey parrot; *Psittacus erithacus*)[78] or 18 mg/kg PO q8h (Amazon parrots; *Amazona* spp.)[79]
SYSTEMIC ANTIFUNGAL TREATMENT—PARENTERAL TREATMENT		
Amphotericin B *(polyene macrolide)*	1.5 mg/kg IV q8h × 3–7 d[49,53,61]	Most species
Miconazole *(azole derivative)*	10–20 mg/kg IM or IV q8–24h × 6–12 d[49,53,70]	Raptors and psittacines to treat generalized aspergillosis;
	20 mg/kg IV q8h[70]	Psittacines with candidiasis/cryptococcosis
Voriconazole *(azole derivative)*	12.5 mg/kg IM q24h[77] 20 mg/kg IV q8–12h[81]	Raptors to treat aspergillosis; Ducks
GASTROINTESTINAL ANTIFUNGAL TREATMENT—TO TREAT GASTROINTESTINAL FUNGAL DISEASES		
Amphotericin B *(polyene macrolide)*	100–109 mg/kg PO q12h × 10–30 d[49,84] 1,000 mg/L drinking water × 10 d[49,85] 0.1 mg/mL drinking water × 28 d (usage of a formulation to prepare infusion solution)[86]	Oral suspension with limited/no absorption from the GI tract is the first choice for the treatment of *Macrorhabdus*; Doses given for treatment of avian gastric yeast in budgerigars *(Melopsittacus undulatus)*; treatment of candidiasis in neonatal raptors; Authors' experience: 0.1 mL oral suspension (100 mg/mL) q12h × 28 d or 1 mL oral suspension (100 mg/mL) in 50 mL drinking water (requires frequent remixing/stirring to prevent demixing) to treat *Macrorhabdus/Candida* infections; for flock treatment marinate food with 1 mL/kg (use total body mass of all individuals) of oral suspension (100 mg/mL), mixed 1:4–1:10 with water
Fluconazole *(azole derivative)*	2–6 mg/kg PO q24h × 7 d; 5–15 mg/kg PO q12h × 14–60 d[87–89]	Treatment of candidiasis in psittacines, finches, and raptors; systemic activity; may also penetrate into CNS and eye; Death observed at 10 mg/kg q12h in budgerigars *(Melopsittacus undulatus)*;
	8 mg/kg PO q24h × 30 d[90]	Treatment of cryptococcosis in psittacines;
	50 mg/L drinking water × 14–60 d[49]	Most species; in cockatiels *(Nymphicus hollandicus)*: 100 mg/L drinking water × 8 d; in Gouldian finches *(Chloebia gouldiae)* up to 100 mg/L drinking water or 100 mg/kg soft food; Authors' experience: 50 mg mixed with 20 mL nystatin oral solution (100,000 IU/mL) and use 1 mL/kg PO q12h for the treatment of *candidiasis*
Nystatin *(polyene macrolide)*	300,000–600,000 IU/kg PO q8–12h × 7–14 d[49,67]	First choice for the treatment of GI candidiasis; may be effective against other yeast or fungi but is not systemically absorbed from GI tract; should not be given if GI epithelium is not intact; Dose given to most species; author's experience: 200,000–300,000 IU/kg PO q12h × 28 d
	20,000–100,000 IU/kg PO q12h × 7–14 d[67]	Dose given to raptors and pigeons *(Columba livia domestica)* to treat candidiasis;
	100,000 IU/L drinking water[72,89]	Dose given to canaries *(Serinus canaria)* and finches to treat candidiasis
TOPICAL TREATMENT		
Amphotericin B *(polyene macrolide)*	10% solution[67] 3% cream q12h[63]	Direct application in the oropharynx; Topical application to infected skin
Enilconazole *(azole derivative)*	1:10 dilution q12–72h × 21 d[62]	Topical treatment of cutaneous aspergillosis/candidiasis

Continued

TABLE 8.1

Overview of Antifungal Treatment Schedules—cont'd

F10 *(blend of quaternary ammonium and biguanide compound)*	q8h	Treatment of cutaneous fungal infections
Iodine 1%	q8–12h[61]	Treatment of oral or cutaneous candidiasis
Miconazole *(azole derivative)*	q12h	Treatment of cutaneous fungal infections such as cutaneous aspergillosis/dermatophytosis
Nystatin *(polyene macrolide)*	q6h[91]	Topical administration onto lesions in hummingbirds (*Trochilus* spp.)/candidiasis, e.g., by using a cotton swab for direct application
Silver sulfadiazine	q12–24h[63,92]	Topical administration to affected areas; bandage application is preferred
STA solution (salicylic acid 3 g, tannic acid 3 g, ethyl alcohol to 100 mL)	q24h[70]	Topical administration in case of fungal dermatitis
Terbinafine *(allylamine)*	q12h	Treatment of cutaneous fungal infection
SPECIAL CASE: TREATMENT OF MICROSPORIDIA/*ENCEPHALITOZOON HELLEM*		
Albendazole	25 mg/kg PO q24h × 30–90 d, then repeat × 120 d in case of relapse[29,93]	Dose recommended for the treatment of keratoconjunctivitis in cockatoos (Cacatuidae); may be combined with fumagillin;
	50 mg/kg PO q24h × 5 d[29,94]	dose given to treat microsporidial keratoconjunctivitis in Amazon parrots (*Amazona* spp.)
NEW APPROACHES FOR THE TREATMENT OF MUCOSAL OR DERMAL FUNGAL INFECTIONS		
Cold plasma	HF Plasmajet 5 ± 1 slm argon gas N48 (99.998%), temperature 38°–40°C, moved with a speed of 5 mm/sec resulting in a contact time of 20–30 sec/cm² × q48h × 14–30 d	
Ozone therapy	Sessions of 40–60 sec q12–24h × 3–6 d per spot, power setting 8 of 12	
Soft laser	980 nm in the continuous-wave mode (CW mode) in noncontact mode with a power of 2–2.5 W using a defocusing handpiece	

BW, Body weight; *°C*, degree Celsius; *d*, days; *GI*, gastrointestinal; *h*, hours; *IAS*, inside the air sac; *IM*, intramuscular; *IP*, intrapulmonary; *IT*, intratracheal; *IV*, intravenous; *min*, minutes; *PO*, oral; *q*, interval; *SC*, subcutaneous; *sec*, seconds; *slm*, standard liter per minute; *w*, weeks; *W*, watts.

CHAPTER 9

Antiparasitic Drugs

Christal G. Pollock • Christopher Fernandez-Prada

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

To control parasitic infection, avian veterinarians have several classes of antiparasitic drugs in their arsenal, each with a different mode of action. In order to prescribe these drugs effectively, it is necessary to understand not only the parasiticide in question but also the life cycle of the parasite of interest. Although the focus of this text is exotic and companion birds, it is impossible to properly and completely discuss antiparasitic drugs in birds without exploring their impact on poultry production, and therefore this taxonomic group will also be mentioned frequently.

ANTHELMINTIC AGENTS

Macrocyclic Lactones

Macrocyclic lactones (MLs) are broad-spectrum drugs, referred to as endectocides because of their activity against both endo- and ectoparasites.[1,2] MLs are used not only in animals but also for pest control of crops because of their high activity against arthropod and nematode pests, low toxicity to birds and mammals, and their unique mode of action.[1] MLs are gamma-aminobutyric acid (GABA) agonists that also bind to glutamate-gated chloride channels in the nerve and muscle cells of invertebrates.[3,4] MLs include two types of compounds: avermectins and milbemycins.[3,4] Most members of the ML family belong to the avermectin subfamily, which includes abamectin, ivermectin (IVM), doramectin, eprinomectin, and selamectin.[3–5] Examples of milbemycins include moxidectin and milbemycin oxime, which have a similar mechanism of action to avermectins but a longer half-life (Table 9.1).[1,3,4]

Ivermectin

IVM is the most commonly used avermectin.[1,3] Although IVM is not licensed for use in any avian species, oral, topical, and injectable formulations licensed for cattle or sheep are widely used off-label to control parasites in various bird species.[4] Multiple studies have indicated that IVM is highly effective against nematode infections in poultry.[5] There have also been pharmacokinetic studies in gallinaceous birds (Table 9.2).[5,36] Regardless of the route of administration, IVM is widely distributed to tissues[5]; however, the high lipophilicity of IVM means that much more of this agent accumulates in egg yolk and fat compared to other tissues.[5,52] Therefore IVM should not be used in laying hens (Table 9.1).

Benzimidazoles

Benzimidazole (BZD) anthelmintics are a large class of broad-spectrum anthelmintics that includes albendazole (ABZ), mebendazole (MBZ), fenbendazole (FBZ), flubendazole (FLBZ), and thiabendazole (TBZ) (Table 9.1).[6] BZDs act by directly destabilizing tubulin, a system of proteins present in plasma and mitochondrial membranes and microtubules. Microtubules impact the cell's ability to undergo mitosis or regulate intracellular transport.[6,53] Helminths die as energy reserves are progressively depleted and excretion of cellular waste is inhibited.[53]

Much is known about the pharmacokinetic parameters of BZDs in the chicken.[52] Following oral administration to chickens, FLBZ and ABZ are absorbed relatively quickly, reaching peak plasma concentrations in 2 to 4 hours.[52] Despite a rapid rate of elimination, detectable residues of FLBZ and ABZ can be found in eggs laid up to 1 week or more after treatment.[52] BZD anthelmintics require extensive hepatic metabolism for excretion.[54] A study investigating FLBZ metabolism found that there were very significant differences in the pattern of metabolism observed among tested species.[54] Therefore caution should be applied in extrapolating data on metabolism, efficacy, and safety of drugs from one species to another.[54]

Benzimidazole toxicosis

Confirmed or suspected BZD toxicosis has been reported in pigeons and doves, two vulture species, two stork species, the American white pelican *(Pelecanus erythrorhynchos)*, and a harpy eagle *(Harpia harpyja)*.[9–15,55] Since BZDs affect cellular division, this can lead to extreme suppression of rapidly dividing cells in the host, such as intestinal crypt cells and bone marrow precursors.[10,14] Bone marrow dysplasia can rapidly result in anemia, marked leukopenia or heteropenia, septicemia, and secondary infection.[9,10,14,15] Affected birds may display nonspecific signs of illness and even sudden death within 72 hours of drug administration.[9–12,14] The overall mortality rate is typically high in affected birds, but some individuals can recover with aggressive supportive care.[10] Feather dystrophy has also been observed in surviving birds that were treated during active molt.[15,25]

TABLE 9.1

Anthelmintic Agents for Use in Birds

	Benzimidazoles	Macrocyclic Lactones
Examples	Albendazole (ABZ) Cambendazole (CBZ) Fenbendazole (FBZ) Flubendazole (FLBZ) Mebendazole (MBZ) Oxfendazole (OFZ) Thiabendazole (TBZ)	Doramectin (DOR) Eprinomectin (EPR) Ivermectin (IVM) Milbemycin oxime (MO) Moxidectin (MOX) Selamectin (SEL)
Clinical applications	Helminths, particularly nematodes like *Serratospiculum* Some BZDs, like FBZ, ABZ, and MBZ, are also active against *Giardia*[6]	Broad-spectrum, widely used to control endo- and ectoparasites IVM: Dilute with water or saline for immediate use; dilute with propylene glycol for long-term use[7,8]
Potential adverse effects or toxicity	Toxicosis or suspected toxicosis has been reported in a variety of avian species (see Benzimidazole Toxicosis) but is most often reported in pigeons and doves[8–14] ABZ may be toxic in keas *(Nestor notabilis)*[8]	No adverse effects have been reported in the chicken[5]; however, there are sporadic, anecdotal reports of IVM toxicosis in exotic birds, including finches[15] Risk of IVM toxicity may be higher if the drug is injected, particularly via the IM route[16] IVM (3 mg/kg IM) in falcons (*Falco* spp.) led to blindness, anorexia, vomiting, and ataxia that lasted up to 48 hours[17]
Contraindications, precautions	Avoid BZD use during breeding season as embryotoxic effects have been observed[16] Avoid use in birds molting primary feathers because it will cause weakness and breakage of growing remiges[16,25] Shake suspension products thoroughly before each use to minimize the risk of toxic effects	Avoid IVM in laying hens due to high residues found in eggs[5] Budgerigars *(Melopsittacus undulatus)*, African finches, and European finches may be more sensitive[16]
Dosage in most species	FBZ 10–50 mg/kg PO[8] FBZ 25 mg/kg PO, repeat in 14d[7] OFZ 10–40 mg/kg PO once[7] TBZ 40–100 mg/kg PO q24h × 7d[8,16]	IVM 0.2–0.4 mg/kg PO, topically, SC, IM (see Potential adverse effects or toxicity, earlier); can repeat in 10–14d[8,16,25,26]
Anseriformes	FBZ 5–15 mg/kg PO q24h × 5d[21] MBZ 5–15 mg/kg PO q24h × 2d[30] MBZ 1.2 mg/kg feed × 14d[30]	—
Columbiformes	CBZ 75 mg/kg PO q24h × 2d[7] FBZ 10–12 mg/kg PO q24h × 3d[25] FBZ 20–50 mg/kg PO once, repeat in 10d (ascarids)[7]	—
Galliformes	FBZ 50 mg/kg PO q24h × 3d[20] FBZ 100 ppm feed × 7d—peafowl, Chinese ring-necked pheasants *(Phasianus colchicus)*[31] FBZ in the water 5 mg/kg BW for 1d[32] FLBZ 1.43 mg/kg administered in drinking water × 7d[33] FLBZ 60 mg/kg feed × 7d (partridges, pheasants)[30]	MO 2 mg/kg PO, repeat in 28d[34] SEL 20 mg/kg topical (helmeted guineafowl *[Numida meleagris]*, PK)[35]
Passeriformes	CBZ 60–100 mg/kg PO q24h × 3–7d[16] FBZ 8–10 mg/kg PO q24h × 3–4d[16] FBZ 50 mg/kg PO q24h × 3–5d[38] FBZ 25 mg/L drinking water[39] FBZ 25 mg/kg soft food[39] MBZ 10 mg/kg PO q12h × 5d (canaries [*Serinus canaria*])[7] MBZ 10–25 mg/kg PO q12h × 5d)[16] MBZ 10–20 mg/L drinking water × 3–5d[16] OFZ 10–40 mg/kg PO once[16] TBZ 100–500 mg/kg once[16]	IVM 9 mg/L drinking water[39]
Piciformes	ABZ 15–20 mg/kg PO once (toucans)[7] MBZ 25 mg/kg PO q12h × 5d (toucans)[7,41]	MOX 0.2 mg/kg IM once[41]

Pyrazino-Isoquinoline	Imidathiazole	Tetrahydro-Pyrimidine
Praziquantel	Levamisole	Pyrantel embonate Pyrantel pamoate Pyrantel tartrate
Trematodes, cestodes	Adult nematodes of the lungs and intestinal tract (i.e., *Capillaria*)	Broad-spectrum activity against GI nematodes, most commonly used for ascarids
Injectable form toxic in finches and associated with depression, death in some other species[7,18] Death occurred in Gouldian finches *(Erythrura gouldiae)* at 45 mg/kg[19] Collapse, loss of balance observed in chickens *(Gallus gallus domesticus)* at 100 mg/kg Signs resolved within 3 hours[20]	Relatively narrow margin of safety. Adverse effects can include regurgitation, dyspnea, anorexia, diarrhea, ataxia, head tilt, torticollis, limb paralysis, and death[7,16,21,22] Respiratory distress, death in a North Island brown kiwi *(Apteryx mantelli)* within hours of one dose (25–43 mg/kg PO)[23] IM administration may cause severe toxicity[7]	Reported effects in humans in case of overdose include GI disturbance, CNS effects, and superficial skin reactions[24]
Caution with IM administration in finches; sudden death has been reported[16] Very unpalatable[16]	Not recommended in finches, lories, white-faced ibis *(Plegadis chihi)*, debilitated birds[7,16] Withhold food before administration to prevent regurgitation[7]	Does not penetrate the intestinal wall and therefore does not kill encysted strongyles[6] Not recommended for use in debilitated animals due to potential for pronounced cholinergic effects
10–20 mg/kg PO, repeat in 10–14d prn[7,18,27,28]	10–20 mg/kg SC once[18,29] 20–40 mg/kg PO once[16] 100–200 mg/L drinking water × 3d, repeat in 2 weeks[16] 264–396 mg/L drinking water × 1–3d[7]	7 mg/kg PO, repeat in 14d[7]

Bioavailability (%)	N/A	132.3[b]	11.9[c]

[a,b,c]Values with different superscripts in same row differ ($P < 0.01$).

AUC, Area under the curve from time zero to infinity; C_{max}, maximum concentration; *IV*, intravenous; *MAT*, mean absorption time; *MRT*, mean residence time; *N/A*, not applicable; *PO*, per os; *SC*, subcutaneous; *SD*, standard deviation; $T_{1/2}$, elimination half-life; T_{max}, time to reach maximum concentration; Vd_{ss}, volume of distribution at steady state.

The toxic effects of BZDs are also highly species specific. Therefore every use of a BZD in a novel avian species should be approached with caution. Morbidity and mortality induced by FBZ are known to be dose related in pigeons and doves.[10] Use of FBZ (50 mg/kg PO q24h for 5 days) caused death in doves.[12,25] In a study evaluating FBZ use in day-old common peafowl *(Pavo cristatus)*, there were no morbidities or mortalities with up to 300 mg/kg fed for 21 days.[56] Therefore the proposed dose of 100 mg/kg in the feed for 7 consecutive days is well within the margin of safety for this species.[56] The risk of toxic effects from a BZD suspension may potentially be reduced by thoroughly shaking the suspension before administration.

Levamisole and Pyrantel

Cholinergic agonists, such as the synthetic imidazothiazole derivative, levamisole, and the pyrimidine anthelmintic, pyrantel pamoate, are widely used to treat nematode infestations (Table 9.1), including ascarids, *Capillaria*, and *Heterakis* (Table 9.3).[57] These cholinergic agonists target a restricted subgroup of nematode acetylcholine receptor ion channels in parasite nerves and muscles causing spastic contraction paralysis, followed by expulsion of worms by normal gut peristalsis, and death.[6,53,57] Levamisole has also been shown to enhance immunity in chickens and ducklings.[6,58,59]

Praziquantel

Praziquantel (PZQ) is a synthetic isoquinoline-pyrazine derivative that is active against a wide range of cestodes as well as trematodes (Table 9.1).[6] PZQ increases cell membrane permeability to calcium by disrupting ion transport, which damages the parasite tegument and causes spastic, paralytic muscle contractions of the parasite, followed by their expulsion and death.[6,53]

Niclosamide

The salicylamide derivative, niclosamide, is highly effective for the treatment of cestode infections.[6,20,53,61] Its proposed mechanism of action involves uncoupling of oxidative phosphorylation, but there is also mounting evidence that niclosamide has potential antineoplastic activity.[53,62] Use caution when handling this chemical as it is highly toxic to aquatic life with long-lasting effects,[61] which should be taken into consideration when birds are housed in mixed aquatic zoo exhibits. Niclosamide was voluntarily withdrawn from the US market in 1996.[53]

Therapy for Specific Helminthic Concerns

Ascarids

MLs are important for the control of nematodes, such as *Tetrameres* and *Dispharynx* (Table 9.3),[1] and studies have confirmed the high efficacy of IVM against nematodes in poultry (Table 9.3).[5] Most use of MLs in exotic birds is based on anecdotal experience; however, a study in ostrich *(Struthio camelus)* did confirm that IVM was effective against *Libyostrongylus* spp.[51]

BZDs are also frequently selected to treat helminthic diseases. In fact, only FLBZ and FBZ are currently approved in the European Union (EU) for treatment of nematodiasis in laying hens.[33] Due to a ban on battery cages, infection with the poultry roundworm *Ascaridia galli* has increased in European countries; however, FLBZ (1.43 mg/kg administered in the drinking water for 7 days) was highly effective against both adult worms and larvae although birds were reinfected within 1 week.[33]

Syngamus/Cyathostoma

The nematode *Syngamus trachea* (gapeworm or redworm) is primarily seen in gallinaceous birds and waterfowl; however, it has been reported in a variety of avian species, including birds of prey, passerine birds, particularly starlings and crows, as well as emus *(Dromaius novaehollandiae)*.[38,39,56,63–67] *Syngamus* spp. have a direct life cycle (Box 9.1), but transmission can involve a paratenic host, such as earthworms, snails, slugs, or insects, consumed by the host bird (Table 9.3). Adult worms are typically found within the trachea or lungs. Rapidly growing worms can cause inflammation or obstruction leading to open-mouth breathing, cough-like sounds, sneezing, blood in the oral cavity or at the commissure of the beak, head shaking, and severe respiratory distress.[38,39,63] Young birds are most seriously affected; adult birds rarely develop heavy infections.[68]

Closely related *Cyathostoma* spp. are found in the trachea, air sacs, or orbital sinuses of birds.[64] Cyathostomes have been reported quite commonly in raptors, like merlins (*Falco columbarius*), hawks, and owls. These birds do not feed directly on invertebrate paratenic hosts but it is thought they acquire infections by eating rodents or small birds with such prey in their gastrointestinal tract.[64]

TABLE 9.3

Life Cycle of Common Helminths[25,60]

Parasite	Life Cycle	Comments
Ascarids	Direct intestinal	Larvae may encyst in lungs and liver
Capillaria	Direct intestinal	
Cyathostoma	Direct	Infection can also be transmitted through ingestion of a paratenic host, the earthworm
Dispharynx	Intermediate host required	Pill bug
Heterakis	Direct	Eggs are ingested in contaminated food or water. All larval development occurs within the cecal lumen.
Syngamus	Direct	Infection can also be transmitted through ingestion of a paratenic host, such as earthworms, snails, slugs, and insects like flies, cockroaches
Tetrameres	Intermediate host required	Pill bug

BOX 9.1 DIRECT LIFE CYCLE OF *SYNGAMUS* SPP.[69]

- Birds become infected through ingestion of food or water contaminated with infective eggs or through ingestion of invertebrate paratenic hosts contaminated with larvae.
- Earthworms are particularly important in maintaining as paratenic hosts because third-stage larvae (L3) can survive for an extended period (months to years).
- After ingestion, *Syngamus* L3 hatch, cross the intestinal tract lining, and are carried in the blood stream to the lungs where they molt twice.
- Male and female worms migrate to larger airways where they permanently copulate.
- The pair then migrates to the trachea at about 7 days postinfection where they attach to the wall and suck blood, which causes the worms to appear reddish.
- Adult females lay eggs within the airways between 7 and 20 days later.
- Eggs are coughed up, swallowed, and then passed in the feces.
- Infective larvae develop within the egg beginning at about day 3 and hatch in 9 days when they are subsequently ingested by the host directly or by the host eating an earthworm or snail that ate the infective larva.

Birds with gapeworms often present as emergent cases requiring supplemental oxygen.[39] Dexamethasone can be administered intramuscularly or intratracheally to reduce airway inflammation and mucosal swelling.[39] Anthelmintics that have demonstrated efficacy against gapeworm/cyathostome infections include MLs, like IVM, and BZDs, such as FBZ, FLBZ, MBZ, and TBZ.[39,56,64] In fact, TBZ is registered for the control of *S. trachea* in pheasants in the United States.[70] Use of these anthelmintics will kill adult worms, which are then coughed up and swallowed.[39] If patient size allows, worms can also be removed endoscopically or with biopsy forceps. Restriction of young birds' access to soil, and potential transport hosts, can also reduce the impact of these parasites.[64]

Cestodes

PZQ, niclosamide, and the acridine derivative, quinacrine (see Antiprotozoal Agents), have been effective for the treatment of cestode infections.[6,53,71]

Trematodes

Although PZQ is reportedly effective against schistosomes,[6] most cases described in the literature have been less than promising. A study evaluating treatment of the eye fluke *Philophthalmus gralli* in specific-pathogen-free chickens *(Gallus gallus domesticus)* using PZQ (10-50-100 mg/kg IM once) or FBZ (50 mg/kg PO q24h for 3 days) found that neither treatment was effective for complete elimination of *P. gralli*.[20] Similarly, ineffective results were seen in greater rheas *(Rhea americana)* naturally infected with *P. gralli* and treated with 1% PZQ ointment twice daily.[20,72] Levamisole (1.5 mg/kg PO) was only partially effective in the treatment of ostriches infected with *P. gralli*.[20,73] Additionally, no differences in total counts of trematodes, cestodes, or *Capillaria* were noted in black stilts *(Himantopus novaezelandiae)* treated with PZQ (~20 mg/kg).[74]

ANTIPROTOZOAL AGENTS

Several drugs and drug classes demonstrate activity against protozoan parasites (Table 9.4).

Ionophores

Polyether ionophorous antibiotics or ionophores are fermentation products of *Streptomyces* spp. or *Actinomadura* spp. that act by disrupting ion gradients across the cell membrane of the parasite.[6,78,121] Monovalent ionophores, such as monensin, narasin, salinomycin, maduramicin, and semduramicin, preferentially bind to the monovalent ions sodium and potassium, affecting the transport of cations through biological membranes and leading to cytotoxicity.[6,52,121] Lasalocid has the ability to bind divalent cations, like calcium and magnesium, and is therefore termed a divalent ionophore.[6] Ionophores act on the intestinal free forms of coccidian stages when the drug comes into contact with them within the intestinal lumen.[6] This drug class does not completely suppress parasite development, which allows immunity to develop in the host.[78] Both monensin and salinomycin have been described as possessing broad-spectrum anticoccidial activity (Table 9.4).[6,121]

Ionophores are most widely used in the EU; however, monensin is approved for prevention of coccidiosis in chickens, turkeys, and bobwhite quail *(Colinus virginianus)* in the United States. Monensin has also demonstrated efficacy in the ring-necked pheasant *(Phasianus colchicus)* and Japanese quail *(Coturnix japonica)*.[77,78] Lasalocid is approved for use in the chukar partridge *(Alectoris chukar)*.[122]

Ionophores have a rather narrow safety margin; however, monensin is considered safe in poultry when fed at approved dosages.[77,78] Toxic effects can include neuropathy, manifested by myelin degeneration and ataxia, muscle degeneration, and cardiotoxicity.[78] Maduramicin is the most toxic of all the ionophores, potentially causing severe cardiovascular defects. Monensin has greater toxicity for turkeys than chickens.[6] Semduramicin is also well tolerated by chickens.[78] Lasalocid has relatively low toxicity, and salinomycin is the least toxic of all the ionophores; however, severe toxicity has been described in turkeys, manifesting as paralysis of the head and legs and death.[6]

Triazines

Triazines, such as toltrazuril, ponazuril, and diclazuril, have been used globally for years to combat protozoal parasites (Table 9.4). Unlike other anticoccidial drugs, triazines are effective against all intracellular stages although preformed oocysts do not appear to be susceptible.[75] Their mechanism of action is not completely understood but triazines inhibit cytokinesis of schizonts and in so doing prevent complete nuclear division.[122] Triazines may also promote the development of a strong humoral immune response, thereby preventing reinfection.[75,76,90,94,123]

In one study evaluating clazuril in pigeons (*Columba livia domestica*; 2.5 mg/bird), no adverse effects or changes in reproductive physiology or body weight were detected in birds dosed weekly for 6 months.[75] The pharmacokinetics of diclazuril and toltrazuril have also been studied in the chicken (Table 9.5).[75,123] Bioavailability after oral diclazuril has been described as approximately 5%.[75] Additionally, in a study evaluating triazines in broiler chickens, the clinical efficacy of

TABLE 9.4

Antiprotozoal Agents for Use in Birds

	Nitroimidazoles	Triazine Derivatives	Ionophores
Examples	Metronidazole (MTZ) Carnidazole (CRZ) Dimetridazole (DMZ) Ronidazole (RNZ) Tinidazole (TNZ)	Clazuril (CZ) Diclazuril (DIC) Ethanamizuril Nitromezuril (NTM) Ponazuril (PON) Toltrazuril (TOL)	Monensin (M) Narasin (N) Salinomycin (S) Maduramicin (MAD) Semduramicin (SEM) Lasalocid (L)
Clinical applications	Broad-spectrum antiprotozoal and anticoccidial activity, including *Giardia*, *Trichomonas*, *Cochlosoma*. Also active against anaerobic, microaerophilic bacteria[6] Former drug class of choice for *Histomonas*, *Spironucleus* in turkeys and game birds (see Potential adverse effects or toxicity, later)	Broad-spectrum anticoccidial and antiprotozoal activity, but primarily used for *Eimeria*, *Isospora*. Also used for refractory coccidiosis (e.g., *Atoxoplasma*)[6,75,76]	M: Approved for use in turkey, bobwhite quail *(Colinus virginianus)* in the United States, effective in the ring-necked pheasant *(Phasianus colchicus)* and Japanese quail *(Coturnix japonica)* but not the chukar *(Alectoris chukar)*[77] M, S: Broad-spectrum anticoccidial activity[6] SEM: Highly effective against *Eimeria*[78]
Contraindications, precautions	Nitroimidazole use is prohibited in food animals in many nations, including the United States and European Union[30,51] *Candida* overgrowth can occur after prolonged therapy, especially in cockatiels *(Nymphicus hollandicus)*[16] CRZ must be given on an empty stomach, otherwise vomiting can occur[16] DRZ: do not use in Pekin robins *(Leiothrix lutea)* and finches. Use lower dose with caution in lorikeets and mynahs[16]	DIC: some *Eimeria* resistance in poultry[8] Baycox 2.5% (TOL) should not be administered directly into the crop via gavage tube because of its harsh, alkaline properties[7,81]	Most ionophores are incompatible with several ABX, including tiamulin, chloramphenicol, erythromycin, certain sulfonamides, and some antioxidants[6,67,78] M (100 mg/kg) reduced fertility when given to broiler breeders but had no effect on egg production, egg weight, or hatch.[77] There are also anecdotal reports of anorexia with M administration during hot weather[77]
Potential adverse effects or toxicity	In some animal studies, high-dose, long-term MTZ has shown mutagenic or carcinogenic effects[80]; therefore nitroimidazole use has been suspended in many countries[6] Reversible CNS signs (ataxia, seizure) have been observed with MTZ or DMZ overdose[16,38,84–86]	Minimal adverse effects, such as GI problems, have been reported in mammals when given at approved dosages[75] Mild-to-severe feather damage has been reported in an 8.5-wk-old offspring of adult pigeons treated with TOL[81]	M: Relatively narrow safety margin[66]; however, safe in poultry when fed at approved dosages[67] M: Toxic effects include neuropathy, muscle degeneration, cardiotoxicity,[78] which appears as anorexia, decreased growth rate and weight gain, depression, ruffled feathers, recumbency, ataxia, leg weakness, paralysis, and death[77,87] N: Toxic to turkeys[36]
Dosage in most species	CRZ 3–7 mg/kg PO[8] MTZ 10–30 mg/kg PO q12h[8] MTZ 30–50 mg/kg PO q24h[8,16] RNZ 6–10 mg/kg PO q24h × 6–10d[8,16] RNZ 60–600 mg/L drinking water × 7d[16,25,91]	CZ 3–7 mg/kg PO[8] CZ 7 mg/kg PO × 3d, off 2d, on 3 d[7,18] PON 10–20 mg/kg PO; repeat in 10–14d[8]	—
Anseriformes	—	CZ 5–10 mg/kg PO q72h q3 trmts[47] CZ 5–10 mg/kg PO q24h × 3d, off 2d, on 3d[30] TOL 12.5 mg/L drinking water × 2d[30] TOL 25 mg/L drinking water × 2d[30]	—

Thiamine Analog	Aminoglycoside	Sulfonamides
Amprolium hydrochloride	Paromomycin	Sulfachlorpyridazine (SCP) Sulfadiazine-trimethoprim (TMP/SDZ) Sulfadimethoxine (SDM) Sulfamethazine (SMT) Sulfadimidine (SDI) Sulfamethoxazole (SMX) Sulfaquinoxaline (SQX)
Coccidiostat, poorly active against some *Eimeria* spp.[78] Largely used in combination products to extend its spectrum of activity, such as amprolium with ethopabate[78]	Antiprotozoal activity against *Entamoeba*, *Trichomonas*, *Giardia, Balantidium*, *Cryptosporidium*. Also active against gram-negative bacteria[6] Largely unabsorbed resulting in high drug levels within the GI tract[79,80]	Broad-spectrum activity against protozoa as well as aerobic bacteria; coccidiostatic at low doses, coccidiocidal at higher doses[6] Long-acting sulfonamides (e.g., sulfamethoxine) are highly active against avian malaria and coccidia when given in combination with pyrimethamine and other diaminopyrimidines
Resistance is common[16] Treatment periods >2 wks may require folic acid supplementation[16] Efficacy can be reduced by high doses of thiamine[7]	May result in secondary bacterial or fungal infections[7] Use with caution if ulcerative intestinal lesions are suspected because renal toxicity may occur[7]	Contraindicated with dehydration, liver disease, renal disease Sulfa drugs reduce pyridoxine and B6 absorption. Begin vitamin B supplementation for 6d after short-term therapy has been completed[25,82] A vitamin supplement containing vitamin B6 should also be used during long-term trmt (>2 wks)[16,83]
Large safety margin of at least 5-fold when used at the recommended level in feed (125 ppm)[78] Seizure activity responsive to thiamine supplementation described in a merlin *(Falco columbarius)* given amprolium (22 mg/kg PO q24h × 6d, then 7.5 mg/kg PO q24h × 4d)[88]	If absorbed systemically, paromomycin can induce ototoxicity and nephrotoxicity; however, it is less ototoxic than other aminoglycosides[80]	Can be associated with nausea, anorexia, diarrhea[6,89] In birds, sulfas can cause reproductive disorders, inhibit vitamin K synthesis, thus impairing blood coagulation, and contribute to bone marrow hypoplasia, agranulocytosis, hematoma, and necrotic changes in the spleen[90]
15–30 mg/kg PO q24h × 1–5d, rest for 5d then repeat trmt[16] 50–100 mg/L drinking water × 5–7d; rest 5d, then repeat trmt[7,16]	100 mg/kg PO q12h × 7d[16]	SCP 100–400 mg/L drinking water × 3–5d, rest × 5d then repeat trmt[16] SCP 400–500 mg/L drinking water × 5d, rest 2d, on 5d[8] SDM 20–50 mg/kg PO q12h × 3–5d, rest × 5d then repeat trmt[16] SDM 250–500 mg/L drinking water × 5–7d, rest × 5d then repeat trmt[16] SDI 50–150 mg/kg PO q12h, rest × 5d then repeat trmt[16] SDI 3330–6660 mg/L drinking water × 5d, rest × 5d then repeat trmt[16] SMT 75–185 mg/kg PO q24h × 3d, rest × 5d then repeat trmt[16] SMT 125 mg/L drinking water × 3d, rest for 5d then repeat trmt[16] SQX 100 mg/kg PO q24h × 3d, rest × 5d then repeat trmt[16] SQX 250–500 mg/L drinking water × 5–7d, rest for 5d then repeat trmt[16]
0.5–1.0 mL/L of 9.6% solution PO in drinking water × 5d[21]	—	—

Antiprotozoal Agents for Use in Birds—cont'd

	Nitroimidazoles	Triazine Derivatives	Ionophores
Columbiformes	CRZ 10 mg/kg PO (adult pink pigeons [*Nesoenas mayeri*], squabs >18d old, *Trichomonas*)[92] CRZ 20 mg/kg PO once[30] MTZ 25–50 mg/kg PO q12–24h × 5d; use lower dose if twice daily[25] MTZ 1057 mg/L drinking water × 2d[25] CRZ 20 mg/kg PO once[25,91] CRZ 20–30 mg/kg PO q24h × 1–2d[18,27] DMZ 400 mg/L drinking water × at least 3d[93] RNZ 2.5 mg/kg PO × 6d[25] RNZ 10–20 mg/kg PO q24h × 7d[91]	CZ 2.5 mg tablet per pigeon once[6,25,75,81,94] CZ 7 mg/kg PO q24h × 2–3d; rest for 5d then repeat trmt[16] TOL 20 mg/kg[94] TOL 20 mg/kg in drinking water × 2d[25,81]	—
Galliformes	DMZ 200 mg/kg feed *(Histomonas)*[95] MTZ 25 mg/kg PO q12h × 10d[36] MTZ 30 mg/kg PO q12h (poultry, PK/PD)[96] MTZ 110 mg/kg PO q12h (poultry, *Histomonas*)[36] MTZ 200–400 mg/kg feed[95] MTZ 400 mg/L drinking water × 5–15d (game birds)[36] DMZ 800 mg/L drinking water (poultry, game birds)[36] DMZ 185–187.5 mg/kg feed (poultry, game birds)[36] DMZ 200–400 mg/kg feed (chickens [*Gallus gallus domesticus*], *Histomonas*)[95] DMZ 200–400 mg/L drinking water × 5d (game birds)[36] TNZ 200–400 mg/kg feed (chickens, *Histomonas*)[95]	CZ 3 mg/kg PO once or × 5d (chickens [*Gallus gallus domesticus*], PK)[97] DIC 2.5 mg/L drinking water[98] DIC 5–10 mg/L drinking water[8] DIC 1 mg/kg diet[99] DIC 5 mg/L drinking water[100] NTM 3 mg/kg feed (coccidia prophylaxis in broiler chickens, see Box 9.10)[76] PON 20 or 40 mg/kg PO once (peafowl [*Pavo cristatus*])[101] TOL 5–20 mg/kg PO q24h (suggested based on PK)[102] TOL 7.5–24.5 mg/kg PO in a variety of species or in drinking water × 2d (Japanese quail [*Coturnix japonica*])[90] TOL 25 mg/L drinking water × 2d (chickens, *Eimeria*)[100] TOL 75 ppm in drinking water (chickens)[103]	L 67–125 mg/kg feed (game birds, chickens)[36] L 125 mg/kg feed (Chinese ring-necked pheasants [*Phasianus colchicus*])[104] M 59.5–99 mg/kg (turkey [*Meleagris gallopavo*])[77] M 80.5 mg/kg feed (bobwhite quail [*Colinus virginianus*])[77] M 99–121 mg/kg feed (chicken [*Gallus gallus domesticus*])[77] MAD 5–6 mg/kg feed (chicken, turkey; coccidia)[36] N 20–80 mg/kg feed (chicken, prophylaxis; see Box 9.10)[36]
Passeriformes	CRZ 20–30 mg/kg PO q24h × 5d[38] CRZ 33 mg/kg PO, repeat in 14 and 28d (society finches [*Lonchura striata domestica*], Gouldian finches [*Erythrura gouldiae*]; flagellates)[7] DMZ 100 mg/L drinking water × 5 days *(Cochlosoma)*[39] MTZ 20 mg/kg PO q24h × 5d (canaries [*Serinus canaria*], *Trichomonas*)[106,a] MTZ 30 mg/kg PO once *(Cochlosoma)*[38] MTZ 100 mg/L drinking water[39] MTZ 100 mg/kg soft food[39] MTZ 200 mg/L drinking water × 5d (canaries, partially effective against *Trichomonas*)[106] RNZ 50 mg/L drinking water and 50 mg/kg in soft food × 7d *(Cochlosoma)*[39] RNZ 350 mg/L drinking water or 350 mg/kg soft food[39]	DIC 2.5 mg/L drinking water and sulfadiazine (400 mg) - trimethoprim (80 mg) (0.2 mL/L) added to the drinking water × 5d (mynah, *Atoxoplasma*)[98] DIC 5 mg/L drinking water *(Toxoplasma)*[7] DIC 10 mg/kg PO q12h on days 0, 1, 2, 4, 6, 8, 10 (Hawaiian crows [*Corvus hawaiiensis*], *Toxoplasma*)[7] TOL 7–15 mg/kg PO q24h × 3d[16] TOL 12.5 mg/kg PO q24h × 14d *(Atoxoplasma)*[38] TOL 12.5 mg/kg PO q24h × 2d, stop for 5d, repeat 7d cycle over 3 months (blue-crowned laughing thrush [*Pterorhinus courtoisi*], reduced *Atoxoplasma* oocysts in feces)[82] TOL 20–35 mg/kg PO once[16] TOL 25–75 mg/L drinking water × 5d[16] TOL 25 mg/kg in the food q24h × 2d for 10 wks (blue-crowned laughing thrush, *Atoxoplasma*)[107] TOL 180 mg/L drinking water[39]	—

Thiamine Analog	Aminoglycoside	Sulfonamides
200 mg/L × 5d[25] 25 mg/kg/d PO[25]	—	SMT 50–65 mg/pigeon PO × q24h × 3d, 2–3d rest, then a 2–5d trmt period[74] SMT 50–65 mg/pigeon PO × 5d[25] SMT 400 mg/L drinking water × 1d followed by 200–270 mg/L × 4d[25] SDM 330–400 mg/L drinking water × 1d, followed by 200 mg/L × 4d[25]
3 mL/L drinking water (using a 9.6% solution) × 3–5d[30] 115–235 mg/kg feed (poultry, pheasants; lower dose prophylaxis, higher dose therapeutic, *Sarcocystis*, see Box 9.10)[36]	100 mg/kg PO q12h or 50 mg/kg PO q8h × 1–2 wks[105]	SDM 250 mg/L drinking water × 5d (turkeys [*Meleagris gallopavo*])[36] SDM 500 mg/L drinking water × 6d (chickens [*Gallus gallus domesticus*])[30]
50–100 mg/L drinking water × 5–7d[38]	SDI 1000 mg/kg soft food or hulled millet for Gouldian finches *(Erythrura gouldiae)*[19]	SDI 150 mg/L drinking water[39] SCP 150–300 mg/L drinking water[39] SCP 300 mg/L drinking water × 5d, off 3d (repeat cycle 4 times) *(Atoxoplasma)*[38,83] DIC (2.5 mg/L) and SDZ (400 mg)—TMP (80 mg) (0.2 mL/L) added to drinking water × 5d (mynah, *Atoxoplasma*)[98] Sulfachloropyrazine (ESB3) (n/a in the United States)—mix 1 g of 30% powder in 1 L drinking water × 5d, off 3d, then repeat the 5d trmt. Repeat the cycle 4 times (Bali mynah [*Leucopsar rothschildi*] and other passerine birds)[83]

TABLE 9.4

Antiprotozoal Agents for Use in Birds—cont'd

	Nitroimidazoles	Triazine Derivatives	Ionophores
Psittaciformes	CRZ 20–30 mg/kg PO once[16,18] CRZ 30–50 mg/kg PO, repeat in 10–14d (cockatiels [Nymphicus hollandicus]/*Giardia*)[7] DMZ 200–400 mg/L drinking water × 5d[7,16] MTZ 50 mg/kg PO q12–24h[16] MTZ 40–80 mg/L drinking water × 3d[16] RNZ 6 mg/kg PO q12h and RNZ 2000 mg/L drinking water (budgerigar [*Melopsittacus undulatus*], *Giardia*)[109]	DIC 1 mg/kg PO q24h (TBP, *Sarcocystis* prophylaxis mixed in mashed pine nuts; see *Sarcocystosis* and Box 9.10)[110] PON 20 mg/kg PO q24h (part of a triple-drug combo with pyrimethamine and SMX in TBP; see *Sarcocystosis*)[110] TOL 2 mg/L drinking water × 2 consecutive days per wk[7] TOL 5 mg/L drinking water × 2d, repeat in 14–21d (10 mg/L administered during second course of trmt)[8]	
Raptors	CRZ 20–25 mg/kg PO once[29] CRZ 20 mg/kg PO q24h × 2–5d (Strigiformes)[114] CRZ 25 mg/kg once[47] CRZ 30 mg/kg PO q24h × 1–3d[26] CRZ 120 mg/kg PO once or divided over 2–5d (American kestrels [*Falco sparverius*], screech owls [*Megascops* spp.], resistant *Trichomonas*)[7] DMZ 50 mg/kg PO q24h × 10d (falcons, *Enterocytozoon*)[115] MTZ 50 mg/kg PO q24h × 5–7d (vulture, *Trichomonas*)[116,b] MTZ 50 mg/kg PO q12h × 5d (ABE, *Trichomonas*)[117] MTZ 50 mg/kg PO q12h and toltrazuril 20 mg/kg PO q24h × 2d, then on day 5 (sparrowhawk [*Accipiter nisus*], *Sarcocystis*)[118] MTZ 50–100 mg/kg PO q24h[29] MTZ 100 mg/kg PO q24h × 3d (for severe cases with large granulomas, tissue destruction, follow with surgical removal)[26]	CZ 5–10 mg/kg PO q72h for 3 cycles (coccidiosis)[47] PON 20 mg/kg PO q24h × 7d (falcons, respiratory *Cryptosporidium*)[119] TOL 10 mg/kg PO q8h every other day for three cycles OR one dose per wk for 3 wks[47] TOL 10 mg/kg PO q24h × 2d, repeat in 14d[26] TOL 10 mg/kg PO q24h × 2d *(Caryospora)*[7] TOL 15–25 mg/kg PO q24h × 2d or EOD for 3 doses; repeat in 2 wks[29]	—
Ratites	DMZ 250 mg/kg feed (ostrich [*Struthio camelus*], *Trichomonas*)[18] MTZ 20–25 mg/kg PO q12h[50] MTZ 40 mg/kg PO q24h (rheas)[7] MTZ 1250 mg/L drinking water × 7–10d[7]	—	—

[a]A trichomoniasis outbreak in a flock of canaries (*Serinus canaria* f. *domestica*) was initially managed with metronidazole (200 mg/L) in drinking water for 5 days. This regimen was only partially effective; however, no further clinical signs were observed in the flock after the oral course described was completed.[106]

[b]Used to successful treat *Trichomonas gypaetinii* in a juvenile Cinereous vulture *(Aegypius monachus)*; however, a new plaque was observed in the bird's oropharynx 10 days after completing MTZ administration, and a second 5-day course of MTZ was provided.[116]

ABE, American bald eagle; *ABX*, antibiotics; *CNS*, central nervous system; *d*, day(s); *EOD*, every other day; *GI*, gastrointestinal; *IM*, intramuscular; *PD*, pharmacodynamics; *PK*, pharmacokinetics; *PO*, per os; *SC*, subcutaneous; *TBP*, thick-billed parrots; *trmt*, treatment; *wk*, week.

Thiamine Analog	Aminoglycoside	Sulfonamides
250 mg/L drinking water × 7d (keas [*Nestor notabilis*], *Sarcocystis*; use in combination with pyrimethamine and primaquine)[7]	100 mg/kg PO q24h × 5–7d diluted in dextrose by crop gavage (black cockatoos, *Cryptosporidium*)[111] 100 mg/kg PO q12h × 7d (macaw [*Ara* spp.] chicks)[7]	Combination 2 wk regimen of TMP/SDZ (30 mg/kg IM 12qh) with pyrimethamine (0.5 mg/kg PO 12qh) (3 psittacine birds relapsed within 1 wk trmt was renewed and extended for an additional 30d, *Sarcocystis*)[112,113] SCP 400 mg/L drinking water × 30d (budgerigars [*Melopsittacus undulatus*], cockatiels [*Nymphicus hollandicus*])[36] SDM 50 mg/kg PO q24h × 5d, off 3d, on 5d[36]
30 mg/kg PO q24h × 5d[7,18,29]	100 mg/kg PO q12h *Cryptosporidium* (gyrfalcons [*Falco rusticulos*])[120] 100 mg/kg PO q12h × 7d (falcons)[7,108]	SDM 25–50 mg/kg PO q24h × 3d[36] SDM 25–50 mg/kg PO q24h × 3d, off 2d, then q24h × 3d[36] SDM 50 mg/kg PO once, then 25 mg/kg PO q24h × 3–7d[26]

TABLE 9.5

Pharmacokinetic Parameters of Clazuril Following Single and Multiple Doses (3 mg/kg) in Laying Hens (*Gallus gallus domesticus*)[97]

Parameter	Single Dose	Multiple Doses
AUC (μg hour/mL)	129.9 ± 43.1	223.8 ± 13.7
K_{01} (L/hour)	3.4	0.3
K_{10} (L/hour)	0.6	0.1
K_{01} $t_{1/2}$ (hours)	3.6 ± 1.9	2.0 ± 0.7
K_{10} $t_{1/2}$ (hours)	7.4 ± 4.3	16.4 ± 4.2
T_{max} (hours)	7.3 ± 2.3	6.8 ± 4.21
C_{max} (μg/mL)	6.2 ± 0.8	7.1 ± 0.7

Data are shown as mean + SD.
AUC, Area under the concentration-time curve; C_{max}, peak plasma concentration; K_{01}, constant for the absorption phase; K_{01} $t_{1/2}$, half-life of the absorption phase; K_{10}, constant of the elimination phase; K_{10} $t_{1/2}$, half-life of the elimination phase; T_{max}, time to reach peak plasma concentration.

nitromezuril (3 mg/kg) was superior to diclazuril (1 mg/kg) based on comparison of anticoccidial indices, such as weight gain and lesion scores.[75,76]

Amprolium

The pyrimidine derivative, amprolium, is structurally similar to thiamine and is therefore able to competitively inhibit thiamine uptake by schizonts and prevent many essential metabolic reactions.[78] Amprolium demonstrates a large margin of safety, but it is poorly active against some *Eimeria* spp.[78] Amprolium is largely used in combination products or mixtures to extend its spectrum of activity (Table 9.4).[78]

Azithromycin

The macrolide antibiotic, azithromycin, acts through inhibition of protein synthesis.[6,79] Azithromycin has shown some efficacy against *Cryptosporidium*, *Giardia*, and *Entamoeba*,[6,80,105,124]

as well as variable degrees of schizontocidal activity against avian malaria.[125–129]

Paromomycin

The aminoglycoside, paromomycin, has also shown some efficacy against *Giardia* and *Entamoeba* (Table 9.4).[6,79,80,105,124] Paromomycin has also been used for resistant *Trichomonas* spp. in human patients.[130] Like azithromycin, this antimicrobial acts through inhibition of protein synthesis.[6,79,80]

Nitroimidazoles

Nitroimidazoles are a class of drugs that have remarkable broad-spectrum activity against a wide range of protozoa, including *Giardia*, *Trichomonas*, *Spironucleus*, *Histomonas meleagridis*, and *Entamoeba* spp., as well as a few nematode worms, *Mycobacteria* spp., and anaerobic bacteria (Table 9.4).[6,53,131,132] Metronidazole is a prototype of the 5-nitroimidazole group and the most widely used drug of its class.[132] Close structural analogs include dimetridazole, ornidazole, ronidazole, tinidazole, carnidazole, and nimorazole. The mechanism of action for nitroimidazoles is not completely understood, but the target organism likely preferentially reduces the 5-nitro group on the molecule.[6,131] This creates active metabolites that cause a loss of helical DNA structure, strand breakage, and eventual cell death.[6,131]

In many countries, some nitroimidazoles are unavailable due to toxicity concerns.[6] Nitroimidazoles, like dimetridazole and metronidazole, are suspected mutagens and carcinogens, and their use in food animals is completely prohibited in both the United States and the EU.[52] Adverse effects specifically described in birds have been neurological. Reversible central nervous system deficits have been observed in some avian patients following metronidazole or dimetridazole administration.[39,84–86] Ronidazole neurotoxicity has also been described in three society finches *(Lonchura striata)*.[84]

Quinacrine

Quinacrine hydrochloride, also known as mepacrine, is an acridine derivative that is chemically and clinically very similar to 4-aminoquinolines, like chloroquine and amodiaquine (see Therapy for Specific Protozoal Concerns).[133] Quinacrine was initially the drug of choice for prevention and therapy of malaria and other tropical infections,[71,133] but today it is used to treat giardiasis and amebiasis.[79,133,134] Quinacrine has also been used as an immunomodulator, a form of contraception/sterilization, and recent research has shown potential antineoplastic activity.[71,135] In human patients, quinacrine is usually reserved for treatment of refractory protozoal disease, due to the potential for severe, acute hepatotoxicity, especially with high doses.[7,79,135] The most serious toxicity reported in human patients is acute aplastic anemia.[71] The mechanism of action is not fully understood[53]; however, quinacrine may intercalate with parasite DNA.[71,79] Quinacrine is unlicensed in the United Kingdom and it has also been discontinued in the United States since 1992,[134] although the drug could be accessed through compounding pharmacies until very recently.[136]

Therapy for Specific Protozoal Concerns

Intestinal coccidiosis

Coccidiosis is an infectious disease of the intestinal tract of wild and domestic birds caused by *Isospora* spp. and *Eimeria* spp. (Box 9.2). Coccidia are widespread, particularly where intensive production systems are used, making coccidiosis the most important parasitic disease of the poultry industry.[77,78,123] Signs of coccidiosis can range from reduced growth, impaired performance, and increased susceptibility to secondary infections, to weight loss, severe diarrhea, and even death.[78,81] Drug therapy is not indicated for mild cases.[74] Disease is self-limiting when proper management is instituted that focuses on strict attention to hygiene, sanitation, and biosecurity.[78,81]

BOX 9.2 DIRECT LIFE CYCLE OF *EIMERIA* spp.[77,78,106]

- The host animal ingests sporulated oocysts, an infectious stage that contains sporozoites.
- Once ingested, the oocyst wall degrades, releasing first-generation sporozoites into the small intestine.
- Activated sporozoites enter intestinal epithelia where they become trophozoites, acquiring nutrients from host cells.
- Both asexual and sexual reproduction (schizogony and gametogony) then occur within the host.
- After about 1 week, noninfectious, unsporulated oocysts are shed in the feces into the environment.

Anticoccidial drugs belong to one of two categories: ionophores and synthetic compounds. In large poultry flocks, ionophores are the principal choice for controlling coccidiosis.[78] Synthetic compounds include amprolium, decoquinate, clopidol, sulfonamides, halofuginone hydrobromide, robenidine, and triazines, like toltrazuril and diclazuril (Table 9.4).[78,90,123] The carbanilide, nicarbazin, can also be used; however, this broad-spectrum agent has only a small safety margin.[78] Nicarbazin disrupts ion and water equilibrium. Therefore medicated birds are at increased risk for heat stress in hot, humid conditions.[78] Nicarbazin also has an adverse effect on layers, causing mottling of yolks, reduced hatchability, and decreased egg production.[78] Combination products, consisting of a synthetic compound and an ionophore, such as nicarbazin and narasin or two synthetic compounds, like clopidol and methyl benzoquate, are also available.[78] All anticoccidial drugs are effective during only the asexual stage, except for triazines, which are effective against all intracellular stages although preformed oocysts do not appear to be susceptible.[75]

In a recent pharmacokinetic study evaluating a single dose of ponazuril (20 or 40 mg/kg PO) in peafowl, coccidial shedding ceased in all birds by the end of the study and no adverse effects were observed.[101] In a study investigating the efficacy of toltrazuril in pigeons against heavy experimental infections with *Eimeria* spp. infections, the minimum required dose of toltrazuril to completely suppress oocyst excretion was 20 mg/kg for 1 day.[75,94] After treatment with toltrazuril, there was also a dose-dependent period during which pigeons remained negative.[75,94] A period of persistent toltrazuril activity ranging from 7 to 28 days has been documented in both pigeons and poultry.[75,94] Nevertheless, toltrazuril is not a cure-all. Despite recent administration of toltrazuril (25 mg/kg PO), an abundance of *Eimeria apteryxii* and *E. kiwii* oocysts were identified in droppings from three brown kiwi *(Apteryx mantelli)*.[137]

Disseminated visceral coccidiosis

Disseminated visceral coccidiosis caused by *Eimeria* spp., particularly *E. reichenowi*, was first recognized in captive sandhill

BOX 9.3 PROBABLE LIFE CYCLE OF *EIMERIA* sp. IN CRANES[77,87,138]

- A sporulated oocyst is consumed and ruptures in the gut releasing sporocysts
- Sporocysts rupture to release sporozoites
- Sporozoites penetrate mucosal epithelium of the distal jejunum
- Sporozoites undergo asexual merogony for one or more generations
- Merozoites reinfect intestinal cells OR are taken up by mononuclear phagocytes, moving to the lungs and other organs, including the liver, heart, and spleen
- In chronic disease, merozoites survive in granulomas in various tissues

BOX 9.5 LIFE CYCLE OF *CRYPTOSPORIDIUM* spp.[105,143]

- Thick-walled, sporulated oocysts in contaminated food, water, or materials are ingested or inhaled by a new host
- Sporozoites are released and parasitize epithelial cells of the gastrointestinal tract or other tissues, undergoing asexual multiplication (schizogony or merogony) and sexual multiplication (gametogony)
- Two types of oocysts develop that sporulate within the host
- Thin-walled oocysts are autoinfective (sporozoite > trophozoite > meronts)
- Thick-walled oocysts are excreted in feces or coughed up from the respiratory tract

cranes *(Grus canadensis)* and whooping cranes *(G. americana)*.[87,138] These organisms demonstrate an unusual proliferative phase that can develop within the respiratory tract and disseminate to the viscera (Box 9.3).[77]

Reports describe the successful use of monensin (99 mg/kg feed), offered continuously or for 2 months before and 2 months after the chick-rearing season, and trimethoprim-sulfamethoxazole (16–24 mg/kg trimethoprim PO q12h) to successfully control visceral coccidiosis in *G. canadensis*.[77,138,139] Some anticoccidial drugs, such as amprolium and clazuril, have shown poor efficacy against disseminated visceral coccidiosis.[139]

Atoxoplasmosis

Atoxoplasmosis, also known as systemic isosporosis or visceral coccidiosis, is caused by *Isospora* spp. that invade circulating lymphocytes affecting internal organs and intestines (Box 9.4).[140] *Isospora* spp. are most commonly described in passerine birds.[98,140] These organisms are highly host specific, with approximately 500 *Isospora* spp. reported within the order Passeriformes.[140] There is no effective treatment to completely clear extraintestinal stages of isosporoid coccidia from a host species, and the variety of regimens described is a testament to the fact that no single treatment has proven consistently effective.[82] Drug regimens that have been tried include toltrazuril paired with sulfachlorpyrazine or sulfachlorpyridazine, trimethoprim-sulfamethoxazole alone or in combination with the folic acid antagonist, pyrimethamine, toltrazuril alone, as well as diclazuril and sulfadiazine-trimethoprim.[38,82,98]

Cryptosporidiosis

Cryptosporidiosis is one of the most common parasitic infections in domesticated, caged, and wild birds (Box 9.5),[141] and infections caused by this small, coccidian parasite have been observed in over 30 avian species.[142–144] Cryptosporidia are typically considered secondary, opportunistic pathogens more likely to impact young and/or immunocompromised birds.[105,124,142] Several different species and genotypes have been described in birds including *Cryptosporidium meleagridis*, first discovered in turkeys, *Cryptosporidium baileyi*, first described in broiler chickens, and *C. galli*. *Cryptosporidium baileyi* is the most commonly reported cryptosporidial pathogen in birds.[141–143] Among the species using avian hosts, *C. meleagridis* presents the known zoonotic risk.[142]

Management of cryptosporidiosis is challenging, requiring treatment of affected birds, as well as prevention of spread through the flock.[105] It is also important to identify the source of contamination and to implement proper hygiene and quarantine protocols.[105] Therapeutic agents that have shown activity against *Cryptosporidium* include paromomycin, ionophores, halofuginone, nitazoxanide, and toltrazuril.[6,105,124,145] Paromomycin (100 mg/kg PO q12h or 50 mg/kg PO q8h for 1–2 weeks) was the first drug that proved effective for treatment of intestinal cryptosporidiosis in poultry; however, paromomycin (100 mg/kg PO q12h) was ineffective in falcons with otitis, tracheitis, upper respiratory signs, and central nervous signs caused by *C. baileyi*.[105] Azithromycin (50–80 mg/kg q24h PO) has also been recommended for cryptosporidiosis in poultry.[105] The low end of this dose range was partially effective in treating scops owl (*Otus* spp.) in a rescue center, where 11 of 16 birds fully recovered clinically; however, this dose did not halt excretion of the protozoa in feces or improve endoscopic findings.[124] Azithromycin (50 mg/kg PO q24h for 1 month) given to two falcons with atypical cryptosporidiosis caused by *C. parvum* did not reduce excretion of protozoa or improve respiratory signs.[144]

BOX 9.4 LIFE CYCLE OF *ATOXOPLASMA*[140]

- The host animal ingests sporulated oocysts.
- Both sexual (gametogenesis) and asexual (merogeny) reproduction occur within the parasitized host, forming an environmentally resilient oocyst.
  - Merozoites in lymphocytes are disseminated via the circulation to the viscera where merogeny continues.
  - Gametogenesis occurs within intestinal epithelial cells.
- Oocysts are then released into the environment where they sporulate and become infective after ~5 to 7 days.

Trichomoniasis

Trichomonas gallinae is a flagellated protozoan that parasitizes the upper gastrointestinal tract (see Chapter 22). This organism has a direct life cycle and reproduces by binary fission. Under favorable conditions, trichomonads exist at the trophozoite stage in vitro.[146] Cyst-like stages or pseudocysts may survive up to 20 months during unfavorable environmental conditions.[116,146] Pigeons and doves serve as the reservoir hosts for *T. gallinae*.[116,146] Clinical disease is most common in Accipitriformes, Falconiformes, and Strigiformes.[116,146,147]

Trichomonas gallinae is also found in Psittaciformes, particularly budgerigars *(Melopsittacus undulatus)*, and trichomoniasis is also an emerging infectious disease of wild finches, mainly in Europe and the United Kingdom.[146,148]

Nitroimidazoles are the treatment of choice for avian trichomoniasis,[25,91,146,147] although dimetridazole and ronidazole were associated with only limited success in one subpopulation of wild pink pigeons *(Columba mayeri)*.[92] Some nitroimidazoles, such as dimetridazole, metronidazole, and ronidazole, can be administered in drinking water. To successfully suppress *T. gallinae* infection in the homing pigeon *(Columba livia)*, medicated drinking water containing dimetridazole (400 mg/L) had to be administered for at least 3 days.[93] There is a risk for overdose and toxicity when drugs are added to drinking water.[81] Base the dosage on the daily volume of water consumed by the individual pigeon loft, which should ideally be measured 1 day before treatment is initiated.[81] Water intake can vary considerably with the age of the bird and weather conditions.[81] Nestlings consume up to five times more water than adult birds.[81] Birds also tend to drink more during the warm summer months. Therefore, it is recommended to select a lower dose during hot weather and a higher dose during cool weather.[7]

Some nitroimidazoles can also be administered as tablets by gently advancing the pill into the crop with a digit or a curved hemostat.[149] The bioavailability of a sustained-release ronidazole tablet was studied in the homing pigeon.[149] The tablet exhibited prolonged drug release in vitro and drug absorption was nearly complete after oral administration of the tablet. When given on an empty stomach, the tablet failed as a prolonged release system.[149] Evaluation of a 2-day treatment with a dimetridazole tablet (20 mg/tablet) in both fasted and fed pigeons was shown to be ineffective.[93] The absolute bioavailability of the tablet in fasted pigeons was 83.8%. Bioavailability was reduced by 20% when the tablet was administered with food.[93]

Giardiasis

Giardia spp. is a flagellated protozoan capable of colonizing the small intestine of many vertebrates, including birds (see Chapter 23).[5] *Giardia psittaci* is relatively common in budgerigars.[150] Transmission of *Giardia* occurs through the fecal-oral route and may be either direct or indirect via contaminated food or water (Box 9.6).[34]

There is no ideal drug for treatment of giardiasis; however, nitroimidazoles, particularly metronidazole, are most commonly used for first-line treatment.[79,80] Nitroimidazoles attack the trophozoite form of *Giardia* effectively; however, they demonstrate poor penetration through the cyst wall.[80] Azithromycin has also demonstrated in vitro activity comparable to that of metronidazole.[80] Other drugs used to treat giardiasis include chloroquine, which reduces *Giardia*'s ability to attach to intestinal epithelium, the nitrofuran derivative, furazolidone; the synthetic benzamide, nitazoxanide; quinacrine, and BZDs, like ABZ and MBZ.[6,79,80] In some human studies, BZDs were more active against *Giardia* than metronidazole and quinacrine, even at low concentrations.[80] ABZ was also associated with fewer adverse effects in human patients when compared to metronidazole.[80] Know that ABZ's efficacy against *Giardia* is dose-dependent, ranging from 25% to 90%.[80] Paromomycin has also demonstrated antigiardial activity, but its effects were lower than with nitroimidazoles, quinacrine, or furazolidone, and it is therefore rarely used in clinical practice.[79,80] Combination therapies are frequently employed against *Giardia* and generally incorporate a nitroimidazole, like metronidazole.[79] For instance, in a survey of human patients, metronidazole and ABZ demonstrated a higher cure rate in vivo than ABZ alone.[79] Recent investigations have also found that cysteine-modifying agents, such as omeprazole and auranofin, had activity against *Giardia* resistant to first-line drugs.[80,151,152]

Sarcocystosis

Sarcocystis spp. is a coccidian parasite with an indirect life cycle. Predator species serve as definitive hosts and prey species serve as intermediate hosts (Box 9.7).[112,143] At least 12 *Sarcocystis* spp. use birds as definitive hosts and at least 22 *Sarcocystis* spp. use birds as intermediate hosts.[143] Two main species of *Sarcocystis* occur in birds: *S. rileyi*, between ducks and skunks, and *S. falcatula*, with a variety of passerine birds serving as intermediate hosts and the Virginia opossum *(Didelphis virginiana)* serving as the definitive host.[112,143,153] Old World psittacine birds are considered highly susceptible to *S. falcatula* infection.[112] Infection in psittacine birds typically occurs through ingestion of food contaminated with opossum feces, but insects like cockroaches can also serve as paratenic hosts or mechanical vectors.[112,153] *Sarcocystis calchasi* is typically reported in Germany but has also been found in the muscle of columbiforms in North America.[112]

Although sarcocystosis is generally fatal, resolution of clinical signs is possible with extensive supportive care and long-term treatment.[112] Recommended treatment protocols often include pyrimethamine with potentiated sulfonamides.[60,112] Supplementation with yeast and folinic acid

BOX 9.6 LIFE CYCLE OF *GIARDIA* spp.[80]

- The host ingests a viable and mature cyst, the infectious form, which is typically found in fecal-contaminated water, food, or soil.
- When the cyst reaches the duodenum, its wall dissolves, resulting in trophozoites, which bind to the intestinal epithelium.
- Trophozoites feed and grow and eventually encyst within the intestinal wall.
- Newly formed (infectious) cysts are shed in the feces, immediately starting the cycle over again.

BOX 9.7 INDIRECT LIFE CYCLE OF *SARCOCYSTIS* spp.[143,153]

- The intermediate host is infected through the fecal-oral route by ingesting sporocysts.
- The organism then invades various tissues where it undergoes schizogony or merogony, forming large, distinctive cysts in cardiac or striated muscles.
- When the intermediate host is ingested by the definitive host, the organism undergoes sexual multiplication within the intestinal tract.
- Oocysts sporulate internally and are shed in the feces.

(leucovorin) can also aid in the treatment.[112] Prevention and control of infection relies upon keeping definitive and paratenic hosts or their feces away from susceptible birds.[60,112]

A treatment protocol consisting of amprolium with either sulfamethazine or chlortetracycline did not appear to reduce mortality in a flock of chickens infected with *Sarcocystis* spp.[112] Toltrazuril administered at the onset of neurologic signs (25 mg/kg PO q24h for 3 days) was similarly ineffective in pigeons experimentally infected with *S. calchasi*,[154] although the researchers hypothesized that a longer treatment period could warrant further investigation. A triple-drug combination of pyrimethamine (1 mg/kg PO q24h), trimethoprim-sulfamethoxazole (60 mg/kg PO q24h), and ponazuril (20 mg/kg PO q24h) administered for up to 6 months achieved clinical resolution in a captive flock of thick-billed parrots *(Rhynchopsitta pachyrhyncha)*.[110] Also, a 2-week regimen of pyrimethamine (0.5 mg/kg PO q12h) and trimethoprim-sulfadiazine (30 mg/kg IM q12h) was used to successfully treat three psittacine birds.[112] The regimen was reinstated after 1 week and extended for an additional 30 days.[112] All birds recovered clinically after the second regimen; however, birds that recover from sarcocystosis are at risk for recurrence of the disease.[112]

Hemoparasites

Vector-borne haemosporidians are commonly found in birds worldwide.[155–157] Most hemoparasites in raptors are associated with subclinical infection[157,158]; however, Strigiformes show significantly higher prevalence of infection by blood parasites than diurnal raptors.[158] Some fatal infections have been reported in captive psittacine birds; however, free-ranging parrots are infrequently infected.[158] In an interesting survey of 19 Psittaciformes species from a range of habitats, hemoparasites were only found in two of the species sampled.[159] All species that consumed at least one food item known for its secondary metabolites with antimalarial, trypanocidal, or general antiparasitic properties were free from hemoparasites.[159]

Hemoproteus. *Hemoproteus* spp. are transmitted by biting midges, hippoboscid flies, or tabanids (horseflies).[156] Infections are usually relatively benign in birds with asymptomatic or mild clinical findings predominating, such as anemia and splenomegaly.[156,160] Some *Hemoproteus* spp. can cause severe disease and mortality, especially in captive birds removed from their original habitat.[160] Fatal cases have been described in a lorikeet *(Trichoglossus haematodus)*, plum-headed parakeet *(Psittacula cyanocephala)*, snowy owls *(Bubo scandiacus)*, and exotic passerine birds housed in California.[157,158,160–162]

Treatment for *Hemoproteus* is seldom indicated, but when necessary it is generally identical to that for avian malaria (see Plasmodium).[156] Treatment of a goshawk *(Accipiter gentilis)* relied upon a combination of atovaquone and proguanil hydrochloride (Malarone, GlaxoSmithKline, Mississauga, ON, Canada) administered orally.[162] Specifically, half of a Malarone tablet was given with food once a day for 3 days.[162] After 1 week the treatment course was repeated for another 3 days. After 2 weeks, the *Hemoproteus* infection was completely cleared and no parasites were observed in a blood smear stained with Wright solution.[162] A study evaluating *Hemoproteus* treatment with primaquine (0.1 mg SC) in free-ranging blue tits *(Cyanistes caeruleus)* showed increased local survival in female birds but not males.[163] Because few studies are available on experimental infection with *Hemoproteus*, more work is needed to assess the effect of sex on the course of disease.

BOX 9.8 INDIRECT LIFE CYCLE OF *PLASMODIUM* spp.[6,156,157,165–167]

- Gametocytes are ingested during a blood meal by a female mosquito.
- Sporogony occurs within the invertebrate host.
- The parasite reproduces and multiplies within the mosquito midgut. Oocytes eventually rupture releasing sporozoites.
- Sporozoites migrate to the salivary glands of the mosquito.
- Sporozoites are injected into a new avian host when the female mosquito takes a blood meal.
- Sporozoites migrate to the liver and other tissues like the lungs, spleen, kidney, and brain (tissue stage).
- Schizogony occurs within avian erythrocytes; the parasite multiplies in and destroys erythrocytes (blood stage).
- Merozoites are released from the destroyed erythrocytes and they continue the cycle by invading more erythrocytes.

Leucocytozoon. *Leucocytozoon* sporogony occurs in black flies (*Simulium* spp.) or *Culicoides* midges.[6,164,165] These parasites infect many species of avian hosts, with merogony in tissues, like the liver, and multiplication of sexual stages (gametocytes) within erythrocytes.[164,165] Most *Leucocytozoon* infections are subclinical,[156,158,164,166] although nonspecific signs of illness and death have been reported in some captive birds.[156,158,166] *Leucocytozoon* has also been associated with heavy economic losses in the poultry industry due to decreased egg production, anemia, and even death.[165]

Various antimalarial and anticoccidial compounds have shown activity against *Leucocytozoon* parasites including clopidol, primaquine, and halofuginone.[164] Sulfamonomethoxine and ormetoprim combinations have also been reported to prevent or reduce *Leucocytozoon* infection.[164]

Plasmodium. This cyclical infection involves avian hosts and female mosquitoes (Box 9.8).[89] There are over 30 *Plasmodium* spp. that affect birds, and many of these organisms can complete life cycles in a variety of avian species that belong to different families and even different orders.[6,165] Free-ranging birds are most commonly affected; however, avian malaria is occasionally found in domestic fowl and captive birds.[6,156] The clinical picture is often asymptomatic but *Plasmodium* infection can cause severe, acute disease in species that have not evolved with the parasite, such as captive penguins.[89,167]

The complex *Plasmodium* life cycle means that no single drug can eradicate all forms of the organism.[89,125,162,168] Antiplasmodial activity against the malaria life cycle can be divided into the following (Table 9.6)[169]:

- Tissue schizonticides are active against the tissue form of *Plasmodium* spp.
- Blood schizonticides are active against asexual erythrocyte forms of *Plasmodium*. In a study evaluating five antimalarial drugs in broilers infected with *P. gallinaceum*, the two most effective drugs against the asexual erythrocyte stage were chloroquine and doxycycline.[170]
- Gametocidal drugs destroy gametocytes of the malaria parasite, thereby inhibiting the transfer of *Plasmodium* from an infected host to an uninfected female mosquito.

TABLE 9.6

Antimalarial Drugs Used in Birds, Their Parasite Stage's Target, and Mechanism of Action[89,125,165,171,172]

Drug	Target(s)	Drug Class	Mechanism of Action	Comments
Amodiaquine	BS, G	Aryl aminoalcohol, 4-aminoquinoline compound	Not completely understood, but like other quinolone derivatives, likely able to inhibit heme polymerase activity in the body resulting in the accumulation of free heme, which is toxic to parasites[173]	Similar to chloroquine in structure and activity, but effective against some chloroquine-resistant strains[173]
Artemisinin (ART)	BS, G	Artemisinins are a new class of antimicrobial drugs	This prodrug is activated by intraparasitic heme or iron, which catalyzes the cleavage of this endoperoxide, resulting in the release of free radicals that kill the parasite by alkylating and poisoning one or more essential malarial protein(s)[174]	Rare instances of liver injury have been described in human patients
Atovaquone	BS, G, SP	Hydroxynaphthoquinone or an analog of ubiquinone	Inhibition of electron transport by atovaquone will result in indirect inhibition of these enzymes leading to metabolic effects that may include inhibition of nucleic acid and ATP synthesis of the parasite	The mitochondrial toxicity of atovaquone is enhanced by proguanil The adult Malarone (GlaxoSmithKline) tablet is a 250 mg atovaquone/100 mg proguanil combination
Chloroquine	BS, G, SP	Aryl aminoalcohol, 4-aminoquinoline compound	Inhibition of hemozoin formation, hemozoin being a biocrystal synthesized as a disposal product by the parasite[175]	A neuronal storage disease developed in Humboldt penguins *(Spheniscus humboldti)* treated prophylactically with chloroquine.[176] Chloroquine has been shown to cause similar effects in rats and miniature pigs under experimental conditions, therefore caution is advised when employing high and long-term treatment with this drug
Lumefantrine	BS	Aryl aminoalcohol	Unknown, but believed to inhibit nucleic acid and protein synthesis through the inhibition of hematin formation[177]	Currently used only in combination with artemether under the trade name Coartem[177]
Mefloquine	BS	Aryl aminoalcohol, quinoline-methanol derivative of quinine	Unknown, but believed to interfere with the transport of hemoglobin from the erythrocyte to the food vacuole	
Mepacrine				See quinacrine
Piperaquine	BS	Aryl aminoalcohol	The mechanism of piperaquine inhibition of the heme detoxification pathway is unknown but is expected to be similar to that of chloroquine	Currently used in combination with the artemisinin derivative, artenimol, as Eurartesim
Primaquine	TS, G	Aryl aminoalcohol, 8-aminoquinoline compound	Unknown, believed to act as oxidation-reduction mediator, inhibits electron transport processes by inhibiting pyrimidine synthesis[6]	Although primaquine has activity against blood-stage parasites, the levels required to achieve blood schizonticidal action are toxic
Proguanil hydrochloride	BS, SP	Antifolate compound	Selective inhibition of folate biosynthesis, making DNA synthesis impossible and depleting folate cofactors	Also known as chloroguanide See atovaquone, earlier

TABLE 9.6

Antimalarial Drugs Used in Birds, Their Parasite Stage's Target, and Mechanism of Action—cont'd

Drug	Target(s)	Drug Class	Mechanism of Action	Comments
Pyrimethamine	TS, BS, SP	Antifolate compound	Selective inhibition of folate biosynthesis	Similar action to proguanil but with greater efficacy (although with less efficacy on tissue stages). Effects on folate biosynthesis increase when used in combination with sulfonamides In addition to avian malaria, pyrimethamine is also used in the management of *Toxoplasma*, *Atoxoplasma*, *Sarcocystis* infections[16,47]
Quinine	BS, G	Aryl aminoalcohol	Interferes with the parasite's ability to break down and digest hemoglobin. Consequently, the parasite starves and/or builds up toxic levels of partially degraded hemoglobin in itself	An alkaloid derived from the bark of the cinchona tree. Since it was first isolated in 1820, quinine has been the fundamental medical tool for the treatment of malaria, particularly severe disease
Quinacrine hydrochloride	BS, weakly G	Aryl aminoalcohol, 4-aminoquinoline derivative	The exact mechanism of antiparasitic action is unknown; however, quinacrine binds to DNA by intercalation between adjacent base pairs	Also known as mepacrine, quinacrine was formerly used widely as an antimalarial but it is now superseded by chloroquine. Quinacrine has also been used to treat giardiasis as well as some inflammatory diseases, like lupus Overdosage may cause hepatotoxicity[135]
Sulfonamides	BS	—	Used in combination with pyrimethamine to enhance the inhibition of folate biosynthesis	
Tafenoquine	TS, BS, G	Aryl aminoalcohol, 8-aminoquinoline compound	Poorly understood; however, tafenoquine produces hydrogen peroxide and hydroxyl radicals that lead to the parasite death Also inhibits heme polymerase in blood stage of parasites	
Tetracyclines and derivatives such as doxycycline	BS	—	Tetracyclines act by inhibiting bacterial protein synthesis.[129] Their mechanisms of action on *Plasmodium* have not been as well described; however, doxycycline inhibits the synthesis of nucleotides and deoxynucleotides in *P. falciparum*[129]	

BS, schizonticide—active against the asexual blood-stage parasite; *G*, gametocytocide—kills the sexual stage of malaria parasite infective to mosquitoes; *SP*, sporontocide—inhibits the development of oocysts in the mosquito stage of the *Plasmodium* life cycle; *TS*, schizonticide—active against the tissue form of *Plasmodium* spp.

- Sporontocide drugs inhibit the development of oocysts in the mosquito stage of the *Plasmodium* life cycle, thereby preventing transmission of the disease.

In human patients with acute malaria, the complex life cycle of *Plasmodium* spp. also means that complete eradication of a patient's parasite load requires therapeutic drug levels to be present for four cycles to effect a cure.[125]

Antimalarials fall into three broad drug categories: aryl aminoalcohol, antifolate, and artemisinin compounds.[125,169] There is also atovaquone, an antimalarial in its own class, as well as antibiotics with antimalarial activity. Treatment protocols can vary widely (Table 9.7). Combination therapy is frequently used to overcome the limitations of each individual drug group.[169]

Aryl aminoalcohol compounds. The quinoline alkaloid, quinine, was first isolated from cinchona bark in 1820.[125,175,176] Since that time, a number of other natural and synthetic quinoline-based compounds have been developed, including quinidine,

TABLE 9.7

Select Hemoparasite Treatment Protocols

Drug	Species	Dosage	Combination Therapy	Comments	References
Atovaquone	Snowy owls *(Bubo scandiacus)*	½ of an atovaquone-proguanil tablet PO q24h with food × 3d, break for 1 week, then repeat treatment *(Hemoproteus)*		Malarone (GlaxoSmithKline) is a 250 mg atovaquone/100 mg proguanil tablet	162
Chloroquine	Sphenisciformes	5 mg/kg PO q24h for 10d	Primaquine 0.3 mg/kg PO q24h × 10d	*Plasmodium*	178
	Sphenisciformes	10 mg/kg PO q24h × 10–14d, then 5 mg/kg q12h PO × 3d	Primaquine 1.25 mg/kg PO q24h × 10–14d	Some institutions stop therapy at this point and others continue chloroquine 5 mg/kg PO q24h) concurrently with primaquine	89
	Sphenisciformes	10 mg/kg PO on day 1, then 5 mg/kg PO q24h × 9d	Primaquine one 26.3 mg tablet PO q24h × 10d	*Plasmodium*	178
	Broiler chicks *(Gallus gallus domesticus)*	10 mg/kg PO q24h × 5d		Significantly lowest *Plasmodium* infectivity rate (66.67%) for experimentally infected broiler chicks	170
	Psittaciformes and Passeriformes	10–25 mg/kg PO, then 5–15 mg/kg at 6, 18, and 24 h	Primaquine 0.3–1 mg/kg PO q24h × 3–10d	*Plasmodium* and other hemoparasites	16
	Most species, including raptors	25 mg/kg PO followed after 12 h by 15 mg/kg PO followed after 24 h by 15 mg/kg PO followed after 48 h by 15 mg/kg PO	Primaquine 0.75–1 mg/kg PO once	*Plasmodium*	155
	Raptors	Chloroquine 20 mg/kg IV initially, followed by 10 mg/kg PO at 6, 18, and 24 h	Primaquine 1 mg/kg PO q24h × 2d, repeat q7d × 3–5 treatments	*Plasmodium*	8
	Raptors	25 mg/kg IM q24h		*Plasmodium, Leucocytozoon*	47
	Galliformes, Passeriformes	2000 mg/L drinking water × 14d (juice covers bitter taste of drug)			27
Doxycycline	Humboldt penguins *(Spheniscus humboldti)*	20 mg/kg PO q12h × 10d			7
	Sphenisciformes	50 mg or 100 mg (based on penguin weight) PO q24h × 2–3 weeks		*Plasmodium*	178
Mefloquine	Strigiformes	30 mg/kg PO at times 0, 12, 24, and 48 h			114
	Falconiformes	30 mg/kg PO at times 0, 12, 24, 48, and 72 h, then weekly			29
	Strigiformes (eastern screech owl [*Otus asio*])	30 mg/kg PO q12h × 1d, then q24h × 1–2d		*Plasmodium* ± *Hemoproteus*	179
	Raptors	30 mg/kg PO q12h × 1d, then q24h × 2d, then q7d × up to 6 months		Long-term administration	7
	Raptors	50 mg/kg PO q24h × 7d			27
Primaquine				Dosage based on amount of active base, not total tablet weight	7
	Most species	0.3–1.0 mg/kg PO q24h × 3–10d	10–25 mg/kg PO loading dose, then 5–15 mg/kg at 6, 18, and 24 h	*Plasmodium* and other hemoparasites *(Atoxoplasma, Sarcocystis)*	7,16

TABLE 9.7

Select Hemoparasite Treatment Protocols—cont'd

Drug	Species	Dosage	Combination Therapy	Comments	References
	Broiler chicks *(Gallus gallus domesticus)*	0.50 mg/kg PO q24h × 5d		The lowest mortality rate (4.76%) for broiler chicks experimentally infected with *Plasmodium gallinaceum*	170
	Falconiformes	0.75 mg/kg PO q24h × 5d		*Hemoproteus tinnunculi*	180
	Sphenisciformes	26.3 mg tablet PO q24h × 10d	Chloroquine 10 mg/kg PO loading dose, then 5 mg/kg PO q24h × 9d	*Plasmodium*	178
Pyrimethamine	Raptors	0.5 mg/kg PO q12h × 14–28d		*Leucocytozoon*	8
	Psittaciformes, Passeriformes	0.5 mg/kg PO q12h × 30d		*Leucocytozoon (Atoxoplasma, Sarcocystis, Toxoplasma)*	16
Quinacrine	Canaries (*Serinus canaria* f. *domestica*)	0.24 mg/kg PO q12h		*Plasmodium* (mepacrine)	16
	Most species	5–10 mg/kg PO q24h × 7–10d		*Plasmodium*	8
	Psittaciformes, Passeriformes	5–10 mg/kg PO q24h × 10d		*Plasmodium (Atoxoplasma)*	16
	Most species	7.5 mg/kg PO q24h × 7–10d		*Atoxoplasma*	18
Tafenoquine	Chickens *(Gallus gallus domesticus)*	30 mg/kg IM q24h × 5d		Unable to clear the blood-stage *Plasmodium* parasites but did reduce mortality in chickens	171
		30 mg/kg IM q24h × 5d	Artesunate 1 mg/kg q24h × 5d	Completely cleared experimental *P. gallinaceum* blood stages and sped up gametocyte clearance	171

d, Day(s); *h*, hour(s); *IM*, intramuscular; *IV*, intravenous; *PO*, per os.

mefloquine, and halofantrine, as well as aminoquinoline derivatives like chloroquine, amodiaquine, primaquine, lumefantrine, piperaquine, and tafenoquine.[125,175,177]

The use of primaquine and chloroquine together has been a popular treatment choice for avian patients.[89,165] This regimen is based on the combined effect of chloroquine on blood-stage parasites and of primaquine on tissue stages of *Plasmodium*. Grilo et al. have summarized a variety of protocols used in captive penguin colonies, including a regimen recommended by the Association of Zoos and Aquariums Penguin Taxon Advisory Group consisting of primaquine (1.25 mg/kg PO q24h) and chloroquine (10 mg/kg PO q24h) over 10 to 14 days, then continuation with chloroquine (5 mg/kg q12h PO) over 3 days.[89] Some institutions stop therapy at this point and others continue chloroquine (5 mg/kg PO q24h) concurrently with primaquine.[89] A treatment regimen described in two snowy owls consisted of chloroquine (10 mg/kg loading dose, then 5 mg/kg PO q24h for three doses, then 5 mg/kg PO q7d for four doses) and primaquine (1 mg/kg PO q7d for five doses).[157] Blood smears evaluated at 3 and 4 weeks after initiation of treatment were negative for all hemoparasites.[157] This was followed by an additional round of chloroquine (10 mg/kg PO q24h for 10 doses) and primaquine (1 mg/kg PO q24h for 10 doses) to ensure parasitemia had been eliminated.[157] Tafenoquine is active against both liver and blood stages of malaria.[125] Tafenoquine (30 mg/kg IM for 5 days) was highly effective against gametocytes and completely blocked the transmission of *P. gallinaceum* to the mosquito vector.[171] A 5-day low-dose treatment of tafenoquine (3–10 mg/kg) was unable to clear blood-stage parasites, but did reduce the mortality rate.[171] It should also be noted that higher doses of tafenoquine (60 or 100 mg/kg IM once) caused death in chickens.[171]

Mefloquine can be used for treatment or prophylaxis (see Prophylaxis) of malaria.[125] Treatment of an eastern screech owl *(Otus asio)* with mefloquine (30 mg/kg PO) repeated after 12, 24, and 48 hours proved successful in eliminating *P. subpraecox* from blood smears and resolving clinical signs consistent with malaria.[179]

Antifolate compounds. Antifolate combination drugs include dihydrofolate reductase inhibitors, such as pyrimethamine, proguanil, and chlorproguanil. The inhibitory effect that these drugs have on folic acid synthesis increases when used in combination with sulfa drugs.[125,169]

Artemisinin compounds. Artemisinin and its derivatives, dihydroartemisinin, arteether, artemether, and artesunate, are the current first-line antimalarials for activity against the blood stage and gametocytes of *Plasmodium*.[125,171] Artemisinin compounds are exceptionally fast-acting against asexual, intraerythrocytic *Plasmodium*, effecting up to 10,000-fold reductions in parasite burden every 48 hours.[125,181] A disadvantage of artemisinin compounds is their very short in vivo half-lives,

approximately 1 hour in humans.[181] Therefore artemisinins are most successful in nonsevere malaria when used in combination with a second drug, such as mefloquine or sulfadoxine-pyrimethamine.[125,127,181] A 5-day combination of tafenoquine (30 mg/kg IM q24h) and low-dose artesunate (1 mg/kg q24h) completely cleared experimental *P. gallinaceum* blood stages and sped up gametocyte clearance from chickens, suggesting synergistic action between the two drugs.[171] Recent studies demonstrated that a 7-day regimen of artesunate (10 mg/kg) cleared the blood-stage parasites and gametocytes and also blocked transmission of the parasite to mosquitoes.[182,183]

Atovaquone. Atovaquone has a unique mode of action that involves selective action against mitochondrial electron transport in the parasite. The mitochondrial toxicity of atovaquone is enhanced by proguanil hydrochloride (chloroguanide).[125] The combination of atovaquone and proguanil (Malarone, GlaxoSmithKline) is a fixed-dose combination containing 250 mg of atovaquone and 100 mg of proguanil in a single tablet.[125,162] Malarone clears blood-borne forms of *Plasmodium*.[125,162,168,169] Malarone was highly efficient for clearing blood stages of *P. relictum* in experimentally infected greenfinches *(Carduelis chloris)*.[168]

Antimicrobials. Tetracyclines, clindamycin, azithromycin, and fluoroquinolones have demonstrated variable degrees of schizontocidal activity.[125–129] Antibacterial protein synthesis inhibitors, like doxycycline and azithromycin, exert antimalarial activity by inhibiting function of the apicoplast.[129,184] This action is necessarily slow, presumably due to the ability of parasites to survive most of their life cycle without functional apicoplasts.[184] The slow-acting, sometimes weak activity of these antimicrobials against *Plasmodium* means that they are recommended for treatment only in combination with a fast-acting schizonticide like quinine, or as a single agent for prophylaxis (see Prophylaxis).[125,185] A mohua *(Mohoua ochrocephala)* with avian malaria survived for a year following treatment with chloroquine and doxycycline.[186]

To overcome the challenges caused by the spread of antimalarial drug resistance (see Prophylaxis), new antimicrobials that are being explored include eravacycline, tigecycline, mirincamycin, fusidic acid, thiostrepton, and nocathiacin.[127,187]

Ionophores. In a 2015 study, the monovalent ionophores, salinomycin, monensin, and nigericin, efficiently killed both asexual forms and gametocytes of *P. falciparum*.[188]

Prophylaxis. The effectiveness of treatment for avian malaria usually decreases dramatically by the time the first clinical signs appear.[89,156] Therefore continuous or seasonal prophylactic treatment is widely used at some institutions with susceptible collections, like penguins, to prevent the development of and/or reduce the severity of clinical signs.[89] Protocols often rely on daily to weekly administration of prophylactic antimalarial drugs, such as primaquine, pyrimethamine, or proguanil (Table 9.8).[6,89,169] Doxycycline is also considered a highly effective antimalarial prophylaxis against *P. falciparum*, the cause of human malaria,[126,187] particularly in multidrug resistance zones.[128,187] When drug prophylaxis is employed, it is usually done on an annual basis since this practice can prevent some individuals from developing natural immunity to *Plasmodium* spp.[89]

Oral supplementation with folic acid can be administered when prophylaxis includes an antifolate compound.[89] Caution must also be taken when a folic acid inhibitor is used in laying females during the reproductive season.[89] Discontinuation of pyrimethamine treatment has been recommended 10 days before breeding/laying season.[89]

ECTOPARASITICIDES

A variety of drugs can be used to control or destroy ectoparasites in birds (Table 9.9). Broad-spectrum ectoparasiticides include MLs, organophosphates and carbamates (OP/C), phenylprazoles, pyrethroids, isoxazolines, and spinosyns.[4,191–193] Although MLs and isoxazolines can also be administered systemically, most ectoparasiticides are administered topically as sprays, mists or fogs, and dusts.[4,191,192] On most large-scale production farms in the United States, pesticides are sprayed from underneath as birds sit within suspended wire or "battery cages."[192,194] These pesticides are most effective when they are applied where mites are concentrated to feathers in the vent region.[192,194] The pesticides are sprayed at high pressure because it can be difficult to penetrate the plumage in the vent region.[192] It can also be difficult to achieve acaricidal levels in all the hard-to-reach areas that mites may hide.[4,192] Topical application of ectoparasiticides tends to be a bit less aggressive for individual birds. Powders or dusts can be applied with a shaker can or hand duster; however, the dust can be difficult to apply and is easily inhaled. Another technique involves placing the bird in a canvas bag, with the head sticking out. The bag (and bird) can then be gently manipulated to spread the dust into the plumage and around the vent. Following application of any insecticide to a cage or room, the environment should be vacated and thoroughly cleaned.[39] Nests and perches should also be replaced.[39]

Organophosphates/Carbamates

Organophosphates (OPs) are applied to housing or individual birds to treat infestations of ectoparasites, like ticks, mites, and lice (Table 9.9).[52] OP are potent acetylcholinesterase inhibitors that cause acetylcholine to accumulate at the autonomic ganglia, neuromuscular junction, and central nervous system, which in turn leads to parasite paralysis and death.[6,52] OP can be absorbed through the skin as well as through mucous membranes of the eyes, respiratory tract, and digestive system.[52] Following absorption, OP is extensively metabolized and distributed widely to tissues.[52] OP can persist on the surface for reasonable periods even though residues within animal tissues are relatively short-lived.[6] Phoxim, malathion, and dichlorvos are examples of OP. The closely related carbamates (C), such as carbaryl and propoxur, behave similarly.[52]

Although veterinary OP/C products are considered relatively safe in birds, their potential impact on the environment and nontarget species like honey bees is extremely serious.[203] Therefore the use of many OP/C insecticides has narrowed considerably in recent years. Carbaryl and many other OP/C are no longer approved for use in poultry. If a product like carbaryl is administered to a companion bird, it should be used indoors, with masks and gloves and the handlers should clean their shoes before going outside.

Pyrethrins

Pyrethrins are a group of insecticides derived from the pyrethrum flower *(Chrysanthemum cinerariaefolium)*. Synthetic forms

TABLE 9.8

Avian Malaria Prophylaxis Protocols (See Box 9.10)

Drug	Species	Dosage	Combination Therapy	Comments	References
Chloroquine	Most species	10 mg/kg PO q7d	Primaquine 1 mg/kg PO q7d	Preventive regimen for birds recovering from *Plasmodium* infection, once bird is stable	7,8
	Penguins	15 mg PO q24h	Primaquine 1–4 mg/kg PO q24h to SIW (26.3 mg most common dose)	Primaquine was most commonly dosed SIW	178
Doxycycline	Penguins	100 mg PO q24h		One institution reported administering the medication for 14 days and then resting the birds for 7 days	178
Mefloquine	African penguins *(Spheniscus demersus)*	30 mg/kg PO SIW		Regurgitation has been noticed in birds treated for several consecutive days	89
Primaquine	African and Humboldt penguins *(Spheniscus demersus, Spheniscus humboldti)*	0.75 mg/kg PO SIW or twice in a week		During vector season or year round depending on location	189
	African and Humboldt penguins *(Spheniscus demersus, Spheniscus humboldti)*	1.25 mg/kg PO SID		During vector season or year round depending on location	189,190
	Penguins	1.25 mg/kg PO q24h during vector season		During vector season or year round depending on location	190
	Penguins	1–4 mg/kg PO SIW		26.3 mg was the most common dose reported	178
Sulfonamides	Penguins	Sulfadiazine 125 mg PO q48–72h	Pyrimethamine 4 mg PO q48–72h	Regimen most commonly dosed q48h, alternatively q72h Supplement folic acid 0.4 mg PO	178

h, Hour(s); *PO*, per os; *q*, every; *SIW*, once weekly.

based on this naturally occurring compound are called pyrethroids.[52] Permethrin is the primary pyrethroid used in poultry.[52] Additional pyrethroids include deltamethrin, cypermethrin, and fenvalerate.[52] These drugs act by altering the activity of the sodium ion channels of nerves, leading to insect paralysis and ultimately death. All pyrethroids are lipophilic, which helps them to serve as contact insecticides.[52] Pyrethroids also have a repellent effect, persisting on plumage and skin but not in tissue.[6] Therefore these ectoparasiticides are of particular value against parasites that feed on the skin surface, like lice, some mites, fleas, and nuisance flies (Table 9.9).[52]

Pyrethrins and pyrethroids are among the least toxic of the insecticides and are not as well absorbed through skin as other insecticidal compounds.[52] The death of two zebra finches *(Taeniopygia guttata)* was attributed to a pyrethrin-based spray (0.16 mg/100 mL water).[199] Spray was applied twice to a flock of approximately 350 birds in situ, with a 2-week interval between treatments. Examinations carried out a few weeks later demonstrated incomplete mite eradication, and four additional treatments at biweekly intervals were performed by individually spraying each bird that lived outside a nest box.[199] Hatchlings were sprayed within the nest.[199] Pyrethroids are extremely toxic to fish and aquatic invertebrates,[6] which should be a consideration if birds are housed in mixed aquatic zoo exhibits.

Phenylpyrazoles

Phenylpyrazole insecticides are a class of broad-spectrum compounds that act by interfering with activation of insect-specific GABA receptors leading to neuronal hyperexcitation of the insect nervous system and death.[6,204,213] Fipronil (Frontline, Boehringer Ingelheim, Duluth, GA) is a phenylpyrazole that is used for the treatment and control of tick infestations as well as some mites (Table 9.9).[6]

Fipronil is not approved for use in any food animal species because it is highly lipophilic and concentrates within eggs.[6,60,197,204] It is important to use this product with caution in any novel avian species because metabolites of fipronil have shown higher toxicity to birds than the parent compound.[25] This toxic response appears to be quite variable and has appeared in different avian families.[25,213,214]

Macrocyclic Lactones

MLs, such as IVM, doramectin, abamectin, and selamectin, are important for ectoparasite control in birds,[1] showing very high potency against various mites (Table 9.9).[4] IVM is also of

TABLE 9.9

Ectoparasiticides for Use in Birds

	Pyrethrins Permethrins Pyrethroids	Organophosphates/ Carbamates	Macrocyclic Lactones	Isoxazolines	Phenylprazole	Spinosyn
Examples	Bifenthrin Cypermethrin Deltamethrin Permethrin	Carbaryl (C) Propoxur (C) Dichlorvos (OP) Phoxim (OP) Tetrachlorvinphos (OP)	Doramectin (DOR) Eprinomectin (EPR) Ivermectin (IVM) Milbemycin oxime Moxidectin (MOX) Selamectin (SEL)	Afoxolaner Fluralaner Sarolaner	Fipronil	Spinosad
Clinical applications	Mites,[a] lice, fleas, ticks, nuisance flies[52,60]	Broad-spectrum activity against insects, ticks, arachnids, surface mites, fleas, flies, and lice[3,195]	Broad-spectrum anthelmintic and insecticidal activity, including mites, particularly burrowing mites (i.e., *Knemidokoptes*)[3,196]	Mites, lice[197]	Broad-spectrum insecticidal activity, including mites, lice, ticks, flies[6,39]	Mites
Administration	Two topical applications are necessary at an interval of 10d; more applications[b] may be required Lightly dust plumage, spray until runoff, or dip with dilution[7] Permethrin-impregnated plastic strips[c] are marketed for ectoparasite control in caged or cage-free commercial and backyard poultry flocks[198]	Two topical applications at an interval of 10d Lightly dust plumage and/or paint, spray, and/or dust perches, nest box, and/or premises[7] Remove treated litter after 24 hours[7,18]	Two systemic or topical doses 10–14d apart[d] IVM or DOR can be diluted 1:10 with propylene glycol or sesame oil, respectively[39] Apply topical IVM to the skin in the axillary and inguinal regions, or on the bare skin dorsolateral to the thoracic inlet (at the site of jugular vein blood collection)[199,200]		Apply two to three squirts using a pad to skin at base of neck, tail base, axillary and/or inguinal area. Avoid plumage. Do not soak bird[8,25,16,201] Use spray formulation and not spot-on preparation[7]	Topical spray (1.94 or 3.88 g/L) [202] Residual activity was maintained throughout the course of a 28d post-spray study period, with a peak in product efficacy seen 14d after spraying.[202]
Contraindications, precautions	Topical application can be stressful for birds[199] Hang dichlorvos strips out of reach of the birds[39]	Topical application can be stressful for birds and a potential health risk for humans exposed to pesticides and residues[4] Veterinary products are considered relatively safe in birds; however, carbaryl and many other OP/C are no longer approved for use in poultry because of their potential impact on the environment and nontarget species[203]	Due to high residue levels found in eggs, IVM should be avoided in laying hens until establishment of reliable withdrawal periods[5] Propylene glycol-based IVM can cause severe respiratory tract irritation if aspirated during oral administration[201]	—	Not approved for use in any food animal species. High residue levels within eggs[204] Alcohol may create dry, brittle feathers[8,16] Beware of inhalation or dermal absorption of the alcohol base Do not exceed 7.5 mg/kg[8]	—

		If a product like carbaryl is administered to a companion bird, it should be used indoors, with masks and gloves and the handlers should clean their shoes before going outside.				
Potential adverse effects or toxicity	The death of two zebra finches *(Taeniopygia guttata)* in a flock of ~350 birds was attributed to spraying[199]	—	No adverse effects have been reported in chickens *(Gallus gallus domesticus)*[5]; however, there are sporadic, reports of IVM toxicosis in birds, including finches (presumably due to propylene glycol)[15] No evidence of IVM toxicity was seen in budgerigars *(Melopsittacus undulatus)* treated with 5–10 times the recommended dose[200] No adverse effects in Gouldian finches *(Erythrura gouldiae)* given SEL up to 92 mg/kg[205] Risk of IVM toxicity may be higher if the drug is injected, particularly via the IM route[16]	No adverse effects have been described in poultry treated with flural aner[191,197,206,207] In fact, a 3-fold safety margin has been demonstrated with fluralaner in chickens[191,206]	One fipronil metabolite has higher toxicity to birds than the parent compound; therefore this product should be used with caution because it shows variable toxicity in different avian families[25] Use with caution in raptors, pigeons, passerine birds[7] Reported toxic effects include death, tremors, seizure activity, anemia, leukopenia, impaired immune function, reduced growth and reproductive success[7,208–210]	Application of spinosad in vivo had no effect on hen body weight or egg production parameters (number and weight)[202]
Dosage in most species			IVM 0.2–0.4 mg/kg PO, topical, SC, IM once; repeat in 10–14d prn (see Potential adverse effects or toxicity, earlier)[8] See Table 9.1 for additional doses		7.5 mg/kg topically once, repeat in 30d as needed in most birds, including raptors, pigeons, passerine birds[8,18,25,38]	
Galliformes	Cypermethrin 60–120 mg per chicken[30]		EPR, MOX, or IVM 5.0 mg/kg PO (chicks, *Dermanyssus*)[4] SEL 20 mg/kg topical (helmeted guineafowl [*Numida meleagris*])[35]	Fluralaner 0.5 mg/kg PO given twice at 7d intervals administered in the drinking water or by gavage[e] was shown to be safe and to have a 0d egg withdrawal period following treatment[4,191,197,206] Afoxolaner 2.5 mg/kg PO once to pheasants, chachalacas[211]		
Passeriformes	—	—	—	—	3 mg/kg topically once[16]	—

TABLE 9.9

Ectoparasiticides for Use in Birds—cont'd

	Pyrethrins Permethrins Pyrethroids	Organophosphates/ Carbamates	Macrocyclic Lactones	Isoxazolines	Phenylprazole	Spinosyn
Psittaciformes	—	—	MOX 1 mg/bird topically once, repeat q10d × 2 treatments prn (budgerigars [*Melopsittacus undulatus*], *Knemidokoptes*)[7] SEL 23 mg/kg topically, repeat in 3–4 weeks (budgerigars, *Knemidokoptes*)[7,45]	—	3 mg/kg topically once[16]	—
Raptors	—	—	SEL 23 mg/kg topically, repeat in 4 weeks (golden eagle [*Aquila chrysaetos*], *Micnemidocoptes*)[212]	—	—	—

[a]Pyrethrin-based spray (0.16 mg/100 mL water) was applied twice to zebra finches *(Taeniopygia guttata)* in situ, with a 2-week interval between treatments. However, feather examinations carried out a few weeks later demonstrated incomplete mite eradication, and four additional treatments at biweekly intervals were performed by individually spraying each bird that lived outside a nest box. Hatchlings were sprayed within the nest.[199]

[b]To eradicate feather mites from a flock of zebra finches *(T. guttata)*, multiple treatments[a] using a pyrethrin spray were effective. Topical IVM was later found to be more efficacious, better tolerated by birds, and less labor-intensive.[199]

[c]Resistance is a growing problem. In a recent study, permethrin strips had no effect on poultry mite populations.[198]

[d]A "drop on" liquid ivermectin solution containing 0.1% is commercially available in Australia (1000 μg/mL) (Avimec, Vetafarm Pty Ltd, Australia) and 0.01% (100 μg/mL) w/v ivermectin solution were evaluated in budgerigars *(Melopsittacus undulatus)* with *Knemidokoptes*. One drop (0.05 mL) was effective for birds <30 g and two drops (0.1 mL) for birds 30 to 100 g.[200]

[e]Fluralaner (10 mg/mL) had no effect on water consumption at up to 5× the recommended dose.[206,207]

proven benefit in pediculosis (see Macrocyclic Lactones for precautions with respect to the use of MLs in poultry).[3]

There are sporadic, anecdotal reports of acute, potentially fatal IVM toxicosis in birds, particularly small passerine birds like finches.[18] This effect is believed to be an acute anaphylactic reaction to the propylene glycol in IVM,[39] although there was no evidence of toxicity in budgerigars treated with five to ten times the recommended dose.[200] Some clinicians avoid injecting IVM into birds altogether, particularly small birds, and instead use doramectin, which contains sesame oil.[39,196]

Isoxazolines

Isoxazolines are a class of insecticides that paralyze and kill parasites by selectively targeting noncompetitive GABA receptors, binding to chloride channels within insect nerve and muscle cells.[6] Isoxazoline compounds include fluralaner, sarolaner, lotilaner, and afoxolaner (Table 9.9).[6] Fluralaner in drinking water has been used to control mites and lice infestations in the chicken.[197,211] Afoxolaner has been successfully used for chewing lice *(Goniodes pavonis)* infestations in pheasants (*Chrysolophus* spp., *Lophura* spp., *Phasianus colchicus*, *Syrmaticus reevesii*), West Mexican chachalacas *(Ortalis poliocephala)*, and peacocks *(Pavo cristatus)*.[211,215]

This class of drugs has been used in poultry without a negative impact on health or production and no adverse effects were observed in pheasants, chachalacas, or peacocks.[211,215] Nevertheless, products containing isoxazolines have been associated with adverse neurologic reactions, including muscle tremors, ataxia, and seizures in some dogs and cats.[216]

Spinosyns

Spinosyns quickly kill insects using a novel mode of action that alters the function of nicotinic and GABA-gated ion channels, causing rapid excitation of the insect nervous system, involuntary muscle contractions, tremors, paralysis, and death.[217] Spinosad is a fermentation product derived from the spinosyn-producing soil actinomycete *Saccharopolyspora spinosa* that has demonstrated acaricidal activity against *Dermanyssus gallinae* (see Therapy for Specific Ectoparasite Concerns) (Table 9.9).[192,202,217] *D. gallinae* showed high mortality by 2.5 hours posttreatment.[192]

Therapy for Specific Ectoparasite Concerns

Dermanyssus gallinae

Dermanyssus gallinae, the poultry red mite (PRM) or roost mite, is a worldwide pest of chickens and other gallinaceous birds.[37,218] The PRM is also seen in passerine birds and sporadically in other exotic birds. This blood-sucking ectoparasite visits its host only during the night.[25,37] During the day, mites hide in the environment of their host, within nest material as well as cracks and crevices in the immediate surroundings.[37,218] Although *D. gallinae* favors poultry and other birds, this mite will feed on blood from other animals, including humans.[218] PRMs usually feed every 2 to 4 days. They are very resistant to desiccation and can survive up to 8 months without feeding.[4] Seasonal activity of mites is mainly temperature-driven.[218] The optimum temperature for egg production is 25°C to 30°C (77°F–86°F) and its best survival rate is observed at a relative humidity of 70% to 90%.[218] Temperatures below −20°C (−4°F) and above 45°C (113°F) are considered lethal.[218]

Treatment of PRM requires treating the environment as well as the birds. The premises, including the nesting material and all equipment associated with birds, should be sprayed with an insecticide, sometimes multiple times.[39] Regular cleaning of housing and maintenance of good hygiene practices is also essential.[218] Cracks and crevices should also be sealed.

Treatment of birds can be administered topically or systemically. Multiple treatments are often required. MLs, such as IVM, eprinomectin, and moxidectin, are an excellent systemic treatment choice for *D. gallinae* in individual birds.[1,4,39,219] In a study evaluating the efficacy of these three MLs administrated orally to chicks at 5.0 mg/kg, all three drugs significantly increased the mortality of *D. gallinae*.[4] Among the three MLs, eprinomectin exhibited the highest performance against PRMs.[4] Fluralaner in drinking water has also been used to control PRM infestations in the chicken and this product is currently approved for use in poultry.[4,197,202,206]

Historically, chemical control of mites in large poultry flocks has been largely dependent on the use of topical acaricides, including OP/C, amidines, pyrethroids, isoxazolines, and spinosyns,[4,191–193,197,202,206] however, legislation frequently (and appropriately) constrains the products that can now be used to prevent the exposure of eggs, poultry, and humans to drug residues.[218] Spinosad spray is currently approved for use in poultry, and a single application of spinosad has demonstrated acaricidal activity against *D. gallinae* when applied at either 1.94 or 3.88 g/L.[202] Residual toxicity to *D. gallinae* was maintained for 28 days post–spinosad spray with a peak in product efficacy 14 days post-spray.[202]

In individual companion birds, for which extra-label drug use is legal, a pyrethroid/permethrin dust, carbaryl powder or spray (5 g–85% carbaryl powder/L water) can be applied.[39] Fipronil is also effective against PRM and well tolerated in many avian patients (see Organophosphates/Carbamates for precautions with respect to use of carbaryls; see Phenylpyrazoles for precautions with regard to fipronil).[39]

Ornithonyssus sylviarum

The northern fowl mite (*Ornithonyssus sylviarum*) is one of the most common and most damaging ectoparasites of poultry.[194] Over 70 species of wild and exotic birds can also serve as hosts of this blood-sucking mite.[192,194] Box 9.9 and Figure 9.1 provide an overview of the life cycle of this parasite. Heavy infestations can be associated with reduced egg production, blackened feathers due to the accumulation of dried blood, as well as scabbed, cracked skin around the vent.[195]

This mite spends its entire life on the bird, and therefore only the bird, and not the enclosure, is treated for *Ornithonyssus*.[195] Permethrin is the primary pyrethroid used to treat infestations in poultry.[52] An ML, like IVM, is also a good choice in many avian patients.[60] Northern fowl mites are also highly sensitive to fluralaner and moderately sensitive to phoxim and propoxur.[192]

Knemidokoptes mites

Knemidokoptes spp., also known as the scaly leg and face mite, is most commonly reported in passerine birds, such as canaries and finches, and psittacine birds, like budgerigars. This common burrowing mite spends its entire life cycle on the

BOX 9.9 LIFE CYCLE OF THE NORTHERN FOWL MITE *(ORNITHONYSSUS SYLVIARUM)*[192]

- Eggs hatch into sessile, nonfeeding larvae that last about a day.
- This is followed by an active, blood-feeding protonymph stage and a nonfeeding deutonymph stage, before molting into active, blood-feeding adults.
- The entire life cycle is completed in approximately 5–12 days.
- Mites are able to survive off-host for at least 1–3 weeks, perhaps months, particularly at high temperatures.

FIGURE 9.1 Life stages of the northern fowl mite *(Ornithonyssus sylviarum)*: egg *(e)*, egg with developing larva *(e-l)*, larvae *(l)*, protonymph *(p)*, and adult female *(a)*. Eggs mature to adults in as few as 5 days. Adults can persist in the environment for weeks and perhaps months. (From Murillo AC, Mullens BA: A review of the biology, ecology, and control of the northern fowl mite, *Ornithonyssus sylviarum* (Acari: Macronyssidae), *Vet Parasitol* 246:30–37, 2017.[194])

bird and is transmitted from bird to bird via prolonged, direct contact.[195] Lesions appear as hyperkeratotic, honeycomb encrustations on featherless skin.[195] Older birds are most commonly affected.[195] Diagnosis is based on the typical pitted appearance of the legs and face of the bird and through microscopic visualization of the mite after a tape prep or scrape of the affected area.

Treatment in many avian species is with IVM (0.2 mg/kg PO, SC, or topically) at 1- to 2-week intervals, for often three to four treatments. In poultry that cannot be treated with IVM, individual birds can be treated by directly applying an oil-based product, such as mineral oil or petroleum jelly, to the entire affected area once daily for at least 2 weeks.[195] After a few days, the dead scales will be softened and can be gently rubbed or scraped from the bird.[195] For larger poultry groups, dusts and sprays (described earlier) can be directly applied.[195]

Sternostoma tracheacolum

Sternostoma tracheacolum is found worldwide in both captive and wild birds.[220] This species can be found throughout the avian respiratory tract, from the trachea to the air sacs.[220] Due to the difficulty of detecting mites, infestation of *S. tracheacolum* is often diagnosed at necropsy after the death of some avian hosts has occurred.[220]

Individual birds can be treated with IVM or doramectin.[39] There is also an intriguing, albeit dated, case report in which a flock of canaries *(Serinus canaria)* with *S. tracheacolum* were exposed to 5% malathion powder pumped into the cage to create a fairly dense fog for 5 minutes.[221] This treatment was repeated weekly for 4 weeks and it was successful in controlling the mite. In another dated study, Gouldian finches *(Erythrura gouldiae)* infested with *S. tracheacolum* were fed millet coated with olive oil (1 mL olive oil to 50 g millet) and thoroughly mixed with Sevin dust (0.04 g carbaryl to 50 g grain) once a week for 3 weeks.[221] Although birds were euthanized at the end of this 3-week study, no deaths occurred while finches were fed treated seed.[221] And although eradication was not achieved, adequate control was obtained. Within 1 to 2 weeks of treatment, the clinical status of birds was noticeably improved and mature birds again began breeding.[221]

Chewing lice

Avian chewing lice belong to suborders *Amblycera* and *Ischnocera*.[222] These small, dorsoventrally flattened insects feed on fragments of feathers and other epidermal products.[197,222] This behavior degrades plumage quality, creating small holes on feathers reducing thermoregulatory capacity, and increasing feather breakage.[222] Over 4000 species of bird lice have been identified,[222] including the slender pigeon louse *(Columbicola columbae)*, the poultry shaft louse *(Menopon gallinae)*, and the chicken body louse *(Menacanthus stramineus)*. Lice that feed on birds typically spend their entire life on the host.[195]

Pyrethrin sprays or permethrin dust are probably the most common options available for use.[60] Fipronil spray is another option.[60] Lice eggs are resistant to insecticides, and topical treatments must be repeated for optimal results.[195] Systemic drug options include IVM and afoxolaner.[3,196,211]

Hippoboscid flies

Hippoboscidae (flat flies), such as *Ornithomyia avicularia*, are commonly found on birds of prey and may cause significant blood loss in very young birds.[29,162] Flat flies may be removed manually or birds can be dusted with pyrethrin (0.5%–2%), malathion (5%), or carbaryl (0.5%).[29] There are also anecdotal reports of fipronil spray (0.29%) used successfully in pigeons and raptors to remove hippoboscids and reduce black flies and mosquitoes.[25]

Myiasis

Myiasis or fly strike is the infestation of healthy or necrotic tissue by fly larvae.[223] Traumatic myiasis has been observed in a variety of wild and companion birds. Treatment requires manual removal of maggots from affected tissue and management of the wound to promote healing.[223] Birds recovering from myiasis should also be kept indoors and protected from flies to prevent reinfestation of the healing wound.[223]

Systemic IVM is frequently used for management of fly strike. The successful use of an IVM sustained-release varnish,

with or without concurrent injectable IVM, has also been described for severely affected patients that would have been stressed by multiple handling events.[224] There are also anecdotal reports on extra-label use of the neonicotinoid, nitenpyram, in a variety of avian patients. Nitenpyram use has been described for fly larvae as well as sticktight fleas *(Echidnophaga gallinacea)* in poultry. Neonicotinoids work by interfering with neural transmission in the central nervous system.[213] They bind to the nicotinic acetylcholine receptors in the postsynaptic neuron, acting as false neurotransmitters that cause continuous activation of the receptor and neurotoxicity in the parasite.[213] Neonicotinoids have greater affinity for, and thus bind more strongly to, insect receptors.[213] Nitenpyram is administered either by mouth or as a topical formulation that can be created by crushing and suspending the tablet in water. Neonicotinoids have demonstrated outstanding potency and they are generally considered to have low toxicity in mammals, birds, and fish.[225] However, more recently, this class of drugs has been shown to have direct negative impacts on wild birds in North America and Europe.[226]

Ticks

Ticks that will feed on birds include *Hyalomma* spp., *Ixodes* spp., *Haemaphysalis* spp., *Amblyomma* spp., and *Argas* spp.[227–231] Ixodid ticks are most commonly found on birds in Europe, particularly passerine birds.[228,229] Most ticks on North American birds are neotropical species with host ranges that involve Central and South America.[231] Birds are most frequently infested by tick larvae and nymphs and much less commonly by adult forms.[230,232] During the nonparasitic phase of their life cycle, ticks reside on the soil surface and in the lower parts of plants, where they have the greatest chance of finding a host.[230] Therefore ground-foraging birds tend to be more heavily infested with ticks,[230,233] particularly orders Galliformes (Phasianidae) and Passeriformes (Alaudidae and Corvidae).[230,233] Although in a survey of 46 gyrfalcon *(Falco rusticolus)* carcasses from Iceland, 20% of first-year birds and second-year birds harbored the tick *Ixodes caledonicus*.[234]

The fowl tick, *Argas persicus*, is a parasite of poultry and wild birds in tropical and subtropical regions around the world.[235] Fowl ticks are rare pests of commercial poultry, but they are likely to be seen in crowded, backyard poultry houses in warm, dry climates.[236,237] Nymphs and adults feed at night for 15 to 30 minutes at a time,[237] and fowl ticks are an important cause of anemia.[236] Additional signs can include a marked reduction in egg production, weight loss, lethargy, and even tick paralysis (see Tick Paralysis).[236,237]

All fowl tick stages may be found hiding in cracks and crevices during the day.[237] After the environment is thoroughly cleaned, all surfaces, including walls, ceilings, cracks, and crevices, should be treated thoroughly.[237] Products that have been applied to the premises include carbaryl, coumaphos, malathion, permethrin, stirofos, or a mixture of stirofos and dichlorvos.[237] A study also revealed that abamectin spray (0.5 mL/L) was sufficient to eradicate *A. persicus* population.[238] After cleaning and treating, cracks and crevices should also be sealed.[237]

For chemical treatment of the bird, MLs, such as IVM or selamectin, are effective for one-host ticks, like the fowl tick.[6,239] Additional topical treatments have included pyrethrin/permethrin and carbaryl.[239] Peracetic acid (0.5%) dips were also a highly effective treatment for *A. persicus*, resulting in 100% mortality of ticks after 2 minutes.[235] Adverse effects were not observed in chickens with this technique.[235] By contrast, respiratory signs, such as temporary coughing and sneezing, as well as ocular inflammation were observed in chickens dipped in deltamethrin.[235] Fipronil, afoxolaner, and fluralaner are also used for tick infestations in small animals and should prove effective in birds based on their proven acaricidal activity.[6]

Tick paralysis

Tick paralysis is a neurotoxin-mediated flaccid paralysis syndrome that has been described in wild birds and gallinaceous birds that has been associated with heavy infestations of *Ixodes* spp. as well as at least 10 species of argasid ticks.[239–241] Birds exhibiting signs of tick paralysis should be treated as a medical emergency, and tick removal should be performed as soon as possible to halt exposure to salivary toxins.[65,240] Removal is best accomplished using fine forceps applied close to the skin with gentle, steady, upward and outward traction, taking care to avoid leaving mouth parts embedded in the wound.[242] Care is otherwise supportive but may require intubation for respiratory support in severe cases. Rapid resolution of clinical signs after tick removal should be observed.[239,241] In a survey of 23 wild birds, most birds (74%) recovered with supportive care within 3 to 7 days.[239–241] After removal of more than 350 adult and larval ticks, a nestling bald eagle *(Haliaeetus leucocephalus)* recovered from paresis within 36 hours and was released after 3 weeks.[239]

DRUG RESISTANCE

Resistance is the inevitable result of natural selection that occurs in response to continuous exposure to antiparasitic drugs.[125,243,244] Selection pressures enhance the fitness of parasites and promote the development of heritable traits that allow the organism to survive and/or multiply despite the administration of a drug in doses equal to or higher than those usually recommended, but within the limits of tolerance of the host.[80,90,243] Ever-rising levels of resistance have been documented in virtually all antiparasitic drug classes.[243] Although veterinary medicine often describes antiparasitic resistance as an emerging problem, resistance was first reported in the 1950s and by the 1970s, resistance had become widespread in poultry production.[2,77,78] Beginning in the 1950s and continuing through the 1980s, the approach to drug resistance was the introduction of a new class of antiparasitic agents each decade.[243] These highly effective and relatively inexpensive drugs led to parasite control strategies that were based on the frequent use of antiparasitics, which in turn fed a cycle of ever-growing drug resistance.[243] Today, judicious use of antiparasitic agents (Box 9.10) and alternative management methods (see Alternative Control Methods) should be encouraged whenever possible.

Surveillance

The fecal egg count reduction test (FECRT) is a useful and inexpensive method for field diagnosis of resistance.[2,51,74,90] This test is based on counting worm eggs in the feces of animal groups.[246] The mean egg count of a group that has been treated with the antiparasitic is compared with a group

BOX 9.10 RESPONSIBLE USE OF ANTIPARASITIC DRUGS IN BIRDS

- Strive to keep resistant parasites out of the flock by quarantining and testing all new additions.[243]
- Avoid the use of antiparasitic drugs as preventative treatment in healthy, adult birds since this promotes the development of resistance.[91,245]
- Administer the proper dose, optimally based on body weight obtained before treatment. Underdosing exposes parasites to sublethal doses of drug, increasing selection for resistance.[80]
- When managing flocks, use a combination of antiparasitics rather than rotating between drugs.[243] Combination drug therapy can increase drug efficacy and decrease the development of resistance. For example, the combination of nitroimidazoles with quinacrine has been shown to have an additive effect in vitro and in vivo against *Giardia*.[6,80,243]
- When managing flocks, do not employ a drug rotation program. Rotation does virtually nothing to slow the development of resistance, and given the rising incidence of resistance among antiparasitic drugs, it is much more likely to expose the flock to a drug that will not be effective.[243]
- Utilize environmental control measures, such as strict attention to sanitation and hygiene to prevent reinfection.[77,79,246]
  - For instance, coccidia oocysts require 3–5 days to sporulate and become infective, so frequent cleaning is the best preventative measure.[25] Also, some parasites, like cestodes and some nematodes, require intermediate hosts, so prevent birds from foraging where such organisms are found.[25]
  - Take measures to prevent wet litter, which aids the sporulation of oocysts. Adequate ventilation and leak-free watering systems serve to reduce excessive moisture.[78]
- Select nondrug approaches to parasitism whenever possible (see Alternative Control Methods).[243]

of equivalent untreated animals to calculate the egg count reduction due to treatment.[246] The FECRT is labor and cost-intensive and relatively insensitive, since usually only a single dose level is tested.[2] Therefore resistance can only be detected at relatively high levels.[2] Another approach is to use susceptibility assays of field isolates to test multiple antiparasitic agents and concentrations.[2,197] Such testing can provide more detailed information about the level of resistance since it is based on a dose response.[2]

Resistance and Drug Classes

Acaricides

Poultry mite resistance to OP/C as well as pyrethrins/pyrethroids is widespread.[4,192,194]

Nitroimidazoles

Resistance to metronidazole and other nitroimidazole drugs has been reported since 1962 for *T. vaginalis*, but it was not documented until the 1990s for *T. gallinae*.[80,147] Nitroimidazoles are routinely administered to racing pigeons at subtherapeutic doses as a preventive treatment. This prolonged exposure promotes the development of *T. gallinae* isolates that have proven resistant to ronidazole, carnidazole, and metronidazole.[86,91,146] Homing pigeons from around the world are considered a reservoir for nitroimidazole-resistant *T. gallinae*.[86,245] Interestingly, variations in sensitivity to nitroimidazoles have been detected within different isolates obtained from the very same bird.[91,147]

Macrocyclic lactones

Resistance to MLs is commonplace in nematode parasites of small ruminants and is of increasing concern in other animals, including birds.[1] In most animals, resistance first arises to avermectins like IVM and subsequently to moxidectin.[1] In ostrich treated for *Libyostrongylus* spp., an efficacy of 60% was found for IVM (0.2 mg/kg), while ABZ and moxidectin were both 100% effective.[51]

Triazines

The first cases of toltrazuril resistance in coccidia were reported in 1990.[90] In a recent study evaluating the effectiveness of toltrazuril against *Eimeria* spp. in critically endangered black grouse *(Tetrao tetrix)*, FECRT indicated that the coccidia infecting black grouse had natural resistance to toltrazuril.[90]

Anticoccidial drugs

Resistance to ionophores develops slowly because this drug class does not completely suppress parasite development, thereby allowing some immunity to develop in the host.[78] However, long-term, prophylactic use of ionophores in the poultry industry has moderated their effectiveness through selection for resistant strains of coccidia.[75,122] There is also evidence of growing drug resistance of *Eimeria* spp. field strains to sulfonamides and amprolium.[25,81] Other (synthetic chemical) products can be used only for a short time because of rapidly emerging drug resistance.[122]

Antimalarial drugs

Resistance of *Plasmodium* to antimalarial drugs is a major concern. Resistance to chloroquine first emerged in the 1960s, and in fact, most of the currently used antimalarial drugs suffer from increasing drug resistance.[125,129,169,171,184] Most antimalarial drugs, including chloroquine and mefloquine, are included on the World Health Organization's Model List of Essential Medicines.[177] Although it is no longer used as a frontline treatment for malaria, even quinine is included on this list because it may be used in combination with doxycycline for severe human cases where artemisinins are not available.[177]

ALTERNATIVE CONTROL METHODS

Alternatives to traditional antiparasitic drugs have been explored in poultry.[192] These techniques have been employed alone or in combination.[218,247]

Temperature

In production settings, a promising control method applied in parts of Europe combines chemical treatments with heating the hen house to temperatures above 45°C (113°F) between production cycles.[218]

Essential Oils

The repellent and/or toxic effects of plant essential oils (EOs) have been evaluated in various studies.[194,218,247–249] Of 10 EOs tested in vitro against *D. gallinae*, thyme and lavender were the most effective acaricides and the strongest repellents.[249] The

combination of *Eucalyptus globulus* EO and *Beauveria bassiana* (see Fungi) was another effective acaricide for *D. gallinae*.[247] In another study evaluating the effects of EOs on *O. sylviarum*, cade applied at 0.21 mg/cm^2 and thyme applied at 0.21 mg/cm^2 were the most consistent and fast-acting of the EOs in terms of toxicity.[248] One limitation to the use of EOs is that the acaricidal effect is rapid, within 2 hours for northern fowl mites, but short-lived.[247,248]

Plant Products

Herbs or plant extracts can also be used as natural acaricides.[218] In one study, garlic was as effective as metronidazole in inhibiting *T. gallinae* trophozoite growth both in vitro and in vivo.[85,194] Garlic (200 mg/kg PO) for 4 days was considered safe and effective for prophylaxis and therapy in pigeons.[85] *Note:* Garlic is often considered potentially toxic to companion birds.[250] More work is needed and caution should be employed before utilizing this alternative control method.

The botanical insecticide, azadirachtin, is a secondary metabolite present in neem seeds.[194,251] Azadirachtin appears to have direct pathological effects on the arthropod cuticle, acting on contact and as a fumigant.[251] In one study, direct application of a 0.06% solution of azadirachtin to infested vent region feathers and skin using a calibrated hand pump sprayer significantly reduced *O. sylviarum* numbers for 24 days after treatment.[251]

"Self-Treatment"

"Self-treatment" is a useful strategy for birds housed in larger, enriched cages or cage-free systems.[192] This practice takes advantage of the chicken's innate need to dustbathe (Figure 9.2).[192] Although sand alone is too coarse to impact mites, very finely textured materials, like diatomaceous earth (DE), can suppress ectoparasites by compromising the thin layer of cuticular wax that is essential to prevent desiccation and death of small terrestrial arthropods.[192,194,252,253] Mite populations can be kept at low levels when DE-filled dust boxes are offered to a flock.[194] Additional dust box products that have been used to reduce ectoparasite populations include kaolin clay and sulfur.[253]

Sulfur is one of the oldest pesticides used for control of *O. sylviarum*.[194,198,251,253] Sulfur appears to act as a biocide through reduction into hydrogen sulfide, which has a fumigating action.[251] Interestingly, the use of sulfur dust boxes eliminated mites from all hens, including individuals that did not use dust boxes.[253] Residual sulfur also controlled mites until the end of the experiment (up to 9 weeks), even after the dust box was removed.[253] Slow-release "dust bags" can also be used to disperse sulfur.[198] Insecticide-filled bags have long been used for fly control in cattle.[198] Animals bump or rub against the bags, which then apply insecticide.[194] On poultry farms, dust bags can be hung near flock resources, such as nest boxes or food dishes.[194,198] Empirical evaluation has determined bags clipped to the inside front of poultry cages were less effective than bags hung from cage tops.[198]

Predatory Mites

The use of predatory mites is a relatively new option for control of *D. gallinae*.[37,218,254] Predatory mites are natural enemies of PRM that are normally found in the environment and even in poultry houses.[37,254,255] In some regions of the world, predatory mites are mass-reared for agricultural use, and biological control of pests is common practice in greenhouse cultivation of vegetables, fruits, and ornamental plants.[218] The use of predatory mites in animal husbandry is still in its infancy; however, predatory mites have been commercially available for PRM control in the poultry industry since 2010.[37] Predatory mites that have been evaluated for biocontrol of *D. gallinae* include *Hypoaspis aculeifer*, *Androlaelaps casalis*, and *Stratiolaelaps scimitus* (formerly *H. miles*).[218,254,255] There are also anecdotal reports of using *S. scimitus* to control *D. gallinae* and other blood-feeding mites on canaries, pigeons, and reptiles.[37] The usefulness of predatory mites could explain why free-ranging birds reuse old nesting sites or old nest material.[254]

Fungi

Entomopathogenic fungi are capable of infecting and killing insect and mite species.[218,251] Fungal spores germinate on and then penetrate the host cuticle, spreading through the insect's

FIGURE 9.2 "Self-treatment" in chickens takes advantage of the normal fowl need to dustbathe. Chickens are offered a dust box containing sand and an inert dust, such as diatomaceous earth or kaolin clay, or a low-toxicity pesticide, like sulfur. body.[218] After the fungus has killed the mite, it can grow out of the mite cadaver and produce more spores, infesting other PRM.[218] A few entomopathogenic fungi are commercially available.[256] Organisms such as *B. bassiana* and *Metarhizium anisopliae* have shown promise for control of *D. gallinae* and perhaps *O. sylviarum*, although the results have been mixed.[192,194,247,251,256] The acaricidal effect of *B. bassiana* is delayed, but long-lived[247]; however, *B. bassiana* tends to perform poorly at temperatures exceeding 30°C (86°F), which makes this strategy particularly challenging for ectoparasite control in the warm-blooded bird.[251]

Future Considerations

Future areas of development that show promise for alternative control of parasites include the use of a vaccine against PRM or volatile organic compounds, such as aggregation pheromone, sex pheromone, and alarm pheromone, to promote attraction behavior in *D. gallinae*.[218,257] The manipulations of photoperiod and odors are additional control methods that are being investigated.[218,258]

CONCLUSION

A wide array of parasites infect birds. These infections and infestations are important causes of morbidity and mortality in birds worldwide. Antiparasitic drugs are a group of medications used in the management and treatment of parasites. Antiparasitic agents include several classes of drugs that can be broadly grouped as anthelmintics, antiprotozoals, and ectoparasiticides. The control of parasitic helminths relies primarily on the use of a few chemical drug classes that exhibit a broad spectrum of biological activity, such as BZDs and MLs, with diverse structures and mechanisms of action.[52] Antiprotozoal activity is observed in a wide and complex range of chemical compounds that often display a narrow spectrum of activity, such as nitroimidazoles, triazines, and ionophores.[6] Control of the ectoparasites found in birds is largely based on the use of chemicals that are used as insecticides or acaricides. Drug resistance is a growing problem in all antiparasitic drug groups.

CHAPTER 10

Antiviral Drugs

Sharman M. Hoppes • Susan Payne

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

While there are many useful treatments for bacterial, fungal, and parasitic infections, antiviral therapies for veterinary medicine are in short supply despite the numerous viral infections common in animals. Three main reasons for the lack of antiviral drugs for veterinary purposes include high cost of development, narrow spectrum of activity, and absence of rapid diagnostic tests that would allow prompt antiviral use in acute infections.[1] Probably the most challenging aspect of antiviral drug development is that virus replication is intimately linked to host cell metabolic processes. Hence, many drugs that inhibit virus replication may also damage the host. Appropriate targets for antiviral drugs must be teased out by performing detailed studies of virus replication and the interactions between host and viral proteins. However, even when a unique facet of viral replication is discovered, a targeted drug may have unforeseen negative effects on the host. Compared to antibiotics, antivirals have a higher risk for side effects and toxicity due to the viral replication cycle utilizing the host cell biochemical machinery. Nephrotoxicity is the main adverse reaction of antiviral drugs in humans and animals.[2] The concept of a "broad-spectrum antiviral" (other than immunomodulators or cytokines) has been difficult to realize, because agents with a broader spectrum of action have normally been associated with increased host cell toxicity. The goal in antiviral development is identifying select targets and developing a drug with few side effects.[3] Other challenges include dosing considerations and the ability to achieve therapeutic doses at appropriate tissue sites. Despite these issues, antiviral use in veterinary medicine is growing, along with increasing antiviral research.

Most of the antiviral drugs currently used in veterinary medicine were originally developed against human viral infections and their clinical use in veterinary medicine is not widespread. Antivirals approved for use in humans, and available for use in veterinary medicine, include drugs that target retroviruses and herpesviruses. Examples include acyclovir (ACV), idoxuridine, famciclovir, and trifluridine for use against feline herpesviruses. Azidothymidine (AZT), used in the treatment of human immunodeficiency virus (HIV), has been evaluated and found effective against feline retroviruses.[1]

Currently, the only licensed veterinary antiviral drugs are feline interferon and polyprenyl immunostimulant. These are both immunomodulating drugs rather than drugs that target a specific biochemical process in virus replication. Feline interferon is approved for use in treating feline retroviruses and canine parvovirus. Feline interferon has also been used off label for feline calicivirus. Unfortunately, treatment protocols and cost prevent its routine use.[1] Polyprenyl immunostimulant has also been approved in the United States for treatment of feline herpesvirus. Other studies have looked at off license use of ACV and famciclovir for feline herpes, oseltamivir and immune plasma for canine parvovirus,[1] and lysine for feline herpesvirus.[1]

In avian medicine, there are a number of viral infections commonly seen, including polyomavirus, psittacine herpesvirus, avian bornavirus, West Nile virus, avian influenza, and Marek disease. As there are no approved antivirals, practitioners have utilized an assortment of antivirals off label in birds with these viral diseases. To date, most research in avian antiviral medicine has occurred in poultry, although amantadine and neuraminidase (NA) inhibitors are prohibited to use in poultry at this time.[4]

Classes of Antiviral Drugs

Many of the commonly used antivirals are nucleoside analogs. Nucleoside analogs are a large and important class of drugs including drugs for cancer, rheumatological disease, and antivirals. This chapter will focus on the antiviral drugs commonly used in human viral disease that have been or have the potential to be utilized in avian medicine. Nucleoside analogs are used in the treatment of hepatitis B and C virus (HBV, HCV), cytomegalovirus (CMV), herpes simplex virus (HSV), and HIV. Nucleoside analogs resemble naturally occurring nucleosides and act by termination of a replicating DNA chain. The nucleoside analogs include those drugs with activity against both DNA- and RNA-dependent polymerases and nucleoside reverse transcriptase inhibitors (NRTIs). While most of the antiviral agents approved for use in humans interfere with the synthesis or regulation of viral nucleic acids and act to block elongation of newly synthetized DNA or RNA chains, an exception is the NA inhibitor oseltamivir that is widely used to treat human influenza. This drug very specifically inhibits a key influenza virus enzyme.[5]

Inhibitors of DNA Replication

ACV, vidarabine, valacyclovir, entecavir, famciclovir, cidofovir (CDV), penciclovir, and ganciclovir are nucleoside analogs

that block nucleic acid synthesis by inhibiting elongation of a growing DNA chain.

Acyclovir

Acyclovir (acycloguanosine) is an acyclic analog of the purine nucleoside deoxyguanosine (Figure 10.1). ACV is used to treat herpesvirus infections.[4] The drug is exquisitely targeted to herpesvirus-infected cells because to be active, it must first be phosphorylated by the herpesvirus thymidine kinase. The phosphorylated drug is then inserted into growing DNA chains by the viral DNA polymerase. Due to its lack of a 3′-hydroxyl group, DNA synthesis stops at the point at which the drug is inserted. (Note that in uninfected cells, the drug is not phosphorylated and thus does not inhibit cellular DNA replication.) As a therapeutic, it is mainly used to treat herpesvirus infections: HSV types 1 and 2 and varicella zoster virus.[6] In veterinary medicine, it has been primarily used against feline herpesvirus-1 (FHV-1) infections.[5-7]

The disposition of ACV has been investigated in several species. The drug was well distributed into all the tissues, including the brain, in mice and rats. Marked species differences were observed in the gastrointestinal absorption and transformation of ACV. Oral dosing produced better absorption in dogs and mice than in rats and rhesus monkeys.[8] Topical ACV treatment was shown to be effective against FHV-1 conjunctivitis and keratitis in cats.[7] Studies in dogs report oral absorption of ACV of 80% to 90%, but it becomes saturated at high doses.[8]

Chickens (*Gallus gallus domesticus*) experimentally infected with Marek disease virus that received ACV daily at 10 mg/kg intramuscularly (IM) for 5 days, beginning day 3 post challenge, developed no clinical signs of disease. When given IM daily for 9 days, beginning 14 days post challenge, mortality was reduced.[9]

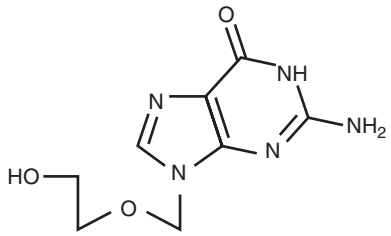

FIGURE 10.1 Chemical composition of acyclovir.

A study utilizing ACV at 120 mg/kg every 12 hours was performed in tragopans (*Tragopan* spp.) to determine the absorption, distribution, and linearity of ACV after administration of a single dose. Oral treatment with an ACV oral suspension (40 mg/mL; Alpharma USPD, Baltimore, MD, USA) at doses of 40, 80, or 120 mg/kg was administered by crop gavage. ACV at 120 mg/kg every 12 hours maintained plasma ACV concentrations above the accepted effective ACV plasma level (1.0 mg/mL) for 12 hours following administration, suggesting that ACV at 120 mg/kg every 12 hours achieved effective plasma concentrations for prevention and treatment of herpesviral infections in tragopans.[10]

The pharmacokinetics of intravenous (IV) and IM single-dose administration of ACV were determined in Quaker parakeets (*Myiopsitta monachus;* Tables 10.1 and 10.2).[11] Peak plasma ACV concentrations occurred 15 minutes following IM injection, and plasma concentrations of ACV were undetectable 4 to 6 hours post IV and 6 to 8 hours post IM injection. In the same study, oral (capsules) and intravenous (sodium salt) formulations of ACV were given by gavage at 80 mg/kg. Peak concentrations with the sodium salt formulation developed slower and were lower than with the capsules. In a second study, ACV was administered IM at 40 mg/kg every 8 hours for 7 days and then gavage-fed at a dose of 80 mg/kg every 8 hours for 4 days to evaluate excessive drug accumulation or adverse side effects. Excessive drug accumulation was not detected in either study, and the birds maintained normal appetite and weight. A third study evaluated plasma concentrations following the addition of ACV in the feed (400 mg in 2 quarts of parrot seed) and water (1 mg/mL). Plasma concentrations of ACV ranged from 2.07 ± 1.09 μg/mL to 3.93 ± 1.13 μg/mL,[11] which is below the accepted effective ACV plasma level (1.0 mg/mL).

Based on the aforementioned PK study, the efficacy of ACV against experimentally induced herpesvirus infection (Pacheco disease) was evaluated in Quaker parakeets.[12] Thirty-two of 40 birds were challenged with 0.1 mL of a suspension of herpesvirus IM. Treatment with ACV was started 24 hours later and continued for 7 days. The birds were divided into five groups with eight birds each. In group 1 (control), eight birds were given the virus IM and were not

IM, Intramuscular; *IV*, intravenous.

treated. In group 2 (infected, gavage fed), eight birds were given a suspension of ACV 80 mg/kg every 8 hours via gavage. In group 3 (infected, low dose, IM), eight birds were given injectable sodium salt of ACV IM at 40 mg/kg q8h. In group 4 (infected, high dose, IM), eight birds were given injectable sodium salt of ACV IM at 250 mg/kg q8h. In group 5 (contact control), eight birds were not given the virus. Four of the uninfected birds were given a suspension of ACV 80 mg/kg every 8 hours via gavage and four birds were untreated. To determine if natural virus transmission would occur between challenge-exposed and nonchallenged-exposed birds, one treated and one untreated bird were placed in cages with birds in groups 1 through 4. Clinical signs observed throughout the study included lethargy, anorexia, regurgitation, polyuria, yellow urates, and seizures. Gross findings in infected birds included hepatomegaly, splenomegaly, and yellow discoloration of organs and coelomic surfaces. Birds given IM ACV had areas of hemorrhage in the pectoral muscles with the most severe lesions seen in group 4. Group 1 (control) had the highest mortality, with six out of eight birds dying; group 2 had one bird die; group 3 had three birds die; group 4 had four birds die; and no birds died in group 5. There was a significant difference in mortality between groups 1 and 2 ($P = .023$), but no difference in mortality among groups 1, 3, and 4. Birds in group 1 died within a mean period of 6 days after virus inoculation. Clinical signs and death occurred in groups 2 and 3 only after ACV treatment was discontinued. Postmortem examination was performed on all birds that died, with histologic evidence of herpesvirus infection found in all birds that died. Lesions were most severe in the positive control group.[12] In addition, herpesvirus could be recovered from all infected birds through inoculation of chick embryo cell culture with pooled tissue suspensions.

Acyclovir Derivatives or Prodrugs

Vidarabine (9-D-arabinofuranosyl adenine) was one of the first antiviral agents licensed for systemic treatment of herpes viral infections in humans.[5] It is an adenosine analog that is converted by cellular enzymes to its active intracellular derivative, vidarabine triphosphate. Vidarabine is used topically in feline herpes keratitis. In vitro studies have demonstrated activity against feline and equine rhinopneumonitis.[6] A vidarabine 3% ophthalmic ointment has been effective and well tolerated in cats for feline keratoconjuctivits.[5] Valacyclovir is a prodrug for ACV. It has enhanced bioavailability over ACV resulting in faster absorption after oral administration. In cats, administration of valacyclovir has been associated with adverse side effects including renal and hepatic necrosis, myelosuppression, and nephrotoxicity. Penciclovir [9-(4-hydroxy-3-hydroxymethylbut-1-yl)] is a guanosine analog that resembles ACV in structure, mechanism of action, and antiviral activity, but penciclovir-triphosphate accumulates in virus-infected cells in much higher concentrations and for a longer half-life (10–20 times longer) than ACV.[5] Unfortunately, it is less potent than ACV and has poor bioavailability (<5%). Due to the low bioavailability of penciclovir, famciclovir was developed. Famciclovir (the diacetyl ester of 6-deoxypenciclovir) is the oral prodrug of ACV with improved bioavailability. Following oral administration, famciclovir gets rapidly converted to its active metabolite penciclovir by di-deacetylation and oxidation. In cats, famciclovir must be administered in high doses orally to get adequate plasma concentrations due to their lack of the hepatic aldehyde oxidase enzyme. Despite the high oral doses, the drug is well tolerated in cats and has been successful in treatment of FHV-1 conjunctivitis.[7] Ganciclovir is another purine nucleoside analog that resembles ACV and is widely used to treat CMV infections in human medicine. In vitro, it has been effective against FHV-1 in cats. Unfortunately, there is lack of data on its efficacy and safety in animals.[5] No anecdotal or clinical studies could be found in these ACV derivatives or prodrugs in birds at this time.

Cidofovir

CDV [(S)-1-(3-hydroxy-2-phosphonylmethoxypropyl) cytosine, HPMPC] is an acyclic nucleoside analog. It is approved for clinical use in the treatment of CMV retinitis in human AIDS patients. CDV has broad-spectrum activity against DNA viruses, including herpesvirus, adenovirus, papillomavirus, polyomavirus, and poxvirus. In vitro, CDV has shown activity against orthopox (vaccinia, variola [smallpox]), cowpox, monkeypox, camelpox, molluscipox (molluscum contagiosum),

and parapox (orf) viruses. In vivo, CDV activity has been shown in different models of pox infection when administered intraperitoneally, intranasally (aerosolized), and topically. In immunocompromised human patients, CDV has been effective in the treatment of recalcitrant molluscum contagiosum virus and orf virus. CDV remains a reference compound against poxviruses and holds potential for the therapy and short-term prophylaxis of not only orthopox but also parapox and molluscipoxvirus infections.[13]

An adult great-horned owl (*Bubo virginianus*; GHOW) was treated successfully with topical CDV 1%, interferon (IFN) alpha 2B ophthalmic solutions, and oral L-lysine for a recurrent corneal ulceration of the right eye caused by a novel alphaherpesvirus.[14] This novel herpesvirus, referred to as Strigid herpesvirus 1 (StrHV1), was identified utilizing polymerase chain reaction (PCR) and gene sequencing.

Nucleoside Reverse Transcriptase Inhibitors

NRTIs are DNA chain terminators that are potent inhibitors of retroviral reverse transcription; they block the synthesis of viral DNA in the infected cell. These drugs are recognized by viral reverse transcriptase and are incorporated into growing DNA chains. Once incorporated, the DNA chains cannot be elongated, thus terminating the DNA chain. These drugs are used in retroviral infections.

Zidovudine

Azidothymidine (AZT) (Figure 10.2), used in the treatment of HIV, acts by inhibiting HIV reverse transcription. Originally, AZT was developed to target reverse transcription of avian retroviruses that may cause cancer in poultry and was later successfully applied to HIV as well.[15]

AZT has been evaluated and found effective in feline retroviruses. The long-term effectiveness of AZT was evaluated in feline immunodeficiency virus (FIV)–seropositive cats with clinical symptoms compared with conventional symptomatic therapy. The long-term oral treatment of AZT at a dosage of 5 mg/kg body weight three times a day led to a total recovery from clinical symptoms in six of nine FIV-seropositive cats. A transient decrease of red blood cell (RBC) count, packed cell volume (PCV), and hemoglobin was noted in treated cats until the 4th week of treatment; the hemogram was within the normal range after 3 months. Hyperglycemia was noted in one cat and Heinz bodies were noted in two treated cats.[16]

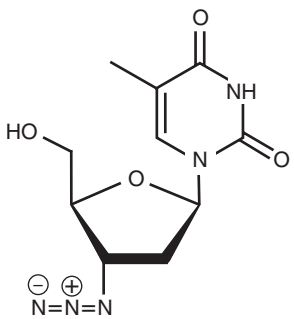

FIGURE 10.2 Chemical composition of zidovudine.

The inhibitory effect of AZT on the replication of avian leukosis virus (ALV) was assessed *in vitro*.[17] AZT was shown to be a potent inhibitor of viral DNA synthesis in infected cells. It was determined that variations in the concentrations of drug were needed to inhibit virus replication in different cell types, with higher concentrations of drug needed to inhibit virus replication in chicken embryo fibroblasts than in the quail cell line QT6. Several parameters of AZT effects on quail cells were evaluated. The effect of AZT to decrease virus replication in a continuous quail line was examined. The amount of AZT required to inhibit colony formation 70% was approximately 40 μM. The amount required to inhibit colony formation 95% was 80 μM. In a separate assay, the effect of AZT on virus spread was tested. Viral spread was inhibited 70% in the presence of 1 μM AZT, 85% at 3 μM AZT, and 95% at 10 μM AZT. No virus was detected at 30, 80, or 200 μM AZT concentrations. The anticipated target of AZT is the viral DNA polymerase reverse transcriptase. To test this hypothesis, they examined viral DNA synthesis in infected cells. At 1 μM, there was no inhibition, and at 30 μM, 80 μM, and 200 μM, there was a 65%, 90%, and 100%, respectively.[17] Based on data in other species and the inhibitory effects seen in vitro, it would stand to reason that AZT may be beneficial clinically in the treatment of avian retroviral infections.

Abacavir

Studies in chickens revealed that phosphorylated abacavir (ABC-1) and phosphorylated derivatives of didanosine reduced Newcastle disease virus (NDV)–induced tissue oxidative stress and inhibited the expression of the fusion protein and was protective in NDV-infected chickens.[18] Suresh et al. assessed the protective role of phosphorylated ABC-1 in vivo in NDV-infected 2-day-old chickens. Chickens were divided into three groups of six birds: group 1 (control), group 2 (NDV infected), and group 3 (NDV infected + ABC-1). Groups 2 and 3 were infected with 200 μL of an infectious dose of NDV IM. Group 1 received 200 μL of phosphate-buffered saline (PBS) IM. Group 3 was treated with phosphorylated ABC-1 orally at 2 mg/kg dissolved in water given daily for 10 days beginning day 4 post infection. The NVD-induced oxidative damage and protective role of ABC-1 were evaluated in vital organs (liver, lung). Results confirmed that phosphorylated ABC-1 protects chickens from NDV-induced pathogenesis and protein oxidation/nitration, and has potent antiviral activity. A similar study by the same author revealed similar findings using a phosphorylated didanosine (DDI-10) in NDV virus in 2-day-old chicks.[19]

NUCLEOSIDE ANALOGS

Ribavirin

Ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide; Figure 10.3) is a triazole nucleoside analog that inhibits replication of both DNA and RNA viruses. Several mechanisms of action have been proposed for ribavirin. These include reduction of intracellular guanosine-5′-triphosphate (GTP) pools, which can inhibit translation; interference with viral genome or mRNA capping; inhibition of viral RNA genome synthesis; and increased mutagenesis of RNA viruses.

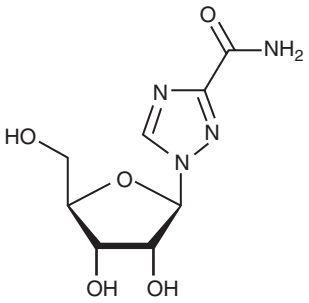

FIGURE 10.3 Chemical composition of ribavirin.

Ribavirin is active against a wide range of viruses including adenoviruses, arenaviruses, bunyaviruses, herpesviruses, orthomyxoviruses, paramyxoviruses, picornaviruses, poxviruses, retroviruses, rhabdoviruses and rotaviruses, and influenza virus. In combination with IFN, ribavirin has activity against HCV.[20]

Ribavirin in cats has resulted in drug-induced thrombocytopenia, depression of red and white blood cells, increased alanine aminotransferase activity, icterus, and weight loss.[21] These side effects have not been observed in humans, dogs, or birds. Ribavirin activity has been demonstrated against bovine viral diarrhea virus and bovine herpesvirus 1.[22] Ribavirin has shown activity against mammalian Borna disease virus 1 (BoDV-1), which is a close relative of the avian bornaviruses, both in mammalian cell lines and experimentally in infected gerbils.[23] Musser et al. reported an antiviral effect in duck embryo fibroblast (DEF) cultures infected with parrot bornavirus-4 (PABV-4).[24]

Ribavirin inhibited avian bornavirus activity in a polymerase reconstitution assay and reduced viral load in avian cell lines infected with two different parrot bornaviruses. It was demonstrated that 1 $\mu g/mL^{-1}$ of ribavirin reduced polymerase activity to 10%, while higher doses reduced it further, indicating that direct interference with viral polymerase activity is the major mode of ribavirin activity against avian bornavirus. The same researchers also evaluated the effect of ribavirin on cell culture. Quail cell cultures persistently infected with PaBV-1 or PaBV-4 were grown in medium containing 1 or 5 $\mu g/mL^{-1}$ of ribavirin passaged twice a week. Both doses of ribavirin substantially decreased the number of infected cells after 5 days of treatment. They also evaluated 10U mL^{-1} of chicken IFN-α (ChIFN-α) alone and combined with 1 $\mu g\ mL^{-1}$ of ribavirin and found that both reduced the number of bornaviral-infected cells, with the combined ribavirin and ChIFN-α having the most pronounced cell reduction. In all models, once the treatment stopped, the proportion of virus-infected cells rapidly retuned. These results suggest that ribavirin and recombinant IFN-α in a combined treatment in vivo may be more effective than ribavirin alone.[25] In a study conducted at the Schubot Avian Health Center at Texas A&M, treatment of three Grey parrots (*Psittacus erithacus*, GP) naturally infected with avian bornavirus infection with ribavirin at 15 mg/kg per os (po) daily for 1 week, 18 mg/kg po daily for 4 weeks, and 18 mg/kg po twice a day for 8 weeks resulted in no change in viral shedding in the feces based on biweekly PCR testing.[26]

Favipiravir (T-705)

Favipiravir (T-705) (Toyama Chemical Company, Ltd. Tokyo, Japan) is an antiviral similar to ribavirin. It is a novel antiviral compound that selectively and potently inhibits the RNA-dependent RNA polymerase (RdRP) of influenza and many other RNA viruses. Favipiravir is active against a broad range of influenza viruses, including influenzas (H1N1), (H5N1), and the recently emerged (H7N9) avian virus. It also inhibits influenza strains resistant to current antiviral drugs and shows a synergistic effect in combination with oseltamivir, thereby expanding influenza treatment options.[27] Favipiravir is also active against many arenaviruses, bunyaviruses, flaviviruses, alphaviruses, picornaviruses, and noroviruses.[28]

Favipiravir was found to be a potent inhibitor of both BoDV-1 and PaBV-4 in vitro. T-705 at 200 or 400 mM given for 28 days suppressed BoDV-1 to undetectable levels with no significant increase in the amount of BoDV-1 RNA by 30 days post treatment. In the same study, quail cells persistently infected with PaBV-4 cells were treated with 20 mM ribavirin or 50 or 400 mM of T-705 for 28 days and avian bornavirus replication was evaluated via immunofluorescence assay (IFA) and real-time (RT) PCR. T-705 decreased the amount of PaBV-4 RNA more effectively than ribavirin, with the 400 mM dose being most effective. There was also no increase in the number of PaBV-4 RNAs at 14 days post treatment cessation. No cytotoxic effects were seen with T-705 at the test doses. Further studies are needed to determine if T-705 could be used to treat persistent bornavirus infection in various animals in vivo, but these results suggest that T-705 may be effective against a broad spectrum of bornaviruses. T-705 is an orally administered drug approved for clinical use in humans, so if studies confirmed effectiveness in vivo, T-705 could be readily used to treat persistent avian bornavirus infection in birds.[29]

INFLUENZA ANTIVIRALS

There have been two types of antivirals developed against influenza; the first were the M2 ion channel blockers (amantadine and rimantadine). The second are the NA inhibitors. The efficacy of the M2 ion channel blockers is limited to influenza A. Currently, most influenza A strains have developed resistance to the M2 channel blockers. The NA inhibitors have efficacy for both influenza A and B viruses, and although there is some documented resistance, they are still effective drugs.

M2 Protein Target Inhibitors

The M2 protein is a protein on the surface of influenza A. It is absent in influenza B. The M2 proton channel is required for virus replication and maturation. The M2 protein is an integral membrane protein that functions as an ion channel. It enables hydrogen ions to enter the virion. When the internal component of the virus achieves a low pH, a dissociation or uncoating occurs. M2 protein inhibitors block the acid-mediated dissociation of the ribonucleoprotein complex in the early replication cycle and initiate pH-induced changes in hemagglutinin during intracellular transport in late replication cycle. M2 inhibitors are effective against influenza A viruses and include amantadine and rimantadine. Both amantadine and rimantadine are active only against susceptible influenza A viruses. Rimantadine is 4- to 10-fold more active than amantadine. Virtually all H3N2 strains of influenza circulating worldwide are resistant to these drugs.

Amantadine hydrochloride and rimantadine hydrochloride are antivirals that inhibit virus replication during the early

stage of infection by blocking the ion channel formed by the M2 protein.[9] Historically, they were effective prophylactic agents in the control of influenza A virus infections in humans. They have no action against influenza B and C viruses. Previous studies in domestic fowl revealed reduced mortality and reduction of disease in treated birds. Currently, amantadine is prohibited for treatment of influenza due to the development of resistance.[30] In a study conducted at the Schubot Avian Health Center at Texas A&M, three GP naturally infected with avian bornavirus infection with amantadine were treated with 1 mg/kg po daily for 8 weeks. There was no reduction in viral shedding in the feces based on PCR (P. Gray, personal communication).

In addition to its antiviral effects, amantadine is also used in humans to reduce the severity of symptoms in Parkinson disease by antagonizing the N-methyl-D-aspartate (NMDA) receptor. Amantadine has many effects on the brain including the release of dopamine and norepinephrine. Amantadine causes NMDA receptors to occupy closed conformations; this interaction with the NMDA receptor makes it effective at inhibiting NMDA responses during prolonged depolarizations that accompany neurological insults, which may occur in ABV-affected birds or in animals experiencing chronic pain. There have been studies looking at the analgesic effects of amantadine in dogs that suggest amantadine may be a useful adjunct therapy for the clinical management of dogs with osteoarthritic pain.[31] There is anecdotal evidence that amantadine hydrochloride (due to its inhibition of NMDA response) may contribute to the reduction of clinical signs in birds with proventricular dilatation disease (PDD) when combined with celecoxib.[32]

Neuraminidase Inhibitors

A key step in the replication cycle of any virus is the ability to exit a cell and infect new cells. NAs (sialidases) cleave glycosidic linkages of neuraminic acids. Influenza A and influenza B viruses require the enzyme NA to efficiently move from an infected cell to other cells. If this activity is inhibited, newly formed flu virus particles remain associated with producer cells and form large clumps, preventing new host cells from being infected. The NA inhibitors oseltamivir and zanamivir are considered our first line of defense against potentially fatal variants of influenza A pandemic strains that may affect humans and susceptible animals and birds worldwide.

Few studies have been performed on the effectiveness of NA inhibitors in birds. The anti-influenza efficacy of the potent NA inhibitor oseltamivir was evaluated in 16 SPF 3-week-old chickens and 24 3-week-old ducks. The birds were divided into four groups: group 1—8 infected, untreated chicken control group, group 2—8 infected, treated chicks, group 3—12 infected, untreated duck control group, and group 4—12 infected, treated ducks. Oseltamivir was mixed 1:1 with PBS and administered orally to groups 2 and 4. Oseltamivir treatment (0.5 mg/kg given twice a day for 5 days) was began 4 hours prior to inoculation. Groups 1 and 3 received sterile PBS on the same schedule. The chickens were sacrificed on day 5 post infection and the ducks on days 3 and 6 post infection for virus isolation and titration. In group 1, virus replication was detected in all eight trachea and cecal tonsil samples. Group 2 birds had significant reduction of viral replication from both the trachea and the cecal tonsils at day 5 post infection with three of eight samples positive for viral replication. Group 3 showed the highest frequency of virus detection in the trachea, with viral replication detected in seven of eight tracheas at 3 days post infection and in seven of eight cecal tonsil samples at 6 days post infection. Group 4 had completely reduced viral replication from both the trachea and cecal tonsils, with no virus detected at 3 and 6 days post infection. In this study, viral replication of low pathogenic avian influenza virus (AIV) was significantly reduced in the chicken model and completely reduced in the duck model indicating that antiviral treatment may be a valuable addition to the prevention of avian influenza in zoological and other avian species collections.[33]

One of the issues with influenza viruses is their ability to mutate and develop resistance to antiviral drugs. This resistance affects all species that might become infected. A study investigated if and to what extent NA inhibitor–resistant mutants exist in the wild population of influenza A viruses that inhabit wild birds.[34] Two sets of databases were examined, evaluating more than 6000 birds, 379 swine, and 122 environmental isolates. Of the sequences from the avian dataset, 132 (2.4%) carried at least one, or in two cases, even two or three NA inhibitor resistance mutations. Swine and environmental isolates from the same data set had 18 (4.75%) mutants and 1 (0.82%) mutant, respectively, with at least one mutation. The Ottenby sequences carried at least one mutation in 15 cases (6.52%). In summary, antiviral resistance–related mutations already exist in populations of avian influenza A viruses isolated from their natural hosts, that is, mallard duck, other waterfowl as well as domestic poultry, and domestic swine.[35]

Arildone

Arildone is an antiviral drug of the 4-[6-(2-chloro-4-methoxy) phenoxyl]hexyl-3,5-heptanedione class; it is a novel aryl diketone which is active against both DNA and RNA viruses.[34] It is primarily used as a broad-spectrum antiviral agent because it is relatively a less toxic drug and inhibits viral replication at lower concentration. Arildone inhibits replication of enterovirus, in particular poliovirus, via interaction with the viral capsid and hence blocking viral uncoating. It has primarily been studied in poliovirus. It also inhibits HSV type 2 protein synthesis and viral DNA replication by an unknown mechanism of action. Due to its poor solubility in water, it is administered as a solution in dimethyl sulfoxide (DMSO). In studies on mice intracerebrally infected with a high dose of polio type 2, arildone was able to block the virion uncoating property and prevent paralysis and death.[36] No studies have been performed on birds.

OTHER ANTIVIRAL APPROACHES

Although research on antivirals continues and the number of antivirals continues to grow, treating viral disease, especially chronic viral disease, remains challenging. Immunotherapy has been utilized to modulate the immune system, and medications such as antifungals, antiparasitic drugs, and antibiotics have been found to have antiviral properties and have been repurposed. In addition, many herbs and plants are known to have antiviral properties.

Immunotherapy

Modification of immune responses is another possible intervention for ongoing viral infections. The most suitable for immunotherapy are chronic viral infections.[37] There are several forms of immunotherapy that are in use, including monoclonal antibodies (mAbs), recombinant antibodies (rAbs), and IFNs.

mAbs, which are antibodies specific for one antigen or one epitope, have been shown to inhibit rabies virus, in a dose-dependent way, by impairing transcription of the genome or neutralizing newly translated proteins. mAbs have been shown to be effective against noncapsid proteins of poliovirus, rotaviral diarrhea, classical swine fever, bluetongue, Hendra, and Nipah viral infections.[2,38]

rAbs are another therapeutic strategy for infectious viral diseases. They are synthetic antibodies that can be created using antibody genes made in the laboratory, eliminating animals from the process. An example is avian antibody against VP2 of infectious bursal disease virus protecting against viral infection of chickens.[37] Advantages of rAbs include non-animal technology, a speedier more efficient process, and high reproducibility. Because rAbs are derived from human or synthetic genes, they do not trigger the intense immunogenic reactions in patients that animal-derived antibodies do, making them ideal for clinical use.[39,40]

IFNs are glycoproteins that possess strong antiviral activity and represent one of the first lines of host defense against invading pathogens. They represent an early host defense prior to the immune response onset. These proteins are classified into three groups, Type I, II, and III IFNs, based on the structure of their receptors on the cell surface. Due to their immune modulating capability, they have become therapeutic options to control chronic viral infections in humans. In combination with other drugs, Type I IFNs are utilized in suppressing HCV and HBV infections, while Type III IFN has generated encouraging results as a treatment for HCV infection.[41]

A study evaluating IFN treatment in GP with psittacine beak and feather disease (PBFD) revealed that IFN-γ of poultry origin has a potential use in the treatment of circovirus infection in young GP. The study evaluated 1 million IU feline interferon in 12 GP infected with PBFD with profound leucopenia and found that feline interferon was not effective. In a second study, 10 GP infected with PBFD with a severe leucopenia were treated with 1 million IU of poultry IFN-γ. Seven of 10 birds treated with poultry IFN-γ were alive at week 30 and had elevations in their total leucocyte count. Nine months post diagnosis, the birds were alive and exhibited no signs of circovirus infection.[42]

Another study demonstrated that pretreatment with ChIFN-α prior to infection with the pandemic H1N1 and H5N9 AIVs significantly reduced viral replication in both chicken and turkey origin lung cells.[43] Similar conclusions were recently described following oral administration of rChIFN-α and H9N2 AIV infection.[44] In this study, 7-day-old and 33-day-old white leghorn SPF chickens were divided into 5 groups of 20 birds each: group 1—preventative group (treated then infected), group 2—the therapeutic group (infected then treated), group 3—virus challenged (untreated), group 4—ChIFN-α treated (uninfected), and group 5—blank control group (uninfected and untreated). Group 1, 2, and 4 birds were given 0.5104 U of ChIFN-α orally to the 7-day-old chicks and a 2-fold dose given to the 33-day-old chicks. Results revealed that the body weight of chickens was not influenced by ChIFN-α, and ChIFN-α significantly reduced the viral load in the trachea of infected chicks. The study indicated that ChIFN-α could be used as a preventive and therapeutic agent against AIV. They found that the therapeutic effect was better than the preventive effect on 7-day-old chicks, which was opposite to 33-day-old chicks.[44]

Previous studies have shown that ChIFN-α administered to chickens by oral ingestion or intravenous injection can inhibit avian viruses including H9N2 AIV, NDV, infectious bursal disease virus, infectious bronchitis virus, Rous sarcoma virus, and Marek disease virus.[45,46]

Based on these studies in birds and in the successful use of IFNs in human medicine, further studies in IFN treatment of avian viral diseases are warranted.

Drug Repurposing

Drug repurposing (or drug repositioning) is the method of assigning a new medical indication for an existing drug. The repositioned drug might be currently on the market for other disease process.[2]

Examples of repurposed drugs include antibiotics and anthelmintics.

Antibiotics

Antiviral potential of antibiotics has been studied on a number of drugs. Rifampin, a widely used derivative of rifampicin, is a semisynthetic rifamycin. Rifamycins can cross mammalian tissue and cell membranes.[6] Among the antibacterial agents of these derivatives, some act by inhibiting the bacterial DNA-dependent RNA polymerase. Rifamycin derivatives were also found to act against type II DNA topoisomerases. Rifampicin, rifapentine, and rifabutin are semisynthetic and water-soluble derivatives used in therapies against different gram-positive and gram-negative bacterial organisms including methicillin-resistant *Staphylococcus aureus* (MRSA), mycobacteria (*Mycobacterium bovis* or *Mycobacterium tuberculosis*), and leprosy. They are also able to prevent viral infections (e.g., influenza, retrovirus).[2,47] In addition, rifampin can inhibit poxvirus replication in vitro. In vitro analysis for selective inhibition of RNA-dependent DNA polymerase (reverse transcriptase) on several rifamycins revealed that certain derivatives inhibited production of Rous sarcoma virus in vitro and prevented focus formation by RNA tumor viruses.[48] Further studies are needed to see if rifampin antiviral activity will be effective in vivo in avian species with poxvirus or retroviral infections.

Minocycline has been investigated for its antiviral action. It is a synthetic second-generation tetracycline derivative that readily crosses the blood-brain barrier. Minocycline has antibacterial, immunomodulatory, and antiinflammatory action and is used for the treatment of gram-negative and gram-positive bacterial infections, chlamydial infections, acne, rheumatoid arthritis, and urinary tract infections in humans.[2] There has been reported antiviral activity of minocycline against HIV, Japanese encephalitis virus, Dengue virus, and West Nile virus. Minocycline diminishes viral RNA synthesis, intracellular viral protein synthesis, and thus viral production.[48] Minocycline reduced the severity of encephalitis, suppressed viral load in the brain, and decreased the expression of CNS inflammatory markers in five simian immunodeficiency virus (SIV)–infected pigtailed macaques that were treated with 4 mg/kg per day of minocycline beginning at

early asymptomatic infection (21 days after inoculation with SIV).[49] Further studies are needed to determine if minocycline could be an effective treatment for West Nile virus or retroviral infections in birds. It is also possible that minocycline could reduce inflammation and clinical signs in avian bornaviral–infected birds.

Fluoroquinolones have shown antiviral activity. Quinolones inhibit prokaryotic type II topoisomerases, namely DNA gyrase and, in a few cases, topoisomerase IV, through direct binding to the bacterial chromosome. Fluoroquinolones were shown to be effective against vaccinia virus and papovaviruses, and with modification (introduction of an aryl group at the piperazine moiety), activity is shifted from antibacterial to antiviral, with a specific action against HIV.[50]

Teicoplanin is an antibiotic used in the prophylaxis and treatment of serious infections caused by gram-positive bacteria, including MRSA and *Enterococcus faecalis*.[2] It is a semisynthetic glycopeptide antibiotic with a spectrum of activity similar to vancomycin. Its mechanism of action is to inhibit bacterial cell wall synthesis. Teicoplanin has shown significant inhibitory activity against Ebola virus, HIV, HCV, flavivirus, coronaviruses, influenza virus, and respiratory syncytial virus (RSV).[51]

Anthelmintics

Ivermectin and abamectin are anthelmintic drugs that have shown antiviral activity against Chikungunya virus and yellow fever virus thru specifically targeting the viral helicase.[51] Antimalarial drugs chloroquine and amodiaquine have displayed activity against West Nile virus, Dengue virus, and Ebola virus by interfering with viral entry and replication.[51] Estrogen receptor inhibitors used for cancer treatment and inhibitors of dopamine receptors used as antipsychotic medications demonstrated antiviral activity against Middle East respiratory syndrome (MERS) and severe acute respiratory syndrome (SARS).[52]

Benzimidazoles

Benzimidazole and its derivatives are best known in veterinary medicine for their activity against intestinal parasites (nematodes and trematodes), but they have a wide variety of biological activities. These include analgesic, antibacterial, antifungal, anticancer, anticonvulsant, and antiviral activities.[52] A number of benzimidazoles are commercially available including telmisartan for hypertension, omeprazole utilized for gastric ulcers, and albendazole which is an antiparasitic drug.

The antiviral activity of benzimidazole nucleosides was first reported in 1954. They developed 5,6-dichloro-1-(β-D-ribofuranosyl) benzimidazole (DRB), which had various biological activities including antiviral activity against RNA and DNA viruses. DRB inhibits cellular RNA polymerase II and viral and cellular RNA synthesis.[53] Biologically active compounds such as vitamin B_{12}, albendazole, mebendazole, and thiabendazole contain a benzimidazole nucleus in their structure.[54] Although no studies have been done in birds, there are studies looking at their use in human viral diseases, including poxvirus, HSV-1, HIV, HBV, HCV, human cytomegalovirus (HCMV), and RSV.[55] Future studies evaluating their effectiveness in avian paramyxovirus, poxvirus, or herpes infections are needed.

Herbal/plant Remedies

Medicinal herbs and plants have been evaluated for antiviral activity and some have shown antiviral activity in vitro and in vivo for many viruses including NDV. Alkaloids, saponins, tannins, and flavonoids in plants have been shown to have some antiviral properties. *Cucumis metuliferus* and *Anthocleista nobilis* have shown some antiviral activity in vivo and *Mangrove halophytes*, *Nigella sativa*, *Polysavone*, *Melissa officinalis*, *Momordica cochinchinensis*, *Echinacea purpurea*, *Withania somnifera*, and *Asparagus racemosus* have shown potential to improve immunity in infected birds.[56]

Baicalin (BA; formulated as 7-D-glucuronic acid-5,6-dihydroxyflavone) was purified from the plant *Scutellaria baicalensis Georgi*. It is used as a traditional Chinese herbal medicine. BA is known for its antiviral properties but solubility is poor. To increase solubility, absorption, and pharmacological activity, a BA phospholipid complex (BAPC) was developed and studied in ducklings infected with duck hepatitis A virus type 1 (DHAV-1). Results showed BAPC inhibited DHAV-1 adsorption, replication, and release. Furthermore, it played antioxidative and immunoenhancing roles in the treatment.[57]

BA's antiviral effects were evaluated against avian leukosis virus subgroup J (ALV-J) in duck fibroblast cells. The cells were treated with 5 or 20 μg/mL of BA and DMSO at different time points: prior to, during, and post viral adsorption. Adding BA pretreatment resulted in much lower viral inhibition. It was found that BA could inhibit viral mRNA, protein levels, and overall virus infection in a dose- and time-dependent manner using a variety of assays. The 20 μg/mL was the most effective dose, with higher doses (of 40, 80, and 100 μg/mL) cytotoxicity occurred.[58]

A flavone/polysaccharide-containing prescription was developed and tested for efficacy against duck viral hepatitis (DVH) and investigated for its hepatoprotective effects. Flavones were derived from *Hypericum japonicum* (HJF) and *Salvia plebeia*, and polysaccharides were derived from *Radix Rehmanniae Recens* (RRRP). This prescription combination of *H. japonicum*, *Radix Rehmanniae Recens*, and *S. plebeia* (HRS) was based on theories in traditional Chinese veterinary medicine. In vitro and in vivo experiments were conducted using the three single ingredients compared to the combined HRS prescription to determine their anti–duck hepatitis A viral (anti-DHAV) activity. The results showed that all experimental conditions displayed anti-DHAV activity, but the HRS prescription was most effective.[59]

Antiviral Drug Therapies in the COVID-19 Pandemic

In 2020, severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), a novel coronavirus that was first detected in China in December 2019, led to a global outbreak that became known as the COVID-19 pandemic. Due to the worldwide spread and severity of the disease, several pharmaceutical companies have worked on developing new antiviral drugs as well as repurposing already available antiviral drugs to reduce morbidity and spread of the virus. Drugs targeting SARS-CoV-2 replication include PF-07321332, also known as nirmatrelvir. PF-07321332 is an antiviral drug that inhibits the main protease (Mpro) of coronaviruses that is essential for viral replication and is highly conserved. Nirmatrelvir binds to Mpro forming a reversible bond with the catalytic cysteine residue, Cys145, thereby inhibiting viral replication. Nirmatrelvir has

demonstrated antiviral activity against all known variants of SARS-CoV-2 but has the potential to treat a variety of coronavirus infections, possibly also in other species.[60] Ritonavir (RTV), an oral antiviral medication that was initially developed to treat HIV infections, is a potent CYP3A (cytochrome P450 isoform) inhibitor that aids to slow down the metabolism of nirmatrelvir, thereby increasing its bioavailability. As such, the combined use of these drugs, which are packaged together under the trade name Paxlovid, has been advocated for effective treatment of COVID-19.[60]

Remdesivir is a nucleoside analog that acts as a competitive inhibitor of viral RdRP. It is a prodrug given intravenously and subsequently transformed in the body into an active molecule known as GS-441524. Initially, remdesivir had been proposed for the treatment of Ebola. However, further research showed that remdesivir not only had antiviral activity against Ebola virus but also against MERS-CoV, SARS-CoV, and other coronaviruses, hence making it a possible candidate drug for treatment of COVID-19.[61]

Aforementioned developments in antiviral drug therapies demonstrate that the medical and scientific communities are capable of acting quickly to find effective antiviral strategies in case of a global viral outbreak. Nevertheless, while close monitoring of the developments in the human field may provide useful starting points toward identifying antiviral drugs that may be useful for implementation in viral infections in birds and animals, there are also notable global concerns that the use of antiviral agents in veterinary medicine, particularly in food-producing animals, may lead to the development of resistance to these medications in human pathogens. Hence, several countries, including the European Union, have restricted the use of antiviral drugs in animals.

Conclusion

The most effective strategy against viral disease includes preventing and reducing exposure when possible and vaccination and antiviral drugs (see Section 4: Infectious Disease Prevention). Most antivirals selectively target only one or a few types of virus but broader-spectrum antivirals are being developed.[59] These drugs will cover multiple viruses and genotypes reducing the potential for resistance. In some cases, the combination therapy of vaccines and antivirals may increase survival. The combined use of antiviral agents to target both viral components and cellular machineries may allow for decreased dosing of the individual drugs and improve antiviral efficacy, reduce viral resistance, and minimize toxicity. Synergistic activity between favipiravir and oseltamivir against influenza virus has been documented.[27] The goals for optimal antiviral use in veterinary medicine include effectiveness of treatment, safety, cost effectiveness, and ease of delivery. The needs of aviculture and flock medicine will be different than that of an owner with only one or two pet birds.

Advances in the field of molecular biology and DNA technology, in particular computational approaches, along with the repurposing of drugs and evaluation of the antiviral effects of plants will contribute to the development of a new generation of antivirals including broader-spectrum antivirals, which will be important in the control of many animal diseases, including those encountered in the avian patient.[62] The COVID-19 pandemic revealed how quickly the medical and science communities can react to severe viral threats. In an effort to keep these drugs readily available and effective for human use, current antiviral use in general is frowned upon in veterinary medicine, and its use is banned in poultry. However, this could change when being confronted with a viral outbreak that poses a severe threat to livestock, poultry, or possibly could lead to extinction of an endangered species.

CHAPTER 11

Interaction of Host, Agent, Environment, and Disease

David N. Phalen

INTRODUCTION

Infectious diseases have been and continue to be major causes of morbidity and mortality in pet and aviary birds. Developing strategies to reduce the impact of infectious diseases requires an understanding of the characteristics of the infectious agent that allow it to cause disease, host factors that may make them susceptible to infection and disease, and environmental factors that predispose to pathogen exposure and host susceptibility. Reducing the impact of infectious diseases also requires an understanding of human behavior. Many effective strategies have been developed that can break infection cycles for specific pathogens in pet and aviary birds. However, these strategies are of no value unless the pet bird owner or aviculturist is willing and able to implement them and often they are not. In these situations, nontraditional or novel means of control are required if control is to be achieved. However, it is a reality that in many bird collections, control of infectious diseases cannot be achieved.

PRIMARY VERSUS OPPORTUNISTIC PATHOGENS

Pathogens can be divided into primary and opportunistic pathogens. Primary pathogens are not typically present in the bird's environment but when introduced to a collection are capable of causing infection and disease. Opportunistic pathogens can be divided into two groups: environmental pathogens and enzootic pathogens. Opportunistic environmental pathogens are ubiquitous and when present in low numbers rarely cause disease on their own. Opportunistic environmental pathogens generally are not passed from one bird to the next. They become pathogens when environmental conditions are optimum for their growth in the environment, resulting in birds being exposed to concentrations of the pathogen that exceed the bird's immune system's capacity to prevent infection. In addition to environmental factors, host factors can predispose birds to infection and disease caused by environmental opportunistic pathogens. Birds whose immune system is compromised by a concurrent infection with an immunosuppressive organism, for example, psittacine beak and feather disease virus (PBFDV), or *Chlamydia psittaci*, are more likely to become infected with environmental opportunistic pathogens. Similarly, birds experiencing stress are more susceptible to opportunistic pathogens. Lastly, naïve species, those that have not coevolved with an opportunistic pathogen, are also at risk of infection and disease by them if these species are added to collections or brought into care in environments that differ significantly from their natural environment.

Examples of environmental opportunistic pathogens are *Pseudomonas aeruginosa*, *Aspergillus* spp. that infect the respiratory systems of birds, and *Candida* spp. that infect the digestive tract of birds. *P. aeruginosa* is a moisture-loving bacterium. It can grow to heavy densities on persistently wet surfaces like hand-rearing implements, bird baths, polyvinylchloride pipes that are used in automatic watering systems and for sprinklers, and sprouted seeds. *Aspergillus* spp. are ubiquitous, but environmental growth is enhanced by warm damp environments. Therefore, their airborne spores reach a higher density in tropical parts of the world where there is a high relative humidity and in warm damp aviaries with poor ventilation. *Candida* spp. cause problems in nestling birds that are improperly managed, finches kept in aviaries where hygiene is poor and where moist foods are left out for many hours, in dense colonies of finches where more timid species are under the constant threat of bullying, birds infected with immunosuppressive circoviruses or *C. psittaci*, and birds whose gut flora has been altered as the result of antibacterial treatments.

Opportunistic enzootic pathogens are pathogens that cause lifelong subclinical infections but only cause disease in birds under conditions of extreme stress. There are not many

documented examples of these in birds, but Psittacid adenovirus 2 is an example of an opportunistic enzootic pathogen, and it is possible that the Gouldian finch adenovirus behaves in the same way.[1] Research has shown that many adenoviruses infect many species of birds persistently and subclinically, but that virus replication increases with resultant disease in some instances, for example, when stressors such as high temperature or co-infection with *Aspergillus* spp. occur.

OPPORTUNISTIC PATHOGENS AND THEIR CONTROL

The key to control opportunistic environmental pathogens is reducing the concentration of the pathogens in the environment and reducing opportunities for them to amplify. How this is done will depend in part on the pathogen. For all environmental pathogens, however, regular cleaning, in particular removing fecal material and uneaten food, is the first step to controlling them. In addition to cleaning, an effective way of reducing contact with feces and spoiled food is to house birds in suspended wire cages and individual pet birds in cages with wire grids at the bottom. The use of medium-sized pebbles or small rocks as substrates in the bottom of bird flights has also worked for some because these allow food to slip between the pebbles and out of reach of the birds in the flight.

Reduction of fecal/oral transmission of environmental pathogens requires the use of appropriate feeding practices and attention to the cleanliness of food and water dispensers. All food and water dispensers should be covered to prevent fecal contamination. Similarly, perches should be arranged in such a way that they are not over food and water dispensers. Many birds will foul their drinking water by putting food in it. When this happens, water containers will need to be changed out more than once a day. It is very common for aviculturists to house finches *(Haemorhous mexicanus)*, canaries *(Serinus canaria)*, budgerigars *(Melopsittacus undulatus)*, and cockatiels *(Nymphicus hollandicus)* in flights and to feed them on tables or wooden shelves where the birds walk through the food and defecate on the food that they are eating. This type of feeding makes control of opportunistic environmental pathogens impossible and should be discouraged in all instances. Another common practice, particularly in finch collections, is to feed soft foods. However, if the uneaten food is not removed from the aviary, it may overgrow with opportunistic pathogens. There are multiple ways to clean and disinfect food and water dispensers using soapy water and disinfectants, but in the author's experience, the most effective and easiest way of preventing pathogen buildup in food and water containers is to run them through a dishwasher. Dishwashers will sterilize the containers, while washing and treating with disinfectants generally does not.

One solution to having to clean water dishes every day is to use an automatic watering system. These are typically fed from a reservoir. In some instances, the reservoir is a rainwater tank that fills from the runoff from a roof. These systems are very effective at providing fresh drinking water but are predisposed to an overgrowth of *P. aeruginosa*. Chlorinating the water in the reservoir or flushing the system regularly with dilute bleach will control *P. aeruginosa* overgrowth. Sprinkler systems used to cool aviaries will also need either a chlorinated water supply or regular flushing with dilute bleach to prevent *P. aeruginosa* overgrowth.

Creating sufficient ventilation in buildings in which birds are housed is essential for multiple reasons. It provides fresh air, can assist with cooling during hot times of the year, and dilutes airborne pathogens. Most importantly, air movement through an aviary reduces the relative humidity and allows the aviary to dry out after cleaning. A damp aviary will support the growth of *Aspergillus* spp. and a lack of ventilation will allow the spore density to rise to dangerous concentrations. Even small enclosures such as brooders and hospital cages can create environments that favor aspergillosis. Often, brooders and hospital cages are designed more to maintain temperature within specific ranges than to facilitate ventilation. Chicks or sick birds fed liquid diets produce moist droppings, as do frugivorous species. If the brooder or hospital cage is not properly ventilated, *Aspergillus* spp. will grow in the areas housing the fan and heating elements, areas that are rarely cleaned.

Also, no matter how good the ventilation is, some environments are not suitable for certain species of birds. Classic examples of birds that cannot be housed in warm and humid environments include the gyrfalcon *(Falco rusticolus)*, penguins *(Sphenisciformes)*, and ostriches *(Struthio camelus)*. Gyrfalcons and penguins must be housed in climate-controlled buildings. Similarly, ostriches do not do well in warm humid coastal environments, and it is not possible to raise emu *(Dromaius novaehollandiae)* chicks in tightly sealed dairy barns with hay used for bedding. Rehabilitation of seabirds poses a number of difficult challenges of which one is infection with *Aspergillus* spp. Even when all housing recommendations are met, and meticulous care is provided, aspergillosis remains a common problem. In these situations, prophylactic systemic antifungal treatment is required to prevent aspergillosis (see Chapter 8).

PRIMARY PATHOGENS AND THEIR CONTROL: BIOSECURITY

Primary pathogens can impact the individual pet bird, small "flocks" of pet birds, and large avicultural collections and are of concern for the avian veterinarian because of the risk of transmission in the hospital. Control or mitigation of the impact of primary pathogens requires a detailed knowledge of the epizootiology of the pathogen, allowing the identification of specific measures that can be implemented to prevent pathogen transmission.

EPIZOOTIOLOGY

The key to mitigating the impact of any infectious disease-causing agent is understanding its epizootiology. The first step to understanding the epizootiology of a primary pathogen is determining how the pathogen is spread. This means that the route of shedding must be determined, including if it can be passed in the egg (vertical transmission), its ability to survive or multiply in the environment, whether it requires or utilizes an intermediate host, by which route it infects the next host, and how many organisms are required to induce infection. Next, it is necessary to know the incubation period between exposure and shedding and what the consequences are of infection (Figure 11.1). Understanding the epizootiology of an infectious disease in one species is complex, let alone when it comes to infectious disease circulation and spread across multiple types of birds as the pattern and

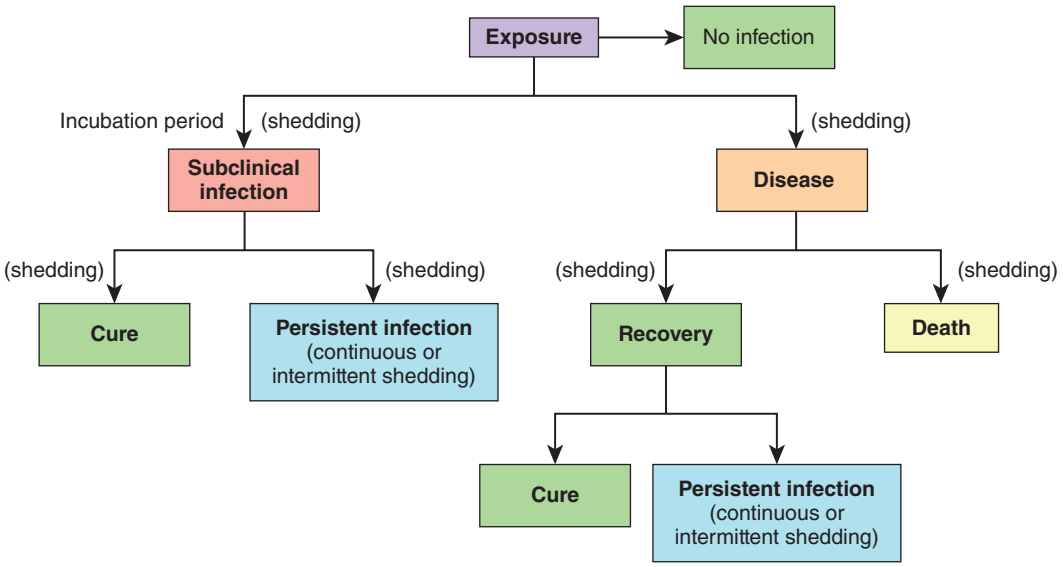

FIGURE 11.1 Possible outcomes resulting from exposure to an infectious disease. Which outcome occurs in the individual bird will depend on the number of organisms to which the bird is exposed, virulence of the pathogen, strain of the pathogen, immune status of the bird at the time of exposure, the species of the bird, and, in some instances, the age of the bird. Knowing when an infected bird will shed the pathogen and for how long will determine what kind of testing and control measures will prevent an infected bird from infecting others, or if control for the infectious agent is even possible.

outcome of infection can vary tremendously. Additionally, the outcome of infections can also be impacted by coinfections with other pathogens. As examples, coinfection with PBFDV can result in avian polyomavirus infection causing death in an adult *Eclectus* parrot *(Eclectus roratus)*, whereas infection in otherwise healthy adult birds is typically subclinical.[2] Similarly, adult lovebirds (*Agapornis* spp.) are more likely to remain persistently infected with and shed avian polyomavirus if concurrently infected with PBFDV. Similarly, they are also more likely to shed *Encephalitozoon hellem* if infected with PBFDV.[3]

In parrots and other species of captively managed birds, the infectious agents that have been the most difficult to control have been those that cause subclinical and lifelong infections in selected individual birds or certain species of birds but are pathogenic in others. Although less common, infectious diseases that spillover from wildlife can cause disease in birds kept in outdoor aviaries. These may result from direct transmission, (e.g., salmonellosis or yersiniosis from mice and rats); vector-borne transmission, (e.g., West Nile virus and poxvirus); or indirect transmission, (e.g., *Sarcocystis falcatula* of the Virginia opossum *[Didelphis virginiana]* that is highly pathogenic to Old World psittacine species).

DISEASE CONTROL TOOLBOX

There are many tools that the veterinarian has to mitigate the impact of infectious disease. Which ones are used will depend on the species of the bird, whether the bird is going into a pet bird home either as an individual companion bird or part of the owner's "flock," or whether it is going into a breeder's collection. Some recommended control measures for specific pathogens are shown in Table 11.1.

GUIDING CLIENTS ON SELECTING THE SOURCE OF THE BIRD

Anyone purchasing a bird should buy it from a breeder that has been recommended by others who have purchased birds from them previously. Also, they should visit the breeder's aviary to make sure that they are happy with the breeder's management. Veterinarians may be able to recommend breeders to their clients and can help the client who wishes to purchase a bird make up a list of questions to ask the breeder and have a checklist of points to consider before purchasing a bird (Box 11.1).

QUARANTINE

Quarantine has proved to be a powerful tool for preventing disease transmission in aviary and pet birds in many settings. Nevertheless, it has significant limitations.[4] The value of quarantine is based on the premise that if birds exposed to infectious diseases are held in quarantine for a sufficiently long period of time, they will either develop manifestations of this infection and not be allowed into the collection or will cease shedding the infectious agent and can be safely released into the aviary. This is true for some infectious diseases, and for these, specific quarantine periods can be developed to prevent their introduction to a bird collection. An example of this is the avian polyomavirus. This virus is typically shed for 3 months following infection.[2] However, quarantine will not prevent birds that are persistently and subclinically infected from introducing a pathogen into an aviary, so additional biosecurity measures are required in all instances in addition to quarantine. Examples of important pathogens that cannot be excluded from an aviary by quarantine alone include avian bornaviruses, *C. psittaci*, and

TABLE 11.1

Control Options for Selected Primary Infectious Diseases of Importance to Pet and Aviary Birds and Their Likelihood of Success

	Quarantine/ Closed Aviary	Physical Examination and Nonspecific Testing	Testing	Treatment	Artificial Incubation of Eggs	Vaccination	Vermin/Vector Control
Adenoviruses[1] (pigeons, psittacine birds, possibly others?)	No	No	Test available, unknown specificity	No	Possible, but unknown	No	NA
Avian polyomavirus[3] (psittacine birds)	Yes	No	Yes	No	Possible, but unknown[a]	No	NA
Avian bornavirus[5] (psittacine birds)	No	No	Likely with repeat testing	No	Viral RNA found in eggs[b]	In development	NA
Psittacine beak and feather disease virus (PBFDV; psittacine birds)	No	Some birds show signs, many do not	Quality test but infected birds not always positive	No	Viral DNA found in eggs[b]	In development	NA
Pigeon circovirus[6]	No	No	Test available, unknown specificity	No	NA[c]	No	NA
Pigeon paramyxovirus	No	No	No	No	NA	Yes	NA
Poxviruses (canaries *(Serinus canaria),* pigeons, poultry and other bird species)	No	Signs are characteristic	No	No	NA	Yes	Yes—canaries
Psittacid herpesvirus 1[7]	Yes	Most do not show signs, some will have mucosal papillomas	Yes	No	Possible, but known	No	No
Columbid herpesvirus	No	No	Test available, sensitivity unknown	No	NA	No	No
Chlamydia psittaci	No	Nonspecific signs and hematological findings, not present in all birds	Yes	Yes	Possible, but unknown	No	No
Mycobacteria spp.	No	Some but not most birds, nonspecific signs	Tests not widely available and not sensitive	No	Possible, but unknown	No	No
Macrorhabdus ornithogaster[8]	No	Some but not most birds, nonspecific signs	Testing is specific, but not sufficiently sensitive	No	Yes	No	No
Sarcocystis falcatula[11]	No	No	No	No	NA	No	Yes
Helminths	Yes	No	Yes	Yes	Yes	No	Yes

[a]One paper suggests vertical transmission, but it is possible that had the eggshells been removed after hatch, that infection may not have occurred.
[b]Viral RNA (bornavirus) and viral DNA (PBFDV) found in a subset of eggs from positive hens. It is uncertain whether this would have resulted in an infection in the chicks.
[c]*NA,* Not applicable. Artificial incubation is rarely used in racing pigeon *(Columba livia domestica)* lofts, so this option was not included.

BOX 11.1 QUESTIONS THAT COULD BE ASKED OF A BIRD BREEDER PRIOR TO PURCHASING A BIRD FROM THEM[a]

- How long have you been breeding birds?
- What species do you breed?
- Would it be possible to do a walkthrough of the collection and see the nursery?
- Do you work with a veterinarian?
- What kind of preventative medicine program do you have?
- Do you quarantine incoming birds? If so, can you describe the procedure that is followed?
- If a bird dies in the collection, are postmortem examinations routinely done?
- Would you be able and willing to give me the names of some of your clients that could serve as a reference for you?
- Was the bird artificially incubated, or incubated naturally?
- Is the bird hand-raised or parent-raised?
- Is the bird fully weaned?[b]
- Are the parents related? (Especially relevant with color mutations)
- What are the parents fed?
- What breeding records do you keep, and can I inspect records relevant to my purchase?
- If a young bird, do you have a growth chart for the bird, and can I see it?
- Has there been any effort to socialize the bird? If so, how?
- What is the bird being fed?
- Is there a guarantee so that a bird can be returned if a problem is found during the first Vet Check? What procedure should be followed in this case?

[a]This list may not apply to all situations. A discussion between a client and their avian veterinarian prior to meeting with the aviculturist may help to refine this list or identify additional pertinent questions to ask.
[b]In many countries it is illegal to sell unweaned birds. Even in countries where the sale of unweaned birds is legal, buying an unweaned bird is generally not recommended for inexperienced owners or handfeeders.

PBFDV. Detecting subclinically infected birds with these pathogens requires that birds be tested for them.

EXAMINATION AND NONSPECIFIC TESTING

Ideally, all newly acquired birds would be examined by a veterinarian as soon as possible after acquisition and before they are in contact with any other birds in the owner's home or aviary. A thorough history and physical examination coupled with a complete white blood cell count, serum biochemistries, wet preparations, Gram stains, and quick stains of crop swabs and feces or cloacal swabs will identify many unwell birds and birds with manifestations of infectious diseases.

TESTING FOR SPECIFIC PATHOGENS

There are an increasing number of infectious agents that can be detected in subclinically infected psittacine birds with targeted tests. The main purpose of testing a newly acquired individual pet bird is to make sure that it is healthy and not carrying an infectious agent that will subsequently make it, other birds, or the owner ill. Depending on the bird's signalment, history, and disease prevalence in your region or country, it may be appropriate to test new birds for one of more of the following: PBFDV (circovirus), polyomavirus, avian bornavirus, Psittacid herpesvirus 1, *C. psittaci*, or *Macrorhabdus ornithogaster*. Testing birds going into a home or an aviary where there are multiple other birds often requires more extensive testing (Table 11.1). Which tests are appropriate from new birds entering a multiple bird aviary will depend on the species of birds in the collection, why these birds are kept, and the disease status of the collection, with final selection being done in consultation with the bird owner or aviculturist.

Testing is not a panacea and there are limitations to every type of test. For example, tests that detect an organism may yield false-negative results if the bird is recently infected and not yet shedding the organism.[2,5] Recent antimicrobial treatment can also interfere with polymerase chain reaction (PCR) assays to detect *C. psittaci*. Similarly, if a bird is only intermittently viremic, or bacteremic, or intermittently sheds the organism, infected birds can be missed. In such instances, repeated testing may be indicated. Alternatively, in some settings, holding a bird in quarantine for 2 weeks prior to testing may allow an infection that occurred in the bird near the time of purchase to progress to a point where the pathogen can be detected.[4]

Lastly, we cannot test for those infectious diseases that we do not know are there. Newer techniques such as next-generation sequencing and other molecular technologies are finding new potential pathogens all the time. Many of these are viruses, but it is often uncertain if these actually are pathogenic or not. In some instances, such microorganisms have been found to be widespread in collections, probably for many years, without evidence that they were causing disease. Two examples of viruses that appear to be widespread in avian collections but are not or are rarely associated with disease are Psittacid adenovirus 2 and the avihepadnaviruses.[1,6] In addition, commercially available testing is often not available for many rarely identified infectious diseases and newly discovered infectious diseases.[1,6]

DISEASE PREVENTION THROUGH TREATMENT

There are few instances where "prophylactic" treatment of birds is indicated. However, this is commonly done by aviculturists and is encouraged by some vendors who sell water-soluble medications. Treatment should be evidence based, whenever possible. This means that a pathogen should be identified in an animal before it is treated, and if the pathogen is a bacterium, then the treatment should be selected on the results of a culture and sensitivity, whenever possible (see Chapters 6 and 7). The only time that treatment might be appropriately used as part of a disease control measure is when attempting to prevent the introduction of parasites into collections. In the prepatent stage of development, nematodes may be present and not be shedding eggs, which may lead to these infestations being easily missed on a fecal examination. Similarly, a bird may be infected with tapeworms,

without eggs being detected in a fecal examination. If deworming is to be done as a "prophylactic" treatment, then follow-up fecal examinations are recommended, as resistance to antiparasiticides can develop (see Chapter 9).

MANAGEMENT PRACTICES THAT CAN REDUCE THE IMPACT OF INFECTIOUS DISEASES IN AVIARIES

The Closed Aviary Concept

The closed aviary concept is a management concept centered on the management of traffic flow of birds, people, and fomites into and within an aviary once the collection has been established (Figure 11.2). Using this concept, management factors can be used to minimize the risks of infectious disease to bird collections. The criteria for movement into, out of, and between segments of the closed aviary are established through careful veterinary consultation and are aimed at the primary goals of the aviculturist. These criteria may range immensely from an absolute rule of no new birds to be introduced to the facility (nor birds returning to the facility once they have left the premises), breeding stock replaced only with offspring from the current breeding stock or specific quarantine timelines and testing criteria prior to (re)introduction of (new) birds to the facility, to mere observational assessment and entry of new birds to the facility with no specific testing procedures required.[6] Under ideal circumstances, specific primary pathogens would also have been eliminated from the aviary as a result of routine testing, treatment, or management practices, resulting in a specific pathogen-free flock.[4] Aside from control of bird movements, human traffic in and out of the closed aviary would also be controlled. Under ideal circumstances, visitors would not be allowed into the aviary at all, and employees would not have contact with birds when off the property.

Unfortunately, even though the modular concept of the closed aviary and its management can be modified, adjusted, and fine-tuned to meet the needs of the collection and aviculturist, acceptance to standardization of traffic flow still remains inconsistent in aviculture. Standards may be set too strictly, an infusion of new birds will generally be necessary to maintain genetic diversity, procedures may carry unacceptable costs, testing procedures selected may not carry an adequate sensitivity, or even a true understanding of the concept may not be fully present.

Species Composition

A general rule of thumb is that the more species held in an aviary, the more likely it is for infectious disease transmission to occur. Minimizing species diversity in an aviculture collection has additional advantages besides disease prevention, including allowing the aviculturist to become an expert in the species that they are raising, typically resulting in increased breeding success and an improved quality of life for their birds.

There are certain species that are known to be commonly and subclinically infected with important primary pathogens. Based on the author's experience, aviculturists who breed high-value birds often enjoy breeding other species like budgerigars, cockatiels, and lovebirds, even bringing chicks from

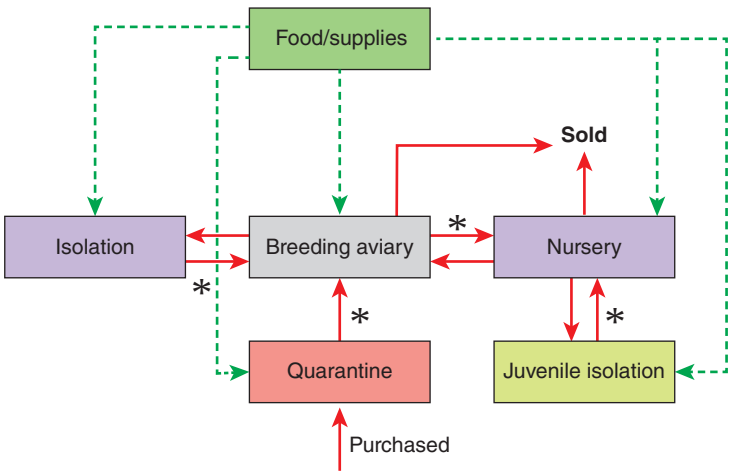

FIGURE 11.2 The closed aviary concept utilizes controlled traffic flow to reduce variables, including but not limited to infectious agents into or within a flock. The modular units of quarantine, the breeding aviary, nursey, isolation, and nursery isolation are depicted, as well as the separate source of food and supplies. Because of its modular concept, there can be multiple quarantines, breeding areas, nurseries, etc. Depending on their purpose, not all collections have to have a breeding aviary or nursery, as not all are focused on breeding. Independent traffic flow of food and supplies to these areas is shown (*green arrows*), not through multiple components. Potential movements of birds are shown with *red arrows*. Areas of key interest for management of pathogen movement are marked with *stars*, and these areas are where management rules, procedures, or protocols will have their greatest merit in strengthening the impact of the use of the concept. Another unique aspect of the closed aviary concept is that the rules or protocols of controlled bird movement are specifically tailored to serve the mission and purpose of the facility, and what is known about the bird species involved as well as the pathogens of interest that are to be managed.

these species into their nursery. This is a recipe for disaster and has resulted in many disease outbreaks resulting from introduction of avian polyomavirus and PBFDV. If aviculturists or institutions want to keep many different species, then housing different species in separated areas in the facility may reduce the risk of disease transmission.

It is a widespread practice for aviculturists to house small species of parrots such as Bourke's parrots (*Neopsephotus bourkii*) and scarlet-chested parrots (*Neophema splendida*) in planted aviaries together with canaries and other finches, buttonquail (*Turnix* spp.), and Japanese quail (*Coturnix japonica*). However, how diseases spread back and forth between these species is largely unknown, thus hindering the design and development of preventive and treatment protocols for such aviaries. Zoos and other institutions that display birds for the public also tend to have mixed collections of birds housed together. In many instances, these are birds from similar environments and the same part of the world, but in others, species from many different geographic origins are housed together. Again, in these instances, disease control will be challenging or even impossible to achieve.

Aviary Design and Workflow

Aviary design can also be used to reduce disease transmission within a bird collection. Birds housed outdoors in separate cages are less likely to transmit diseases because of the dilution effect of wind and the sterilizing effects of the sun. In contrast, birds housed indoors in adjacent flights with a shared wire wall are much more likely to transmit disease.

Keeping birds in outdoor aviaries can also have a number of drawbacks. These aviaries provide an increased chance of contact between captive birds and wild birds. This often requires trade-offs in aviary design between aviaries where birds are exposed to sunshine and rain but have an increased exposure to wild birds, on the one hand, and aviaries that are fully covered by a roof and partially enclosed to keep wild birds from entering and/or defecating into the aviary, on the other. The author has observed many instances where aviary birds were housed in suspended wire cages and wild birds were seen to be feeding on food that fell through the bottom of the cages. This food will also attract mice, rats, and flies. In North America, it can also attract Virginia opossums, thereby increasing the risk for infection with *Sarcocystis*. In large fenced-in aviaries in North America, having a dog free-ranging within the aviary can help to reduce Virginia opossum numbers and also problems with raccoons (*Procyon* spp.). Similarly, allowing chickens (Gallus gallus domesticus), ducks (Anatidae), or guinea fowl (Numididae) to forage under suspended wire cages will reduce the amount of food available to vermin. Vermin control in any aviary, particularly in outdoor aviaries, is essential. It is the author's impression that *Salmonella* outbreaks are more likely to occur in aviaries where mice or rats are in high density. The presence of mice and rats can also be disruptive to breeding birds at night.

Designating specific areas of an aviary to specific purposes, and controlling movement between these designated areas, may reduce the chance of disease movement within a bird collection.[4] Large aviaries can be divided into different functional areas such as the food preparation area, nursery, replacement stock holding facility, main breeding facilities, cleanup area, and quarantine. Ideally, all food preparation would be done before moving into other parts of the aviary, and dirty food and water bowls would be disinfected at a site separate from the food preparation area. Similarly, chicks would only be transferred from the breeding facility into the nursery and never return into the nursery or other parts of the facility once they left, with care for these chicks ideally being done by people who do not work with the breeding stock. Birds in quarantine would either be cared for after care of all other birds is finalized or done by designated staff who have no contact with other birds in the facility. These practices can generally only be applied in full in large collections of birds with multiple staff. However, with some degree of innovation, modifications of these practices can be applied even in small collections. For instance, people caring for the major collection could also care for nestlings if they practice adequate hygiene (e.g., wash hands) and change their clothes or put on coveralls and shoe covers when going into the nursery (and do the same when leaving the nursery again).

Incubator Hatching Eggs

Pulling eggs from adult birds and incubator hatching may result in the interruption of disease transmission from adults to chicks (see also Section 9: Embryology, Neonatology, and Pediatrics). This can be assumed to be the case for parasitic diseases, most bacterial diseases, and with *M. ornithogaster*.[10] How effective it will be with viral diseases is less certain and may depend on whether the eggs are cleaned, if chicks are separated from the shells and put in a clean environment as soon as they hatch, and if viruses are vertically transmitted through the egg.

Hygiene and Disinfection

The same principles regarding hygiene and disinfection apply for primary pathogens as they do for opportunistic pathogens. Diluting pathogens by cleaning reduces the risk that a bird will be exposed to an infectious dose. Disinfection (see Chapter 12) of food preparation and food storage areas, handfeeding utensils, food and water bowls, breeding boxes between breeding seasons, and the nursery after breeding will decrease the chance of the transmission between birds in a bird collection. Hand washing or sanitization and daily washing of work clothes should also be included in a disease prevention program. Similarly, cleaning and disinfecting cages and other surfaces in a veterinary hospital needs to be done multiple times a day to prevent the spread of contagious diseases.

Disease Monitoring

An important part of disease control in a collection is keeping records of the disease problems the collection has experienced. Aviculturists often think that they know what is causing disease in their birds, but they may be wrong. It is therefore highly recommended that necropsies be done on a representative number of birds that die in a collection and on all birds that die unexpectedly. How many birds and which birds that die that should be necropsied would be based on discussions between an aviculturist and their veterinarian. It is these patterns of morbidity and mortality noted in an established flock that can guide to changes in the details of closed aviary management concepts, as well as population management recommendations overall.

MITIGATING THE IMPACT OF DISEASE IN SELECTED CIRCUMSTANCES

Minimizing Infectious Disease Problems in the Pigeon Loft

A protocol for mitigating the impact of disease in the pigeon loft and protecting pigeons *(Columba livia domestica)* from common infectious diseases can be found at https://www.auspigeonco.com.au/rdquoone-loft-racerdquo-protocol.html. This protocol was developed by Dr. Colin Walker, an experienced pigeon veterinarian and a racing pigeon enthusiast. Recommendations include a combination of tools. Dr. Walker recommends a brief quarantine period that allows the owner to examine their new birds for signs of illness and treat for common parasitic diseases, including *Trichomonas gallinae*, coccidia, roundworms, and tapeworms. Birds exhibiting signs of disease are sent back to the breeder. During the quarantine period, pigeons can also be tested for pigeon circovirus infection (assays are available from multiple commercial laboratories) and adenovirus infection (https://www.cd-diatest.com/cdia-sup-tm-sup-pigeon-adenovirus-antigen-test-kit_p542.html). Based on research in Europe and the author's experience, pigeon circovirus is enzootic in Europe and Australia,[6] so testing for it may not be useful as most fledglings will be infected. Adenovirus testing may also not be beneficial as adenovirus infections are likely to be widespread and, at least in the author's experience, rarely cause disease. Columbid herpesvirus is also widespread in feral and captive-raised pigeons and testing for it has little merit, especially as it only appears to cause disease in immunosuppressed birds. Pigeon pox and pigeon paramyxovirus are controlled by immunization.

These recommendations may benefit some pigeon breeders, but it is impossible for racing pigeon lofts to be maintained as closed colonies. Encounters with feral pigeons and pigeons from other lofts occur when birds are released to exercise. During races, pigeons are held the night before the race in proximity with hundreds of other birds and may share water sources, creating opportunities for disease transmission between birds. Also, to maintain the best breeding stock, pigeon breeders often purchase new birds on a regular basis. Excess birds from their loft are sold to others, often through a pigeon auction where there will be many pigeons from multiple aviaries held in relatively close quarters. The ability of viral diseases of racing pigeons to rapidly disseminate across large geographic areas has been well demonstrated in Australia where both pigeon paramyxovirus and then subsequently rotavirus spread across the entire continent from a single point source in 1 year. Therefore, no matter what biosecurity efforts undertaken by racing pigeon fanciers, disease will always be a potential problem.

Preventing Primary Disease Outbreaks in a Rescue Center

Rescue centers for unwanted pet and aviary birds have been established all over the world. Controlling diseases caused by primary pathogens in these settings is challenging, given that there is a constant flow of birds in and out of these facilities; birds are generally a mix of species and they come from many different sources. In these high-risk environments, disease control requires careful examination and nonspecific testing of every bird coming into the facility, testing for specific diseases, and judicious use of quarantine until the disease status of newly acquired birds can be determined. Often, it is necessary to specifically test birds for PBFDV, *C. psittaci*, Psittacid herpesvirus 1, and avian bornavirus. Birds infected with *C. psittaci* can be treated and retested. Birds infected with Psittacid herpesvirus 1 or avian bornavirus can be housed together in a separate location or sent to a home where they are a sole pet or are part of a flock that contains other positive birds. PBFDV–positive birds must be housed away from other negative birds, or, if showing signs of disease, euthanasia may be elected as the best option.

Biosecurity in the Veterinary Hospital

Bird clinics and hospitals can provide an ideal place for disease transfer between patients. Many patients seen by avian veterinarians are either sick with an infectious disease or are subclinically infected with one. Additionally, many veterinarians board healthy birds in their hospitals that could be exposed either directly or indirectly to sick patients, and it is common for wild birds to be seen at veterinary hospitals, creating additional opportunities of disease transmission between wild and client-owned birds.

To minimize the risk of disease transfer in the hospital, a designated isolation ward needs to be available for all birds suspected of having an infectious disease, and policies need to be in place to prevent movement of an infectious disease on clothing, food bowls, or waste out of the isolation ward and into other areas of the hospital. Appropriate ventilation, in both the isolation area and the rest of the hospital, reduces the risk for disease transfer. Wild birds should not be housed in the same ward as client-owned animals, and boarding birds should not be housed in the same ward as hospitalized patients. Many veterinarians require that boarding birds be recently tested for known pathogens such as PBFDV and *C. psittaci* before they can be boarded. Cleaning and disinfection of all aspects of the avian hospital is also a required routine as birds tend to be messy and generate particulate matter that can readily contaminate the hospital. Cage design can also reduce the risk of disease transmission. All cages should have solid walls separating patients from each other and be made of impervious substances that are readily cleaned. Some sophisticated housing units with negative airflow have been used by avian veterinarians and could be considered for use in a specialist avian hospital. Constant attention to hygiene and disinfection is required in treatment areas of the hospital. Swabbing the hospital twice a year and submitting the swabs for molecular testing for, minimally, the beak and feather disease virus will document how successful cleaning and disinfection efforts have been.

Antimicrobial-resistant bacteria including *Escherichia coli*, *Staphylococcus aureus*, *Enterococcus faecium*, and *Enterococcus faecalis* are major sources of nosocomial infections in humans. Once established in a hospital, they can be very difficult to control. Antimicrobial-resistant bacteria can also establish themselves in veterinary hospitals (see Chapter 6). Therefore, all bacterial infections suspected of being acquired in hospitalized patients should be cultured, the organism identified,

and its susceptibility to antimicrobials determined (see Chapters 5 and 7). Repeated detection of the same organism with the same antimicrobial resistance pattern is a call for alarm and should trigger steps to identify and eliminate its source.

The Role of Education in Biosecurity

Talks on biosecurity and diseases of cage and aviary birds are popular with local bird clubs and at regional and national bird club meetings. I recall giving one on biosecurity many years ago, after which I overheard one of the attendees saying, "Man, I wondered when he was going to stop banging on about biosecurity. After all, I quarantine all new birds coming into my aviary, especially if they are sick." This was a bit humbling at the time, but it taught me some lessons. First, no matter how hard veterinarians push clients to improve their biosecurity, they will only do what they consider to be feasible, and this will largely be based on their past experiences and the tendency of all people to be optimists. Secondly, I have learned that comprehensive disease control issues are complex and that they may be difficult to explain. Therefore, focusing on practices that are the most easy and cost-effective to implement is likely to get the best uptake by the audience. Lastly, aviculturists come and go and there are always new ones just starting out. Therefore, continuous education about biosecurity is required, so that those just starting to build their collections do not make the same mistakes as those who proceeded them.

When Traditional Biosecurity Measures Are Not an Option

The infectious disease prevention methods outlined in this chapter cannot be implemented in some bird collections. This is particularly the case for breeders of racing pigeons (discussed earlier) and breeders of various species of birds that are routinely taken to bird shows. Aviculturists breeding show birds must take their birds to shows, where they are exposed to other birds, and return them back to the aviary multiple times during the year, creating opportunities for disease transmission. Most also buy and sell birds regularly. The use of quarantine and, in most instances, any form of testing is rarely practiced in these collections. Additionally, these birds are typically bred in relatively close quarters, and it is difficult to keep these breeding facilities clean, allowing disease spread between adult birds and disease spread to and between nestlings. All these issues are further complicated by a lack of uptake of even basic biosecurity measures by some aviculturists. Because of these challenges, viral, fungal, bacterial, and parasitic pathogens are enzootic in many collections of show birds and small hobbyist collections. Under these conditions, efforts to control diseases are largely done through flock treatment. Treatment typically has only limited short-term and no long-term effect because many of the drugs used are not effective against the pathogen being treated, medication is administered improperly or for an improper duration, and many pathogens are resistant to antimicrobials to which the aviculturists have access. Moreover, there are only limited control options for most viral diseases (see Chapters 10 and 13).

In the end, the only way pigeon breeders and other aviculturists are going to control infectious diseases that are enzootic in these species is to breed for resistance to the common and most significant ones. Based on conversations that the author has had with budgerigar breeders and his own experience, breeding for disease resistance is possible in some circumstances. In Australia, Europe, and possibly other countries, the most common cause of feather dysplasia of the flight feathers in nestling and fledgling budgerigars is PBFDV. Based on anecdotal information that I have received, certain color types appear to be much more likely to develop this disease than others, suggesting a genetic predisposition for the development of disease and genetic factors that might protect from disease. Similarly, if flocks of budgerigars are screened for *M. ornithogaster*, some birds will be found to have extensive colonization of the stomach, while others will have low-level infections or not be infected at all. Given aviculturists' talent for manipulating the genetics of their birds to achieve desired conformation and color mutations, selecting for disease resistance seems like a goal for which they could strive and that perhaps the veterinary profession could encourage.

CONCLUSION

Infectious diseases continue to cause morbidity and mortality in companion and aviary birds. Based on the knowledge of the epizootiology of these infectious diseases, control measures are available for many. These control measures have the greatest use when applied to the individual pet bird. Application in the avicultural setting is more difficult and requires tailored approaches that will depend on the resources and objectives of the aviculturist. Even with this knowledge, the use of biosecurity measures even at the most rudimentary levels is often not an option for many aviculturists and hobbyists. In the future, aviculturists and veterinarians, working together, can work to develop strategically designed novel approaches to disease control that may be more widely practiced.

CHAPTER 12

Hygiene and Disinfection

David N. Phalen

The combination of cleaning and disinfection is a two-step process that is a critical element of disease control for both opportunistic and primary pathogens in the veterinary hospital, aviary, and home environment. Cleaning (sanitation) refers to reduction of the amount of contamination in an environment, but unlike disinfection, which refers to destroying (-cide) or irreversibly inactivating (-static) pathogenic bacteria and viruses, it does not eliminate all infectious agents. Cleaning must always be done first to remove all organic debris, as disinfection is only possible after cleaning has been done. Overall, this process is not rocket science but is often done poorly, and if done poorly is ineffective. Few people enjoy cleaning. Therefore, in veterinary hospitals, pet stores, and small as well as large bird collections, it is important not just to provide protocols for cleaning and disinfection but also to teach staff about the importance of good hygiene, regularly monitor the facility to make sure that protocols are being followed, and to provide positive feedback when they are.

WHAT SURFACES CAN YOU CLEAN AND DISINFECT?

Only surfaces that are impervious to water and completely free of organic material can be disinfected. Therefore, it is possible to disinfect sealed countertops and fronts, stainless steel surfaces, wire cages, many floors, walls that are tiled or made of other impervious surfaces, and plastic or metal chairs. It is not possible to disinfect cloth-covered chairs, unsealed wood, soil, or living plants. Disinfecting rocks or rough concrete surfaces can also be challenging. Wood and concrete surfaces can be painted over with water-resistant paints and then these surfaces can be properly disinfected. This means that most surfaces in a veterinary hospital can be disinfected. It also means that in most aviaries only the kitchen and the nursery can be adequately cleaned and disinfected, and in peoples' homes, only the kitchen can be disinfected. Most cages designed for pet birds can be disinfected, but to do so, they need to be largely disassembled, scrubbed, and hosed down to be thoroughly cleaned. Wooden perches cannot be disinfected and should be replaced regularly.

CLEANING AND DISINFECTION

Cleaning is generally done in two steps. The first step is to remove as much of the loose organic material as possible. To do this, floors are typically swept, dry mopped, or vacuumed. If brooms or dry mops are used, then they also need to be regularly cleaned and disinfected. In the veterinary setting, cleaning and disinfecting brooms and mops is recommended every day. Only brooms that have rubber or plastic bristles should be used. These can be cleaned in the sink and then soaked in disinfectant, or they can be run through a dishwasher. Dry mops should be washed in a washing machine and dried every day. Vacuum cleaners are also efficient for removing loose material. They should have a high-efficiency particulate absorbing (HEPA) filter to prevent aerosolization of pathogens. The head of the vacuum cleaner should be cleaned and disinfected every day that it is used.

The second step in cleaning is to remove organic matter using a detergent solution. Cages, countertops and fronts, and examination tables are generally cleaned with disposable paper towels. To reduce waste, they can also be cleaned with cloth towels of the appropriate size that are used once and laundered. Sponges should never be used as they cannot be disinfected. Given the high levels of waste generated by birds, including powder down in some species of birds, cleaning bird cages and the ward that they are in is difficult. Solid surfaces are relatively easy to clean, but the bars on the front of a typical dog or cat cage or the bars on a traditional bird cage are not. In addition to the individual cage, banks of cages need to have their tops, sides, backs, and underneath surfaces cleaned, as well as the walls behind and to the sides of them and the floor underneath them. Filters in air handling units also need to be replaced regularly.

Cleaning feeding dishes, water bowls, perches, and other cage furniture is best done by removing organic material by cleaning in a sink with detergent followed by additional cleaning and sanitizing them by running them through a dishwasher. Dishwashers reach a high level of sanitation, one that should be acceptable under most circumstances. In the United States, dishwashers should meet the National Sanitation Foundation/ANSI Standard 184. Commercial dishwashers used in restaurants are effective at sanitizing their contents and have the added advantage of having shorter cycles. Sinks used for cleaning dishes can rapidly become contaminated with organic material and need to be aggressively cleaned and disinfected after use. Dishrags and towels should not be used to clean dishes unless they are washed after every use. Plastic scrub brushes can be used but should be run through the

dishwasher between uses. Single-use plastic or metal scrubbing pads can be used, as long as they are discarded after a single use. Soaking water and food bowls and feeding tubes in a disinfectant may also disinfect them but is generally not effective as soaking solutions are often not changed regularly, and the disinfectants in them may be inactivated by detergents and remnant organic material. Ideally, the cleanup area would be separated from the food preparation area.

Towels are used extensively in avian practices to restrain birds, for cleaning surfaces, and occasionally as bedding. Disinfecting towels and other items made of cloth can be challenging. Washing towels or other fabrics in a washing machine is the most commonly used way to clean and disinfect them. To make this method most effective, they should be washed using hot water and washed with a powdered detergent containing activated oxygen bleach.[1] Washing machines with steam cycles may more effectively disinfect laundry than those that do not have this function. Even with these precautions, heavily soiled fabrics may contaminate other fabrics in the same load and may not be fully disinfected. To minimize this chance, heavily soiled fabrics should not be washed with other fabrics, should be washed in small loads, and should be washed twice. Alternatively, heavily soiled towels and other fabrics can be discarded. Washing machines may not be able to inactivate nonenveloped viruses; therefore, towels used to handle birds with virus infections such as the beak and feather disease virus should also be discarded or soaked in bleach after washing and washed again.

Metal and rubber feeding tubes are particularly difficult to clean and disinfect as food can dry inside them, and feeding tubes are slender enough that they fall through the cutlery basket in a dishwasher. To effectively disinfect them, they need to be flushed thoroughly with water containing detergent. They can then be sanitized using the dishwasher. Plastic mesh bags can be used to hold the feeding tubes in the cutlery basket. Not all rubber feeding tubes will tolerate the dishwasher, requiring other means of disinfection. Also, feeding tubes are often in high demand. Therefore, after cleaning, flushing the tubes with alcohol or another disinfectant and allowing them to dry may be a more practical means of disinfection.

Stethoscopes and focused light sources should be wiped with a paper towel soaked with disinfectant between uses. Computer keyboards and handheld electronic devices should also be cleaned and disinfected by wiping with a detergent-soaked paper towel followed by a paper towel soaked in disinfectant. Otoscope cones and oral specula should be washed with detergent after use and then disinfected.

Floors are cleaned using mops and a detergent solution. Mop water gets dirty quickly and needs to be changed regularly; otherwise, the mop serves to move pathogens around rather than reduce their density.[2] Studies suggest that there is little benefit to using disinfectants in the mop water and that soapy water is sufficient to reduce populations of surface bacteria on floors.[3] Flooring is difficult to keep clean especially in heavily used areas. It is recommended that consultation and treatment rooms be mopped with soapy water during breaks in the day (treatment area) or between blocks of consultation periods (consultation rooms). Most mop heads are made of cloth and therefore need to be cleaned and disinfected after every use. The most effective way of doing this is to run them through a washing machine and dryer. Alternatively they can be soaked in freshly prepared diluted bleach.

Microfiber multiple-use and single-use mop heads have been developed and appear to be highly effective at removing dirt and reducing bacterial loads. Current data suggest that clumping of the microfibers occurs in the reusable mop heads after cleaning and may interfere with their function.[4] Therefore, it is recommended that only the single-use microfiber mop heads be used.

Footbaths containing disinfectants are commonly used at the entrance to quarantine rooms or facilities. As most disinfectants are partially or completely inactivated by organic material and footbaths become contaminated quickly, they also quickly lose their effectiveness, even if the disinfectant solution is changed regularly. Using foot covers or changing into boots at the entrance of the quarantine room may be a more effective means of preventing pathogen movement in and out of a quarantine facility.

An emerging disinfectant method that can be applied locally to high touch surfaces and to entire rooms is the use of UVC light–emitting devices (e.g., https://xenex.com/solutions/). These devices rapidly disinfect surfaces and can replace some manual disinfectant protocols or be used to supplement them.[5] They come at a considerable cost and may not be financially viable for a small veterinary hospital but may be cost-effective in larger practices.

Cleaning, disinfection, and sterilization of surgical instruments and endoscopes is outside the remit of this chapter. For details and guidelines on sterilization and disinfection of instruments, see https://www.cdc.gov/infection-control/hcp/disinfection-and-sterilization/index.html.

SELECTION OF DISINFECTANTS

There are many disinfectants, and each has a range of efficacies against different pathogens. They also differ in the amount of time that they have to be in contact with an infectious agent to inactivate it, their corrosiveness, their ability to irritate skin, how long they remain effective after dilution, and the impact of organic material on their effectiveness. Because of the number of pathogens that might be encountered in an avian practice, particularly practices that see wild birds, only disinfectants that are effective against gram-positive and gram-negative bacteria, mycobacteria, enveloped and nonenveloped viruses, fungi, and bacterial spores will be considered here. It is assumed, but not proven, that these disinfectants will also effectively kill rickettsiae, mycoplasmas, and *Chlamydia psittaci* elementary and reticulate bodies. Commonly used disinfectants will not inactivate cryptosporidia oocysts, but it is thought that thorough cleaning is sufficient to reduce the number of cryptosporidia oocysts to below the infectious level.[6] Comprehensive reviews on the efficacy and use of disinfectants have been developed by the Centers for Disease Control and Prevention (CDC; Guideline for Disinfection and Sterilization in Healthcare Facilities; (https://www.epa.gov/pesticide-registration/antimicrobial-pesticide-registration).

SPECIFIC DISINFECTANTS

Four categories of disinfectants with viricidal, bactericidal, fungicidal, and sporicidal activities are discussed in the following (Table 12.1). It is difficult to compare the efficacies of

TABLE 12.1

Overview of Common Disinfectants, Their Mode of Action, and Activity Against Specific Pathogens

						Halogens		Oxidizing Agents Peroxygens			
Type of Disinfectant	**Acids**	**Alcohols**	**Aldehydes Glutaraldehyde Formaldehyde**	**Alkalis**	**Biguanides-Chlorhexidine**	**Chlorines**	**Iodophor Solutions**	**Accelerated Hydrogen Peroxide**	**Potassium Peroxymonosulfate**	**Phenolic Compounds**	**Quaternary Ammonium Compounds**
Examples	Hydrochloric acid Acetic acid Citric acid	Ethyl alcohol Isopropyl alcohol	Formula H	Sodium hydroxide Ammonium hydroxide Sodium carbonate	Hibitane Nolvasan Savlon	Sodium hypochlorite Bleach	Betadine Povidone iodine	Rescue	Virkon S	Lysol Synphenol	Benzalkonium chloride F-10 (+biguanide)
Mode of action	Disrupt nucleic acids, precipitate proteins, change pH	Cell lysis, precipitate proteins, denature lipids	Denature proteins and alkylate nucleic acids	Alter cell membrane permeability	Alter cell membrane permeability	Denature proteins	Denature proteins, disrupt nucleic acids	Denature proteins and lipids	Denature proteins, disrupt cell membrane, inactivate enzymes	Alter cell membrane permeability, denature proteins	Denature proteins, disrupt cell membrane, inactivate enzymes
Dilutions	0.2%–4%, dependent on type	70%–90%	According to datasheet	0.4%–10%, dependent on type	0.5%–2%	2%–10%	10%–100%	3%–6%	0.5%–2%	According to datasheet	0.5%–1%
Contact time	10–30 minutes	20 minutes	20 minutes	10–30 minutes	10 minutes	10 minutes	1–5 minutes	10–30 minutes	10 minutes	10 minutes	5–10 minutes
Common applications	Water delivery systems, surfaces	Instruments, skin	Endoscopy equipment, empty cages, furnishings	Formerly used for disinfection of equipment, animal conveyances, surfaces, and water-resistant clothing	Instruments, cages, hard surfaces, preoperative scrubs	Hard surfaces	Wound aseptic, preoperative scrub	Endoscopy equipment, aerial disinfection	Hard surfaces, floors, equipment, footbaths, aerial disinfection, water delivery systems	Hard surfaces, floors, footbaths, laundry rinse	Hard surfaces, instruments, and rubber equipment

each of these formulations, as not all have been compared to each other, and testing of efficacy has occurred under varying conditions and with different organisms. Nevertheless, it is likely that all of these, if used properly, will be effective at disinfecting cleaned surfaces. At the same time, none of these products will perform as expected if the proper concentration is not used for the pathogen of concern and the proper contact times are not used. In general, for resistant organisms, such as nonenveloped viruses and bacterial spores, required contact times are often long (up to 30 minutes in some instances) and concentrations of the disinfectant need to be increased (up to 10-fold) over concentrations used for other organisms.[7] Therefore, routine disinfection protocols will need to be modified in cases where difficult-to-inactivate pathogens are intermittently or regularly encountered.

Accelerated Hydrogen Peroxide

Accelerated hydrogen peroxide products patented disinfectants (Rescue: Virox Technologies Inc., Oakville, ON, Canada) contain multiple ingredients that provide them with a number of advantages including relatively fast killing times, the ability to wet a surface evenly, efficacy in the presence of organic material and resistance to inactivation by hard water; they are noncorrosive and are environmentally friendly.[8] They are effective against nonenveloped viruses and therefore should be effective against avian polyomavirus and the beak and feather disease virus. They can significantly reduce the concentrations of environmental clostridial spores but are less effective than bleach.[9]

Quarternary Ammonium-Biguanide Combinations

These products, for which F-10SC (Health and Hygiene, Loughborough, South Africa) and Trigene II (MediChem International, Sevenoaks, UK) are examples, are made up of a combination of disinfectants that work in synergy with each other. They have the advantage of not being irritating, of working solutions being stable for long periods (1 year), and having activity in the presence of limited amounts of organic material. They kill bacteria with limited contact time (<1 min) but may require longer times (up to 15 min) to kill nonenveloped viruses and longer periods may be required to inactivate clostridial spores. Different dilutions have different levels of efficacy against different pathogens. Higher concentrations are recommended to inactivate fungi and the highest concentrations are recommended for inactivation of nonenveloped viruses.

Potassium Peroxymonosulfate

Potassium peroxymonosulfate is an oxidizing agent. It is sold under the trade names Trifectant (Evsco Pharmaceutical, Fort Worth, TX, USA), Virkon S (Laxness Corporation, Pittsburgh, PA, USA), and others. One of its advantages is that its efficacy is maintained to some extent in the presence of organic matter. Disadvantages are that it must be made fresh every 7 days, it is mildly corrosive, the powder prior to mixing with water is an irritant, and it may not be effective against spores from dermatophytes.

Sodium Hypochlorite (Household Bleach)

Bleach is an inexpensive board-spectrum disinfectant. It is unaffected by water hardness and is effective against biofilm-producing organisms. It is particularly useful for disinfecting mop heads, brooms, perches, food bowls, and water bowls that can be soaked in diluted bleach. It has a quick kill time for many pathogens, and of the disinfectants considered in this section, it is likely to be the most effective against clostridial spores. It is recommended that for routine disinfection, 20 mL of a 5% bleach concentrate is added to 1 L of water. The main disadvantage of bleach is that it is readily inactivated by organic debris requiring surfaces be cleaned thoroughly before use. Additionally, it is corrosive, tends to bead up and does not provide even surface contact, and should be made up fresh at least daily. There are also concerns that toxic gases, including chloroform, are released during the cleaning process and long-term exposure of patients and staff may represent a health hazard.[10]

Polyvinylchloride (PVC) pipes are commonly used by aviculturists as water conduits in automatic water delivery systems for drinkers and for misters used to cool birds in hot environments. Water reservoirs for these systems and the PVC pipes can become overgrown with *Pseudomonas* spp., particularly if there are gaps in their use.[11] Regular disinfection of water reservoirs and disinfection and flushing of PVC pipes is recommended with diluted bleach. Protocols for disinfection can be found at https://www.health.nsw.gov.au/environment/water/Documents/rainwater_tanks.pdf.

WHAT ABOUT ALCOHOL?

Ethanol and isopropyl alcohol in concentrations of 60% to 90% (volume/volume) are used as disinfectants in most veterinary practices. Alcohol is bactericidal and fungicidal and is effective against enveloped viruses. It is also highly effective at inactivating mycobacteria. It inactivates other bacteria and some viruses almost immediately on contact. Because of its quick kill capacity for bacteria, it has been used to disinfect stethoscopes, thermometers, and rubber stoppers on multiple-dose injection bottles. Its major disadvantage is that it is not effective against some nonenveloped viruses and bacterial spores. Also, because it evaporates quickly, it has limited contact time on surfaces.

Alcohol-based hand sanitizers (60%–80% alcohol) are recommended for use after examining patients or touching potentially contaminated surfaces if hands are not soiled. They have the advantages that they are convenient, dry quickly, and reduce bacterial counts on hands better than handwashing with soap and water. They are only effective if hands are not soiled; soiled hands should be washed. Liquid soap from a dispenser, and not bar soap, should be used for handwashing. The World Health Organization Guidelines on Hand Hygiene in Health Care can be accessed at https://apps.who.int/iris/bitstream/handle/10665/44102/9789241597906_eng.pdf;sequence=1.

TOXICITY OF DISINFECTANTS

All disinfectants are toxins, so every effort should be made to minimize bird exposure of residual disinfectant solutions to them.[12] Cages should never be disinfected while the bird is in the cage. Cage furniture, water and food bowls, and surgical instruments should be rinsed well after disinfecting. If

disinfectants are used on surfaces, they should be allowed to air dry until they can no longer be smelled. In general, however, unless a bird is in direct contact with a concentrated disinfectant, is exposed to concentrated vapors from a disinfectant, ingests the disinfectant, or has long-term exposure to a disinfectant, the risk of toxicity is minimal to none.

CONCLUSION

Cleaning and disinfection are key pillars to infectious disease control in the veterinary hospital, avicultural facilities, and homes. Cleaning and disinfection protocols should be developed following well-established guidelines discussed and referenced here. Failure to follow these guidelines will minimally result in wasted effort or, in a worst-case scenario, outbreaks of preventable diseases.

Infectious bacterial and viral diseases are a constant threat to poultry, exotic pet birds, and wild birds. Infectious bacterial diseases include chlamydiosis, salmonellosis, clostridial infection, and mycoplasmosis. Viruses that affect companion birds and avicultural collections include avian polyomavirus, psittacine herpesvirus, psittacine circovirus, avian bornavirus, West Nile virus (WNV), avian influenza (AI), poxvirus, and paramyxovirus.

VACCINE DEVELOPMENT

In human and domestic animal medicine (dogs, cats, and livestock, including poultry), vaccines have been a life-saving tool. However, in the nondomestic bird populations, commercial production and widespread use of vaccines have been underdeveloped and underutilized.[1] Development and successful promotion of vaccines for use in nondomestic birds have proven to be more difficult than for puppies and kittens. The cost of development, licensing, and marketing for the companion bird market has made vaccines expensive and therefore more difficult to market to the pet bird owner, who often only has one or two birds. This has resulted in pharmaceutical companies being unwilling to invest in new vaccine production for companion birds. In general, the developmental costs associated with minor species' vaccines outweigh the profit margin. Additionally, there are no government mandated vaccines for birds (such as rabies), and many bird owners do not schedule yearly health visits with veterinarians where vaccinations are administered. Although the poultry industry has multiple effective and inexpensive vaccines, delivery of vaccines to small flock owners by veterinarians is uncommon. This in part is because commercial poultry vaccines are typically only available in bulk, thereby making it difficult for the backyard poultry owner to invest in vaccinating a couple of birds. In countries where pigeon racing is popular, vaccination of these birds has become routine for several diseases (and is often mandated in the case of paramyxovirus).

Almost all vaccines are subject to rules and licensing within the country and/or regions of manufacture and use. Companies producing vaccines in the United States must now have their facilities licensed by the US Department of Agriculture (USDA) except for companies located and selling vaccines within California. Procedures for licensing a vaccine in the United States are detailed in a book called the *Code of Federal Regulations #9* (9 CFR).[2] Some vaccines do not have licensing procedures outlined in the 9 CFR (e.g., new products). In these cases, a company must submit to the USDA a proposal detailing the steps that they wish to take to obtain a license for this vaccine. The USDA will then either approve (with or without comments) or disapprove the proposal. If no vaccines are available for a particular disease and a critical need exists, then a company has the option of pursuing a conditional license for that vaccine. Essentially this means that the company only has to prove vaccine safety before releasing the vaccine to the consumer. Eventually, however, the company will be required to submit the appropriate efficacy data to the USDA, CVB (Center of Veterinary Biologics), to acquire a full license for the vaccine. In addition, the vaccine must be labeled as conditional. The only exception to this rule are autogenous vaccines that can be produced by veterinarians, poultry companies, and so on for use against a specific strain or organism. Rules for producing an autogenous vaccine can also be found in the 9 CFR.

After an organism is in the company's possession, the culture is screened for contaminants and a plan is detailed for development of the product. This plan will anticipate whether the isolate needs to be further processed (i.e., attenuated, decontaminated, concentrated, etc.) before a master seed stock is produced. In addition, the most appropriate route(s) of application will be determined. Vaccines are subjected to numerous *in vitro* tests, which include sterility, purity, pleuropneumonia-like organism (PPLO) broth, complement fixation for avian leukosis (COFAL), *Salmonella*, formaldehyde residue (inactivated vaccines), and moisture (lyophilized vaccines). In addition, companies must prove that the vaccine will be safe and efficacious. Efficacy is established by determining the minimum dose that is required to protect a set percentage of birds as specified in the 9 CFR (usually 90%). Once this dose is determined and a "buffer" amount is added, all vaccine produced must have at least this amount of organism per dose to be sold. The buffer amount, which is 1.2 log above the minimum protective dose (MPD) for most vaccines, is added to compensate for any loss of potency that might occur during storage of the vaccine up to the expiration date. However, a vaccine can have a much higher amount of organism per dose when the vaccine is sold; it just cannot be lower.

VACCINE TYPES

Historically, live attenuated or inactivated (killed) forms of microbial pathogens (bacteria or viruses) have been

successfully utilized in both human and veterinary medicine to induce an immunological response that protects the host against subsequent infections.[1] Although effective, both technologies have their limitations (Table 13.1).[3–6] Outbreaks have occurred due to incomplete inactivation or inactivation limiting the immune response. Attenuated vaccines must be able to provide immunity without causing disease, but there is risk of an attenuated vaccine reverting to full virulence.

Based on the pathogen, inactivated and live attenuated vaccine formulations contain a number of proteins that elicit a response. However, immunity is typically dependent on only a few selected proteins, whereas most of the proteins are not immunologically relevant. With some organisms, the immunologically relevant proteins are different from the pathologically important proteins, and separating these can significantly reduce the virulence of live vaccines. However, these immunologically relevant proteins may also induce allergenic reactions. Due to these inherent issues, interest in new vaccine technology to optimize vaccine functionality has grown (Box 13.1).

TABLE 13.1

Comparison of Vaccine Types

Vaccine	Advantages	Disadvantages	Delivery System
Inactivated (killed) vaccines	Long lasting, uniform immunity, fewer systemic reactions, no risk of spread of antigen to other birds, good maternal antibody response	Labor-intensive, reaction to adjuvant, only stimulates humoral immunity, often need live primer, risk of contamination of needles during delivery	IM (leg, breast, or wing) or SC (neck, tail, head)
Live (attenuated) vaccines	Often easier to apply, can be stored easier and fewer local reactions, stimulates cell-mediated, humoral, and local immunity, more options for delivery	May produce shorter immune response compared to killed, may cause adverse reaction in respiratory system, need care in handling of vaccines to keep live organisms	IM, SC, *in ovo*, ocular or nasal, wing web, spray, gel, water
Recombinant/ vectored vaccines	Protection both against the vector (e.g., herpesvirus of turkeys) and the vectored virus (Newcastle disease virus), no risk of reversion to pathogenicity, DIVA compatible, and no interference with maternal immunity	Previous generations of vaccines have limited technology to have multiple antigens, although third-generation recombinant vaccines can now accommodate immunogens from 2+ different pathogens (multivalent vaccines)[3-5] Need for individual vaccination and interference by maternally derived antibodies	SC
Subunit vaccines	No risk of reversion to pathogenicity. Relatively shelf-stable and safe to administer in young and immunocompromised birds	Cost prohibitive, often requires boosters (multiple doses) for long-term immunity	SC
DNA vaccines	DIVA compatible, relatively inexpensive and can be mass applicated, safe and stable vaccine with persistence of immunogenicity toward a specific antigen of interest[6]	Limited to protein immunogens and relatively poor immunogenicity[6]	IM, oral, *in ovo*, eye drop, gene gun, intranasal
Peptide vaccines	Safe and cost-effective for manufacturing	Limited data and use in commercial poultry production (none licensed in the United States)	None available at the moment

DIVA, Discriminates between infected and vaccinated animals; *IM,* intramuscular; *SC,* subcutaneous.

BOX 13.1 GUIDELINES ON THE QUALITIES OF AN IDEAL VACCINE (ROYAL SOCIETY 2002 REPORT ON INFECTIOUS DISEASE OF LIVESTOCK)

Guidelines on the Qualities of an Ideal Vaccine

- Broad-spectrum protection against all virus isolates in the host species, preventing disease and shedding and transmission
- Stimulated immunity to induce effective and long-lasting immune response
- Inexpensive to produce and ease of administration
- Long shelf-life and heat stable
- Live attenuated vaccines do not revert to virulence
- Provides strong levels of maternal immunity
- Discriminates between infected and vaccinated animals (DIVA)

New vaccine technology includes subunit vaccines, split product, isolated protein, peptide, live vector, and nucleic acid (DNA) vaccines. These methods of vaccine production are more economical, safer, and protective and allows for the cloning of viral antigens within bacteria and yeasts producing large quantities of pure antigen.

SUBUNIT AND SPLIT-PRODUCT VACCINES

A subunit vaccine is developed utilizing a fragment of a pathogen, often a surface protein that is used to stimulate an immune response against the pathogen from which it is derived. The simplest form of a subunit vaccine is one that the infectious agent has been disassembled or broken up to its component parts. Although subunit vaccines from natural infectious agents are effective, the cost of production can be prohibitive. It is more economical to identify and produce the immunogenic protein in mass quantity, allowing to produce a safe, effective, and relatively reasonably priced vaccine. Once a sufficiently pure, immunogenic protein is identified, large quantities can be produced. With the development of DNA technology, foreign proteins can be produced, providing an economical and relatively limitless source of protein from an infectious agent for vaccinations.[7] Split virus vaccines are produced by using detergent to disrupt the viral organism.[7]

PEPTIDE VACCINES

Peptide vaccines are developed by identifying and sequencing important immunogenic sites on infectious agents that can be mimicked using short chains of amino acids. Peptides used in these vaccines are 20 to 30 amino acid sequences that are synthesized to form an immunogenic molecule representing the specific epitope of an antigen. These peptides are sufficient for stimulating the immune response while eliminating allergenic and/or reactogenic responses. Production of peptide vaccines is considered safe and cost-effective when compared to conventional vaccines. Peptide vaccines under development include vaccines for human immunodeficiency virus, swine fever, influenza, anthrax, and human papilloma virus. Peptide vaccines may also be effective as therapeutic anticancer vaccines. Only a few peptide-based vaccines have been licensed to date, but studies have shown they can elicit immune response in a wide variety of veterinary viruses, including rabies virus, bovine rotavirus, bovine enterovirus, canine parvovirus, equine herpesvirus, feline leukemia virus (FELV), and bovine leukemia virus.[7,8]

LIVE VECTOR VACCINES/RECOMBINANT VACCINES

Live attenuated vaccines offer some advantages over conventional inactivated and subunit vaccines. They stimulate a more comprehensive immune response, are often easier to administer, provide longer lasting immunity, are easier to store, and typically do not cause muscle or skin reactions. These qualities have led researchers to investigate ways of delivering subunit or peptide vaccines using live vectors.

Viral vectors have focused on relatively large DNA viruses such as poxviruses and herpesviruses. These viruses have a large genome that facilitates insertion of new genes. They express high levels of the recombinant antigen, and in some cases, vectored vaccines appear able to induce immunity even when high levels of maternal antibody are present. Avipoxviruses have been utilized in development of veterinary vaccines, in particular, fowlpox and canarypox.[7] Veterinary herpesviruses and adenoviruses are also being developed as viral vectors. Turkey herpesvirus has been particularly successful as a vector for bivalent and trivalent vaccines against Marek disease (MD), Newcastle disease (NCD), infectious laryngotracheitis (ILT), and infectious bursal disease (IBD).[7,9] Third-generation recombinant vectored vaccines now have the capacity to be trivalent, including an NCD base against IBD and MD (Ultifend ND IBD), as well as a herpesvirus of turkey (HVT) base with IBD and NCD, or IBD and ILT (Vaxxitek). Using the CRISP technology, there are event multivalent vaccines that have simultaneous protection against ILT, AIV, IBD, and MD.[10]

Bacterial and protozoal vectors are also being studied. Most of the work in the study of bacterial vectors has focused on *Salmonella*. Variable vaccination results have been reported, but successful induction of cell-mediated, systemic, and local antibody responses following oral immunization has been achieved, leading to successful production of attenuated vaccines against *Salmonella* in poultry. Other bacterial vectors are being researched.

NUCLEIC ACID (DNA) VACCINES

Nucleic acid vaccines are a relatively new technology. These vaccines utilize DNA-encoded specific antigens inserted into a plasmid or the direct injection of messenger RNA. Nucleic acid vaccines can be produced cost-effectively and can elicit an effective T-cell and antibody response. In addition, there is no risk of infection, and the vaccines can bypass passive immunity. Currently, DNA vaccines are licensed for use against infectious hematopoietic necrosis in Canadian Atlantic salmon, for the control of WNV in horses, salmon pancreas disease infection, and canine melanoma. Recently, a commercial DNA vaccine against H5N1 in chickens has been conditionally approved in the United States.[7,9]

Results of the use of DNA vaccines in poultry have been encouraging, with vaccines being developed and providing full protection against several bacterial, protozoal, and viral diseases including avian influenza virus (AIV) in chickens and quail, IBD virus (IBDv), duck Tembusu virus (DTMUV), and Newcastle disease virus (NDV) in chickens. Host age, the frequency and number of vaccines given, and the vehicle, adjuvant, and delivery system affect the efficacy of these vaccines.

MODIFIED LIVE MARKER VACCINES: DIFFERENTIATING INFECTED FROM VACCINATED ANIMALS

Incorporation of new or unusual antigens into vaccines can be a valuable tool in disease control and eradication programs by allowing the user to discern the infected from vaccinated. These marker or DIVA (differentiating infected from vaccinated animal) vaccines can be recombinant deletion mutants of wild-type pathogens or subunit/peptide vaccines. In birds, these vaccines have specifically been used for AIVs.[11]

VACCINATIONS IN POULTRY

There are many effective vaccines utilized in commercial poultry, but only a few of these are used in backyard flocks. Vaccination protocols are available for viral, bacterial, and parasitic diseases in poultry.[12] The majority of poultry vaccines are inactivated (killed), live, or live recombinant. Delivery routes include injection, oral (in water), spray, ocular, wing web, or in the egg (*in ovo*). Several factors determine delivery route, including species, age, disease, vaccine type, cost, and labor involved in delivery.[12] The focus in this chapter will be on vaccination protocols for backyard chickens and nonpoultry avian species.

VACCINATIONS IN BACKYARD POULTRY

With the many diseases and vaccinations for commercial poultry, it can be confusing when recommending vaccines to backyard flocks. Many of the vaccines available and recommended for commercial poultry are contraindicated in backyard poultry. An example is a *Salmonella* vaccine that could result in a positive reactor for a pullorum-typhoid test that is required for health certificates used in interstate travel or qualifications for a local or regional poultry show. In addition, some live vaccines have side effects that small flock owners may not be comfortable seeing in their pets. These may include agents such as a live, chicken embryo origin ILT vaccine that may revert to virulence and cause disease.

Ideally, vaccine selection should be determined by the prevalence (or geographical distribution) of a particular disease, the risk for the bird becoming infected and developing disease, the value of the bird to the owner (their bond), and the type/location of the immune response needed. Although there are many diseases that can affect backyard poultry, in most cases only a few do. Contacting your state, national or regional veterinary diagnostic laboratory or state, national or regional poultry extension veterinarian will assist you in identifying the diseases present in your area. If a particular disease is not prevalent in the area, then vaccination for that disease may not be necessary. However, if a client shows birds at exhibitions, then the risk of certain diseases may be increased, and vaccination is warranted. In general, vaccine recommendations for backyard flocks include vaccination against MD, and in cases where historical outbreaks are present, fowlpox vaccine and NCD vaccine are recommended.[13]

MAREK DISEASE

The MD vaccine is an example of a successful control strategy in veterinary medicine. MD is caused by an alphaherpesvirus that is ubiquitous in the environment; therefore, chicks can become infected readily after hatching. Prevention requires either *in ovo* vaccination on the 18th day of incubation or a subcutaneous (SC) vaccination when the chicks are 1 day old. However, the MD vaccines available for commercial poultry (serotype I ± II MD) are not readily accessible for backyard flocks due to storage of the cell-associated vaccines in liquid nitrogen. Nevertheless, individual owners may request vaccinated chicks that have received it directly from the hatchery, similarly to commercial poultry.

For backyard breeders, the lyophilized HVT vaccine can be used to vaccinate for MD. The vaccine is easily purchased, reconstituted, and can be given SC to 1-day-old chicks. The vaccine is effective in preventing disease and tumor formation; however, it does not prevent viral infection or shedding. The vaccine is extraordinarily safe, even if all 500 doses were given to one chick. Although the MD vaccine is given at hatch or prior in commercial poultry, the vaccine may be given to adults if there is no history of MD. Time of MD exposure in backyard flocks is often unknown; therefore, adults may still be naive to the virus. However, it is always preferred to vaccinate as early in life as possible. For flocks with a known history of MD infection, no birds are added without vaccination and quarantine for 2 weeks prior to addition. Measures should be in place to decontaminate an area for newly hatched and vaccinated chicks, so that they have time to develop an immune response. Immunity should develop in 2 weeks. Regular cleaning and disinfection programs should be implemented and an all-in/all-out policy needs to be in place whenever bringing in new birds.[13]

AVIAN POX

Avipoxvirus infections have been reported in more than 200 species of birds, including chickens (see also Chapter 15). Several vaccines have been used to control avipoxvirus infections. There may be cross protection, but, in most cases, it is strain specific. When quail, chickens, and turkeys were vaccinated with pigeon and fowlpox virus and challenged with quail poxvirus, they developed severe pox lesions.[14] When quail and chickens were vaccinated with quail poxvirus and challenged with pigeon and fowlpox virus, they were not protected against disease either. Similar results occurred in chickens that were vaccinated with psittacine pox and challenged with quail pox. However, when quail, psittacine, and fowlpox virus were combined in a multivalent vaccine and given to chickens, the birds were protected against challenge with all three respective viruses.[14]

For backyard poultry, the wing web method (Figure 13.1) of vaccine is utilized for poxvirus, which is administered using a double-pronged stab stick into the center of the web, avoiding muscle and vasculature. Turkeys are vaccinated in the thigh after parting the feathers, as a wing web vaccine could cause transference of the vaccine and subsequent lesions on the head due to turkeys sleeping with their heads under their wings. Vaccinated birds should be examined 7 to 10 days post vaccine for an area of swelling or a scab (vaccine "take") to determine that the vaccine was effective (Figure 13.2). However, wing web reactions do not always correlate with immunity. Birds can be vaccinated when chicks are one day old or, alternatively, at 4 weeks of age followed by a booster after 1 month. Pox is one of the very few vaccines that can be administered in the face of challenge to slow the spread. High-risk flocks should be vaccinated annually. A combined pigeon pox and fowlpox vaccine may be utilized for maximum coverage.[15]

NEWCASTLE DISEASE

NCD is caused by avian avulavirus, further subtyped as avian paramyxovirus serotype 1 (APMV-1). NDV can affect all species of birds. The severity of the disease depends on the species affected and virus strain. Severe disease and outbreaks are the result from velogenic Newcastle disease (vND), formerly termed as exotic NCD. Clinical disease is often systemic and can affect the neurologic, gastrointestinal, respiratory, and

FIGURE 13.1 Wing web vaccination for fowlpox in a chicken (*Gallus gallus domesticus*). For this purpose, the chicken is held and one of the wings is spread to locate the vaccination site (i.e., the propatagium or wing web). Following thorough mixing of the vaccine, a double prong sewing machine needle (supplied alongside the vaccine) is dipped into the vaccine and then used to pierce through the wing web while avoiding blood vessels. and musculature.

FIGURE 13.2 Following wing web vaccination for poxviruses, the vaccination site needs to be examined for "take" 6 to 10 days post vaccination. Successful vaccination can be recognized by presence of a swelling and scab formation, as seen in this pigeon (*Columba livia domestica*). Lack of such a response to the vaccine may indicate improper vaccination, administration of an ineffective vaccine (e.g., incorrect storage), or presence of pre-existing antibodies.

reproductive systems. Physical examination and necropsy findings of birds with vND include diphtheritic lesions in the oral cavity and necrotic, hemorrhagic lesions of the gastrointestinal tract including the esophagus, proventriculus, small and large intestines, and cecal tonsils.

Prevention of disease has involved strict biosecurity measures along with vaccination. This has included implementation of quarantine stations for imported birds, controlling movement of birds and eggs in areas of concern, and the administration of vaccines. Effective control and containment of vND outbreaks is achieved with routine vaccination, rapid diagnostic assays, and, if disease occurs, culling of affected flocks.[16]

NDV vaccines are available for chickens, turkeys, and pigeons. The vaccines are used to elicit an antibody response and do not provide complete immunity. Thus, vaccinated birds require a greater vNDV exposure to become ill.[16]

The most widely used vaccines are the live lentogenic vaccines, B1 and La Sota strains.[17] These viruses belong to genotype 11 and are antigenically and genetically similar. The differences between the vaccines are the tropism and ability to replicate in naive chickens (Table 13.2). The La Sota strain is the most antigenic and results in higher antibody levels and is most widely used in countries where virulent NDV is endemic. The B1 strain is the most attenuated and is often used in cases with low exposure or in very young chicks. The VG/GA (Villegas-Glisson/University of Georgia) strain is typically sold as an enterotropic vaccine.[17] All of these are relatively inexpensive yet effective.

Methods of delivery include adding it to the water, ocular or nasal drops, or coarse spray.[16] Coarse spray vaccines result in more significant reactions, but their antibody response is stronger.[18] In contrast to the immune response induced by an inactivated vaccine, the mucosal immunity induced in birds vaccinated through these routes with the live vaccine decreases the viral shedding by infected birds. However, while live vaccines induce mucosal and humoral immunity and can be administered utilizing mass vaccination methods, they may also cause clinical respiratory disease, drop in egg production, and are easily inactivated if not stored at the appropriate temperature (commonly 4°C).[16]

Although mass vaccination methods are less labor-intensive, uneven vaccine application could lead to fewer than 85% of the flock being immunized, thereby reducing herd immunity. Another cause of decreased efficacy of vaccination

TABLE 13.2

Characteristics of Newcastle Disease Virus Vaccines Available for Poultry

Vaccine	Type	Method of Delivery	Tropism	Use
La Sota strain	Live lentogenic	In water, ocular, nasal, spray	Respiratory Increased antigenic stimulation/ higher antibody levels	Regions—endemic velogenic newcastle disease virus (vNDV)
B1 strain	Live lentogenic	In water, ocular, nasal, spray	Respiratory Most attenuated/fewer side effects	Regions—low exposure/young chicks
VG/GA strain	Live lentogenic	In water, ocular, nasal, spray	Enterotropic	Regions—where intestinal shedding for DIVA is not a problem (sold internationally for 20+ years, available in the United States since 2017)

DIVA, Discriminates between infected and vaccinated animals; *VG/GA,* Villegas-Glisson/University of Georgia; *vNDV,* velogenic newcastle disease virus.

is the presence of maternal antibodies that can neutralize the vaccine virus. The frequency of revaccination depends on the risk of exposure and virulence of the field virus challenge.[16]

Bivalent NDV vectored vaccines have been developed to induce solid protective immunity against NDV and other foreign antigens.[17] The Meleagrid alphaherpesvirus 1, commonly called HVT, is one of the most widely used vectors in production of recombinant vaccines. Two studies showed the protective capability of HVT vector–based vaccines to protect chickens from NDV and MD.[19,20] Currently, two of these bivalent recombinant HVT vaccines are commercially available and used internationally.[16] They produce long-term immunity and can be administered *in ovo* or SC at any time post hatch. The disadvantage is that the buildup of protective immunity requires 4 weeks and is hindered by the presence of maternal antibodies. Moreover, the vaccine needs to be kept in liquid nitrogen and administered within an hour of being thawed.

INFLUENZA

AI is an infection of birds with AI type A viruses. AI occurs naturally among wild aquatic birds worldwide and can infect domestic poultry and other bird species. Waterfowl are often asymptomatic carriers, but AI can be very contagious among birds including chickens, ducks, and turkeys. In domestic poultry, many AI viruses are of low pathogenicity (LPAI), causing subclinical infections, respiratory disease, or drops in egg production, but a few AI viruses are highly pathogenic (HPAI); these can cause severe systemic disease with high mortality (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).

Although rare, AI can infect humans. Most human cases have originated from infection with Eurasian H5 HPAI virus (A/Goose/Guangdong lineage) or, most recently, H7N9 LPAI virus (Chinese lineage). Most human infections have been from direct contact with infected poultry. Flu-like signs or respiratory infection is the most frequent presentation in human AI infections. Due to the impact on the poultry industry, the zoonotic potential and the potential threat to other bird species, research on effective vaccines is ongoing.

AIVs are a threat to the poultry industry worldwide. In the United States and EU countries, historically, slaughter of infected birds was the accepted policy. Currently, over 95% of the AI poultry vaccines are inactivated, adjuvanted products and require approval from the state and federal government for administration. A recent study found that formalin-inactivated vaccines induced similar antibody titers and protection against challenge as beta-propiolactone (BPL)–inactivated vaccines. BPL is extremely caustic to humans and is rarely used as an inactivate for commercial vaccines. This study also found that vegetable and mineral oil–based adjuvants induced the highest antibody tiers with 100% seroconversion by 3 weeks post vaccination.[21]

Advances in molecular biology have allowed a number of different viral vector vaccines that express the AI virus hemagglutinin (*HA*) gene to be developed and licensed for AI control. Vector vaccines can stimulate both humoral and cellular immune responses, and when antigenically matched to the target AI strain, they are effective at preventing clinical disease and reducing viral shedding. These vaccines can provide early protection (1-day-old chicks) and are cost-effective. Because they only express the *HA* gene, they can potentially be used to differentiate vaccinated from vaccinated and infected birds (DIVA strategy). Viral vectored vaccines work well with a prime boost strategy, where the vectored vaccine is given first, followed by a killed adjuvanted vaccine booster given 2 to 3 weeks later.[22]

Currently, only inactivated whole AI virus vaccines, typically H1 and H3, are licensed in the USFA for turkey breeders. The use of any licensed AI vaccine requires approval of the state veterinarian. In addition, use of H5 and H7 AI vaccines in the United States requires declaration of an emergency and approval by the Secretary of Agriculture.

VACCINATION IN PIGEONS

The vaccination protocol recommended for racing and show pigeons includes *Salmonella typhimurium*, pigeon paramyxovirus type 1 (PPMV-1), and pigeon poxvirus.[23]

Salmonella typhimurium

S. typhimurium is one of the major health issues in pigeons worldwide. Other strains of *Salmonella* have also been recovered, some with potential to infect humans and that are quite resistant to antibiotics. Historically, *Salmonella* vaccines in pigeons have not been very protective against disease but they have reduced polyuria and fecal shedding.[24]

Recently, a killed adjuvant *Salmonella* vaccine (Nu-Sal Vaccine KM-1), developed by Arko Laboratories Ltd, was licensed by the USDA for use in birds older than 6 weeks. A recent study evaluated the effects of this vaccine against *S. typhimurium* in 15 pigeons (*Columba livia domestica*), which were vaccinated twice through SC injection at 3- to 4-week intervals and challenged 10 days following the booster vaccination. None of the vaccinated birds developed clinical signs, had any shedding of the organism, or had any lesions of *Salmonella* on necropsy. In contrast, control birds became sick, shed the organism, and had *Salmonella*-induced lesions observed on necropsy, demonstrating the effectiveness of the vaccine in preventing disease.[25]

PIGEON PARAMYXOVIRUS TYPE 1

Pigeon paramyxovirus (PPMV) is another major health issue in pigeons worldwide. PPMV-1 is a serious disease that can kill up to 100% of pigeons in some lofts. Some of the signs of PPMV-1 infection include lethargy, vomiting or regurgitation, green diarrhea, circling, head flicking, labored breathing, and ocular discharge and may result in chronic enteritis. Sick birds can die within 3 days. The infection spreads easily between birds and there is no specific treatment. Several vaccines have been studied for prevention of PPMV-1.[26]

Young pigeons were protected for up to 1 year following a SC vaccination with an inactivated aqueous NDV La Sota vaccine. Squabs were vaccinated at different ages: 1 to 8 days of age, 10 to 16 days of age, and at 21 days of age. Maternal antibodies did not affect response.[27] Occasionally, the vaccine caused the development of a granuloma or abscess at the injection site.[28] A bivalent inactivated oil emulsion vaccine was found to be safe and protective in pigeons.[29]

A pigeon (PPMV-1) isolate and the La Sota and Ulster NCD strains were used to prepare BPL-inactivated vaccines.

Pigeons and chickens were vaccinated SC and evaluated for antibody response. The pigeons were challenged 10 weeks post vaccine with a virulent PPMV-1 and were protected from disease and death, but not from infection from the challenge virus. Viral shedding was greatly reduced 6 days following challenge.[30]

One study assessed PPMV-1 and *S. typhimurium* vaccine together. A combined inactivated montanide ISA-206 oil-adjuvanted vaccine of local isolates of PPMV-1 and *S. typhimurium* was utilized. The vaccination challenge assay with the virulent strain of PPMV-1 showed 100% protection in the vaccinated group, while the virulent *S. typhimurium* organism showed 90% protection in vaccinated birds. In the unvaccinated control group, 10% and 20% did not become infected after challenge with both virulent PPMV-1 and *S. typhimurium*, respectively, indicating this vaccine could be recommended as safe, potent, and useful for protection against PPMV-1 and *S. typhimurium* under field conditions.[31]

A recent licensed killed adjuvant PMV vaccine (KM-PMV from Arko Laboratories Ltd) has shown efficacy. This vaccine is given SC twice at 3-week intervals and is licensed for birds greater than 6 weeks of age.[25]

PIGEON POXVIRUS

Poxvirus in pigeons has similar clinical signs of disease and morbidity as fowlpox. The vaccination protocol is similar to backyard chickens.[13]

PIGEON HERPESVIRUS 1

Pigeon herpesvirus 1 causes respiratory disease and encephalitis in doves and pigeons. This disease can also affect raptors that consume infected birds. A comparison of a killed or attenuated vaccine was performed in pigeons with and without the addition of cyclophosphamide to determine if either vaccine could prevent infection, the carrier state, or control shedding. Both vaccines gave similar results, being able to reduce primary viral excretion and clinical signs after challenge. However, neither vaccine was able to prevent reappearance of carriers.[32]

VACCINATIONS IN PSITTACINE BIRDS

Several pathogens are known to cause specific diseases in Psittaciformes, including paramyxovirus, polyomavirus, parrot bornavirus (PaBV), psittacid herpesvirus, psittacine beak and feather disease (PBFD) virus, and *Chlamydia psittaci*. All the listed viruses will give rise to serious, often lethal disease in young birds. With no effective treatment available other than alleviating clinical signs, vaccination strategies may be attempted to prevent disease transmission and development of clinical signs.

PARAMYXOVIRUS

Paramyxovirus type 3 (PMV-3) is found to cause illness and high mortality in small psittacines, most notably *Neophema* spp., and passerines (finches). Gastrointestinal and neurological signs may develop. An inactivated, adjuvanted PMV-3 experimental vaccine has been effective in protecting parakeets from developing disease.[33]

POLYOMAVIRUS

Avian polyomavirus (APV) primarily affects young birds. Clinical signs include a nestling with crop stasis, diarrhea, cutaneous hemorrhage, abdominal distention, and feather abnormalities. APV can cause severe disease and acute mortality in fledgling budgerigars (*Melopsittacus undulatus*), nestling macaws (*Ara* spp), and finches. A commercial inactivated vaccine is available and has been used to vaccinate prior to shipping, in pet stores and in rescue and sanctuary settings. The vaccine is administered IM (intramuscularly) or SC and has had few reported reactions.

Both inactivated and attenuated APV vaccines can safely immunize psittacines.[34,35] In a study reviewing the effects of two vaccines (adjuvant and nonadjuvant), in over 200 parrots, both vaccines induced a virus neutralizing antibody response in previously seronegative birds. Seroconversion occurred in 93% of birds 2 weeks post boosting. There was no significant difference in seroconversion between the two vaccines and only three Grey parrots (*Psittacus erithacus*) had mild local reactions (small scab formation at the injection site).[34]

Avian polyomavirus, in contrast to mammalian polyomavirus, encodes an additional capsid protein (CP) VP4 and its variant VP4D. Both proteins induce apoptosis. Mutation of this initiation codon prevents virus replication. A study assessing a replication competent deletion mutant where either VP4 or VP4D was deleted elicited neutralizing antibodies against APV after intraperitoneal (IP) and intramuscular (IM) infection of the chicken, although only the wild-type virus revealed VP4-specific antibodies. Based on the biological properties of these deletion mutants, they could be candidates for APV marker vaccines. In addition, an APV DIVA vaccine for APV may be possible.[34]

PSITTACINE BORNAVIRUS

Proventricular dilation disease (PDD) or avian ganglioneuritis (AGN) is caused by psittacine bornavirus (PaBV). PaBV is a neurotropic virus that can cause gastrointestinal and/or neurological signs of disease in birds (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease and Chapter 14, Avian Bornavirus). Currently, there is no cure, and treatment only reduces clinical signs of disease. A vaccine, if available, would be instrumental in prevention of disease.[36] Because avian bornavirus disease is T-cell mediated, theoretically, a vaccination could exacerbate disease.[36] Nonetheless, there have been several vaccination studies performed. Two reports utilized viral vector vaccines against PaBVs using a prime boost strategy.[37,38]

One reported vaccination strategy utilized recombinant NDV and modified vaccinia virus Ankara (MVA) that were engineered to express the phosphoprotein and nucleoprotein genes of two avian bornaviruses, parrot bornavirus 4 (PaBV-4) and canary bornavirus 2 (CnBV-2). The vaccine induced a bornavirus-specific humoral immune response in cockatiels (*Nymphicus hollandicus*) and canaries (*Serinus canaria*). Vaccinated birds were challenged with a homologous bornavirus. However, while the immunized birds had significantly reduced shedding of bornavirus RNA and reduced viral loads in tissue, they still developed clinical signs of AGN.[37]

A second study revealed that prime boost vaccination of cockatiels with NDV and MVA vectors expressing the

nucleoprotein and phosphoprotein genes of PaBV-4 blocked bornavirus replication following parenteral challenge infection with PaBV-2. In this study, two of six vaccinated birds developed mild PDD-associated lesions, while the unvaccinated birds were not protected from infection or disease.[38]

A vaccination developed utilizing a killed PaBV with recombinant PaBV-4 nucleoprotein N in alum was protective against disease in cockatiels challenged with a virulent bornavirus isolate (PaBV-2), but birds still developed gross and histologic lesions of PDD. There was no evidence that vaccination prior to or post challenge made infection more severe.[39]

These results suggest that some vaccinations can protect against disease and do not exacerbate infection, but do not reduce viral persistence or shedding. However, none of the studied avian bornavirus vaccines are currently available for commercial use.

PSITTACINE BEAK AND FEATHER DISEASE VIRUS

Psittacine beak and feather disease (PBFD) is primarily a disease of young parrots (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). The etiological agent is a DNA circovirus (PBFD virus [PBFDV]). Clinical signs of disease include abnormal feathers (pinched and hemorrhagic feather shafts), feather loss, necrosis of the beak, and a generalized loss of feather dander. Viral replication begins in the lymphoid organs, spreads to the liver and thymus, with ultimate invasion of the epithelium, which leads to the beak and feather malformations. The disease affects the immune system resulting in immunosuppression, so birds may present with secondary bacterial infections. An acute stage occurs in recently fledged birds, especially Grey parrots, in which birds die of liver failure presenting with severe leukopenia and anemia. Birds that recover from the acute disease may become chronic carriers (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).

There have been several experimental vaccines assessed, but none of these vaccines are currently available for commercial use.[40,41] A recombinant PBFD-CP vaccine was studied in long-billed corellas (*Cacatua tenuirostris*). The vaccine was given IM at approximately 50 days of age. Vaccinated birds were boosted on day 11 and challenged 16 days post booster. The vaccinated birds had a transient viremia but showed no clinical signs of disease or persistent infection post challenge. The control birds developed antibodies against PBFDV, were PCR-positive 41 days post challenge, and developed transient feather lesions. A quantitative PCR revealed decreased viral replication in the vaccinated birds as compared to the control birds.[42]

A second PBFD-CP study in nestling and adult galahs (*Eolophus roseicapillus*) that were vaccinated with an inactivated double oil emulsion vaccine had similar antibody response to those induced with a primary oil emulsion vaccine. The birds were given two IM injections 14 days apart. A post-vaccination challenge demonstrated the nestlings to be protected by both vaccines whereas the unvaccinated controls developed acute PBFD within 4 weeks of challenge.[43]

In another study using 30- to 45-day-old Grey parrots, umbrella cockatoos (*Cacatua alba*), and sulphur-crested cockatoos (*Cacatua sulphurea*), chicks from unvaccinated hens and chicks from vaccinated hens were exposed to PBFDV. Chicks from the unvaccinated hens developed disease, whereas chicks from the vaccinated hens remained free of disease. In the same study, an adult pair of umbrella cockatoos, Moluccan cockatoos (*Cacatua moluccensis*), Grey parrots, and a yellow-headed Amazon parrot (*Amazona ochrocephala oratrix*) were vaccinated IM or SC with a vaccine containing 13-propiolactone (BPL)–inactivated PBFDV. All birds seroconverted. In addition, 30- to 45-day-old chicks were vaccinated with the same inoculum and seroconverted. Following challenge with purified PBFDV, the chicks from vaccinated hens were protected whereas chicks from unvaccinated hens developed disease.[44]

Although no vaccine for PBFDV is currently available, multiple experimental vaccines have been assessed, including a recombinant vaccine, a subunit vaccine, and a live attenuated vaccine. A recombinant vaccine expressing the PBFDV CP, the major antigenic determinant, expressed in a plant, yeast, or bacterial system could be particularly useful and is promising based on recent research.[40,41]

PSITTACID HERPESVIRUS

Herpesviruses are DNA viruses that cause acute and latent infections (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Psittacine herpesvirus is an alphaherpesvirus that is the etiological agent of Pacheco disease and internal papillomatosis in parrots. Pacheco disease manifests as acute hepatitis with a high mortality in New World parrots. Survivors of Pacheco disease may develop internal papillomatosis. Quaker parrots (*Myiopsitta monachus*) vaccinated twice with killed Pacheco vaccine were protected when challenged.[45] A formaldehyde heat-inactivated experimental vaccine prepared from polyethylene glycol purified virus was given to a collection of psittacines. There were no adverse effects and the birds seroconverted.[46] Several oil-adjuvanted, inactivated vaccines have been developed against Pacheco disease. These vaccines were protective but did not prevent shedding of latent infections nor did they protect against all forms of avian herpesvirus. Oil emulsion vaccines have been developed but have led to serious injection site reactions (swelling, muscle necrosis, and formation of granulomas).[47]

An inactivated emulsified vaccine against Pacheco disease in budgerigars demonstrated that an effective vaccine could be produced utilizing concentrated virus. The virus was propagated in chicken kidney cells, sonicated, and concentrated 100× by centrifugation to produce a multiple emulsion vaccine. Young adult budgerigars were vaccinated once IM and challenged 4 weeks post inoculation. The vaccine was protective against challenge, but there was minimal serologic response post vaccine.[48]

An autogenous vaccine was developed to control a Pacheco disease virus outbreak in a zoological setting. This autogenous vaccine, formalin inactivated with an aluminum hydroxide adjuvant, was utilized IM 2 weeks and 6 weeks post outbreak. There were no reported negative reactions to the vaccine, and morbidity and mortality ceased. Vaccinated birds possessed

neutralizing antibodies 9 months following the second vaccination. Two out of four birds remained antibody-positive 25 months post vaccination.[49] Currently, there is no psittacine herpesvirus vaccine commercially available.

CHLAMYDIA PSITTACI

Chlamydia psittaci is a gram-negative intracellular obligate pathogen that causes psittacosis in parrots, ornithosis in other bird species, and chlamydiosis or parrot fever in humans (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Clinical signs in birds range from asymptomatic carriers to severe disease and may include ocular or nasal discharge, anorexia, dyspnea, polyuria, biliverdinuria, and diarrhea. Because many birds can be asymptomatic carriers, an effective vaccine may significantly reduce zoonotic risk.[50]

Turkeys (*Meleagris gallapavo*) were protected from infection with *Chlamydia psittaci* with a plasmid DNA vaccine against the major outer membrane protein.[51] Based on these data, a plasma DNA vaccine expressing the major outer membrane protein of *Chlamydia psittaci* genotype A was evaluated for protective immunity against *C. psittaci* challenge in budgerigars. Prior to the experimental infection, all birds were negative on both PCR and culture; however, all birds revealed a low pre-existing serum antibody titer, indicating previous infection. All birds were vaccinated twice (3 weeks apart) with either the placebo or the DNA vaccine. An aerosol challenge occurred 2 weeks after the booster vaccine. Placebo-vaccinated birds showed severe clinical signs and lesions and excreted high amounts of *C. psittaci* as compared to the DNA-vaccinated group.[50] Currently, there is no vaccine available.

VACCINATIONS IN OTHER SPECIES

Several infectious diseases can pose a threat to the well-being of captive birds. Particularly, birds that are housed in outdoor enclosures are at increased risk for exposure to infectious diseases that are transmitted by wild birds. Such diseases include AIV, poxvirus, paramyxovirus, WNV, equine encephalitis, and picornavirus. Current research related to vaccination strategies to prevent these infectious diseases in companion and zoo birds is discussed in the following sections.

AVIAN INFLUENZA VIRUS

Due to the spread of the H5N1 HPAI virus, preventive vaccination strategies have been implemented in various zoologic institutions to prevent the spread of the disease in their collection (Table 13.3).

In the early 2000s, following the spread of HPAI across Europe, various inactivated influenza vaccines have been successfully administered in various zoological institutions.

In a 2003 HPAI (H7N7) outbreak in the Netherlands, the European commission directive allowed vaccination of valuable susceptible zoo species. Birds were vaccinated IM with an inactivated H7N1 vaccine twice at 6-week intervals. Pre- and post-vaccination titers were measured to establish efficacy. Following booster vaccination, 81.5% of the vaccinated birds

TABLE 13.3
Overview of Selected Studies on Influenza Vaccines in Zoo Birds

Vaccine	Number of Birds	Protocol	Species With Minimal or No Seroconversion	Species With Adequate Seroconversion	Reference
H5N1-inactivated vaccine	540	Two IM vaccinations with 6-week interval; evaluation of serological response 4–6 weeks post second vaccination.	Pelicans, ducks, geese, herons, cranes, guinea fowl, cockatiels, lovebirds, barbets (poor response)	Ibis, rheas, Congo peafowl, flamingos, kookaburras, black-winged stilts, Amazon parrots. Overall 84% of birds seroconverted with 76% achieving titers ≥32	Bertelsen et al.[53]
H5N2-inactivated vaccine	118	Two IM vaccinations with 4-week intervals. Serological testing 4- and 6–8 weeks post vaccination using hemagglutination inhibition test.	Pelecaniformes, Strigiformes (no response)	Galliformes and Anseriformes (100% seroconversion)	Oh et al.[55]
H5N9 commercial–inactivated vaccine and H5N3-inactivated recombinant vaccine	48	Two IM vaccinations with 4-week interval 4 weeks apart, and booster 1.5 years later. Long-term serological effects (>7 years) were studied.	N/A	Flamingos (high titers remained present for over 7 years)	Fernandez-Bellon et al.[56]
H7N1-inactivated vaccine	211	Two IM or SC vaccinations at 6-week intervals. Pre- and post-vaccination antibody titers determined using hemagglutination inhibition test.	Struthioniformes	Anseriformes, Galliformes, and Phoenicopteriformes (81.5% of birds developed titers >40)	Philippa et al.[52]

IM, Intramuscular; *SC*, subcutaneous.

developed a titer greater than 40. Anseriformes, Galliformes, and Phoenicopteriformes showed the largest response. Antibody response decreased with increasing body weight in birds over 1.5 kg.[52]

In 2006, an inactivated H5N9 vaccine was administered to 540 birds from three Danish zoos. The birds were vaccinated twice at 6-week intervals. Serological response was evaluated 4 to 6 weeks following the second vaccination. Seroconversion was documented in 84% of the birds and 76% developed a titer of 32 or more. Species variation in response was noted: pelicans (*Pelecanus* spp.), ducks, geese, penguins, (Sphenisciformes), herons (Ardeidae), cranes (Gruiformes), guineafowl (Numididae), cockatiels, lovebirds (*Agapornis* spp.), and barbets had a poor response, whereas high titers and seroconversion rates were seen in ibis (Threskiornithidae), rheas (*Rhea* spp.), Congo peafowl (*Afropavo congensis*), flamingos (Phoenicopteridae), kookaburras (*Dacelo* spp.), black-winged stilts (*Himantopus himantopus*), and Amazon parrots (*Amazona* spp.).[53]

In 2009, a H5N2 vaccine was administered to approximately 25,000 birds among 135 French zoological institutions.[54] A follow-up serological evaluation using 1686 blood samples collected from 126 species representing 15 different avian orders demonstrated that 71% of the birds developed titers of 32 or more (mean titer 558 following the second vaccination with a subsequent decrease in titers). As a result, the percentage of birds having a titer of 32 or more (the level considered protective in poultry) dropped to 42% at day 180 and to only 26% at day 330. While no deleterious effects were seen in any of the vaccinated birds, the aforementioned results do demonstrate the necessity for adjustments to the protocol (e.g., booster vaccination every 6 months).

During an HPAI outbreak in Asia, the Singapore Zoological Gardens evaluated an inactivated H5N2 vaccine in their high-risk avian species (Galliformes and Anseriformes) along with birds on open exhibit. They used the Nobilis Influenza H5N2 vaccine and vaccinated birds IM with a booster at 4 weeks. A variation in response was noted between species and orders. Some Galliformes and Anseriformes had 100% seroconversion while others had only partial conversion. Some species like the pelicans (order Pelecaniformes) and owls (order Strigiformes) failed to respond to vaccination at all.[55]

A study at the Barcelona Zoo evaluated the long-term efficacy of H5 vaccination in flamingos (order Phoenicopteriformes). H5-antibody titers were maintained at high levels for over 7 years post vaccination against the H5N9 and H5N3 vaccine strains and the H5N3 and H5N1 reference strains.[56]

AVIAN POX

As discussed earlier under Vaccinations in Backyard Poultry, homologous, live virus vaccines that provide long-lasting immunity are available for use in fowlpox. However, nonpoultry species can have severe reactions to pox vaccines, therefore warranting caution when using pox vaccines in species other than poultry. A fowlpox vaccine was found to be protective and safe in zebra finches (*Taeniopygia guttata*) and a live pigeon pox vaccine has been used in hunting falcons.[57,58] A commercial fowlpox vaccine was protective in healthy ostrich chicks (*Struthio camelus*) during an outbreak of poxvirus.[59] Attenuated strains of poxviruses (fowlpox and canarypox) have been utilized as vaccine vectors to deliver heterologous vaccines. These vaccines stimulate both cellular and humoral immunity and are thermostable. Unfortunately, despite a structured vaccination program and strict biosecurity, canarypox virus remains to regularly affect captive houbara bustards (*Chlamydotis undulata*).[60]

PARAMYXOVIRUS/NEWCASTLE DISEASE

Paramyxoviruses can be infectious to all bird species and are found in both wild and captive populations. In the United States, sampling for APMV-1 may occur during periods of morbidity or mortality involving susceptible families of wild birds, such as pigeons, doves, cormorants (*Phalacrocorax* spp.), or pelicans. A study quantifying the prevalence and geographic distribution of APMV-1 in apparently healthy wild birds in 2013 found antibody prevalence was highest in birds of the order Suliformes (44.9%), Pelecaniformes (24.4%), Anseriformes (22.7%), and Columbiformes (11.7%), with a high occurrence of virulent viruses in Columbiformes (100% of virulent viruses isolated). However, viral shedding occurred rarely and in very low numbers.[61]

As paramyxoviruses may also affect captive populations, vaccination may be indicated, especially for birds living in zoos and bird sanctuaries that have a higher risk of being exposed to the virus through contact with wild birds. Vaccination is typically given in methods available to be delivered in small and/or individual doses. In some ostriches vaccinated with live NDV vaccine via eye drop method (Figure 13.3), an antibody response was induced in both the vaccinated birds and the unvaccinated control housed with them, indicating transmission of the virus post vaccination.[62] In contrast, ostriches vaccinated with the La Sota strain NDV vaccine via injection responded in a dose-dependent manner, with no transmission occurring between vaccinated and controls. Ostriches vaccinated with a series of 3 to 4 vaccines developed an

FIGURE 13.3 Application of a vaccine by eye drop method, as shown in this chicken (*Gallus gallus domesticus*), is a very effective route for administering live vaccines in poultry, as the vaccine passes to the Harderian gland just behind the eye, which is a key organ in the development of the immune response. Correct dilution of the vaccine is, however, critical to ensure correct dosing. If eye droppers are being used, they should be calibrated beforehand. Alternatively, it is possible to use the tip of a 1-mL syringe to administer the drop, but this is less accurate and will result in more wastage of vaccine.

adequate antibody response. The results of this study indicated that it is highly unlikely for ostriches vaccinated according to recommended vaccine schedules to transmit the virus to nonvaccinated birds.[63]

WEST NILE VIRUS

WNV infection is an arthropod-borne virus in the genus *Flavivirus* (family Flaviviridae; see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). The virus was introduced in the United States in 1999. Since its introduction, WNV has spread across the continent causing neurological disease in humans, horses, and birds. It has been reported in more than 320 bird species. Many bird species have been affected including corvids, passerines, psittacines, and raptors. Affected endangered or threatened species include the whooping crane (*Grus americana*), the sandhill crane (*Antigone canadensis*), the California condor (*Gymnogyps californianus*), and the Florida scrub jay (*Aphelocoma coerulescens*). Psittacines appear to be somewhat resistant, but the disease has been reported in parakeets, conures, rosellas, cockatoos, caiques, lorikeets, and a king parrot. Clinical signs in birds include depression, anorexia, weight loss, head tremors, ataxia, blindness, seizures, and death. Juvenile birds are the most affected. WNV outbreaks have been reported in Europe since the 1950s. These outbreaks were small and remained focal. In contrast to the United States, bird mortality is rare in Europe.[64]

Recently, a comprehensive review of the current progress of WNV vaccine in birds has been published.[65] Although birds are clearly at risk with this disease, and several studies assessing vaccination efficacy in birds have been performed, no avian WNV vaccine is commercially available. Hence, susceptible species in endemic areas are vaccinated utilizing the equine vaccines.

In the United States, until recently, three commercially available vaccines for use in horses.[66] The first licensed vaccine (K-WN) (West Nile-Innovator; Fort Dodge, Fort Dodge, IA) is a formalin-inactivated whole virus adjuvant and has been available since 2001. In 2004, a recombinant vaccine (CP_WN) was licensed and consists of an adjuvant and canarypox virus vector with insertion and expression of the membrane (prM) and envelope (E) proteins of *WNV* genes (Recombitek equine WNV vaccine; Merial Limited, Athens, GA). The latest equine vaccine, licensed in 2006, is a single dose, attenuated WNV, live flavivirus chimera vaccine (WN-FV; PreveNile; Intervet, De Soto, KS), which is marketed without an adjuvant. The equine vaccine that has been used most extensively in birds is the formalin-inactivated, adjuvanted whole virus vaccine called West Nile-Innovator marketed by Zoetis. As the Recombitek vaccine from Merial is no longer available, currently, the West Nile-Innovator vaccine is also the only vaccine that is commercially available.

Efficacy of West Nile Virus Vaccines in Psittacine Birds

Twelve captive adult thick-billed parrots (*Rhynchopsitta pachyrhyncha*) were given a series of three initial Innovator vaccines at 3-week intervals with an annual booster over 6 years. Most adult birds (67%) seroconverted after 5 years of annual vaccination. In addition, the serological responses of 11 chicks that were given the initial series of Innovator vaccines were assessed. None of the chicks seroconverted following the initial three vaccine series. Two of four chicks seroconverted at the 1-year booster and three of four chicks seroconverted at the 2-year booster.[67]

Efficacy of West Nile Virus Vaccines in Passerine Birds

Three WNV equine vaccines were evaluated in California scrub jays (*Aphelocoma californica*): Innovator, Recombitek, and an experimental DNA plasmid vaccine called pCBWN. Vaccination lowered peak viremia compared to positive controls, but the viremia was sufficient to infect susceptible mosquito vectors. Recombitek vaccination caused five of six vaccinated birds to develop lesions at the injection site. The Innovator vaccine and the experimental pCBWN vaccine stimulated antibody formation with no side effects.[68] A fowlpox vectored vaccine with inserts of ANV prM and E proteins followed by a canarypox virus vector vaccine is protective in geese.[69]

Experimental WNV DNA vaccines have been evaluated in American crows (*Corvus brachyrhynchos*). Crows were vaccinated IM with a DNA vaccine and a DNA vaccine with adjuvant-developed antibodies. A challenge at 10 weeks post initial vaccine resulted in decreased mortality but no sterile immunity. An oral microencapsulated DNA vaccine failed to produce antibodies and did not result in reduced mortality when challenged.[70]

An experimental DNA plasmid WNV vaccine was evaluated in American robins (*Turdus migratorius*), a key WNV amplification host. A single dose of vaccine injected IM resulted in a >400-fold decrease in viremia. Although a small sample size, results suggest that vaccinated robins develop viremia that is unlikely to be infectious to biting *Culex* mosquitoes.[71]

Efficacy of West Nile Virus Vaccines in Birds of Prey

The immunogenicity of both Recombitek and West Nile-Innovator has been evaluated in gyrfalcons (*Falco rusticolus*) and other falcons.[72] Increased protection was achieved with Recombitek as compared to Innovator, but Recombitek caused moderate injection site reactions. The Recombitek 2 dose regimen resulted in only partial protection. Improved results occurred following a third booster.[72] In red-tailed hawks (*Buteo jamaicensis*), however, results were less promising as both the birds that were vaccinated once ($n = 5$) with 0.2 mL of the Innovator vaccine in the pectoral muscle, as well as those receiving a booster vaccination 3 weeks following the first injection ($n = 5$), showed no detectable antibodies to WNV upon serological evaluation 3 weeks post vaccination.[73]

With the further spread of WNV across the continent, and just prior to its arrival to the Western United States, a prospective vaccination program was conducted for both the captive and wild endangered California condors. Due to the negative results with the Innovator vaccine in red-tailed hawks, the researchers chose to use a DNA vaccine. The vaccine DNA (pVWN) used in this study was modified by replacing the ampicillin resistance gene in the published pCBWN construct with a kanamycin resistance gene derived from the pVAX plasmid. The DNA vaccine was safe and induced protective immunity in adults, nestlings, and newly hatched condor chicks (see also *Current Therapy in Avian*

Medicine and Surgery, Vol 1, Chapter 2, Infectious Disease and Chapter 23, Conservation of Avian Species).[74]

In 2011, an experimental WNV DNA plasmid vaccine in an aluminum phosphate adjuvant was tested in red-tailed hawks. All birds received two IM injections 3 weeks apart. Birds were challenged 4 weeks following the second injection. Three vaccinated birds seroconverted after the second booster; all other birds seroconverted following the live virus challenge. Vaccinated birds had reduced viremia and a shorter and reduced shedding period compared to the controls.[75]

Efficacy of West Nile Virus Vaccines in Waterfowl and Poultry

In Attwater's prairie chickens (*Tympanuchus cupido attwateri*) vaccinated at least twice IM with the Innovator vaccine showed insufficient response to the vaccination protocol.[76] However, a WNV vaccine developed for humans (WN-80E) was found to be highly immunogenic for the nene (*Branta sandvicensis*), an endangered Hawaiian goose susceptible to WNV. Six captive nonbreeding birds were vaccinated with two doses 4 weeks apart. Two birds were injected with "mock" controls. The vaccine was highly immunogenic and did not produce adverse effects.[77]

A recombinant avirulent NDV La Sota strain expressing WNV premembrane/envelope proteins was assessed in chickens, ducks, and geese. A significant level of neutralizing antibodies was induced. Moreover, it also elicited significant levels of WNV-specific immunoglobulin (Ig) G in the birds following intramuscular, oral, or intranasal immunization.[78] Similar findings were obtained in another study assessing the efficacy of a WNV enveloped recombinant (rE) protein vaccine in red-legged partridges (*Alectoris rufa*). In this study, the birds were vaccinated three times at 2-week intervals. Vaccinated birds developed anti-WNV antibodies prior to challenge and survived challenge, whereas a third of the unvaccinated birds died. Unvaccinated birds were furthermore found to develop viremia and WNV RNA was detected in their feathers and swabs. In contrast, only 14% of the vaccinated birds developed viremia and no WNV RNA was detected in their feathers or swabs.[79]

In an effort to establish an avian model for testing WNV vaccines, avian antibody–based reagents were assessed for cross-reactivity with Japanese quail (*Coturnix japonica*) T-cell markers CD4 and CD8. The most reactive were found to be the anti-duck CD8 antibody, clone Du-CD8-1, and the anti-chicken/turkey CD4 antibody, clone CT4. These reagents were utilized to assess vaccine performance and T-cell populations in quail. The WNV vaccines developed were based on a nonreplicating recombinant adenovirus platform. Japanese quails were selected for testing the vaccines, as they provide an avian model that represents the population diversity of wild birds. Both WNV-specific antibodies and the number of T cells in vaccinated birds were increased compared to unvaccinated controls indicating that the recombinant vaccines were effective in increasing both humoral and cellular immune responses in quail.[80]

Efficacy of West Nile Virus Vaccines in Other Birds

The West Nile-Innovator vaccine was evaluated in sandhill cranes. The cranes were vaccinated with 0.5 mL IM with a booster at 21 days and 28 days. They were challenged with live WNV following the third booster. None of the vaccinated or controls birds died from the experimental infection, but 2 days post challenge, the vaccinated cranes did have significantly less viremia than the control. Seven days post challenge the vaccinated cranes had less cloacal shedding and 14 days post challenge the vaccinated cranes had significantly higher titers than the controls. At necropsy, unvaccinated challenged cranes had lesions in the brain and brainstem that were not seen in the vaccinated challenged or vaccinated unchallenged birds.[81]

Greater flamingo (*Phoenicopterus roseus*) chicks have also been vaccinated using Innovator vaccine IM. The birds were given 2 vaccines 3 weeks apart with a booster given 280 days post initial vaccination series. Antibody titers were assessed before and after the initial injection and 3 weeks post booster. No adverse reactions were reported, and serum antibodies were detected in 60% of the samples post booster.[82]

Similar findings were obtained in a study investigating the effect in both American (*Phoenicopterus ruber*) and Chilean flamingos (*Phoenicopterus chilensis*).[61] Another study, however, showed lack of detectable antibodies to WNV 3 weeks post vaccination in Chilean flamingos ($n = 16$), which had been vaccinated either once ($n = 8$) or twice (with 3-week interval; $n = 8$) with 0.2 mL of the Innovator vaccine in the pectoral muscle.[73]

The serologic response to WNV vaccines has also been evaluated in penguin species. For the Innovator vaccine, a vaccination protocol consisting of two IM injections with 3-week interval resulted in significant changes in antibody titer over time in black-footed penguins (*Spheniscus demersus*), but not in little blue penguins (*Eudyptula minor*), indicating that efficacy cannot be extrapolated easily to other species.[76] However, another study that evaluated effects of WNV vaccination in four species of penguins showed more promising results. In this study, Humboldt (*Spheniscus humboldti*), Magellanic (*Spheniscus magellanicus*), gentoo (*Pygoscelis papua*), and rockhopper (*Eudyptes chrysocome*) penguins were inoculated with either the Innovator killed virus vaccine or an experimental plasmid-mediated DNA WNV vaccine. Both vaccines induced seroconversion in all four species without adverse reactions. Moreover, the study revealed that in all four species, the Innovator vaccine resulted in a faster and greater seroconversion and a longer duration of antibody response than the DNA vaccine.[83]

EQUINE ENCEPHALITIS VIRUSES

Eastern equine encephalomyelitis (EEE), Western equine encephalomyelitis (WEE), and Venezuelan equine encephalitis (VEE) are caused by members of the genus *Alphavirus* of the family Togaviridae. Disease is arthropod borne and can occur in many species of birds, including pigeons, pheasants, and ratites such as emus (*Dromaius novaehollandiae*). Birds and rodents are the primary reservoirs, but unvaccinated horses are particularly susceptible and often serve as sentinels. Equine encephalitis viruses are zoonotic, infecting humans, and are a public health concern.

Several equine and human vaccines have been evaluated in avian species.[84,85] In 2001, a study evaluated the humoral immune response in emus vaccinated with either one of two commercially available equine polyvalents or an experimental monovalent EEE virus (EEEV) or WEE virus (WEEV) vaccine. All four vaccines induced detectable neutralizing antibody titers and led to full protection of the vaccinated birds when exposed to an otherwise lethal dose of EEEV. In contrast, unvaccinated challenged birds developed viremia and shed virus in feces, oral secretions, and regurgitated material. An unvaccinated pen-mate became infected in the absence of mosquito vectors, presumably because of direct virus transmission between birds. Results indicate that the commercially available polyvalent equine EEE vaccines are protective in emus.[86]

The immune response of whooping cranes and sandhill cranes to a formalin-inactivated EEE vaccine was evaluated. SC and intravenous vaccination failed to induce detectable antibodies in the sandhill cranes, but both species developed neutralizing antibodies to the IM vaccine. Additional boosters elicited detectable antibody and/or increased antibody titers in the whooping cranes, although cranes with naturally preexisting titers exhibited a rapid increase and sustained antibody titers. Even though EEEV vaccine induced neutralizing antibodies with no adverse reactions, its protective efficacy was unclear as no challenge occurred.[87]

An inactivated human EEE vaccine was evaluated in whooping cranes. All whooping cranes received an IM injection of 0.5 mL of inactivated EEE vaccine (PE 6 WRAIR strain) followed by a second injection 6 months later. Neutralizing antibodies were present after IM injection. All newly hatched whooping cranes received 0.5 mL of vaccine with a second injection 30 days later. All whooping cranes received a 1.0 mL IM booster annually. In the years following the vaccination program, there were no adverse reactions. The absence of virus-related deaths and adverse vaccination reactions following the vaccination protocol was evidence that the EEE immunization program was both safe and efficacious.[88] A second study was done years later evaluating the antibody titers measured in whooping cranes vaccinated with the human EEE vaccine for 3 years with those measured using the Equine EEE vaccine Encephaloid M (EEE and WEE vaccine, Fort Dodge Laboratories) for 2 years. Titers observed with the human vaccine were considered protective due to the absence of morbidity or mortality seen in whooping cranes in years since 1984 when EEE was detected in mosquitoes and sentinel birds. The equine vaccine produced titers equal to or higher than those produced by the human vaccine, which would suggest adequate protection.[89]

DUCK VIRAL HEPATITIS (PICORNAVIRUS)

Duck viral hepatitis (DVH) is an acute, highly contagious viral disease typically affecting ducklings less than 6 weeks of age. Duck hepatitis A viruses type 1 (DHAV-1) and type 3 (DHAV-3) are picornaviruses. Affected ducklings become lethargic, lose balance, paddle spasmodically, and often die. Currently, live attenuated virus vaccines of chicken embryo origin for DHAV-1 are either administered to 1-day-old ducklings to induce a protective immune response or to breeder ducks to provide maternal antibodies to their ducklings.[90,91] There is no vaccine for DHAV-3 and no licensed commercial vaccine to address both viruses.

A duck embryo epithelial (DEE) cell line was evaluated as a candidate for DHAV-1 vaccine development. Results showed that the propagated DHAV-1 vaccine strain SDE in DEE cell line was able to protect ducklings against DHAV-1 challenge. Taken together, findings suggest that the DEE cell line can serve as a valuable tool for DHAV-1 propagation and vaccine development.[92]

Immunization of ducklings with a yeast-derived recombinant VP1 (major CP) that was administered SC three times at 2-week intervals induced a significant immune response indicating this could be a candidate for a subunit vaccine against DHV-1.[93]

A live attenuated vaccine with the viral isolate AP-04203P100 given to 1-day-old ducklings via IM injection was protective from viral challenge. In addition, the vaccine candidate exhibited complete protection from circulating pathogenic DHAV-3 isolates.[94]

Ducks that received a single dose of rC-KCE-2VP1 (bacterial recombinant containing viral protein 1) showed potent humoral and cellular immune responses and were completely protected against challenges of both pathogenic DHAV-1 and DHAV-3 strains. Protection was rapid and occurred as early as 3 days post vaccination and viral replication was fully blocked as early as 1 week post vaccination.[95]

COVID-19

In 2019, a novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), was identified in Wuhan, China, which caused a contagious disease that became known as COVID-19. The first known case of COVID-19 was identified in Wuhan, China, in December 2019.[96] Since then, the disease rapidly spread worldwide, resulting in the COVID-19 pandemic. Currently, the disease predominantly affects humans. In addition, COVID-19 has been documented in domesticated dogs, cats, hamsters, ferrets, and mink and is also known to infect zoo species including lions, tigers, snow leopards, a fishing cat, a binturong, a coatimundi, otters, hyenas, hippopotamuses, and manatees. Wildlife reports include white-tailed and mule deer, a giant anteater, and a black-tailed marmoset.[96] To date, the disease has not been reported in any avian species.

The virus is thought to be a spillover infection of natural animal origin. According to the World Health Organization, the virus most likely descended from a coronavirus that infects wild bats, to likely spread to humans through an intermediate wildlife host. Although COVID-19 and its variants have not caused illness in avian species, the zoonotic component and rapid mutation rate could allow for a strain that crosses over to birds.

During the COVID-19 pandemic, several COVID-19 vaccines were developed and approved in a relatively short period of time, including vaccines by Pfizer–BioNTech and Moderna, which utilized RNA to stimulate an immune response,[97] and the Oxford–AstraZeneca COVID-19 vaccine, Convidecia, and the Janssen COVID-19 vaccine, which comprised of adenovirus vector vaccines.[98] These developments

have demonstrated that vaccine production can be accomplished in a relatively short time when the need arises, with mRNA vaccines being especially effective in generating a rapid and appropriate immune response.

VACCINE STRATEGIES IN NONPOULTRY CAPTIVE BIRDS

Deciding when and if to vaccinate a bird for a certain disease can be a challenging question for veterinarians, especially because so many vaccines are off label. Factors to consider include the following:

- Risk of the disease to the individual bird and/or a population of birds.
- Is the bird endangered or threatened?
- Is the vaccine safe and effective in the species your considering vaccinating? Is there a known protocol for vaccination? (Table 13.2)
- What is the cost of the vaccine?
- How do you assess efficacy?
  - Measurement of antibody response?
- Do the risks of disease outweigh the risk of vaccination?

After considering these questions, the attending veterinarian should keep detailed records of the vaccination including, but not limited to, vaccination dose (e.g., full/half-dose), manufacturer, protocol used, age(s) of the birds when vaccinated, signed, and dated with a disclaimer that an off-label vaccine has been used. It is best to have signed informed consent by the client in case adverse reactions may occur.

SUMMARY

Historically, vaccines have been underutilized in nonpoultry avian medicine. The numerous published studies in vaccine strategies that have been successful and protective demonstrate that it is possible to develop safe and effective vaccines. However, a few of these vaccines have made it to commercial development (Table 13.4). Nevertheless, with recent advancement in vaccine technology and increased knowledge of avian immunology, the potential to develop safe, effective, and cost-effective vaccines is available. As more and more of our exotic avian species become threatened or endangered, it is the role of the avian veterinarian to push for the development, production, and commercial sale of safe and effective avian vaccines.

ACKNOWLEDGMENT

The authors would like to thank Dr. Gerry Dorrestein for his review of this chapter and his additions to European avian vaccine protocols.

TABLE 13.4

Overview of Selected Vaccines Available for Use in Birds

Vaccine	Disease	Species	Vaccine Protocol	References
Psittimune APV (Creative Science): inactivated (killed) virus vaccine	Polyoma (polyomavirus)	Parrots	Birds >200 g give 0.5 mL SQ. Birds <200 g give 0.25 mL SQ. First dose at 35 days, repeat in 2–3 weeks. Annual booster.	Ritchie et al.[34]
Psittimune PDV: (Ceva Biomune): inactivated virus, oil emulsion vaccine	Pacheco disease (herpesvirus)	Parrots	Vaccinate before exposure or disease outbreak.	No longer commercially available
Innovator (Zoetis): formalin-inactivated virus vaccine	West Nile virus	Raptors/corvids	1.0 mL IM (>300 g), 0.5 mL (<300 g) IM initially followed by 2–3 boosters 1 month apart then annually before mosquito season.	Angenvoort et al.[72] Wheeler et al.[68] *Merck Manual of Veterinary Medicine:* Viral Diseases of Pet Birds[99]
Innovator (Zoetis): formalin-inactivated virus vaccine	West Nile virus	Flamingos	1.0 mL IM initially followed by 2 boosters 1 month apart and then annually before mosquito season.	Okeson et al.[76] Baitchman et al.[82]
Innovator (Zoetis): formalin-inactivated virus vaccine	West Nile virus	Penguins	1.0 mL IM initially followed by 2 boosters 1 month apart and then annually before mosquito season.	Davis et al.[83] Wallace R.[100]
Equine EEE vaccine Encephaloid M (Fort Dodge Laboratories)	EEE, WEE	Emus (*Dromaius novaehollandiae*)	Emu: give full equine dose IM at 6 weeks, 10 weeks, 5 months, and 6 months, and annually thereafter before and after breeding season and if viral disease occurs within 16 km or before transfer to a known endemic area.	Tengelsen et al.[86]
Equine EEE vaccine Encephaloid M (Fort Dodge Laboratories)	EEE, WEE	Pheasants/cranes	Give 0.5 ml at 30 days of age; 1 mL IM booster in 30 days and then annually.	Clark et al.[87]

CHAPTER 14

Avian Bornavirus

Michael Lierz

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Avian bornavirus was first discovered in 2008 in psittacine birds suffering from proventricular dilatation disease (PDD). This strongly suggested that the cause of this devastating disease, threatening parrot populations in captivity and species conservation projects, was found. In 2012, the postulates of Henle and Koch were fulfilled,[1] and the pathogen was proven as the cause, by reproducing clinical and pathological signs in cockatiels (*Nymphicus hollandicus*) after virus application and reisolation of the same virus afterward. Prevalence studies have demonstrated the worldwide distribution of bornaviruses, both in captive and free-ranging bird populations. Different virus strains are found in various bird orders, in particular, Psittaciformes, Passeriformes, and Anseriformes. The main clinical importance remains in psittacine birds where the virus causes various neurological disorders in addition to the "classic" gastrointestinal signs (PDD). Within just 14 years of its discovery, many forward steps have been made toward understanding the transmission of the virus as well as its pathogenesis. Management strategies with which to control the virus in populations and first steps toward a vaccination protocol have also been made. This chapter provides a short update on recent discoveries in this field and is intended to serve as an addition to the information provided in the first volume of this book. Additionally, some key features are repeated, especially focusing on diagnosis and clinical management in the individual bird.

NOMENCLATURE

The complete taxonomy of the family Bornaviridae is being constantly updated due to the discovery of novel strains, particularly in birds and reptiles. The latest update was made in 2019.[2] Most importantly two new genera, *Carbovirus* and *Cultervirus*, were added to the family. The genus name *Bornavirus* was substituted by *Orthobornavirus*, leading to new virus species names. This was necessary as by adding the new genus, confusion between "Bornaviridae" and "*Bornavirus*" when talking about "bornavirus" or "bornaviral" is to be avoided. Some virus strains, for example, parrot bornavirus 6 (PaBV-6) and PaBV-8, are still not classified due to the lack of genetic information. Table 14.1 provides the current taxonomy of the family Bornaviridae.

Avian Orthobornavirus

The different species of the genus *Orthobornavirus* in birds seem to be specific to the different bird orders—that is, waterbird *Orthobornavirus* is generally detected only in Anseriformes, passeriform orthobornaviruses in Passeriformes, and psittaciform orthobornaviruses in Psittaciformes. Cross-order detection of those viruses is rare and only anecdotally reported. In Japan, PaBV-2- and PaBV-4-RNA was detected in samples of free-ranging birds, other than psittacine birds *(Anas, Grus, Larus, Calidris, Haliaeetus, Emberiza)*, but clinical signs were not investigated.[3] In addition, PaBV-RNA was demonstrated from the brain of a Himalayan monal *(Lophophorus impejanus)* with central nervous system (CNS) signs, flocked together with infected psittacines.[4] Aquatic bird bornavirus 1 (ABBV-1) was described in 9 of 439 investigated free-ranging gulls, with only one bird showing an encephalitis,[5] and once in a captive emu *(Dromaius novaehollandiae)*, demonstrating anorexia, maldigestion, weight loss, and various subtle neurological deficits.[6] Despite these reports, crossing birds orders, and particularly the development of clinical signs following cross-infection, seem to be a very rare occurrence, hence indicating the risk of infection with *Orthobornavirus* from other bird orders to be low. Nevertheless, close monitoring and reporting of cross-order infections and clinical cases should provide further insight as to whether this risk indeed is negligible.

TABLE 14.1
Taxonomy of the Family Bornaviridae

Genus	Species	Virus	Abbreviation
FAMILY BORNAVIRIDAE			
Carbovirus	Queensland carbovirus	Jungle carpet python virus	JCPV
	Southwest carbovirus	Southwest carpet python virus	SWCPV
Cultervirus	Sharpbelly cultervirus	Wǔhàn sharpbelly bornavirus	WhSBV
Orthobornavirus	Elapid orthobornavirus	Loveridge's garter snake virus 1	LGSV-1
	Mammalian orthobornavirus 1	Borna disease virus 1	BoDV-1
		Borna disease virus 2	BoDV-2
	Mammalian orthobornavirus 2	Variegated squirrel bornavirus 1	VSBV-1
	Passeriform orthobornavirus 1	Canary bornavirus 1	CnBV-1
		Canary bornavirus 2	CnBV-2
		Canary bornavirus 3	CnBV-3
	Passeriform orthobornavirus 2	Estrildid finch bornavirus 1	EsBV-1
	Psittaciform orthobornavirus 1	Parrot bornavirus 1	PaBV-1
		Parrot bornavirus 2	PaBV-2
		Parrot bornavirus 3	PaBV-3
		Parrot bornavirus 4	PaBV-4
		Parrot bornavirus 7	PaBV-7
	Psittaciform orthobornavirus 2	Parrot bornavirus 5	PaBV-5
	Waterbird orthobornavirus 1	Aquatic bird bornavirus 1	ABBV-1
		Aquatic bird bornavirus 2	ABBV-2

OCCURRENCE OF AVIAN ORTHOBORNAVIRUS

Avian orthobornaviruses (ABVs) are detected worldwide. Infections have been found in the United States,[7,8] Australia, Europe,[9–12] Brazil,[13–16] Japan,[17,18] South Africa,[19] Thailand,[20] and Canada.[21,22] In Denmark, ABBV-1 was found in free-ranging geese, which is the same strain occurring in waterfowl in North America.[23] Canary bornavirus 1 (CnBV-1), first discovered in Germany, was also found in free-ranging and captive passerine birds in Brazil, indicating worldwide distribution of *Orthobornavirus* among Passeriformes.[24] Most studies, however, have focused on the prevalence of orthobornaviruses in Psittaciformes. In psittacine birds the most prevalent virus types remain PaBV-4 followed by PaBV-2. Other types, such as PaBV-5, are detected in different countries and only reported in single case reports.[20] So far, there is no evidence that certain subtypes are restricted to certain countries or populations. Studies in captive psittacine collections indicate a prevalence of approximately 4.3% to 32.2% in clinically healthy birds.[9,10,25] The prevalence of asymptomatic infections among captive-maintained birds makes worldwide viral distribution through international trade easily possible. It can realistically be assumed that nearly all larger breeding flocks of psittacines contain infected individuals, except for those flocks where diligent efforts to clear the presence of the pathogen are being employed. In contrast, studies in free-ranging psittacine populations demonstrate a very low prevalence.[15,26] The reason for the difference between captive and free-ranging flocks is not yet clear. Interestingly, in neozoan free-ranging psittacine populations established in Europe, PaBV could not be found.[27] It is hypothesized that through the release of a few birds, which were negative, a PaBV-free population may have been established. Given that this study investigated free-ranging *Psittacula* species, which also demonstrated a very low prevalence in captivity in Europe (~2%), this would be a plausible explanation. Alternatively, the routes of transmission might explain the found differences, as birds in captivity have closer contact and bird exchange between groups occurs more often in captivity than in the wild. Asymptomatically infected birds might not seroconvert and shed virus intermittently, as compared to clinically affected birds with high titers and high viral RNA shedding. This latter group usually does not occur in the sample bag when investigating free-ranging populations as they are chronically ill and die without being found. The occurrence of new strains in some free-ranging populations, which are not detected by current laboratory methods, can also not be excluded. Last but not least, the bird species investigated in the wild might play a role. However, so far there is no evidence that PaBV strains are specific to some species and all studies involving different parrot species on different continents resume a similar prevalence.

AVIAN ORTHOBORNAVIRUS TRANSMISSION

ABV-RNA is regularly detected in feces and urine as well as in cloacal and crop swabs. A fecal-oral route of transmission has therefore been postulated.[28–31] Reports also demonstrated that ABV spreads in a flock after introduction of infected birds,[32] indicating horizontal transmission. However, a fecal-oral route of transmission would not explain the variable, and often rather low prevalence in psittacine flocks, the very low prevalence in free-ranging populations, and the observation that, in single pairs of parrots, only one of the partners is found to test positive for PaBV. Multiple studies demonstrate that uninfected

sentinel birds kept in close contact to experimentally infected animals did not get infected.[1,29,33–35] Experimental infection is usually accomplished through intramuscular, subcutaneous, intravenous, or intracerebral injections or a combination of these routes,[1,29,33,36] which do not represent natural routes of transmission. Recent infection studies clearly showed that oral or nasal inoculation of PaBV does not result in valid infections in various bird species, including cockatiels, canaries (*Serinus canaria* f.d.), and grey parrots (*Psittacus erithacus*).[37,38] Heckmann et al.[39] were able to demonstrate that infection through wounds is possible, but ability to transmit infection seems to differ according to the type of wound. After experimental inoculation of PaBV-4 on lesions in the oral cavity, infection did not occur. In contrast, inoculation of a similar virus suspension on footpad lesions leads to a successful infection. PaBV-RNA was found in sciatic nerves, the footpad tissue, skin, and intestine in that study. Histopathology demonstrated mononuclear infiltrations in the skin and footpad tissue typical for PaBV infection and immunohistochemistry showed positive reactions in spinal ganglia and spinal cord, and, to a lesser amount, in the skin, footpad tissues, and ischiatic nerves.[39] The reason why lesions in the oral cavity did not act as a portal of entrance, compared to footpad lesions, remains unclear. It was speculated that the severe bleeding of oral cavity lesions during the experimental infection might have washed out inoculated virus. Footpad lesions, in contrast, did not bleed as much and were covered by a bandage after inoculation, preventing early removal of the virus. Therefore, it seems fair to conclude that wounds in general represent a valid port of entrance. The results of the footpad infection group suggested a spread of the virus in the host through retrograde axonal transport, like rabies. This assumption is supported by another study where after intramuscular inoculation, PaBV-2 was first detected in macrophages and lymphocytes, followed by invasion of the brachial plexus and spread centripetally through the spinal cord toward the brain.[40] This was followed by a centrifugal spread toward the ganglia in the periphery, including the gastrointestinal system. Only after this, at a late time point following infection, the virus was no longer restricted to the nervous system.[40] This viral movement explains the different findings noted previously, where in some cases PaBV was restricted to the nervous system, whereas in other cases the virus was found in a multitude of other tissues. The speed of viral spread in the body, as well as the phase which is reached are likely influenced by different host factors including immunocompetency, which might explain the observed high variation of clinical signs or latency. As said, the literature[39,40] strongly suggests that PaBV uses the nervous system as a port of entry and spread within the host, and that the CNS is the first target. Following PaBV-2 injection into the pectoral muscle, the virus was observed in the spinal cord after 20 days postinfection (dpi) and after 25 dpi in the brain, indicating rapid spread of the virus into the nervous system tissues. Until day 40 postinfection, the virus was only detected in the central core of the brain to spread to gray and white matter of the CNS at 60 dpi, where it was accompanied by encephalitis.[41] Depending on the port of entry, the brain is reached at a variable time frame, hence in part explaining the different incubation times prior to the onset of clinical signs. Moreover, the study showed that, if the brain is affected severely first, severe clinical signs develop rapidly, often in birds with good body condition. However, if the spread of the virus within the nervous system takes longer and is not as severe, clinical CNS signs might not be as overt and easily missed, leading to further spread of the infection through the body. As it takes longer for the virus to reach the peripheral nervous tissues, this would also explain why the development of gastrointestinal signs takes much longer to develop.

In addition to horizontal transmission, vertical transmission is also possible. Knowledge about the circumstances of vertical transmission is highly important as it would allow for breeding with rare birds, even if they are PaBV infected. PaBV antigen has been demonstrated in ovarian follicular cells of diseased birds[42] and PaBV-RNA has been identified in eggs and embryos.[43,44] It has been shown that CnBV-RNA was present in canary embryos of CnBV-positive parents. Only female birds with a persistent CnBV infection and high levels of virus shedding laid eggs with CnBV-positive embryos. Intermittent CnBV-RNA–shedding females and females of the contact group laid only CnBV-RNA–negative eggs.[45] However, all of these studies failed to isolate live virus, which leaves some doubt regarding vertical transmission. Hand-raised Amazon chicks originating from PaBV-positive parents were tested negative for PaBV-RNA from crop and cloacal swabs.[46] Wüst et al.[47] investigated vertical transmission of PaBV-4 and PaBV-2 in a laboratory setup using cockatiels as a model. Susceptibility of the inoculates for infectivity of embryonic cockatiel cells was first examined. Embryonic cockatiel brain cell cultures (CEB) and embryonic cockatiel fibroblast cell culture (CEF) from 10-day-old cockatiel embryos were compared with viral growth patterns in cells from CEC-32 cell lines that were typically used before to grow ABVs. In CEC-32 cell culture, PaBV-2 showed slower growth compared to PaBV-4. CEB cells were successfully infected with PaBV-2 and PaBV-4 without differences in growth speed. Fertile cockatiel eggs were inoculated with PaBV-4 by yolk sac route at days 3 to 5 of incubation. The organs of each embryo were examined at 13 to 14 days postinfection (day 17 of incubation) by different laboratory methods. In 28.1% of the inoculated embryos PaBV-4-RNA and in 81.3% PaBV-4 antigen were detected in the brain. Nevertheless, similar to the studies previously described, virus isolation failed. In a different component of this study, inoculated embryonated cockatiel eggs inoculated with PaBV-2 or PaBV-4 via yolk sac or chorioallantois membrane were inoculated at days 5 to 7 of incubation. Compared to the first part of the study where organs were divided between different types of examinations, this time the complete organ was subjected to one laboratory method to increase sensitivity. Now, in 80% to 100% of the embryos PaBV-RNA and in 90% to 100% PaBV antigen were detected only in the brain, independently of the PaBV strain. The infected cells demonstrated a clear pattern through all the embryos but could not be identified using different brain cell markers (i.e., anti–neuronal nuclear protein [NeuN] antibody [neuron marker], anti–glial fibrillary acidic protein [GFAP] antibody [astrocyte marker], and anti–S-100 [glia cell and neuron marker]. While virus isolation again was unsuccessful, these studies do demonstrate a specific distribution pattern and spread of PaBV-4 and PaBV-2 with restriction to the brain when injected into fertile eggs. Hence, the potential for vertical transmission remained in place. However, an abortive infection can also not be ruled out at this point.[47]

Successful vertical transmission of PaBV was proven in another study for the first time.[48] Vertical transmission of the virus was compared in eggs originating from birds that were experimentally infected with PaBV as adults (group 1), and eggs originating from birds infected at the first days of life and raised until sexual maturity with persistent infection (group 2) Ninety-two eggs (49 from group 1 and 43 from group 2) were laid and incubated until day 17, following which the embryos were examined by immunohistology, PaBV-specific real-time polymerase chain reaction (PCR), and virus isolation. Results indicated 45.2% of the embryos to be positive by PCR in group 1 versus 74.9% of the embryos in group 2. Reisolation of PaBV was unsuccessful from embryos in group 1, but in group 2, reisolation of PaBV was possible from 42.9% of the embryos.[48] Based on these findings, it appears that vertical transmission may only occur under specific circumstances. Specifically, the time point of infection of the birds and the degree of development of the immune system are hypothesized to play a role (see Pathogenesis). In summary, results of this study indicate that vertical transmission might play a major role in transmission and the development of asymptomatically infected birds, which in turn may serve to maintain and spread infections in and between flocks. Controlling vertical transmission could therefore be a key factor in controlling viral spread and clearing the virus from flocks.

PATHOGENESIS

There remains considerable need for further understanding of the factors that influence the development from infection to clinical disease. It is known that several birds may be positive in a flock, but only a few develop clinical signs.[10] Clinically healthy but infected individuals are often seen, which could play a major role in the epidemiology of the disease.[9,15] It appears clear that bornavirus infections cause an immune-mediated disease and that clinical signs are in line with signs of inflammation, in particular involving the nervous system tissues. These inflammatory changes are triggered as an immune response, rather than through direct cell damage. Transmission of T lymphocytes from borna disease virus (BDV)-diseased rats to infected but immunoincompetent, healthy rats induced clinical signs, clearly indicating a T-cell–mediated disease, at least in rats.[49] In rats, a neural invasion of CD8 T lymphocytes seems to cause the cellular damage rather than the virus itself.[49–53] It is fair to speculate that a similar pathogenesis can be presumed for ABV. A delayed-type hypersensitivity effect, as suggested by Payne et al.,[54] could fit with the hypothesis of clinical disease resulting from a T-cell–mediated response.

Hameed et al.[55] showed that in cockatiels, a treatment with cyclosporin A (which reduces the immune T-cell response) was successful in preventing clinical signs. Gartner et al.[56] evaluated the age of the bird at the time of infection as a factor for developing clinical disease. For this purpose, the authors compared differences in latency, development, and severity of clinical signs, as well as shedding of virus and seroconversion between newly hatched cockatiels (1–6 days old; with a non–fully competent immune system, $n = 11$) and adult birds ($n = 11$) following intravenous inoculation with a PaBV-4 isolate. All 22 birds seroconverted and demonstrated PaBV-RNA shedding during the investigation period of 233 days. However, the juvenile group seroconverted and began shedding virus RNA earlier and more homogeneously than the adult group. In contrast, only one juvenile bird died following a bacterial septicemia, whereas 9 of 11 birds from the adult group developed clinical signs, of which 5 eventually died or were euthanized. Postmortem examination of the birds revealed eight birds of the adult group to demonstrate a dilatation of the proventriculus versus none of the juvenile group. In all birds, PaBV-RNA was detected in various tissues, followed by successful virus reisolation. Clinical outcome of a PaBV infection thus seems to be influenced by the age of the host at the time of infection, with infection at a younger age, when the immune system is not fully developed, seemingly predisposing to the development of asymptomatically infected birds. This is of particular importance, as eggs originating from birds infected as chicks allowed vertical transmission,[48] hence increasing the likelihood of production of positive offspring and potential spread of the infection across the flock. However, it remains unclear whether PaBV-RNA–positive embryos, originating from parents infected as adults, remain positive during their development, thereby developing into asymptomatically infected carriers as well. The development of carriers is a key factor to understand the epidemiology of the disease and is essential to manage the virus in psittacine populations, especially in species conservation programs where the exclusion of positive birds is very difficult due to the low number of birds available.

Viral factors may also play a role in the pathogenesis of a PaBV infection. So far, it has not been determined which factors are of importance. Different ABV strains act differently within the same host, by terms of viral replication and pathogenicity. It was experimentally shown that PaBV-2 was more pathogenic to cockatiels than PaBV-4 and that viral RNA shedding occurred significantly earlier in PaBV-4–infected birds compared to those with PaBV-2. However, seroconversion occurred significantly earlier in the PaBV-2 group.[57] In the PaBV-2–infected group, reisolation of the virus from birds that died earlier was only successful after several passages compared to the birds that died late, in which reisolation was already possible after the first passage. This indicates a lower viral load in birds dying quickly after infection, hence demonstrating that viral load (and viral replication) seemingly does not correlate with the severity and progress of the disease. This underlines the hypothesis that the virus induces disease through mechanisms independent from the viral load (e.g., earlier activation of the immune system), or even that earlier activation of the immune system may prevent quick virus replication, but nevertheless cause more severe disease. Hence, immunocompetency at the time of infection and other immunological factors, or factors influencing the strength or weakness of the immune system, are likely to be key factors in the clinical outcome of infections.

CLINICAL SIGNS OF AVIAN ORTHOBORNAVIRUS INFECTION

In general, it seems that all orthobornaviruses found in birds have the potential to cause clinical illness. Infection with subsequent clinical signs has been reported in Passeriformes,

Anseriformes, and Psittaciformes. Recently, ABBV-1–associated clinical signs, including esophageal dilation and encephalitis, were reported in free-ranging Canada geese *(Branta canadensis)*.[21] Seeing the high prevalence of ABBV in free-ranging waterfowl, occurrence of clinical signs nevertheless seems to be a rare event, with most infections seemingly staying subclinical. However, it needs to be considered that in free-ranging birds, sick birds are often not found. Currently, psittaciform orthobornaviruses appear to be of large clinical significance to Psittaciformes as compared to the other groups. PaBV-2 and PaBV-4 have been clearly demonstrated as the causative agent of PDD,[1,57] a syndrome that is known for decades. PDD is therefore considered the main clinical sign of a clinically apparent PaBV infection. PDD is characterized by a nonpurulent, lymphoplasmacytic infiltration in neural ganglia of the peripheral nerves, particularly the autonomic nervous system of the gastrointestinal tract (esophagus, crop, proventriculus, and ventriculus).[58] As a consequence, peristalsis becomes impaired, and food accumulates in the proventriculus and crop.[59] Clinically, this results in maldigestion, passage of undigested seed in feces, and emaciation of the bird despite normal food intake. Birds can show ruffled feathers and often show reduced activity. As the virus may also cause an inflammatory response in the nervous system (i.e., lymphoplasmacytic ganglioneuritis), neurological disorders have been seen regularly by this infection and may occur more commonly than previously thought.[58] Clinical signs resulting from central nervous involvement may include head shaking or incoordination.

One study detected neurologic lesions in 82% (23/28) of birds naturally infected with PaBV-4. In addition, epicardial ganglioneuritis has been found regularly in naturally and experimentally infected psittacines,[60] which may explain sudden death in some PaBV-infected birds. A recent study demonstrated that PaBV infection was more prevalent in birds presenting with neurological disorders in the absence of PDD-associated clinical signs than in healthy birds presenting for routine examinations. Importantly, they had much higher antibody titers and demonstrated higher levels of viral shedding as compared to birds from the healthy control group.[61] Based on these results, the authors concluded that PaBV infection and associated disease should be included in the differential diagnosis of birds presenting with neurologic signs.[61] It has also been suggested that some feather-damaging behaviors may, at least in part, be signaled by PaBV infection. Birds with feather-damaging behaviors showed a higher prevalence of PaBV infection than control birds, with some having higher antibody titers and viral shedding. However, comparison to healthy controls was not as significant as compared to birds demonstrating neurological disorders.[61] Therefore, feather-damaging behavior (which often is a multifactorial condition) cannot be clearly linked to the presence of PaBV infection.[61] Further long-term studies would be needed to evaluate whether such a correlation, even in individual cases, does exist. Different virus strains seem to be associated with different disease patterns, with some predominantly affecting the CNS tracts leading to neurological signs without presence of gastrointestinal signs whereas others predominantly affect the enteric nervous system, causing gastrointestinal signs, in the absence of central neurologic disease.[57] Due to the consistent involvement of inflammatory changes surrounding the nervous tissues, several experts have suggested to rename the disease to avian ganglioneuritis

DIAGNOSIS OF AVIAN ORTHOBORNAVIRUS INFECTION AND PARROT BORNAVIRUS–INDUCED CLINICAL DISEASE

It is very important to differentiate between the diagnosis of the virus infection and the diagnosis of clinical signs induced by PaBV. As mentioned earlier, PaBV infection does not automatically lead to clinical disease, and clinically healthy carriers are regularly seen. These infected but asymptomatic birds seem to play a major role in virus transmission and distribution. On the other hand, they might become clinically ill due to other reasons while remaining positive for PaBV when tested. Therefore, it is important for the practitioner to be clear in regard to the goal(s) of the testing of the bird, i.e., to determine whether a bird is infected with the virus (e.g., for a prepurchase examination, transfer or release of birds, pairing of birds, establishment of flocks that are free from PaBV, etc.) or to investigate the underlying cause for clinical disease to determine a therapeutic plan or prognosis. Diagnosing the presence or absence of ABV infection in an individual as well as in a flock is explained in more detail in the first volume of this book. Here, a short summary is provided.

Diagnosis of Avian Orthobornavirus Infection

Veterinarians are regularly requested to investigate whether a bird is infected with ABV or not. This request is particularly common as part of a prepurchase examination to exclude entry of infected birds into a flock in an effort to establish and maintain a flock free from the virus, to transfer birds to other places (e.g., breeding, vacation care), or release birds back into the wild. In these situations, it is important to find out if a bird is infected and carries the virus, thereby posing a risk to other birds. For this purpose, it is important to keep in mind that it has lifelong consequences for the bird once it is diagnosed to be infected, as orthobornaviruses appear to cause lifelong infections in most birds. Infected birds may shed the virus for years without developing clinical signs, as was discovered following long-term monitoring of shedding by PaBV-infected birds. Nevertheless, the possibility that some birds might clear the infection cannot be ruled out. Some cockatiels that tested positive for PaBV-RNA in cloacal swabs at least once, showed discontinual of viral shedding and lack of signs of PaBV infection following necropsy.[62] Possible explanations for these findings are that birds were either able to clear the infection or that the cloacal swab tested positive due to passing PaBV-RNA ingested from other positive birds in the flock, while the bird with the positive test had actually never been infected. Usually birds shedding the virus do this for a very long time and most likely lifelong.

Like in other infectious diseases, diagnosis of ABV infection is focused on the demonstration of the pathogen in samples of the birds (direct proof) or the detection of specific antibodies against the pathogen (indirect proof). In veterinary practice, direct demonstration of the pathogen is most frequently accomplished by PCR. It must be underlined that different PCR protocols detect different avian orthobornaviruses, especially from different avian taxonomic groups. If focusing on the detection of ABV from bird groups other than psittacines (e.g., waterfowl, songbirds), specific PCR

protocols need to be used.[45,22] For psittacine birds, commercial laboratories commonly use real-time PCR protocols to detect PaBV-2 and/or PaBV-4 (which represent the most common strains in psittacines). However, this might lead to a false negative diagnosis if facing other PaBV genotypes or strains of the same genotype.[57] Therefore, it is vital to ask the laboratory which PCR protocol is used and which strains can be detected with the test, as this will help to identify whether the test will be useful to help answer the question that initiated the testing in the first place.

Best samples for ABV-RNA detection by PCR are crop and cloacal swabs (merged in one sample) in the live bird, or nerve tissue (e.g., brain, retina) or adrenal gland tissue from a deceased bird. Feces is not recommended, as it carries certain disadvantages for use in PCR, such as presence of inhibitors leading to false-negative results. It has also been shown that blood is not very sensitive as sample material, as blood samples from PaBV-positive birds regularly test negative for the virus.[63] Feather calamus has been suggested to provide adequate samples for testing, but experimental studies have demonstrated feathers to not be first choice sample material. Feathers also contain a higher risk of being contaminated by other birds or the environment leading to false-positive results. Samples for PCR must be stored cooled or in transport media (RNAlater, Qiagen, Hilden, Germany) and sent immediately to the laboratory. False-negative results might occur simply due to poor transport conditions. Repeated freezing and thawing of samples can also lead to false-negative results. Apart from false-negative results, birds might not shed viral RNA at the time of sampling. Hence, a negative PCR result does not mean that the bird is not infected. Repeated sampling, and especially serologic evaluation, is therefore important.

For a complete investigation, screening for anti-PaBV antibodies is indispensable. Some birds may shed viral RNA intermittently but will demonstrate specific anti-PaBV antibodies. This means without serological investigations for anti-PaBV antibodies such birds may be falsely classified as noninfected when tested only with PCR. On the other hand, some birds are detected as shedders without seroconversion.[10,64] This clearly demonstrates that only the combined investigation using PCR and serology will be able to provide a complete picture and allow for interpretation of clinical signs and infection status of a bird.

There are different assays available to detect anti–ABV-specific antibodies, including indirect enzyme-linked immunosorbent assay (ELISA) tests,[65] and Western blot[9] tests, which use specific recombinant proteins as antigens. When using a single protein as antigen, it is required that the protein demonstrates cross-reaction between different ABV genotypes to ensure a positive reaction when antibodies against any ABV subtypes should be detected. This is not ensured yet. Therefore, the sensitivity of tests focusing on one protein only needs to be questioned until otherwise proven. Comparison of these serological tests with tests based on infected cell cultures (providing several antigens) points toward a higher sensitivity for the latter method, especially when low antibody titers are present. However, comparison of the tests also showed that results between the methods were congruent in birds with high antibody titers as commonly found in clinically affected birds. Based on these findings, it may be concluded that results from ELISA or Western blot focusing on single proteins might be adequate for diagnosing clinically ill birds in daily veterinary practice, but not for managing flocks where the aim is to also detect clinically healthy carriers that might have low antibody titers. As a result, tests based on ABV-infected cell cultures (e.g., indirect immunofluorescence test [IFT]),[66] which present a wide range of different ABV antigens, are recommended if a higher sensitivity is needed, even though these tests are more difficult to perform.

Diagnosis of Parrot Bornavirus–Induced Clinical Disease

Diagnosis of PaBV-induced clinical disease is not easy, particularly in the living patient. As birds are commonly asymptomatically infected, detection of the presence of PaBV should not automatically be presumed as the cause of the clinical signs observed in a patient. Instead, other causes for the clinical signs must be ruled out in addition to the detection of a PaBV infection by PCR and serology (Figure 14.1). Typical clinical signs that are induced by PaBV are maldigestion, which may present by shedding of undigested seeds in feces, as well as signs indicative of neurologic disease, such as ataxia, convulsions, or tremors. Experimental trials have shown that some birds only demonstrate gastrointestinal signs (referred to as PDD), whereas others only show neurological signs, and others show involvement of both organ systems. Whether and which organ system is involved seems to be related to the individual bird, the age at which the bird got infected, and the PaBV strain involved. In birds with gastrointestinal signs, radiographic imaging should be considered to evaluate the size of the proventriculus. If the proventricular silhouette is found to be enlarged with a thin-walled proventricular lining (as can be demonstrated during contrast radiography or fluoroscopy), PDD becomes more likely as several other diseases (including infection with *Macrorhabdus ornithogaster* or *Candida* spp.) more commonly lead to a thickening of the proventricular wall. A fecal cytologic examination from the bird with Giemsa or Diff-Quick will easily demonstrate *M. ornithogaster* should these organisms be present, whereas a crop swab stained by methylene blue can help to rule out the presence of *Candida* spp. Contrast radiographic or fluoroscopic imaging will also provide evidence for foreign bodies, which should be listed in the differential diagnosis for PDD. As other systemic diseases or infections might lead to gastrointestinal signs, a blood chemistry and hematological profile should be performed. If abnormal, the data obtained might point toward other disease processes than PaBV-associated disease. Hematological and blood chemistry values are seemingly of little significance to PaBV-induced clinical disease. After experimental infection, grey parrots *(Psittacus erithacus)* showed only minor hematological alterations.[67] Blood chemistry values of aspartate aminotransferase, creatine kinase, total protein, glucose, and uric acid did alter compared to values of the same individuals prior to infection, but not in a predictable degree. An increase in γ-globulin fraction was noted 10 weeks postinfection, but by week 34, postinfection values decreased again to levels like those noted before infection. During the trial, three birds died of typical PDD signs. However, none of these birds demonstrated alterations in their blood panel prior to death. This means that significant alterations in the blood profile could point toward other diseases as the underlying cause for the clinical signs.

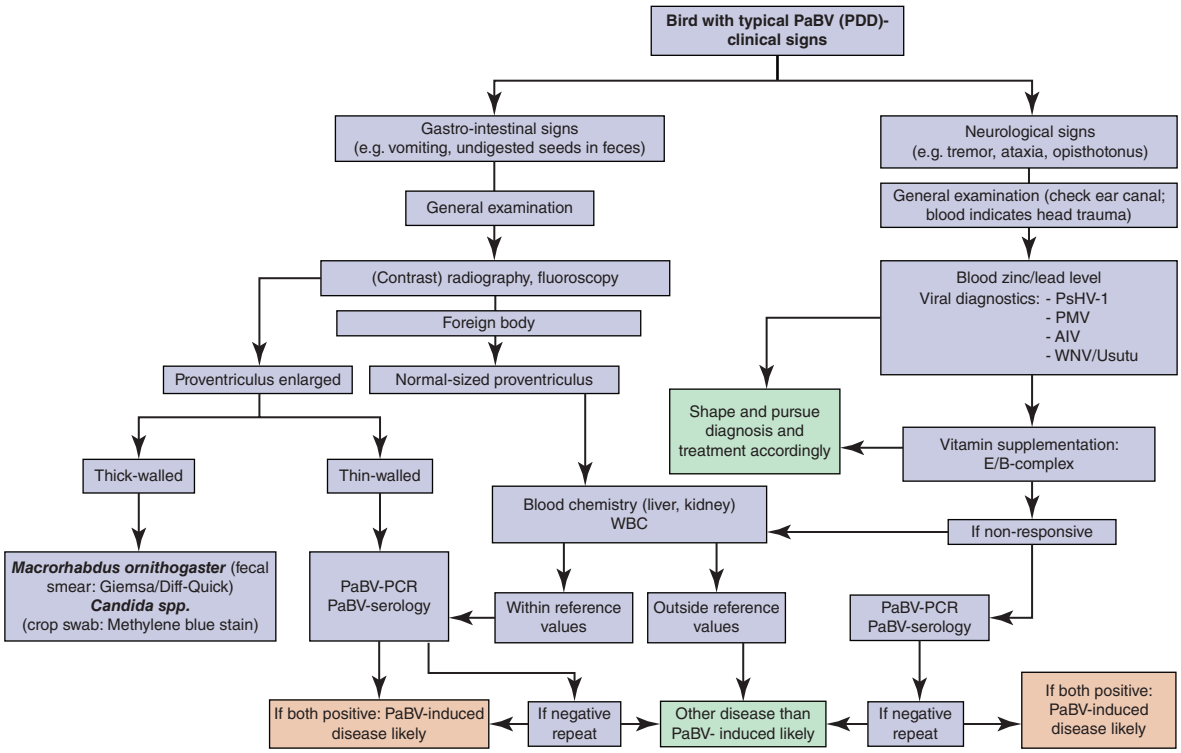

FIGURE 14.1 Diagnostic process schematic for a bird presenting with compatible clinical signs attributable to bornavirus infection, but which could also include a differential diagnosis of other disease processes. Because avian bornavirus infections are common in birds without causing clinically apparent disease, a bird can be showing clinical signs due to another disease process or combination of conditions while additionally being positive for bornavirus. Ruling out and identifying comorbidities that could contribute to the presenting clinical signs is important, in addition to diagnostic investigation for bornavirus infection. *AIV*, Avian influenza virus; *PaBV*, parrot bornavirus; *PCR*, polymerase chain reaction; *PDD*, proventricular dilatation disease; *PsHV-1*, Psittacine Herpesvirus 1; *PMV*, Paramyxovirus; *WBC*, white blood cell; *WNV*, West Nile virus.

If neurologic signs are present, heavy metal intoxication (zinc, lead), vitamin deficiencies, and infections with paramyxoviruses, orthomyxoviruses, herpesviruses, and flaviviruses should be on the list of differential diagnostic considerations, hence necessitating these to be ruled out. This can be done by toxicologic and viral testing and by supplementing the bird with vitamins, which should lead to a fast recovery if a deficiency was present. Similarly, trauma should be ruled out as a cause. Radiographic imaging may be helpful to identify the presence of anatomical alterations (e.g., aspergillosis) or detect the presence of a dilated proventriculus suggestive for PDD. To exclude metabolic causes, a complete blood biochemistry and hematologic profile can be performed.

Crop and cloacal swabs should be taken for PaBV PCR, whereas serological samples can be collected to detect anti–PaBV-specific antibodies. It cannot be emphasized enough how important it is to combine both PCR and serology to maximize the chances of detecting a PaBV infection. Field observations as well as infection trials demonstrate that birds developing clinical disease from a PaBV infection do shed viral RNA and will often demonstrate high antibody titers. Especially titers seem to be an excellent predictor for association of the clinical signs with a PaBV infection. However, it needs to be mentioned that there is no exact "limit" to the antibody level confirming the diagnosis, as interpretation of the serological results highly depends on the test that is used. Therefore, the laboratory should set its standards regarding what is considered a low, moderate, or high titer. In experimental settings, birds with clinical PaBV infection will often demonstrate seroconversion, even in the rare event of a quick death, prior to shedding viral RNA. If PaBV-RNA is detected together with high antibody titers and presence of typical clinical signs in the absence of evidence for the most important other differential diagnoses, it becomes very likely that clinical signs are PaBV related.

Very few cases will demonstrate typical PaBV-associated clinical signs with negative PaBV PCR and serology while all other differential diagnoses have effectively been excluded. In such cases, it should be kept in mind that due to the high variability of PaBV, primers might fail to detect a specific PaBV genome or that antibodies are not detected due to the selection of a serologic assay using only a single antigen. Therefore, negative PCR results especially should be interpreted in the context of the type of PCR that has been used, and balanced against the clinical presentation and serological test results as well as the possibility of occurrence of novel genomic variants that are not readily detected. In such cases, further testing should be considered and discussed with the laboratory. This may include retesting of birds after 2 weeks, as seroconversion may have taken place, thereby allowing for

detection of seropositive birds that were initially negative on serology.

Owners with clinically healthy birds sometimes inquire about testing for PaBV infections to obtain a prognosis regarding the lifespan of their bird(s) or the potential onset of clinical disease. Such a prognosis cannot be given, as the factors influencing the development of clinical disease have not been fully elucidated. Birds with low viral shedding or low antibody titers might demonstrate an increase in viral shedding or rise in antibody titers and develop clinical disease some weeks later. On the other hand, several birds that demonstrated high titers and/or high viral shedding have remained clinically healthy for several years. This last group might represent carriers, which may have been infected vertically or early in life and might remain infected their entire without ever developing clinical disease.

Before PaBV was proven as the cause of PDD, antiganglioside antibodies were proposed to cause the nonpurulent inflammation typical for PDD as part of an autoimmune disease. At present time, the detection of antiganglioside antibodies is considered by some as a PDD test, used to gain inductive strength in diagnosing clinical disease. However, this would imply that the presence of those antibodies leads to the development of PDD, hence suggesting that these should always present in birds with PDD. Unfortunately, thus far there is no proven evidence for this, even though this theory might have its merit. Early comparative studies have shown a poor correlation between antiganglioside antibody levels and PDD-associated clinical signs, as well as between PaBV infection and the occurrence of antiganglioside antibodies.[68] Further doubt is raised by studies immunizing quaker parrots (*Myiopsitta monachus*) with gangliosides (producing antiganglioside antibodies), following which no PDD-like lesions were induced.[69] Hence, confirming infection through detection of the causative agent seems more straightforward. However, if a test were to be developed that would be able to confirm the presence of PDD resulting from PaBV infection or the use of antiganglioside test were confirmed for support or confirmation of diagnosis, this might be helpful in daily clinical practice. To evaluate the merit of such novel tests, studies with experimentally infected birds are necessary, as this will allow for correlation with the time point following infection and the occurrence of clinical disease.

To summarize, a test for PaBV infection (neither PCR nor serology) *is not* a test to detect PDD. Typically, PDD can only be diagnosed by histopathology or by demonstrating PaBV infection in the presence of the typical clinical signs and following exclusion of other causes for the clinical signs. In such cases, PaBV PCR and serology are indispensable and can strengthen the diagnosis by considering the amount of shed PaBV-RNA and antibody titer.

Diagnosis of Parrot Bornavirus Infection to Identify Positive Birds

Independent from clinical disease, there is a strong request to test individual birds for PaBV infection. This is very useful as it allows for control of the virus and sanitizing flocks. Isolating PaBV-positive birds will certainly lead to reduced transmission, and clearing flocks will lead to elimination of the virus, hence reducing the number of clinical cases. As such, tests to rule out PaBV infection are highly recommended in prepurchase examinations, when translocating birds to other collections, when releasing birds back into the wild, or when adding new individuals to pathogen-free flocks. In these circumstances, in which the tested birds are usually clinically healthy, combined testing using PaBV PCR and serology is warranted.

Birds with positive test results in both PaBV PCR and serology should be considered as clearly positive. Those being positive by PCR only should be retested, to confirm the result and exclude contamination of the sample. It is advised to retest 4 to 6 weeks later, as this helps to evaluate whether seroconversion has occurred in the meantime. During this time, birds should be separated from other birds. In case of seroconversion or repeatedly positive PCR results, birds should be considered positive. Birds positive by serology only are likely to be infected, as PaBV seems to cause lifelong infections.[29,62] However, despite this being likely, lifelong infectivity has not been proven and with existing evidence and reports regarding birds that have been able to clear infection, conclusions should be drawn with some caution.[65] The height of antibody titers may be helpful to determine whether retesting is needed. Birds with a high PaBV antibody titer usually do not vary in their results; hence there is no immediate need to retest them. However, retesting is warranted for birds with low titers that are negative in additional tests, as evidence for persistent infection is lacking in these. In such cases, false-positive serological results from cross-reaction with antibodies directed against other antigen cannot fully be excluded albeit being unlikely. Separating these birds from other birds and retesting them after 4 to 6 weeks using PCR and serology is therefore recommended. If titers are maintained or increase and/or if viral RNA is detected, these birds should be considered positive. Decreasing titers or seronegativity, together with negative PCR, warrants retesting after 4 to 6 weeks. Only if repeated testing demonstrates the bird to remain seronegative and there is repeated failure of virus demonstration by PCR, the birds can be considered ABV negative. Figure 14.2 provides an overview of suggested interpretation of test results to categorize tested birds.

The main goal in controlling PaBV is to clear flocks from the virus. This should be feasible, since the virus is not easily transmitted horizontally between two birds (see Avian Orthobornavirus Transmission). Efficacy of this approach has been demonstrated in recent years, even in large breeding flocks involving several thousands of birds. Clearance of PaBV from flocks will also result in less infected birds being sold to the market, thereby decreasing the spread of the infection and resulting in less pet birds being affected by clinical disease. Hence, viral control is the best measure to prevent disease. Managers of large flocks cleared from PaBV report no further PDD cases, as compared to discovering several cases per year before the flock achieving a specific pathogen-free status. However, clearance of PaBV from a flock can be a long, expensive, and sometimes frustrating task and will only be successful with strict compliance of the owner. Requests to investigate a flock are common, but when owners or managers learn that, at least initially, it is likely that a considerable number of birds will test PaBV positive, conflict arises, in particular when this implies the need to separate or exclude expensive and successfully breeding birds from the collection. Therefore, owners should be counseled as to exactly what is involved and expected at the onset of the effort to establish a PaBV-free collection.

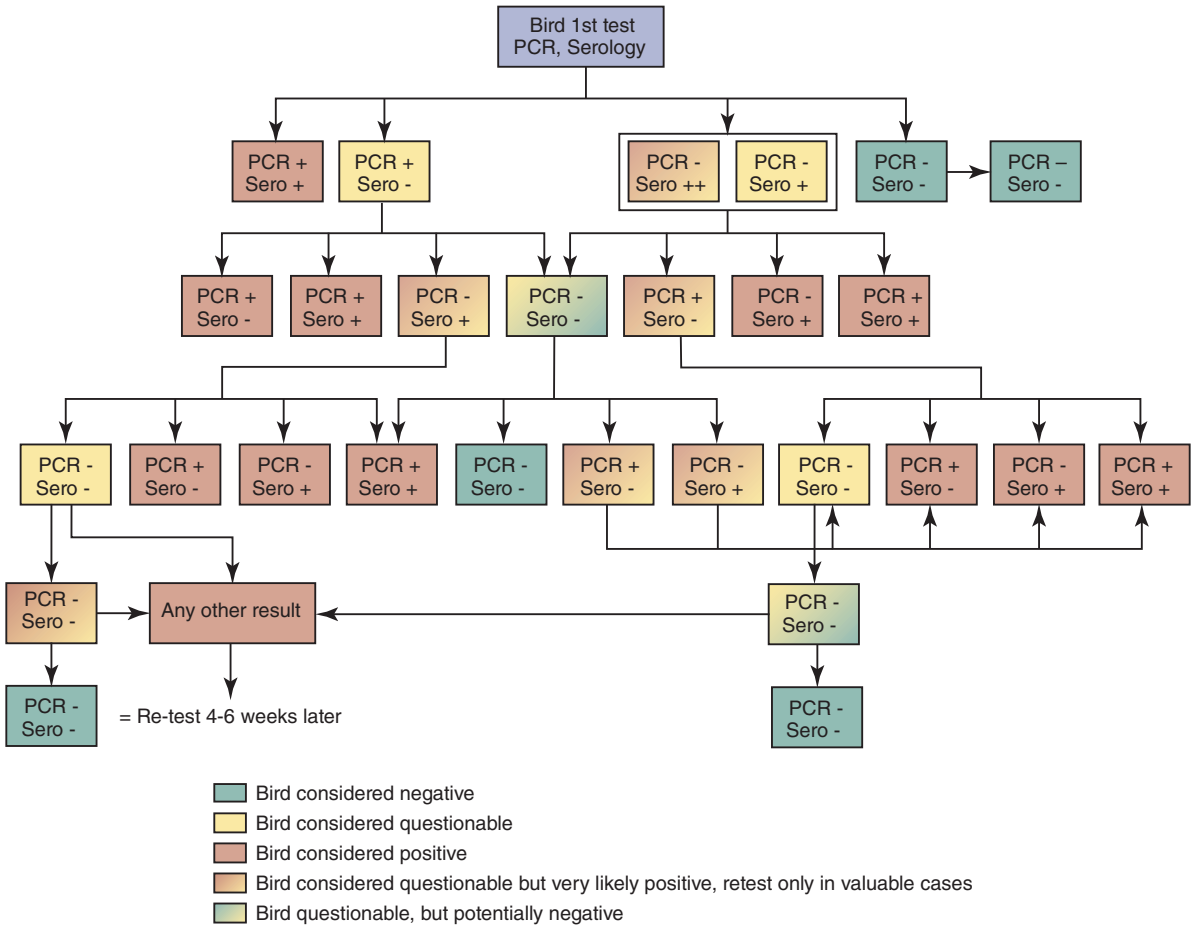

FIGURE 14.2 Suggested interpretation of laboratory test results to categorize birds as positive or negative for avian bornavirus (ABV). Polymerase chain reaction (*PCR*) should be made from a pooled cloacal and crop swabs of each bird, serology with a multiprotein enzyme-linked immunosorbent assay (ELISA) or preferably immunofluorescence test based on ABV persistently infected cell culture. Each *box* represents an individual bird, and so all the potential test results can be seen by following a box through the complete diagnosing process. Each *arrow* represents a retest 4 to 6 weeks apart with combined PCR and serology. Usually, most of the birds tested are assigned to a final result after two (second row) or three tests (third row). Only in very rare cases, more tests are necessary, or the birds should be considered positive. First of all, the individual bird is tested and then assigned a positive, negative, or questionable status. *Red* means that those birds should be taken as positive. *Yellow* indicates that there is a questionable interpretive status and that from those birds all possibilities may arise; hence, a retest is necessary. *Green* birds are negative, but it is advised to have at least two negative tests of one individual bird to ensure negativity. In the circumstance that a bird is considered positive, no retest is necessary. Often in clinical circumstances, a negative bird is considered as such in a single test. In the case where the bird is planned to be sold or integrated into a known negative flock, the test should be repeated, and only with a second negative result is the bird considered negative. In case a bird has a high antibody titer with a negative PCR, it should be considered positive. However, in the case of a bird that is deemed very rare or valuable species or individual, the test may be repeated. These birds are depicted as *red/yellow*. Questionable birds are retested and usually will be assigned positive or potentially negative status. As described previously, only in very rare events birds being positive in one of the tests again may still be considered questionable and tested again. The vast majority of these previously positive cases, when retested, will remain positive. Potentially negative birds with a prior questionable status are tested a third time and are only considered negative if they are found to be negative again, i.e. after having two consecutive negative tests. The odds that from a *red/yellow box* a result other than a positive can occur are very low, according to the experience of this author, but can theoretically happen. −, Negative test result, +, positive test result, ++, high anti-ABV antibody titer. (From Lierz M. Avian bornaviruses and proventricular dilation disease. In: Speer B. L., editor. Current Therapy in Avian Medicine and Surgery. St. Louis, MO: Elsevier, Inc.; 2016. pp. 28–46.)

All birds of the flock need to be tested by PCR and serology. After the first round of tests, three groups will be established according to the diagnostic criteria discussed previously (Figure 14.2). These three groups, of which the first contains the positive birds, the second the questionable birds, and the third the negative birds, need to be kept epidemiologically separated. The assignment of birds to one of these groups should be purely based on the laboratory results, not on the owner's preference or pairing status of the birds. If an owner prefers to not split a pair when one partner is positive and the other negative, then both birds should be placed in the positive group. Owners might also decide to relinquish the positive birds, which can be a difficult task and might only be accomplished by rehoming them to private owners to be kept as pets. Euthanasia of positive birds is sometimes also requested, but this should only be considered in clinically affected birds. Ethically, the euthanasia of PaBV-positive but clinically healthy birds is hard to justify and not recommended. In breeding programs with several partner institutions, it should be considered to have one of the institutes establish a separate breeding flock with positive birds (which are kept strictly isolated from the negative birds), as it is feasible to produce negative offspring from this flock.

The second phase involves retesting of all birds from the questionable and negative groups after 4 to 6 weeks (retesting always implies a combined PCR and serologic test performed simultaneously). Based on the new results, some birds from the questionable group will now have to be regarded as positive for PaBV and will thus be transferred to this group, whereas others are potentially considered negative and will remain in the group of questionable birds, while separated from the others that still have a questionable status (Figure 14.3). In the negative group, some birds might retest positive, necessitating a transfer of these birds to either the positive or the questionable group, whereas others remain negative and can remain in the negative group. Once the negative group reveals negative results for both PCR and serology in all birds from this group on two consecutive test moments performed 4 to 6 weeks apart, the negative group can be considered as clear(ed) from infection. Once birds from the questionable group are tested negative on PCR and serology on two consecutive occasions, without having had contact with birds that had positive results in the meantime, these birds can be transferred to the negative group. Over time, the questionable group will therefore dissolve, as birds will be transferred to either the negative or positive group. Especially in a flock setting, sample contamination or passing of PaBV-RNA originating from other positive birds in the flock is possible. Special care should thus be taken to prevent this, as this may necessitate additional retesting. After all, whenever one or more birds from the questionable or negative groups show up as being positive in one or both tests, the risk remains that virus was transferred from this bird to another individual from the group, therefore warranting retesting of all birds from this group until no further positives are identified on two consecutive tests.

If positive birds are rehomed as pets or positive flocks from different origins are created, it might be worthwhile to investigate which PaBV genotype infected the bird(s), as infection of PaBV-4–positive birds with PaBV-2 has been reported to trigger clinical disease.[36] As stress might trigger the development of clinical disease in PaBV-infected birds, clinical disease may ensue following relocation of positive birds to the new home. This warrants new owners to carefully monitor these birds following arrival so that onset of disease is caught as early as possible.

Further details on flock management, especially in managing positive breeding birds, can be found in the first volume of this book.

THERAPY

To date, there is no proven treatment to control ABV infection in birds. In studies using bornavirus-infected cell lines, ribavirin was able to reduce the viral load and bornavirus activity.[70,71] If the treatment was combined with IFN-α, the observed effect was stronger.[70] Clinically, ribavirin treatment was found ineffective on its own,[72] but the proposed combination of drugs has yet to be evaluated in infected birds. Favipiravir (T-705) showed an effect on orthobornaviruses in vitro,[73] but *in vivo* studies evaluating its effect are also still lacking.

Currently, treatment options focus on the reduction of clinical signs of disease, rather than antiviral treatments. One strategy is to use immunosuppressive drugs to reduce the ABV immune-mediated lesions, while adjusting the dosing regimen based on observed clinical signs during follow-up visits. The other strategy focuses on reducing the inflammatory lesions associated with the disease.

Immunosuppression is accomplished with cyclosporine A, which induces a selective T-cell suppression and has been described as promoting a favorable response in single case reports.[74] Cyclosporine was used at 10 mg/kg per os (PO) BID in combination with a COX-2 inhibitor in birds where the COX-2 inhibitor alone did not show any effectiveness. In those cases where combined immunosuppressive and COX-2 inhibition were used, reduction of clinical signs has been observed in single cases.[62] Nevertheless, (placebo-) controlled studies in infected and clinically ill birds are required to definitively demonstrate its benefits. Moreover, as immunosuppression can potentially increase the susceptibility to other infections, the risks and benefits of such treatments need to be carefully weighed.

To reduce the perigangliar and perineural inflammation, the use of anti-inflammatory drugs has been advocated. Meloxicam is widely used with variable success in dosages ranging from 0.5 to 1 mg/kg intramuscularly (IM) or PO BID or SID. In one study, meloxicam was administered in a dose of 0.5 mg/kg PO BID to cockatiels challenged experimentally with PaBV-4. Surprisingly, challenged birds that received the drug showed more severe clinical signs and higher incidence of death compared to birds that were only challenged or only received the drug.[75] However, based on more recent insights, the dose that was given could have been too low to exert an effect. Alternatively, the frequency of handling of the birds from these groups was different, which may have negatively influenced the results, as stress is suggested to influence the onset of clinical disease. A recent study investigated the effect of meloxicam (1.0 mg/kg PO q24h) and celecoxib (10 mg/kg PO q24h) on the clinical outcome of PaBV-2 experimentally infected cockatiels. Treatment with either drug was started

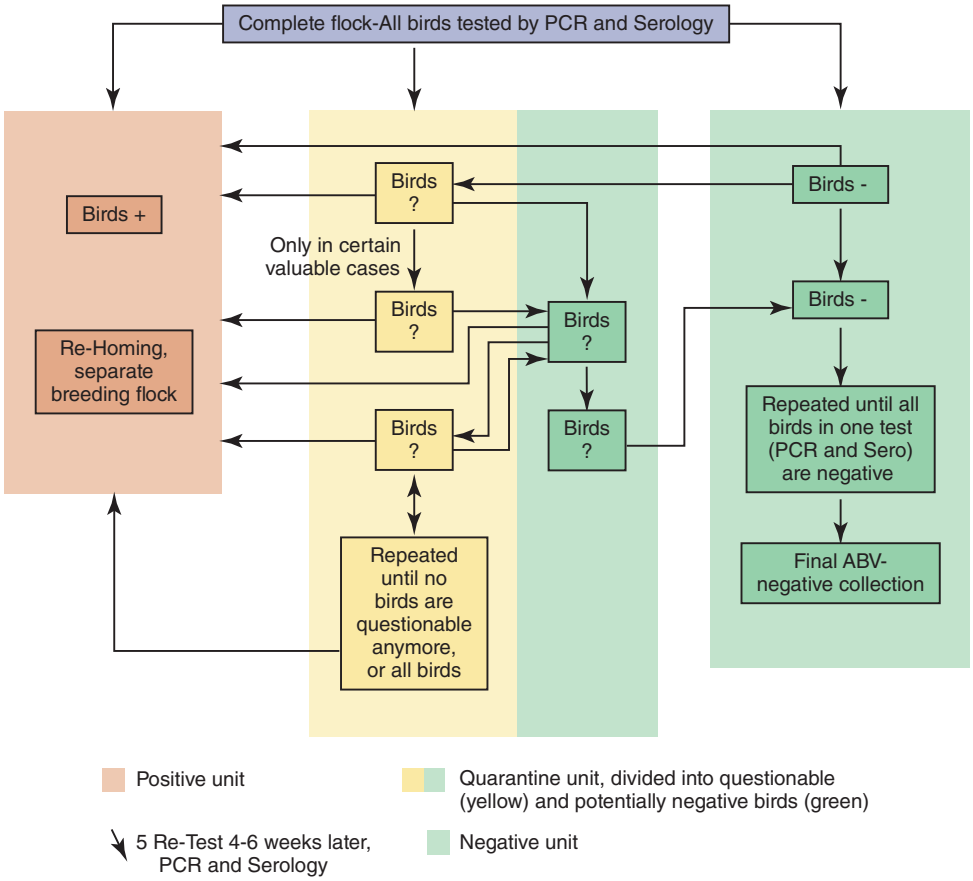

FIGURE 14.3 Suggested diagnostic plan to clear a flock from avian bornavirus (ABV) infection. The *large box* represents the epidemiologic units (populations), which should be clearly separated and treated as independent populations. The *smaller boxes* represent the group of birds that demonstrated the same results (positive, questionable, negative). Each *arrow* represents a retest 4 to 6 weeks later of all birds in that group at the same time. It is important that all birds within these groups are sampled on the same day and that polymerase chain reaction (*PCR*) and serology are performed always performed simultaneously on an individual bird. First, the complete flock is tested, and three major groups are established (positive, questionable, and negative). A retest 4 to 6 weeks later places additional birds from the negative group into the positive and questionable groups and from the questionable group to the positive group and establishes a potentially negative group within the quarantine section. The negative group is only ultimately considered ABV negative if all birds in that group are tested at the same time and are found to be negative in two consecutive tests. Questionable birds within the questionable groups are only placed in the negative group after two negative testing rounds while housed separately within the isolation area from the others after their first negative test result. Birds that are retested as questionable (very rare; see Figure 14.2) should be considered positive for the purpose of clearing a flock of ABV; however, in very rare or valuable species, the risk might be taken to keep them in quarantine in the questionable group. However, should those birds test questionable again, they should definitely be considered positive. The isolated population is tested until all the birds are assigned to one of the other groups (positive or negative) or the owner decides that the remaining birds should not be retested, and at that time, all remaining birds in isolation will be assigned to the positive group. Once a bird is assigned to the positive group, it will remain there. Reprinted from: Lierz M. Avian bornaviruses and proventricular dilation disease. In: Speer B. L., editor. Current Therapy in Avian Medicine and Surgery. St. Louis, MO: Elsevier, Inc.; 2016. pp. 28–46.

23 days postinfection; however, no differences were detected between the two treatment groups or the untreated infected control group in the clinical outcome or histopathological lesions.[76] As a result, the beneficial effects of anti-inflammatory drugs have not been definitively proven.

At present, the use of the selective COX-2 inhibitor celecoxib remains the treatment of choice for birds with PaBV-induced clinical signs. In the past, dosages of 10 mg/kg orally SID for 6 to 12 weeks were recommended.[77,78] Based on anecdotal reports from varying practitioners, the current

recommended dosage is 13 to 30 mg/kg PO BID for several weeks. If severe CNS signs occur, the use of higher dosages (up to 30–40 mg/kg PO BID) has been suggested.[79] Before the discovery of ABV tepoxalin, a combined COX-1, COX-2, and 5-lipoxygenase (LOX) inhibitor was experimentally used to treat PDD-related signs.[78] A treatment effect was seen only by administering 40 mg/kg and placing the birds on a rice-based hypoallergenic diet. In the same dose on a seed diet, no treatment effects were seen,[80] hence making its efficacy in PDD cases questionable.[80] The use of robenacoxib, another COX-2 inhibitor, has also been reported in the treatment of birds with PaBV-related clinical signs at dosages from 2 to 10 mg/kg IM weekly for 4 weeks and then monthly.[62,79] In many cases, treatment will be pursued for several months, whereby cessation of treatment is regularly suggested to lead to recurrence of clinical signs, necessitating treatment to be resumed either sooner or later. Bird owners should therefore be informed that these treatments do not cure the bird, but rather serve to help increase their lifespan.

A novel, yet interesting, approach includes the use of gabapentin, a gamma-aminobutyric acid agonist, which is commonly used to relieve neuropathic pain. In the author's experience, the drug has had excellent effects in birds with chronic pain or chronic, neurologic lameness, especially in cases where other drugs for pain management such as nonsteroidal anti-inflammatory drugs (NSAIDs) have not been successful. For birds with PaBV-related CNS signs, including seizures and ataxia, dosages of 10 to 25 mg/kg PO BID have been recommended,[62] whereas dosages of up to 50 mg/kg PO have been recommended in cases that demonstrate self-mutilation.[79]

VACCINATION

Efforts to produce an effective vaccine against orthobornavirus infections have been made, with the primary aim to protect birds from clinical disease. Some vaccination trials were performed with recombinant live viruses. Newcastle disease virus (NDV) and modified vaccinia virus Ankara (MVA) were produced to express PaBV-4 phosphoprotein (P) and nucleoprotein (N), respectively.[81] Cockatiels were subsequently vaccinated with the mixture of NDV-PaBV-4/P and NDV-PaBV-4-N strain and boosted with MVA-PaBV-4/P and MVA-PaBV-4/N virus at day 21 or at day 14 and 29. The obtained results demonstrated that the NDV-virus replicated in the cockatiels and caused a self-limiting infection. The first anti-PaBV antibodies were detected between 28 to 42 days postvaccination, and titers did not increase further after the second vaccine booster. Challenge with a PaBV-4 isolate demonstrated both a reduced shedding of PaBV-RNA and a reduced viral load in investigated tissues in the vaccinated group compared to the challenged, nonvaccinated control group.[81] However, birds of the vaccinated groups still developed clinical signs of PDD. In another group of six cockatiels, which were vaccinated using the same protocol but challenged with a heterologous PaBV-2 at a lower infection titer, only one bird developed a PDD-typical inflammatory response, whereas viral load in different tissues could only be demonstrated in two birds.[82] It remains unclear why partial protection was seen upon heterologous challenge with PaBV-2 but not following challenge with homologous PaBV-4 virus. However, as the minimal infectious doses of PaBV and the route of transmission at the time of this study were unknown, interpretation of the results remains difficult as both factors may have had a huge influence on the results of the study. A vaccine study with similar study design was performed in canaries, using NDV and MVA viruses expressing CnBV-2 phosphoprotein or nucleoprotein and challenging the birds with a CnBV-2 strain postvaccination. Here, viral challenge was repeated after 12 weeks, as the first challenge did not lead to infection. Subsequent findings demonstrated a significant reduction in shedding of CnBV-2-RNA, but virus distribution was demonstrated in all tissues of the birds. All canaries seroconverted and titers stayed high, indicating persistent infection.[81] A different study using different recombinant viruses carrying PaBV showed that cockatiels that were challenged with PaBV-2 following vaccination and two boosters with NDV-PaBV-4 or Orf virus constructs (ORFV-PaBV-4) were not protected and became permanently infected with PaBV-2. Cockatiels vaccinated and boostered twice with MVA-PaBV-4, in contrast, showed protection when challenged with PaBV-2, with only one bird developing a latent infection of PaBV-2.[83] Challenge with PaBV-4 virus was not investigated in this study. In another study, inactivated PaBV-2 was used as a vaccine. Even after two booster vaccinations with this vaccine, birds did not seroconvert. However, they did seroconvert following an additional booster with a recombinant PaBV-4 nucleoprotein, with 7 out of 9 cockatiels producing PaBV-specific antibodies. A second group was vaccinated twice with the recombinant PaBV-4 nucleoprotein. All birds were subsequently challenged with a PaBV-2 isolate. In all groups, PaBV-RNA shedding as well as a persistent infection in various tissues were observed. Similarly, pathological lesions typical for PDD were observed in some of vaccinated birds from either group, but to a much lesser extent than in the controls. Vaccination trials have also been performed with birds already infected with PaBV. While vaccination of these birds did not induce clinical signs during the follow-up period, it also did not reduce the virus load in tissues, hence indicating that the used vaccination protocols are unsuccessful in clearing the infection.[55]

To date, a reliable vaccination protocol has yet to be established. Recombinant vaccines appear to offer the best protection against heterologous challenge. However, many questions still need to be answered, such as protection against homologous challenge or against other PaBV types. It also remains unclear how long this partial protection lasts, or whether latent infection in vaccinated birds will develop into clinical disease at a later stage. Vaccination of already infected birds did not result in clearance of the infection in any of the cited studies. Although in the future, vaccination protocols might offer (partial) protection against clinical disease, uncertainties remain whether a sterile immunity against PaBV can be reached. If carrier birds remain after vaccination, vaccination strategies cannot be recommended as the mainstay of PaBV control. In addition, flock management strategies, which include the use of serology paired with PCR to detect carrier birds, may be complicated by vaccine-induced seroconversion. Especially in the light of the novel knowledge about transmission routes, the best option to control the virus globally is to sanitize flocks from the infection. Vaccination, inducing titers, but leaving carriers, may interfere with this important strategy.

TAKE-HOME MESSAGE AND OUTLOOK

In recent years, large steps have been taken to further our understanding of ABV infection in birds, including its transmission and factors influencing the clinical manifestations of disease. It is becoming increasingly obvious that understanding the details of viral transmission offers a large window of opportunities to help control the virus within flocks, which will subsequently lead to a reduction of clinical cases seen in practice. As the virus is not readily transmitted horizontally between birds, separation and repeated testing of birds from a flock provides good opportunities to establish and maintain orthobornavirus-free collections. Transmission and time point of infection may also be key to understanding which circumstances lead to development of clinical disease. While further clarification is needed, there is strong evidence to indicate that birds infected later on in life (through horizontal transmission) are more prone to develop clinical disease, whereas birds infected early on in life (through vertical transmission) seemingly develop into carriers. These findings also disprove the theory that infected yet clinically healthy birds are genetically resistant to develop clinical disease and should therefore be selected for breeding. In the absence of proof of heritability of clinical resistance against infection, and in light of the results regarding vertical transmission, infected yet clinically healthy birds are more likely to produce carriers due to vertical transmission. Thus preventing infection is still the best prophylaxis from clinical disease. This is important, as there is still no proven effective therapy. In future, novel vaccination strategies might lead to effective immunity and will then represent another option to control infections. Until then, if no effective vaccination strategies are in place, flock management and retesting birds remains the best way of controlling the virus (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Carrier birds need to be identified and separated. Similarly, breeding circumstances need to be critically evaluated in relation to the potential for vertical transmission as this may allow to produce negative offspring from positive parents. This seems to be especially important for species conservation projects where the number of breeding birds is limited. In addition, there should be a close monitoring of viral occurrence and tracking of bird movements and releases into the wild. Although prevalence of ABVs in the wild is seemingly low, there is a risk of introducing novel strains into a naïve population, which can have a severe negative impact on species conservation and should therefore be avoided at all costs.

CHAPTER 15

Poxvirus

Patricia S. Wakenell • Yuko Sato

Visit eBooks.Health.Elsevier.com for a complete set of references.

Avian poxvirus is a group of large, relatively stable, double-stranded DNA virus strains that include fowlpox, pigeon pox, canarypox, and other poxviruses of birds. All of the strains are in the genus *Avipoxvirus*, subfamily Chordopoxvirinae. Strains are somewhat species-specific but can occasionally affect other bird species. One strain may not cross-protect with another. Poxviruses are "old" viruses recognized more than a century ago and are known to affect more than 232 species of birds worldwide.[1] However, new isolates/species/strains are frequently reported (Table 15.1). Poxviruses can be particularly devastating to endangered species.[2] Vaccines are available for some of the strains and/or avian species affected.

AVIPOXVIRUS FAMILY

Fowlpox virus is the type strain for the avian poxvirus family. Basic morphology for all strains is a large brick-shaped virus. Historically, 10 separate species have been recognized using restriction fragment length polymorphism (RFLP) analysis of DNA. These include fowlpox virus, canarypox virus, juncopox virus, mynah pox virus, psittacine pox virus, sparrowpox virus, starlingpox virus, pigeon pox virus, turkeypox virus, and quailpox virus (International Committee on Taxonomy of Viruses). Both fowlpox virus and canarypox virus have been completely sequenced.[8,9] The avian poxvirus family recently has been phylogenetically separated into different clades.[2,10,11] The relationships among species are determined using the P4b core protein–coding region and the DNA polymerase gene.[2,12,13] Fowlpox virus, canarypox virus, and poxviruses from psittacine birds form the three major clades, with most of the avipoxvirus species showing relatedness to one or the others. Poxvirus is not a public health concern, with only one mammalian isolation of fowlpox virus being reported, found in a rhinoceros.[14]

EPIDEMIOLOGY AND TRANSMISSION

Clinical infection is most frequently observed in warm regions. Fowlpox infection is transmitted horizontally through mechanical transmission of the virus through injury or breach of the skin. The primary vectors are insects, specifically mosquitos. Other insects including chicken mites *(Dermanyssus gallinae)* and 11 different species of Diptera have also been reported to be mechanical vectors.[15] There is no evidence that the virus replicates within the vector.[16] Aerosolized dried scabs and dander can infect via the respiratory route. Viral movement within a flock is aided by cannibalism of lesions on other birds or via aerosol generated by feathers and dried scabs containing the virus.

The virus, once entering the epithelium, replicates within the cytoplasm and varies greatly in duration. Electron microscopic evidence suggests that pH-independent fusion with the plasma membrane is the primary route of virus entry into the cell. The virion protein and lipid are lost, followed by exposure of the genome to DNase, allowing almost immediate synthesis of virus-specific transcripts, which are approximately 50% homologous to the host genome upon entry into the cell. Poxvirus replication is independent of the host nucleus within the viroplasm. Manufactured viruses are then disseminated by either migrating to the cell surface and exiting via microvilli, transported by the Golgi apparatus, and released via vacuoles or independently, or attached with the proteinaceous inclusion body.[16] Upon the formation of virus copies, massive migration of inflammatory cells into the cell cytoplasm results in formation of vesicles and/or diphtheritic membranes on mucous membrane surfaces. Once the diphtheritic membrane is removed, a hemorrhagic surface remains, later forming a scar.[15]

CLINICAL SIGNS AND GROSS EXAMINATION FINDINGS

Infection of the skin (dry pox) is the most common clinical presentation, and it has a variable mortality dependent both upon the strain of poxvirus and the species of bird infected. Morbidity rate is highly variable (10%–95%). For example, the dry form of fowlpox infection in gallinaceous birds such as chickens *(Gallus gallus domesticus)* and turkeys *(Meleagris gallopavo)* is usually associated with a low mortality (1%–5% without secondary infections) and turkeys is usually associated with a low mortality (1%–5% without secondary infections); however, wet pox infection in the same birds can result in up to 50% to 60% mortality in unvaccinated flocks.[17] Infection tends to be more severe in psittacine birds, and in passerines such as canaries *(Serinus canaria)*, with canarypox infection approaching 100% mortality. Infection of mucous membranes of the mouth, esophagus, and trachea (wet pox) can have a high mortality due to asphyxiation. Canary pox infections, and co-infections with disease agents such

[a]Denotes new species/strains isolated in the last decade. References listed with location where the new species/strain identification occurred. Adapted from Bolte AL, Meurer J, Kaleta EF: Avian host spectrum of avipoxviruses, *Avian Pathol* 28(5):415–432, 1999. doi: https://doi.org/10.1080/03079459994434.[7]

FIGURE 15.1 Canarypox virus infection in a canary *(Serinus canaria)*. In canaries, systemic poxvirus infection has been associated with mortality rates approaching 100%.

FIGURE 15.2 Dry poxvirus lesion on the leg of a chicken *(Gallus gallus domesticus)*. Cutaneous, wartlike lesions most commonly develop on the nonfeathered parts of the skin.

FIGURE 15.3 Wet pox lesions in the oral cavity of a chicken *(Gallus gallus domesticus)*.

as psittacine pox and Psittacid alphaherpesvirus 1 (PsHV-1; see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease), can result in systemic poxvirus infection[18] (Figure 15.1). Intravenously infected chickens have lesions in the epithelial cells of the kidney and thymus.[19] Lesions can persist for 4 weeks or more. In birds of prey, storks (Ciconiidae), cranes (Gruidae), and other wild birds, infection of the legs, feet, and surrounding the eye is often fatal due to both starvation and predation. Chronic infection in layers and turkeys can result in weight loss and a drop in production. The incubation period ranges between 4 (canaries with canarypox) and 10 (turkeys with turkeypox) days.[15]

The most common gross lesions with dry pox are pustules and papules on the epidermis and underlying feather follicles with white to yellow exudates and epithelial hyperplasia of the nonfeathered skin[20] (Figure 15.2). Initially the lesions consist of small white focal nodules that then begin to coalesce and become purulent. Papules start forming after day 5 to 6, which turn into vesicles. After 1 to 2 weeks, lesions generally become hemorrhagic eventually leading to erosions when the scabs fall off. In the wet form, yellow to opaque white diphtheritic lesions form in the oral mucosa, esophagus, and trachea and coalescence of lesions can block the airway (Figure 15.3). The lesion may extend into the sinus, pharynx, and larynx (leading to asphyxiation) and the esophagus (leading to dysphagia). Removal of lesions leads to bleeding erosions.[21] It is possible to find both the dry and wet forms in the same bird. The fowlpox

FIGURE 15.4 Poxvirus affecting the right eye in a blue-fronted Amazon parrot *(Amazona aestiva)*.

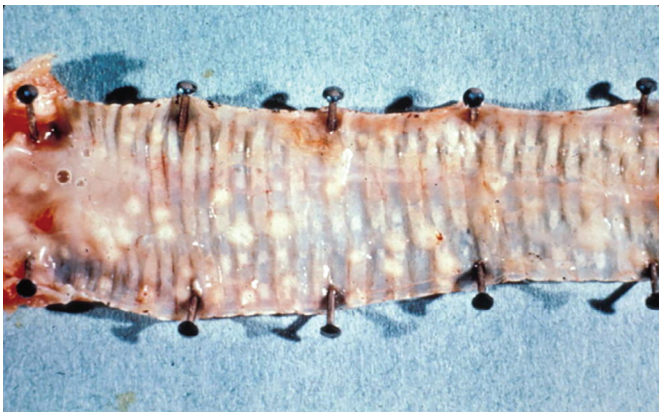

FIGURE 15.6 Wet pox pustules in the trachea of a chicken *(Gallus gallus domesticus)*.

genome carries a gene similar to epidermal growth factor, which may be responsible for cellular hyperplasia.[15] For canaries with canarypox[22] and blue-fronted Amazon parrots *(Amazona aestiva)* with psittacine pox, nodules on the eyelids can lead to loss of the eye and blindness (Figure 15.4). With systemic pox, firm white nodules can be observed in the viscera.[23]

DIAGNOSIS

Gross lesions alone are sometimes enough for diagnosis, although histopathologic examination is beneficial in making a definitive diagnosis. Severe hyperplasia of the epithelium with ballooning degeneration is the classic microscopic lesion in all forms of avian pox. With turkeypox, inclusion bodies may be uncommon and not readily observed. Inclusion bodies can become so large that they cause cellular degeneration. Viral inclusions recognized on histopathology are large eosinophilic intracytoplasmic inclusion bodies (Bollinger bodies) containing small viral particles (Borrell bodies; Figure 15.5). The inclusion bodies can be observed 72 to 96 hours after infection of the epithelial cells, and exit of the virus particles from cells is through budding.[24,25] Lesions in the tracheal and laryngeal mucosa are characterized by proliferative hypertrophy and ballooning degeneration of epithelial cells containing intracytoplasmic inclusion bodies. The lesions resemble papillomas and can range from partial to full obstruction of the tracheal lumen (Figure 15.6). There is hyperplasia and hypertrophy of goblet cells.[26]

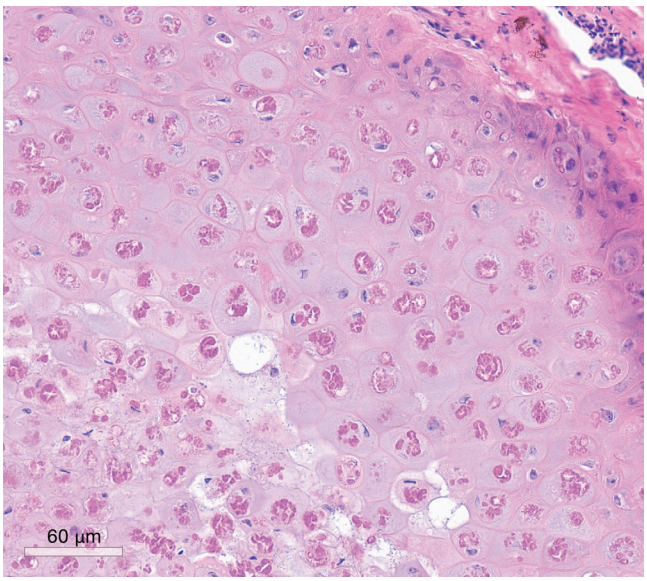

FIGURE 15.5 Large eosinohili intracytoplasmic pox inclusion bodies in the epithelium of a chicken.

Field strains of fowlpox virus often contain nearly intact provirus copies of reticuloendotheliosis virus (REV).[27] This can be used to help distinguish between vaccine strains and field strains. Traditionally, isolation of poxviruses has been in 10- to 12-day-old embryonated chicken eggs via chorioallantoic membrane (CAM) injection. Visualization of "pocks" on the CAM 7 days later is indicative of pox infection.[15] CAM injection does not identify strains of poxviruses. Cell cultures of avian origin can also be used, but most mammalian cell cultures are refractive to infection. Fowlpox is a very stable virus and can last in dried scabs and skin cells for years. Fowlpox viruses can also be propagated in cell cultures of avian origin including chicken embryo fibroblasts and kidney cells. A permanent cell line, QT35 of Japanese quail *(Coturnix japonica)* origin, and a chicken liver cell line LMH, can also support the growth of some avian poxviruses after adaptation.[15]

For practical purposes, diagnosis is usually based on clinical presentation, with histopathology and observation of inclusion bodies being confirmatory.[28] Cytology of lesions in wild turkeys has been reported to have a 90% specificity and sensitivity when compared to polymerase chain reaction (PCR).[29] Although cell-mediated immunity is the most important, antibodies are elicited and can be measured by ELISA (enzyme-linked immunosorbent assay) and used to monitor vaccine immunity.[30] Neither of these will identify the strain of the virus. Historically, strain identification required cross-protection assays, which are labor intensive and cost prohibitive. Immunoblotting can differentiate some strains but not all due to the number of shared antigens.[31] The most economical choice is strain identification by RFLP and restriction endonuclease analysis. On RFLP, different strains of pox can be like the standard fowlpox virus. However, strains can be further separated with restriction endonuclease analysis. Fowlpox virus strains are highly related but distinct from canary, mynah, quail, and Hawaiian poxvirus strains. It has been suggested

that the number of ankyrin repeat genes is associated with the host range.[15] Mixed infections of fowlpox and infectious laryngotracheitis virus are common in commercial layers and can be distinguished by PCR. P4b is a highly conserved protein and has been used to distinguish strains by PCR.[32] PCR is mainly used to distinguish between vaccine and field strains by looking for REV provirus in field strains versus LTRs (long terminal repeats) in vaccine strains.[28]

Differentials for fowlpox infection depend largely on the type of manifestation. For cutaneous pox, gross lesions may include rule-outs such as skin scabs from trauma, avian ringworm, ectoparasites such as lice and mites, bacterial dermatitis, and papillomavirus infections. Observations of skin scabs and scrapings through microscopy or histopathology can be utilized for diagnosis. If infections are at a flock level, cutaneous lesions may also appear similar to pantothenic acid deficiency, biotin deficiency, and fungal infections such as T-2 (trichothecene) toxicity. Feed analysis may be warranted if there is a wide-spread problem within a flock, especially in young chicks. Differentials for wet pox include trichomoniasis (canker/frounce; see Chapter 22), oral candidiasis and other fungal infections such as aspergillosis (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease), hypovitaminosis A, capillariasis, and most commonly in chickens, infectious laryngotracheitis (ILT) virus infection.[33] Especially in commercial chickens, histopathologic diagnosis of fowlpox and ILT is a simple and quick procedure, and these diseases must be distinguished in order to employ proper management strategies, including vaccination.

TREATMENT

There is no treatment for pox infections other than supportive care. Isolation of birds to prevent pecking/cannibalism is recommended. Supportive care in pet birds may include fluids, oxygen supplementation, parenteral vitamin A, ointments for eye infections, assisted feedings, and antibiotics to treat secondary infections.[35]

Skin lesions can be kept clean daily with mild detergents, diluted iodine, or soaps being careful to avoid the eyes. In the wet form, oral iodine in the water can be used at a flock level to dehydrate the proliferative epithelial lesions in order to avoid asphyxiation or anorexia, depending on location. For individual or small numbers of anorexic birds, such as backyard chickens, a two times dilution of powdered dry milk will help with hydration and protein.

Birds should not be returned to the flock until completely healed, which may take up to several weeks. Severely infected birds with poor quality of life should be removed and humanely euthanized.

PREVENTION AND CONTROL

Vaccination is the primary method of control in those species where the vaccine is well tolerated. There is limited attenuation of the two primary pox vaccines, Fowlpox and Pigeonpox. Vaccination in the wing web or the drumstick (turkeys) places the virus in areas that are usually not infected, thus reducing any pathogenic effects of the vaccine. However, some exotic species can have significant reactions to the vaccine viruses and caution is recommended. Both Fowlpox and Pigeonpox vaccines are usually freeze-dried, and often used in combination to achieve more cross-protection. Combining vaccines can lead to over dilution of each vaccine; therefore, each vial needs to be reconstituted using only half of the diluent before mixing the two together. Care needs to be taken to avoid contamination of parts of the bird other than the site of vaccination. Vaccination of laying hens is not recommended. In endemic areas, vaccination may need to be done yearly. Fowlpox vaccine cannot be used for pigeons *(Columba livia)* and Pigeonpox vaccine can cause severe reactions if not used properly. All canaries raised in large numbers should be vaccinated with Canarypox vaccine every 6 to 12 months and prior to lay. Quailpox and turkeypox vaccines were historically available commercially. Autogenous vaccines may be needed for strains other than fowlpox, pigeon pox, and canarypox viruses. Several recombinant vaccines using fowlpox as a vector are available for commercial poultry. However, these are not recommended for small flocks or exotic birds (see also Chapter 13).

Currently available commercial vaccines do not 100% protect against poxvirus infections particularly if the field strain is not contained in the vaccine. Flocks with high density and multiple ages are at greatest risk of ongoing infections despite vaccination.

In commercial poultry, vaccination in the face of an outbreak is utilized to reduce mortality in cases where the flock is naïve to infection or vaccine failure is suspected. Due to the viral immunity being predominantly cell mediated, the infection spreads slower in large flocks, and thus timely vaccination may help protect a susceptible population. In wet pox infections, low-dose oral iodine may be used in waterlines to dehydrate diphtheritic lesions to increase the chance of survival and to prevent secondary bacterial infections.[34]

Pest control for mosquitos and other insect vectors is crucial. An integrated pest control program and good biosecurity practices to reduce other mechanical vectors (e.g., crews/personnel used for vaccination, transfers, etc.) from spreading the virus are recommended (see Chapter 11). In addition, controlling cannibalism with proper beak trimming and reducing environmental stimuli (e.g., high intensity lights, high stocking density, poor sanitation) along with effective cleaning and disinfection using common household disinfectants (e.g., 10% bleach and water) is warranted to prevent future infections (see Chapter 12).

SUMMARY

Avian pox is a disease caused by many divergent strains. The predominant groups, or clades, are fowlpox, canarypox, and poxviruses from Psittaciformes. All the avian poxviruses cause similar lesions in cutaneous and mucosal tissues. Lesions confined to the skin are the "dry" form and lesions in the mucosa and/or internal organs are the "wet" form. Mosquitos and other insects are the primary mechanical vectors from flock to flock and pecking within a flock. There is no treatment, and vaccination is recommended for poultry in endemic areas and canaries and pigeons in large flocks.

CHAPTER 16

West Nile Virus and Other Flaviviruses

Dominik Fischer • *Ute Ziegler*

Visit eBooks.Health.Elsevier.com for a complete set of references.

The family Flaviviridae consists of four genera—*Flavivirus*, *Pestivirus*, *Hepacivirus*, and *Pegivirus*—with more than 70 small, enveloped viruses, composed of spherical virions with a diameter of 40 to 60 nm and positive-sense RNA genomes of approximately 9.0 to 13 kb.[1] While the genera *Pestivirus*, *Hepacivirus*, and *Pegivirus* are usually restricted to mammalian hosts, several members of the genus *Flavivirus* may act as pathogens in birds and other vertebrates.[1]

GENUS *FLAVIVIRUS*

The genus *Flavivirus* includes more than 50 arthropod-borne viruses (arboviruses), with distinct groups infecting mosquitoes or ticks.[1,2] These viruses are amplified and transmitted via their arthropod vectors following consumption of a vertebrate host's blood and are usually maintained in an enzootic cycle between vertebrates and arthropods (dual-host viruses; Figure 16.1). Viruses are transmitted horizontally by mosquito or tick bites to vertebrates. Viral transmission takes place when an infected arthropod takes a blood meal from a naïve animal host and injects the virus during this process.[2] Inside the vertebrate host, the virus starts its amplification process, replicating itself at large quantities within the bloodstream (viremia) to enable transmission to further hosts via the biologic arthropod vector. The transmission of flaviviruses is generally influenced by environmental factors, as these influence the population dynamics of the biological vectors, the extrinsic incubation period (time it takes for the virus to develop inside the vector from the point of ingestion via the blood meal to the point when the arthropod becomes infectious), and the population densities of the amplifying hosts. In this regard, warmer weather conditions are usually advantageous for host and vectors as seen in Europe in the unusually hot summer of 2018.[3] The extremely long period of high temperatures over months may have provided conditions for the incursion and establishment of flavivirus infections, such as West Nile virus (WNV) and the Usutu virus (USUV), into new areas and countries. The availability of artificial light during nighttime has been demonstrated to additionally extend the infectious-to-vector period of avian reservoir hosts of WNV in urban regions and contributes to prolonged maintenance of transmissible viral titers.[4,5]

Depending on the virus, some incidental host species are "dead-end hosts" as the viral load does not reach sufficient levels to allow the virus to be transmitted back to the arthropod; however, many avian species are regarded as competent amplifying hosts and various flaviviruses are important epornitic (capable of causing epizootics in birds) pathogens in free-ranging and companion birds as well as in domestic poultry (Table 16.1).[2,3] Around 40 flavivirus species are known

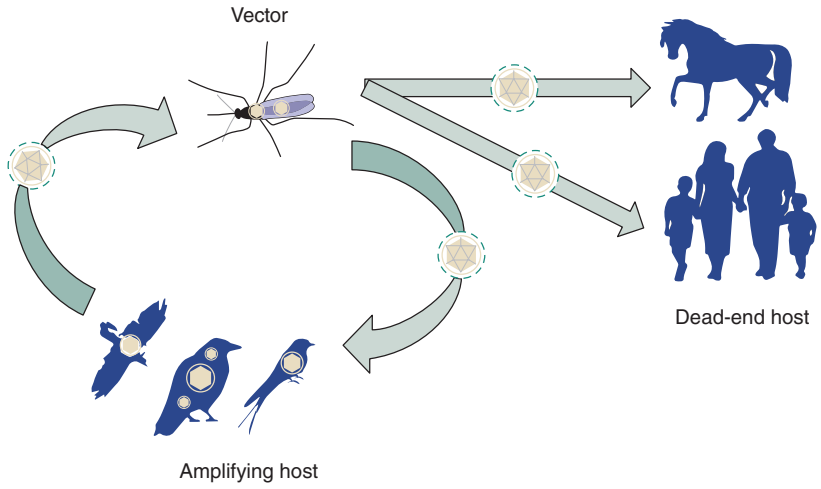

FIGURE 16.1 Transmission cycle of flaviviruses using mosquito-borne West Nile virus as an example.

TABLE 16.1

Flaviviruses Isolated From Avian Species

Virus Type	Virus Name	Abbreviation	Avian Hosts
mbfv	Alfuy virus	ALFV	Cuculiformes (Pheasant coucal *[Centropus phasianinus]*)
mbfv, nvc	Bagaza virus (together with ITV summarized as avian meningoencephalomyelitis virus [AMEV])	BAGV	Phasianidae (partridges, pheasants)
mbfv, nvc	Baiyangdian virus (subtype of TMUV)	BYDV	Anseriformes
mbfv, jevc	Cacipacore virus	CPCV	
mbfv, nvc	Duck egg drop syndrome virus (subtype of TMUV)	DEDSV	Anseriformes

to be able to infect humans (zoonotic potential) and nonavian vertebrates. Recent prognoses predict an increase and spread of zoonotic flaviviruses into wildlife avian hosts parallel to an increase of potential biological vectors associated to climate change and increase in global temperatures.[6] This already corresponds to the increase and the expansion of geographic distribution of emerging flaviviruses in the last two decades, as seen for Tembusu virus (TMUV) in China, USUV and Bagaza virus (BAGV) in Europe, and WNV in the Americas and Eurasia.[2,4] New flaviviruses are discovered regularly, and accordingly the taxonomy of this genus changes frequently.[1] Hence, the impact and the pathological role of many "new" flaviviruses in avian species are currently unknown. Likewise, the role of birds as vectors and as wildlife reservoirs of these recently discovered flaviviruses is not elucidated, and thus the relevance of birds during the spread of various zoonotic flaviviruses is poorly understood. In the absence of specific studies, there is a need to extrapolate and transfer knowledge from well-known and extensively studied flaviviruses such as WNV and USUV to other flaviviruses, even though mistakes are possible following this strategy.

WEST NILE VIRUS AND USUTU VIRUS

WNV is regarded as the most widespread flavivirus with reports from all continents except Antarctica, and with increasing numbers of bird infections in European countries (particularly in South Europe), in the Americas, and in Australasia. Besides WNV, USUV is regarded as most important avian pathogen in the genus *Flavivirus* in Europe.[7–9]

WNV and USUV belong to the Japanese encephalitis virus (JEV) serogroup and share cross-neutralization antibodies with other encephalitis viruses of this group. Both viruses are named after the African place of origin—WNV after the former West Nile District, today's Uganda, and USUV after the Usutu River in Swaziland/Kingdom of Eswatini.[10] These viruses have been spread over long distances to other countries and continents via migration of infected birds and accidental transport of infected arthropod vectors.[11] Additionally, overwintering mechanisms such as hibernation of infected mosquitoes or of chronically infected amphibians have been demonstrated as important factors for the establishment of WNV infections in temperate zones besides a transovarial infection of mosquitoes.[12]

WNV was first isolated in 1937 from the blood of a woman suffering from a febrile illness in Uganda.[12] In avian species, it was isolated in 1953 from the blood of two rock pigeons *(Columba livia)* and one hooded crow *(Corvus cornix)* in Egypt. In Europe, neutralizing antibodies against WNV were first detected in humans from Albania in 1959; however, no viral RNA was detected in these patients.[13] The first WNV outbreak in Europe associated with clinical symptoms and death in humans and horses occurred in the Camargue region in Southern France in 1962/1963.[13] Since the 1990s, epidemics have occurred in several European countries, such as Romania, Russia, France, Italy, and Hungary.[14] Between 1997 and 2000, WNV has been associated with two outbreaks in white storks *(Ciconia ciconia)* and domestic geese *(Anser anser domesticus)* in Israel. In 1999, a closely related WNV isolate was introduced into the United States, with the first WNV outbreak in the city of New York and surrounding areas.[12] Over the next years, WNV spread over the whole American continent, causing neurological disease among humans and horses and epornitics with high mortality (see https://www.cdc.gov/westnile/index.html). Likewise, WNV has spread further throughout Europe during the last two decades, starting from the Mediterranean countries northward.[8,13] Especially in the hot summer of 2018, a large number of WNV cases were observed by the European Centre for Disease Prevention and Control (ECDC) in southeast, south, and central Europe, with a total of 2,083 autochthonous human WNV cases in the European Union (EU) member states and EU neighboring countries (see https://www.ecdc.europa.eu/en/west-nile-virus-infection). This represented a 7.2-fold increase compared to 2017 and was linked to an unusually early start of the WNV transmission season. In 2019, a larger epizootic outbreak occurred in Germany with 76 confirmed cases in free-ranging and zoo birds, 36 confirmed cases in horses as well as 5 clinical cases in humans.[15] There are currently nine lineages known for WNV worldwide, with lineages 1 (clade 1a, clade 1b or Kunjin virus, and clade 1c) being reported in Europe, the United States, Africa, and the Middle East. Lineages 2, 3, and 8 are also reported from Europe.[7] Several mosquito species, mainly ornithophilic species of the *Culex* genus, are involved in WNV transmission. *Culex pipiens* is considered to be the main vector in Europe. Moreover, other genera such as *Aedes*, *Anopheles*, *Culiseta*, *Mansonia*, and *Ochlerotatus* may be involved as biological vectors,[16] and recently, WNV replication has been demonstrated even in tick species. The number of avian species with confirmed WNV infection exceeds 300 and includes Accipitridae (eagles, hawks, Old World vultures), Cathartidae (Cathartid vultures and condors), Falconiformes (falcons), Strigiformes (owls), Psittaciformes, Passeriformes, Corvidae (corvids), Anserinae (geese), Phoenicopteridae (flamingos), Rheidae (rheas), Ciconiidae (storks), and many other birds as summarized previously.[10,17,18] In North America, corvids, great horned owls *(Bubo virginianus)*, American kestrels *(Falco sparverius)*, red-tailed hawks *(Buteo jamaicensis)*, Cooper's hawks *(Accipiter cooperi)*, bald eagles *(Haliaeetus leucocephalus)*, American white pelicans *(Pelecanus erythrorhynchos)*, and eared grebes *(Podiceps nigricollis)* have been affected in large numbers, with the latter two in course of large mortality events.[18] In Europe, most clinical cases have been reported in the Eurasian goshawk *(Accipiter gentilis)*, the sparrow hawk *(Accipiter nisus)*, great gray owls *(Strix nebulosa)*, and snowy owls *(Bubo scandiaca)*, even though various WNV-positive songbirds and different zoo birds were found dead regularly as well.[3,10,15]

USUV was first detected in a *Culex naevei* mosquito (originally described as *C. univittatus*) near the Usutu River, Natal, South Africa, in 1959 (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).[16] A retrospective study in the Tuscany region (Italy) demonstrated the first evidence in Europe dating back to 1996. From Italy, USUV spread to several other European countries.[9,16] The most important outbreak of USUV occurred in 2001 in and around Vienna, Austria, with significant wild bird mortality, primarily in common blackbirds *(Turdus merula)*,[9] but also in different captive birds such as great gray owls. Thereafter, USUV has been demonstrated to circulate in different European countries, including Austria, Italy, Hungary, Switzerland, and Spain (only mosquitoes), leading to the first human infections outside Africa in two immunocompromised patients in Italy in 2009.[16] USUV introduction in Germany in 2011 caused a massive reduction of the local blackbird populations. Today, USUV isolates can be phylogenetically differentiated into eight different lineages: Africa 1 to 3 and Europe 1 to 5, with introduction events from Africa into Europe still ongoing.[4,7]

More than 93 bird species have been listed as susceptible to USUV.[4,10,16] This list contains the following avian orders: Passeriformes, Strigiformes, Accipitriformes, Anseriformes, Caprimulgiformes, Ciconiiformes, Charadriiformes, Columbiformes, Coraciiformes, Falconiformes, Galliformes, Pelecaniformes, Phoenicopteriformes, Piciformes, Psittaciformes, and Rheiformes.[10,16] In the Strigiformes order, highly susceptible species include great gray owl, snowy owl, and northern hawk-owl *(Surnia ulula)*. In the passerine order, highly susceptible species include Eurasian blackbird, song thrush *(Turdus philomelos)*, barn swallow *(Hirundo rustica)*, fieldfare *(Turdus pilaris)*, common starling *(Sturnus vulgaris)*, house sparrow *(Passer domesticus)*, Eurasian bullfinch *(Pyrrhula pyrrhula)*, lesser whitethroat *(Sylvia curruca)*, European pied flycatcher *(Ficedula hypoleuca)*, gray-headed bullfinch *(Pyrrhula erythaca)*, great tit *(Parus major)*, blue tit *(Cyanistes caeruleus)*, domestic canary bird *(Serinus canaria forma domestica)*, golden-breasted starling *(Cosmopsarus regius)*, magpie *(Pica pica)*, carrion crow *(Corvus corone)*, and western jackdaw *(Coloeus monedula)*.

OTHER FLAVIVIRUSES ISOLATED FROM BIRDS

Sea birds may be subclinical hosts of the tick-borne flaviviruses Meaban virus (MEAV), Saumarez Reef virus (SREV), Kadam virus (KADV), and Tyuleniy virus (TYUV) and may contribute to the distribution of infected ticks.

The TMUV, the duck egg drop syndrome virus (DEDSV), and the Baiyangdian virus (BYDV) have been associated with egg drop syndrome, retarded growth, inappetence, and mortality in waterfowl in Asia.[2]

Neurological signs and pathological lesions have been associated with the Israel turkey meningoencephalitis virus (ITV) in turkeys, the BAGV in partridges and pheasants, the Sitiawan virus (SV/STWV) in chickens *(Gallus gallus domesticus)*, the Malaysian duck Tembusu virus (DTMUV, Perak virus) in Peking ducks *(Anas platyrhynchos domesticus)*, the louping ill virus (LIV) in red grouses *(Lagopus lagopus)* as well as with the Ntaya virus (NTAV) in avian species of various bird orders.[2,4] NTAV has been reported to cause additional clinical signs in birds including splenomegaly and hemorrhages in the central nervous system (CNS), liver, lung, and ovaries.

Other flaviviruses have been isolated from bird species with or without clinical manifestation. This applies to the Saint Louis encephalitis virus (SLEV), the Kunjin virus (KUNV), the Yaoundé virus (YAOV), the Koutango virus (KOUV), the Murray Valley encephalitis virus (MVEV), the Alfuy virus (ALFV), the JEV, the Cacipacore virus (CPCV), the Ilheus virus (ILHV), the Rocio virus (ROCV), and the tick-borne encephalitis virus (TBEV).[2,4]

CLINICAL SIGNS IN BIRDS

Clinical signs associated with flaviviruses vary from subclinical infections and mild viral signs to severe neurological and hemorrhagic diseases depending on the virulence of the virus strain and the susceptibility of the host species.[10,17,18] Many birds are subclinically infected by flaviviruses, and therefore the *intra vitam* detection of viral diseases may be challenging. However, severe and fatal clinical diseases are reported in susceptible avian species varying from acute to chronic courses.[19] Especially in immunocompromised and highly susceptible individuals, death may occur without previous clinical signs in the course of flavivirus infection. Acute courses and sudden death are frequently observed in naïve bird populations, as seen during the WNV outbreak in 1999 in New York City.[19,20] There 17 of 27 birds were observed clinically with neurological signs several hours to maximum 6 days prior to death.[19]

Likewise, USUV has been reported with high mortality, especially in blackbirds and other members of the genus *Turdus* (Figure 16.2).[9]

Unspecific signs of flavivirus infection include general signs of illness such as depression, apathy, weakness, reduced stamina, drooping wings, inability to fly, dysphagia, regurgitation, anorexia, weight loss, disorientation, bad posture, and recumbency.[9,18,19,21,22] Especially in USUV-infected wild birds, nutritional status has been reported to be poor, whereas the nutritional status of captive birds was more variable.[9] In large falcons, the shedding of greenish urine/urates has been reported following artificial infection with WNV and associated damage to inner organs.[10,23] In commercial poultry, infections may cause a drop in performance such as reduced egg numbers and quality (egg drop), decreased spermatogenesis and spermatocyte swelling, retarded growth, and weight loss, as demonstrated in ducks and geese associated with TMUV, DEDSV, and BYDV infections and in chickens associated with SV/STWV.[2,4] Additionally, diarrhea has been observed in partridges and pheasants following BAGV infection.[2]

Feather disorders including ruffled feathers, pinching of blood feathers, discoloration, abnormal development or loss of feathers have also been reported as clinical signs of flavivirus infections, especially in birds that survived the acute stage of the WNV- or USUV-associated disease (Figure 16.3; see also Chapter 32).[9,10] This corresponds to a persistence of WNV in feather pulps as demonstrated in gyr-saker *(Falco rusticolus x Falco cherrug)* hybrid falcons.[4]

Most common signs of flavivirus infection are neurological signs such as head tremors, circling, stumbling, staggered movements, ataxia, torticollis, and convulsions (Figure 16.4).[9,10,24] They have been reported in association with ITV in turkeys *(Meleagris gallopavo)*, BAGV in partridges and pheasants, SV/STWV in chickens, DTMUV in Peking ducks, LIV in grouses, as well as with NTAV, USUV, and WNV in various avian species.[4,9] Flamingos and gulls (*Larus* spp.) have been reported with difficulties to hold their heads and wobbly gait, and cormorants swimming in circles in the course of a WNV infection.[19] Leg stretching and impaired mobility were caused in 4- to 6-week-old chickens due to SV/STWV infections.

FIGURE 16.2 Usutu virus is known to cause mortality among songbirds and owls. Mortality is particularly high in common blackbirds *(Turdus merula)*, house sparrows *(Passer domesticus)*, and great gray owls *(Strix nebulosa)*. Prior to death, birds may show general signs of illness, including depression, apathy, weakness, anorexia, drooping of the wings, disorientation (A), and inability to fly (B). (Courtesy Sylvia Urbaniak, Germany)

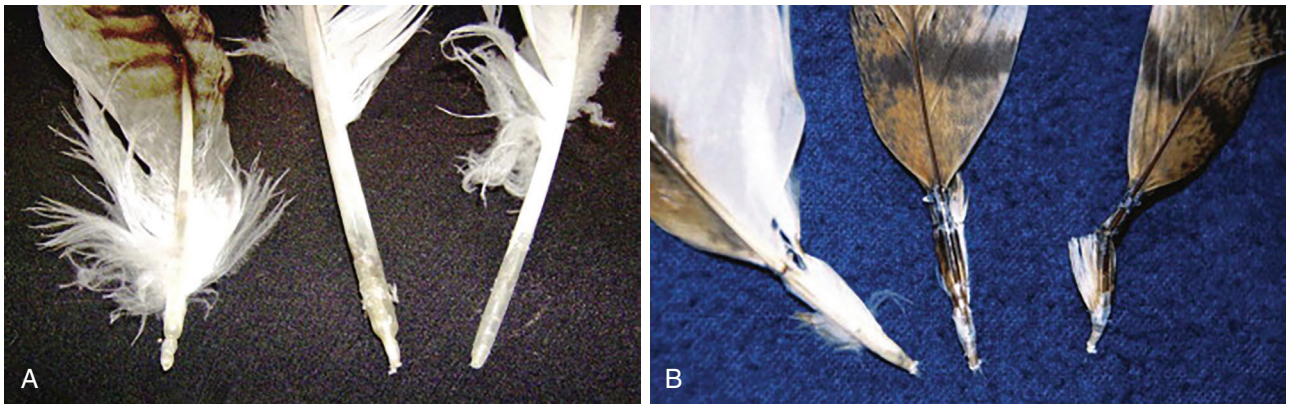

FIGURE 16.3 Feathers with abnormal morphology that molted prematurely from West Nile virus–infected raptors. (A) Red-tailed hawk *(Buteo jamaicensis)*; (B) Barn owl *(Tyto alba)*. (From Miller R, Fowler M, editors: *Fowler's Zoo and Wild Animal Medicine*, Vol 7, St. Louis, 2011, Elsevier.)

FIGURE 16.4 European goshawks *(Accipiter gentilis)* with central neurological signs caused by natural West Nile virus infection. (*Left:* courtesy Georgios Vergatos, Germany; *Right:* courtesy Thomas Schön, Wildvogelhilfe Saalekreis, Germany.)

Additionally, WNV has been associated with anisocoria, nystagmus, difficulties to accommodate, and impaired vision or blindness due to ocular lesions.[9,10,18,19,23,24] These lesions varied from anterior uveitis and fundic disorders such as fibrin adhesions to chorioretinal lesions and retinal atrophy. Vision disorders have also been diagnosed in pheasants and partridges infected with BAGV.[4] Half-closed eyes and nystagmus have been associated with WNV in blackbirds.[9]

CLINICAL SIGNS IN HUMANS AND OTHER VERTEBRATES

Mammals, amphibians (e.g., *Rana ridibunda*), and reptiles (e.g., *Varana salvidorii* and *Alligator mississippiensis*) have been infected by WNV.[25] Infected mammals include more than 30 species of livestock and companion animals such as horses, hamsters, cats, dogs, camelids, and sheep, as well as zoo and wildlife animals such as rodents, rabbits, polar bears, marine mammals, wolves, and skunks.[10,25] These nonavian hosts are usually considered to be dead-end hosts of WNV due to the lower level of viremia. Clinical signs are reported in horses and humans, even though the majority of WNV infections are asymptomatic. In horses, fever is rarely seen, and neurologic signs may develop in 8% of the infected individuals. Neurologic signs may persist throughout life, and up to 44% of the horses with central nervous signs may die in the course of a WNV infection.[10]

USUV-specific antibodies have been detected in the serum of humans and many mammalian species including horses, dogs, wild boar, wild ruminants, bats, squirrels, and rodents, which most likely act as dead-end hosts for USUV with less severe

pathogenicity.[26] Moreover, viable USUV has been isolated from the brain of bats (*Pipistrellus* sp.), as well as from rodent and shrew species. The expanding range of wild animals susceptible to USUV highlights its potential as an important emerging pathogen.

Around one-fifth of the infected humans may develop flu-like symptoms (e.g., fever, malaise, headache, rash, myalgia, sore throat, chills, gastrointestinal, and ocular disorders such as conjunctival congestion, ocular pain due to uveitis, chorioretinitis, vitritis, or optic neuritis) in association to an infection with WNV and several other zoonotic flaviviruses.[10,17] A severe and potentially fatal neuroinvasive disease may occur in less than 1% of WNV-infected people, but in larger numbers after JEV infection. In comparison, USUV was considered to have a low zoonotic potential because the number of human infections is comparably low. In Europe, the first USUV disease with clinical symptoms similar to WNV was detected in 2009 in Italy in two immunocompromised elderly patients.[27] Recently, neuroinvasive disease of USUV was also reported in Croatia (6 cases) and France (1 case), summarizing to date a total number of 25 human cases of USUV infection.[27]

GROSS PATHOLOGICAL FINDINGS

Gross pathological findings of flavivirus infections are limited. Depending on the course of the disease, the body condition may vary from good to thin or emaciated.[28] Swelling, mottling, and necrosis of spleen and liver are most common findings due to infections with WNV, USUV, NTAV, BYDV, and BAGV (Figure 16.5).[2,4] Additionally, USUV may cause seromucous (catarrhal) enteritis and BAGV ovary atrophy and oophoritis with hemorrhages and necrosis.[4,10]

Myocardial hemorrhages, myocarditis (with multiple 2–3 mm sized pale foci), and lesions such as degeneration, mineralization, necrosis, and fibrosis in several organs may be associated to WNV infection (Figure 16.6).[19,21,24,29] In this regard, tubular epithelial and glomerular cell degeneration and necrosis may develop besides congestion, swellings, and pinpoint white foci in the kidneys.[19] White streaks may be seen in the ventricular walls and interventricular septum, producing a mottled to striped appearance. Bleedings may occur in the mucosa or lumen of the jejunum and the duodenum, possibly transforming to necrotic or diphtheric lesions due to secondary bacterial infection.[20] Minor bleedings may be seen in mucosa of the upper gastrointestinal tract. Intraosseous calvarial hemorrhages

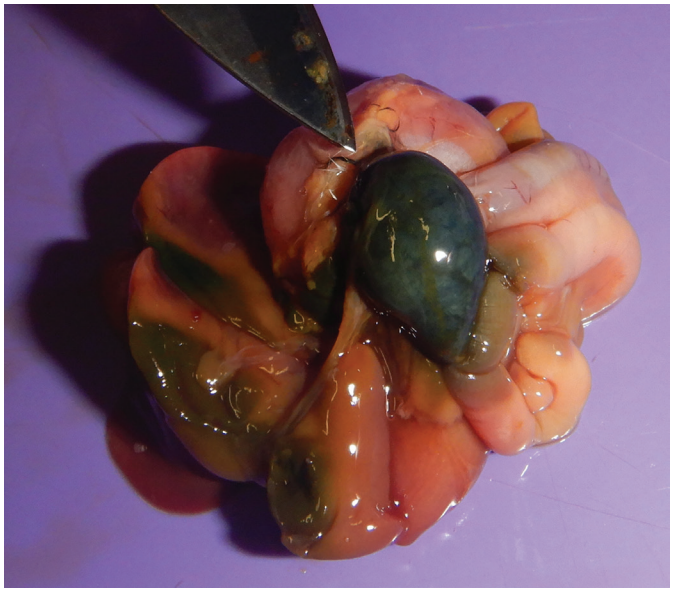

FIGURE 16.5 The most common postmortem finding in songbirds infected with Usutu virus infection and disease is an enlarged spleen, as can be seen in this common hill mynah *(Gracula religiosa)*. Other findings may include a seromucoid (catarrhal) enteritis and swelling, mottling, and necrosis of the liver. (B) Cerebrum of a juvenile, female scarlet-breasted lorikeet *(Trichoglossus forsteni)* with military necrosis, multifocal hemorrhage, hyperemia, and intravascular fibrin thrombi. Perivascular, mononuclear cuffing is spurious to absent. PCR was positive for WNV-2. Hematoxylin and eosin stain, 100×. (A, From Steele KE, Linn MJ, Schoepp RJ, et al: Pathology of fatal West Nile virus infections in native and exotic birds during the 1999 outbreak in New York City, New York, *Vet Pathol* 37(3):208–224, 2000. doi: https://doi.org/10.1354/vp.37-3-208. B, Courtesy Dr. Helene Pendl, Pendl Lab, Zug, Switzerland.)

(especially in the supraoccipital region of the skull) and acute meningeal hemorrhages have been reported in WNV-infected corvids, flamingos, and other birds (Figure 16.7).[19]

In bald eagles, severe cerebral pan-necrosis with hydrocephalus *ex vacuo* is described.[24] Other findings of WNV infections may include subdural hematomas and cerebral congestion as reported in mallards *(Anas platyrhynchos)*. Similar hemorrhages in the CNS, liver, lung, and ovaries have been associated to NTAV infections in several bird species.[4]

HISTOPATHOLOGICAL FINDINGS IN BIRDS

Various degrees of inflammatory lymphoid and histiocytic infiltrates and multifocal acute hemorrhage and necrosis in the spleen, liver, kidney, brain, eyes, and heart have been described besides intestinal lesions in lieu of USUV, WNV, and BAGV infections.[4,19]

Myocardial lesions may include mild to severe, lymphoplasmacytic, and histiocytic to necrotizing myocarditis with multifocal to coalescing dense inflammatory infiltrates adjacent to fairly unaffected tissue (Figure 16.6).[21]

Acute nonsuppurative encephalitis with multifocal areas of neuronophagia and microgliosis has been associated with USUV, BAGV, ITV, and TMUV infection. Similarly, mild to severe acute nonsuppurative (lymphoplasmacytic and histiocytic) encephalitis and meningoencephalitis with mononuclear infiltrates, glial nodules, and perivascular cuffing have been described in the course of WNV infections (Figures 16.7 and 16.8), primarily affecting the cerebral periventricular parenchyma and mesencephalon.[19,26,27] Additionally, WNV and BAGV may cause nonsuppurative nephritis, hepatitis, and pneumonia. TMUV has been reported to cause oophoritis and vacuolar degeneration of the testes in ducks.[4]

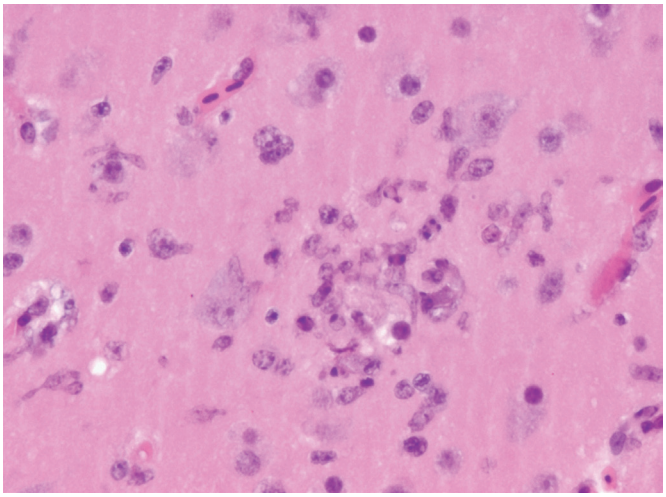

FIGURE 16.8 Cerebrum of the juvenile, female scarlet-breasted lorikeet *(Trichoglossus forsteni)* from Figure 16.7, demonstrating miliary necrosis with glia nodule formation as a result of WNV-2 infection. Hematoxylin and eosin stain, 400×. (Courtesy Dr. Helene Pendl, Pendl Lab, Zug, Switzerland.)

Ocular lesions of WNV may consist of lymphoplasmacytic and histiocytic uveitis, iridocyclitis, endophthalmitis, optic neuritis, and pectenitis, with inflammatory cells marginating in and around (cuffing) the dilated vessels of the pectin.[29]

Rarely, inflammatory lesions in adrenals and pancreas have been documented for WNV and TMUV.[4]

FURTHER DIAGNOSTICS

For specific flavivirus diagnosis, serum and blood clot samples (preferably paired, acute, and convalescent samples), oral and cloacal swabs, and feather pulp may be taken in live birds.[10] Additionally, a complete blood count and blood chemistry evaluation may help to assess the current general health status and organ function of the patient.

For the detection of antibodies against WNV and some other flaviviruses, plaque reduction neutralization tests (PRNT), virus neutralization tests (VNT), and indirect enzyme-linked immunosorbent assays (ELISAs; blocking ELISAs using monoclonal antibodies) are available.[17,30] As there is the potential for cross-reactivity with other members of one serogroup (e.g., the JEV antigen complex) within the family of Flaviviridae, blood should be collected using serum tubes without anticoagulant. Then viral genome may be detected from blood cells of the coagulum using polymerase chain reaction (PCR) parallel to the assessment of antibodies.[17] This increases the likelihood of (correct) pathogen identification.[30]

Virus isolation may be performed from oral and cloacal swabs, serum or liver, kidney, heart, spleen, and brain samples. Several mammalian cell lines as well as mosquito cells have been described for this method.[31–33]

The demonstration of viral antigen or genomic sequences is more often used and may be performed by using infected tissues (especially brain, liver, heart, kidney, and spleen), blood, cerebrospinal fluid, or other body fluids.[22,24] Real-time reverse transcriptase-polymerase chain reaction (RT-PCR) is a fast and sensitive test for virus RNA detection; however, in situ hybridization, NASBA (nucleic acid sequence-based amplification) assays and VecTest antigen-capture assays are also used regularly.[17] Immunohistochemistry may be performed on tissue samples from these organs as well, offering nearly equivalent sensitivity compared to virus isolation. In raptors, brain (cerebrum and cerebellum), heart, kidney, eye, and spleen have been demonstrated to be more often positive for WNV compared to pancreas, proventriculus duodenum, and other organs (Figure 16.9).[24,29]

THERAPY IN BIRDS

Supportive and symptomatic treatment is a key factor of flaviviral therapy, as there are no confirmed effective antiviral treatments available. This includes intravenous fluid supplementation (e.g., lactated Ringer solution), nutritional support (e.g., forced or tube feeding), and padding and sling support for ataxic and/or recumbent individuals. Medication usually includes antimicrobial (antibiosis and antimycosis to cover secondary infections), antiinflammatory and analgesic treatment (e.g., nonsteroidal antiinflammatory drugs [NSAIDs] such as meloxicam or celecoxib), vitamin supplementation (especially vitamins B and E), and thermal support.[10] Ivermectin has been anecdotally reported to have the ability to suppress virus replication and therefore may be added to the treatment for WNV infections in raptors.[34] This treatment may also be applicable to other flavivirus infections based on recent confirmation of its effect in USUV infected cell cultures. Likewise, robenacoxib has been suggested to promote favorable results in geese with CNS signs from WNV infection, with a return to clinical normalcy achieved in some birds. However, given the lack of evidence-based studies on the efficacy of these drugs, no definitive recommendations can be made on their use in the treatment of avian flaviviral infections. In any case, the infected birds should be isolated from the flock and strict hygiene and vector control must be implemented to prevent further spreading of the pathogen to other animals and humans. All involved staff must furthermore be informed about the potential zoonotic risk of flaviviral diseases, and personal protective cloth should be provided besides disinfectants.[10]

DISINFECTION AFTER FLAVIVIRUS CONTACT

Disinfection and virus inactivation of flaviviruses may be archived by low pH, ultraviolet light, gamma irradiation, and/or high temperature.[10] To inactivate WNV, the thermal inactivation point (TIP) has been set to 40°C and temperatures above 56°C for over 30 minutes have been tested sufficient.

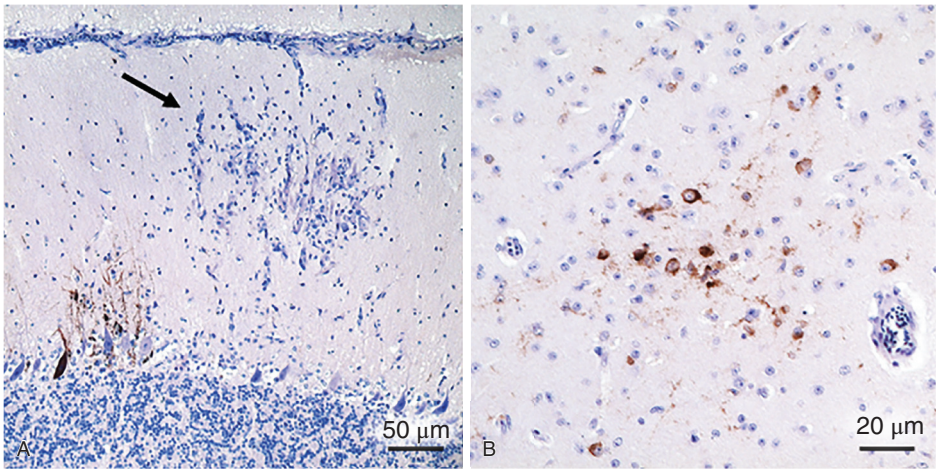

FIGURE 16.9 Immunohistochemical detection of West Nile virus (WNV) antigen in the brain of two Eurasian goshawks *(Accipiter gentilis)*. (B) Cerebrum with focal accumulation of viral antigen in few neurons and glia cells of gray matter, bar 20 µm; in-house polyclonal antibody specific for WNV (pab OM8). (Courtesy Dr. Christine Fast, Friedrich-Loeffler-Institut (FLI), Federal Research Institute for Animal Health, Institute of Novel and Emerging Infectious Diseases, Greifswald, Germany.)

WNV has been reported to be stable in alkaline environment (pH 7–9), but it may be inactivated in acid environment (pH 1–3). Common detergents, organic and lipid solvents, 70% ethanol, phenol iodophors, 1% iodine, 2% to 3% hydrogen peroxide, 2% glutaraldehyde, 3% to 8% formaldehyde, 1% sodium hypochlorite, and 500 to 5000 ppm available chlorine are reported to offer a sufficient disinfection.[10]

MONITORING AND SURVEILLANCE

A robust disease surveillance protocol should be implemented to monitor flaviviral diseases in free-ranging and captive bird populations. This may provide an early warning system for veterinarians, aviculturists, and authorities. In Europe, Australia, and the United States, different surveillance and monitoring regimes are implemented for flaviviruses in the avifauna and every veterinarian is encouraged to contribute and support these initiatives.[30,35] Especially in larger collections, dead birds should be sent for necropsy and screened for flaviviruses.[10] Examples of monitoring sites include the following: ECDC (https://www.ecdc.europa.eu/en/west-nile-fever/surveillance-and-disease-data/disease-data-ecdc); CDC (https://www.cdc.gov/west-nile-virus/php/resources/surveillance.html); California West Nile Virus Monitoring (https://westnile.ca.gov); and the Government of Canada (https://www.canada.ca/en/public-health/services/diseases/west-nile-virus/surveillance-west-nile-virus.html).

Besides monitoring programs as listed above, free-ranging birds found dead near aviaries should also be screened. A list of selected laboratories that offer PCR or serologic testing can be found in Table 16.2.

GENERAL MEASURES FOR FLAVIVIRUS PREVENTION

To reduce flavivirus transmission, vector control measures are crucial.[10,36] For mosquito control this may include monitoring of water-management systems, draining of pools, and removal of stagnant water sites, as these may serve as breeding habitat for mosquitoes. Adding fish to ponds may also

[a]In Australia, certain laboratories have a multiplexed MVEV/Kunjin virus PCR available, which has been used on bird tissues. However, it is questionable whether the PCR would detect exotic strains of WNV.

PCR, Polymerase chain reaction; *WNV*, West Nile virus; *MVEV*, Murray Valley encephalitis virus.

help to reduce the number of mosquito larvae.[10] The use of chemical insecticides, detergents, and biological agents from agriculture (e.g., *Bacillus thuringiensis*) may be effective for controlling mosquito plagues, but they should be used carefully, as they may be harmful to the environment and other organisms.[10]

The use of light- or pheromone-based live traps and mosquito netting to mosquito-proof aviaries is recommended.[10] Application of repellents might be beneficial, but most repellents may have strong side effects in birds and therefore should be used with caution. Independently, quarantine and disease screening of newly introduced birds are strongly recommended prior to including the animals in the collection.[10]

SPECIFIC PROPHYLAXIS—VACCINATION

Various flavivirus vaccines have been developed for the protection of humans against JEV and horses against WNV.[17,37] Even though these vaccines are not licensed for use in birds, several WNV vaccines have been used in various domestic and nondomestic/wild bird species with variable results, as recently thoroughly reviewed by Jiménez de Oya et al. (see Chapter 13).[37] Specific vaccines for use in birds have been developed against ITV in Israel and against TMUV in China.[4]

INACTIVATED VACCINES/KILLED VACCINES

The application of formalin-inactivated WNV lineage 1 vaccines (e.g., Duvaxyn WNV, Fort Dodge Animal Health, Hedge End, Southhampton, UK; Equilis West Nile, Intervet International BV, Boxmeer, Netherlands; West Nile-Innovator, Zoetis Inc., Florham Park, NJ, USA and Equip WNV, Zoetis Belgium SA, Louvain-la-Neuve, Belgium) induced antibody response against WNV in various avian species, even though a protection has not been assessed by virus challenge in many studies (see Chapter 13). In falcons, vaccination results were evaluated by virus challenge, recommending a three-injection scheme of the killed vaccine to achieve protection from lethal infection and reduced levels of viremia and virus shedding (Figure 16.10).[37] An inactivated TMUV vaccine (HB strain, Ringpu, Tianjin, China) is available to protect ducks against TMUV.[4]

RECOMBINANT VACCINES

Recombinant vaccines (e.g., PreveNile, Intervet; RecombiTEK, Boehringer Ingelheim Animal Health USA Inc., Duluth, GA, USA; Proteq West Nile, Boehringer Ingelheim GmbH & Co. KG, Ingelheim am Rhein, Germany), using live attenuated strains of different viruses as genetic backbone, have been evaluated in various bird species (see Chapter 13).[4,35] The recombinant vaccine RecombiTEK expressing the membrane precursor and envelop protein of WNV has been used successfully in falcons and led to decreased levels of viremia and virus shedding and reduced mortality using a three-injection scheme. Only minor side effects (local inflammation and low-grade necrotic lesions) at the injection site have been noted.[33]

Vaccination with recombinant vaccines induced specific antibody response in Japanese quail *(Coturnix japonica)* but not in western scrub-jays *(Aphelocoma californica)*.[4] Anecdotally, a three-injection scheme (interval 4 weeks) has been used successfully in snowy owls in Slovenia; however, seroconversion has not been

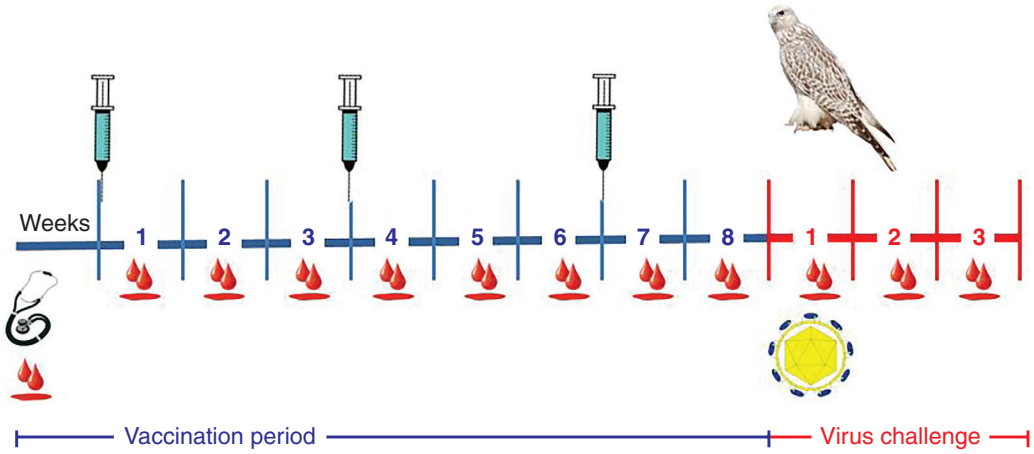

FIGURE 16.10 Example of a vaccination scheme for protection against West Nile virus (WNV) in large falcons using the killed vaccine Duvaxyn WNV, Fort Dodge (Fort Dodge Animal Health Limited, Hedge End, Southampton, UK; in the European Union [EU] now Equip WNV, Zoetis Belgium SA, Louvain-la-Neuve, Belgium; in the United States, West Nile-Innovator, Zoetis Inc., Florham Park, NJ, USA) and a canarypox recombinant live virus vector vaccine RecombiTEK-Equine rWNV vaccine, Boehringer Ingelheim Animal Health USA Inc., Duluth, GA, USA (now approved in the EU as Proteq West Nile, Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim am Rhein, Germany). Best results were obtained for both vaccines using a three-dose vaccination scheme with an interval of 3 weeks between the intramuscular injections, resulting in alleviation of clinical signs, absence of fatalities, and reduction of virus shedding and viremia. (From Angenvoort J, Fischer D, Fast C et al: Limited efficacy of West Nile virus vaccines in large falcons (*Falco* spp.), *Vet Res* 45:41, 2014).

evaluated and no virus challenge was performed in these birds. In Israel, ITV is controlled by vaccination using a live attenuated virus vaccine (Biovac Biological Laboratories, Akiva, and Phibro, Beth Shemesh, Israel). To protect against TMUV, the live duck Tembesu virus vaccine (Zhengye, Jilin, China) has been used in ducklings and layer ducks.[4] Moreover, multivalent vaccines using recombinant avian viruses as vectors for the membrane precursor and the envelop protein of TMUV resulted in full protection of ducks during virus challenge tests.[4]

CHIMERIC VACCINES

Three chimeric vaccine candidates (ChimeriVax-WN, chimeric WN/DEN4, and WN/DEN4-3'D30) were used in fish crows *(Corvus ossifragus)* and geese, but failed to prevent clinical signs, viremia, or mortality after WNV challenge.[4,37]

SUBUNIT VACCINES

Subunit vaccines based on the truncated envelope protein of WNV have been used in domestic goose, Hawaiian goose *(Branta sandvicensis)*, and red-legged partridge *(Alectoris rufa)* and protected the partridges against WNV challenge.[4]

DNA VACCINES

DNA vaccines encoding the truncated envelope protein of WNV lineages 1 and 2 induced partial protection against live WNV challenge in falcons when *in vivo* electroporation was applied parallel to vaccination.[38] In fish crows, a DNA vaccine expressing the membrane precursor and envelop protein of WNV prevented mortality and reduced viremia levels after experimental WNV infection.[39] However, antibodies were absent in island scrub-jays *(Aphelocoma insularis)*, and western scrub-jays were not protected during WNV challenge by using the same vaccine.[4] In American crows *(Corvus brachyrhynchos)*, American robins *(Turdus migratorius)*, and red-tailed hawks, the intramuscular administration of DNA vaccines reduced viremia levels effectively, even though antibody titers were low after vaccination.[4] Likewise, in penguins, immune response to plasmid DNA vaccine has been inferior compared to a killed vaccine.[4] In contrast, stimulation of antibody production has been demonstrated in Californian condors *(Gymnogyps californianus)* 4 weeks after vaccination.[4] A DNA vaccine expressing the membrane precursor and envelope or the core genes of TMUV reduced clinical signs and prevented death in ducks following TMUV challenge.[4]

CHAPTER 17

Campylobacteriosis

Yuko Sato

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Campylobacteriosis in poultry has historically been focused on its zoonotic significance for human public health. *Campylobacter* spp. are generally regarded as a commensal bacteria in birds, and their infection rarely results in clinical disease or significant pathological lesions. This chapter focuses on four *Campylobacter* species isolated from birds and their significance to human or poultry health. These species are *Campylobacter jejuni*, *Campylobacter coli*, *Campylobacter lari*, and *Campylobacter hepaticus*. All of these are associated with foodborne illness in humans except for *C. hepaticus*, a recent etiological agent of spotty liver disease historically known as avian vibrionic hepatitis, where the pathogenesis of the disease in poultry is poorly understood due to its recent identification and characterization.

ETIOLOGY

Campylobacter spp. are motile, non–spore-forming, spiral-shaped, gram-negative rod bacteria. The genus *Campylobacter* contains at least 30 species and subspecies, with genus *Campylobacter* being associated with a wide variety of diseases in humans and animals. Of significance to poultry and human health are the thermophilic *Campylobacter* spp., *C. jejuni*, *C. coli*, and *C. lari*. These species grow optimally at 37°C to 42°C on artificial media and are slow-growing, fastidious organisms that require a microaerobic atmosphere.[1] Other species including *Campylobacter upsaliensis* and *Campylobacter hyointestinalis* have been isolated from poultry, but at a much lower rate with no significance to poultry health.[2]

Many species of poultry, especially gallinaceous birds, frequently carry *C. jejuni* or *C. coli* as a commensal organism. Despite it producing little to no pathology in birds, colonization of *Campylobacter* spp. in commercial chickens and turkeys results in it being among the leading cause of bacterial pathogens in food safety and public health. *C. jejuni* is most frequently associated with human campylobacteriosis, followed by *C. coli*, and—rarely—*C. lari* or others.[3]

In the 1950s, a condition known as avian vibrionic hepatitis associated with *C. jejuni* and *C. coli* was been described in laying hens and ostriches in the United States. The disease was recognized in many countries including Australia, New Zealand, Canada, Egypt, Germany, Austria, Italy, Hungary, Bulgaria, Switzerland, the United Kingdom, Ukraine, and the Netherlands.[4] However, an experimental study suggested that *Campylobacter* alone would not be sufficient to cause mortality or lesions associated with vibrionic hepatitis, but that, rather, a predisposing factor in chickens might be required for the development of the disease.[2,5] A novel *Campylobacter* spp. was isolated from infected birds in England (2015) and subsequently in Australia (2016). In 2016, this novel species was characterized and named *C. hepaticus*. Currently, the disease it causes has been redefined as spotty liver disease (SLD), and it has been identified from the United States and from other parts of the world.[6,7]

EPIDEMIOLOGY AND PATHOGENESIS

Generally, *C. jejuni* and other commensal *Campylobacter* species colonize the avian gut in their ceca around 2 to 3 weeks of age. The bacterium is introduced horizontally by fecal-oral route and is very well adapted to the avian species. As few as 35 colony-forming units (cfu) can be sufficient for colonization in the chicken gut.[4] Within 24 hours postingestion, *C. jejuni* reaches the cecum and multiplies. Although the main sites of colonization include the ceca and colon, other organs such as the small intestines and liver have also been colonized.[8] A unique feature of *Campylobacter* colonization is the fact that it resides predominantly in the mucus layer of the intestinal crypts without direct adhesion or invasion of the epithelial cells.[1,4] This explains why there may be no overt clinical signs associated with poultry infected with the bacterium.[3]

Although circumstantial evidence suggests that vertical transmission of *C. jejuni* from breeder flocks to progeny may occur, the current understanding is that *Campylobacter* is a horizontally transmitted bacteria, as isolation from newly hatched poultry has not been reported under field conditions. This most likely is due to the presence of maternally derived antibodies in young chicks conferring protection against colonization of the bacteria in their gut.[2,3,9] However, vertical transmission has been hypothesized because of isolation of *Campylobacter* spp. from the outer and inner shell surfaces of infected breeders, from reproductive tracts of hens, and from semen of infected broiler breeder roosters.[3,10–12] Recent molecular diagnostics also detected *Campylobacter* DNA from embryos and newly hatched chicks.[13,14] Contrasting studies indicate that transmission of *Campylobacter* through fecal contamination of eggshells post-lay is unlikely due to its limited capability for invading the eggshell and poor survivability on

eggshell surface, in air sacs and albumen.[15] Most studies indicate that the bacteria only survive a couple of hours (up to 6 hours) in any part of the egg laid at body temperature of the bird.[1,9,10,16] In addition, many studies report the finding of different *Campylobacter* strain genotypes in broiler flocks versus their parent flocks. Based on these findings, it was concluded that transmission of *Campylobacter* spp. through the egg is a rare, though not impossible, event and does not play a role in transmission in poultry farms. Introduction of *Campylobacter* to newly hatched flocks remains a gap in our knowledge of the epidemiology of this bacteria.[3,9]

The prevalence of *Campylobacter* spp. in commercial poultry is relatively high but may vary according to region, seasons, and production types, ranging from 2% to 100%. Seasonal variations occur with a peak in summer and autumn months, perhaps due to an increase in fly population and fly-mediated transmission.[3,11,17,18] This correlates with human campylobacteriosis that peaks in summer months, especially in temperate climates.[2] In addition to flies, epidemiologic studies also indicate that other mammals including rodents and the presence of other livestock, including cattle, sheep, pigs, pets, and other birds, have been indicated as potential vectors and associated with risk factors for poultry with *Campylobacter* infection.[3,19]

In terms of the novel *C. hepaticus*, much is still to be discovered. *C. hepaticus* DNA has been detected in a variety of environmental samples including wild bird feces, flies, rat feces (and ceca), soil, water, dust, and mites from farms positive with SLD.[7] However, the organism is quite fastidious compared to other *Campylobacter* spp. and no viable isolate was recovered from these samples. In addition, there were instances where *C. hepaticus* was detected but disease was not detected for several weeks later. This study suggests that perhaps presence of the organism is not enough to induce disease, and predisposing/concurrent factors may be required to either increase abundance of the organism or by increasing susceptibility of the host to the organism.[5] In terms of commercial chickens *(Gallus gallus domesticus)*, *C. hepaticus* is more prevalent in organic and free-range flocks versus conventional production, with perhaps predilection toward floor-raised birds due to the fecal-oral transmission of the organism.[6,7] Due to the majority of egg production being in cages in the United States, the disease was not identified until recently in 2018.[6,7] However, disease has also been observed in caged layers and broiler breeders, although to a much lesser extent.[2]

CLINICAL SIGNS

Campylobacter infections in poultry, with the exception of *C. hepaticus*, typically produce no clinical signs of disease under natural conditions. There is one report that ostriches *(Struthio camelus)* can have clinical illness that resulted in lesions in the liver and intestines.[20] Some studies reported that experimental infection of young chickens with high doses of *Campylobacter* can induce clinical diseases including watery/mucoid/bloody diarrhea, weight loss, or mortality as early as within 72 hours.[2,3]

Clinical signs with SLD are much more dramatic, especially with birds coming into peak lay. SLD can have upwards of a 10% increase in mortality and a 10% to 25% drop in egg production, which can occur simultaneously but without any effects on external and internal egg quality. Hens can also appear normal with no apparent clinical signs.[6,7] A few reports furthermore mention loose stools.[2]

GROSS AND HISTOPATHOLOGIC LESIONS

The lack of clinical signs correlates to the lack of gross lesions in most cases of natural *Campylobacter* infections. In experimentally infected chicks, lesions are often mild, nonspecific, and confined to the gastrointestinal tract. There may be accumulation of fluid, gas, or excess mucus, distention of the gut including ceca with watery/foamy contents. Blood and mucus in the lumen of the small intestine and petechial hemorrhages in the gizzard mucosa of chicks can be seen occasionally.[2,3]

Microscopic lesions are often absent in natural infections but have been described in experimental infections. Lesions are typically observed in the ileum and ceca, with studies that report mild to moderate responses including increased inflammatory cells (predominantly lymphocytes and heterophils), mucosal damage with thickening, shortening, and fusion of the villi in the ileum, as well as edema of the lamina propria and submucosa.[21] In some cases, the bacteria can be seen attached to the brush borders on enterocytes, within intestinal epithelial cells, and inside or outside of the cells of lamina propria with minimal damage and a lack of necrosis.[2]

Gross lesions with SLD are typically characterized by 1- to 2-mm, white to gray or cream, random military foci on the surface of the liver (Figure 17.1). In most cases, these military foci are observed in all liver lobes, but in some cases, only one or two lobes are involved. Liver foci may also occasionally coalesce, especially in coinfections with cecal worms and mild intestinal lesions characterized by watery/catarrhal enteritis.[6,7] Livers may be swollen or slightly enlarged, and the liver lesions may be accompanied by catarrhal enteritis on rare occasions.[2]

Histopathologic lesions of SLD are characterized by multifocal to coalescing hepatocellular necrosis characterized by discrete margins and necrotic centers mixed with degenerating heterophils in acute to subacute stages (Figure 17.2). Lesions do not have a predilection or affinity to any specific cell type or structure and appear to be random. Earlier studies with avian vibrionic hepatitis showed that histopathologic examination of these livers did not reveal any intralesional bacteria, which is true in cases of *C. hepaticus* infections. Coupled with this observation and the random necrosis, studies speculate that the liver necrosis is a result of a hepatotoxin produced at a remote location, although this has not yet been discovered.[7]

DIAGNOSIS

Thermophilic *Campylobacter* spp. grow optimally at 37°C to 42°C (98.6°F–107.6°F) on artificial media and are slow-growing, fastidious organisms that require a microaerobic atmosphere (5% O_2, 10% CO_2, 85% N_2). Because target organs are typically intestines and intestinal contents where many background organisms may be present, the use of selective media containing a cocktail of antibiotics to inhibit growth of others is typically used. In addition, an enrichment step in liquid media followed by plating on agar plates is usually preferred to direct plating for the isolation of *Campylobacter* from

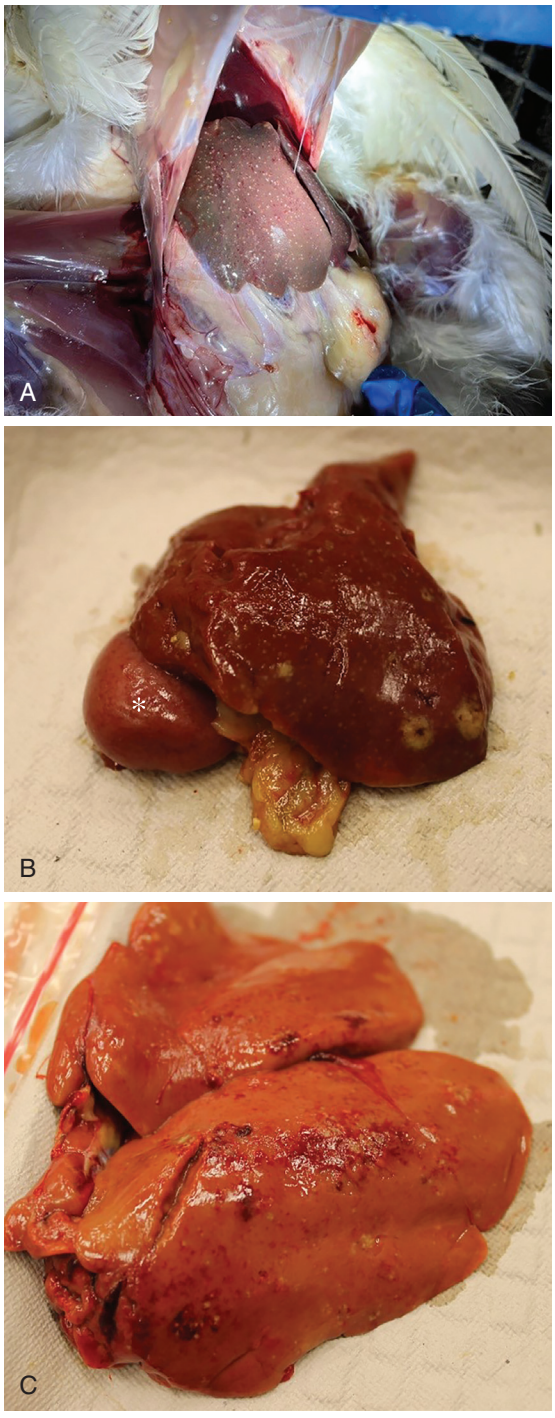

FIGURE 17.1 Gross lesion of typical livers with spotty liver disease characterized by (A) numerous necrotic foci throughout the surface of the liver. (B) Necrotic lesions can coalesce in some cases. Note splenomegaly (*) in this case. (C) The liver's edges are rounded, and it is slightly pale. (Courtesy Yuko Sato, Iowa State University.)

(A) Large lesions can coalesce, with this lesion surrounding a portal vein (4× magnification, hematoxylin and eosin [H&E]). (B) Higher magnification of necrotic foci showing diffuse hepatocellular necrosis and marked heterophilic infiltrates surrounding areas of necrosis. (40× magnification, H&E).

processed foods in which bacteria are usually in relatively low numbers. Colonies are visible on solid media after 48 hours of incubation, but it may take up to between 72 and 96 hours to observe some slow-growing strains.[2] Moisture tends to affect appearance of the colonies: colonies may appear gray, flat, irregular, and thinly spreading in moist plates versus round, convex, and glistening colonies when plates are dry. Classical bacteriology identification of *Campylobacter* is based on morphology, typical cellular shapes (spiral or curved rods; Figure 17.3) using fuchsin stain, and characteristic rapid darting motility observed under a phase-contrast microscope.[2,22] Currently, many diagnostic laboratories utilize matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry for species-level identification of *Campylobacter* similarly to other bacteria. Species-level polymerase chain reaction (PCR) targeting housekeeping or species-specific genes, including *23S rRNA*, *glyA*, *ceuE*, *lpxA*, *hipO*, *mapA*, and *ask*, have been developed and used. However, several studies report its inferiority in sensitivity and specificity compared to real-time multiplex PCR; hence, these molecular assays have been increasing in popularity.[23]

In terms of *C. hepaticus*, isolation has been best from bile samples despite the lesions being present in the liver. This organism is even harder to grow compared to other *Campylobacter* spp. and does best in incubation in Preston broth for up

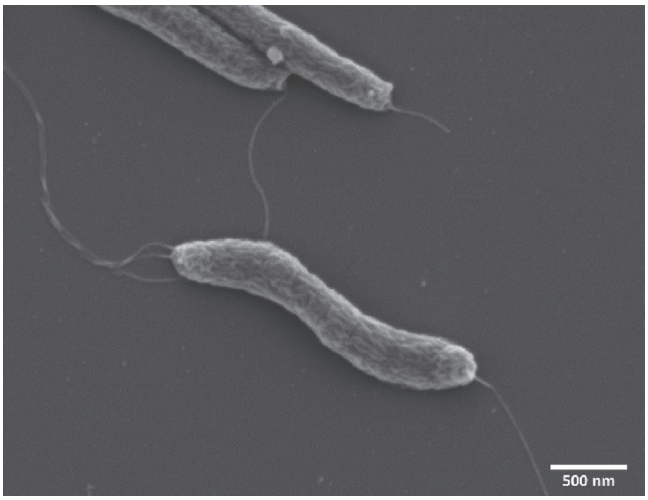

FIGURE 17.3 *Campylobacter* spp. can be diagnosed using phase-contrast microscopy, where they can be recognized as spiral or curve-shaped rods, with a single flagellum at each end. (Courtesy LAGier, Pratt and Threadgill. ASM MicrobeLibrary.org.)

to 7 days at 35°C (95°F), followed by plating into *Brucella* agar with 5% horse blood for up to 7 days prior to subculturing. Similar to other *Campylobacter* spp., biochemical reactions as well as MALDI-TOF methods have also been used for identification. 16S rRNA gene sequencing methods and PCR identification using targets such as glycerol kinase gene specific to *C. hepaticus* have been used for higher sensitivity in identification.[5,6]

TREATMENT, PREVENTION, AND CONTROL

Anecdotal evidence states that the use of broad-spectrum antibiotics such as tetracyclines in addition to management strategies has been helpful to reduce clinical signs and mortality associated with *C. hepaticus* infections. However, these antibiotics are not labeled for controlling these infections. Thus, judicious use is recommended, only when secondary pathogens contribute to significant and/or elevated mortality. Historically, erythromycin and fluoroquinolones have been used to control avian vibrionic hepatitis, but these are not approved for use in commercial poultry. There have also been issues with high incidences of antibiotic-resistant *Campylobacter* strains, some of which are multidrug resistant.[1,2,21]

Because thermophilic *Campylobacter* is considered a commensal and, in most instances, birds do not exhibit clinical disease, nor do they have associated mortality, the focus has been predominantly on control rather than treatment. However, because colonization in poultry intestines is very optimized and the organism is ubiquitous in a farm environment, prevention of a flock from turning up *Campylobacter* positive is an extremely difficult task.[24] In general, preharvest control methods focus on three principles: reduction of environmental exposure, increase in host resistance, and using alternatives to antimicrobials. Single strategies are not successful when applied alone for preharvest and postharvest control[1–3,18]; hence, it is recommended to instill multiple measures in combination for higher efficacy. However, this may prove to be challenging due to economic and practical reasons.

The most fundamental method is implementation of strict biosecurity and good hygiene methods to prevent *Campylobacter* from entering poultry houses. Focus and attention to potential routes of infection (see Epidemiology and Pathogenesis) appear to be successful. One study looked at tidiness and sanitation in the facilities including frequency of changing footbaths and the cleanliness of the anterooms correlated with prevalence of *Campylobacter* in flocks. Another study looked at rodent control associated with lower risk (odds ratio [OR] = 0.15) of colonization.[25] A Danish study looked at the use of fly screens around barns and reducing prevalence of *Campylobacter*-positive flocks from 41.4% to 10.3% while also preventing peak incidence during summer months.[26] Similar studies looking at flies as mechanical vectors of the bacteria saw a similar approximately 30% decrease in positive flocks.[19,26] One study decreased the prevalence of *Campylobacter* in broiler houses from 80% to less than 40% where strict personnel hygiene and disinfection protocols were utilized.[27] In contrast, production practices such as thinning (early removal of a subset of birds to allow more space for the rest of the flock), commonly used in Europe, reported an increase in risk of *Campylobacter* contamination due to higher human traffic, use of equipment, and contaminated vehicles.[3,28] However, challenges exist with biosecurity measures in commercial settings due to it being cost prohibitive, hard to maintain compliance, and highly variable in effectiveness, dependent on the production systems used.[2,3,9]

Reduction of colonization through administration of feed additives and water acidification has also been explored.[29] Water additives include short- and medium-chain fatty acids, plant-derived additives, egg yolk powder, chlorination, monocaprin, and organic acids. The idea behind its use is that these acids might aid in lowering pH of the gut, making it unfavorable for colonization by *Campylobacter* spp., as these organisms do not tolerate pH levels below 2.5 or 3 for more than an hour in in vitro experiments.[2] Organic acids such as lactic acid, formic acid, acetic acid, and propionic acid, during grow-out and feed withdrawal prior to harvest were reported to reduce recovery and colonization of *Campylobacter* (62.3% vs 85.1%) from the crop in one study.[30] Another study showed a combination of 2% formic acid and 0.1% potassium sorbate, resulting in total prevention of colonization of broilers *C. jejuni*.[31] Other studies showed log reductions of *Campylobacter* in broiler ceca.[32] However, conflicting studies showed that addition of organic acids in experimentally infected birds continued to shed and be colonized with *Campylobacter*.[33] Feed additives including prebiotics (such as lactose, fructooligosaccharides, mannose-oligosaccharide), immune response stimulators (such as selenium and beta-glucan), activated charcoal, and other organic acids have been used to acidify the feed, similar to their use in water. Many of these products have limited success when used alone and are often used in combination with water and other management strategies. It is interesting to note that *Campylobacter* spp. associated with protozoa such as *Acanthamoeba polyphaga* allows increased tolerance to these products including chlorine and acids.[2,9]

Litter treatments have been assessed for their efficacy in controlling *Campylobacter* colonization. There is some success in decreasing colonization (from 90% to 10% in treatment groups) and cecal load (up to 5 $\log_{10}$ reductions) in laboratory trials using aluminum sulfate and sodium bisulfate in broiler barns.[34] However, the effect on commercial farms was found to be negligible unless low pH in the litter was maintained throughout the entire grow-finish period.[2,9] In addition, the organism thrives better in wet environments, so maintaining low moisture levels will also help. A study by Sahin et al. showed that paw quality (due to wet litter and poorly ventilated barns, resulting in ammonia burns) had a positive association (OR = 21.67, 1.36-fold increase in odds ratio of having positive cfu for each 10% increase in paw lesions) with increased risk of *Campylobacter* colonization. This correlates with the fact that higher litter temperature and lower ammonia levels in the litter have negative correlations with *Campylobacter* colonization within broiler flocks (Sahin et al., unpublished data).

Another method to control *Campylobacter* colonization implicates the use of antibiotic alternatives for competitive exclusion of *Campylobacter* in the gut. The potential use of bacteriophages has been evaluated in several studies.[32,35] Some studies had immediate effects of log reductions of cfu in poultry ceca after oral administration, but there seem to be conflicting studies that show limited success depending on strains and combination of bacteriophages.[36] In addition, a few studies indicated that the impact of the bacteriophages deteriorated after a few days and stabilized to potentially insignificant differences between the controls.[37] Overall, there seem to be several challenges with the use of bacteriophages, including the narrow spectrum of efficacy, rapid development of resistance, and the low efficiency of phage production in *Campylobacter*.[2,23]

AMP (antimicrobial peptides) such as bacteriocins have had some promise as a means for controlling *Campylobacter* colonization in chickens. Most successes described are those produced from commensal bacteria isolated from the chicken gut. Several AMPs purified from *Paenibacillus polymyxa*, *Lactobacillus salivarius*, and *Enterococcus* spp. have shown high efficacy in reducing *C. jejuni* infections and even total prevention of detectable levels,[38] although on-farm control has not been evaluated due to the cost. Purified AMPs such as defensins and cathelicidins also have promise for broad-spectrum antimicrobial activity, but it is not a cost-effective option for commercial use and also has potential issues in relation to meeting regulatory approval.[2,9]

Although there is well-established evidence that protective host responses do occur with *C. jejuni* infection,[4,39] hence supporting development of immunization strategies, currently, there are no commercial vaccines available for controlling *Campylobacter* infections in poultry. Some of the challenges include antigenic/genetic diversity of different strains, lack of understanding of protective immunity in poultry, and failure to induce strong and persistent local, mucosal immune responses. Two types of vaccines have been described in the literature, including killed whole-cell, live-attenuated, flagellin-based subunit vaccines and glycoconjugate vaccines using the conserved bacterial N-glycan. Both vaccines showed up to 10-log reduction in *C. jejuni* colonization and induced specific antibodies.[40] Coupled with the short life span of broilers (6–7 weeks) and the high cost of development and administration of a vaccine for food safety purposes, the use of vaccination in commercial poultry farms needs further investigation.[2,9]

Finally, host genetic resistance research has been ongoing to look at different lines of chickens to look at susceptibility to infection. Recent studies report that resistance to infection is linked with the inhibition of small, GTPase-mediated signal transduction as well as the tumor necrosis factor receptor superfamily genes.[41] In the future where antibiotic use is severely limited, perhaps there will be a time where selective breeding of broilers with resistance to *Campylobacter* infection will occur.[2,9]

NONPOULTRY AVIAN HOSTS

As in poultry, healthy, nonpoultry avian hosts have been implicated in carrying *Campylobacter* spp. However, there is a knowledge gap about the epidemiology of *Campylobacter* spp. in wild bird populations. In studies looking at prevalence of *Campylobacter* spp. in wild birds, important factors that influence recovery include feeding habit, forage area, and proximity to livestock operations.[19] In addition, sparrows (*Passer* spp.) at poultry or swine farms in the summer were more likely to carry the organism than those caught at cattle farms, speculating on the fact that there is lower cross-contamination of foraging areas due to the fact that cattle were out grazing in the pasture and thus minimizing contact with sparrows closer to farm buildings.[19] Although the prevalence rate of wild birds carrying *Campylobacter* spp. is much lower (7.7%–12.9%) than of domestic poultry, there have been several instances where human outbreaks have been linked to wild birds, thus suggesting that wild birds are potential vectors and reservoirs of infection for poultry and for humans.[42]

A study in the United Kingdom surveilled wild animals, including birds, that exhibited clinical signs of diarrhea and other gastrointestinal disease for presence of *Campylobacter*. There was a positive association with mixed concurrent infections with other bacterial infections, with the highest prevalence in Gruiformes, Ciconiiformes, and Anseriformes.[43] Although disease from infection is rare, *Campylobacter* spp. has been isolated as a coinfection or opportunistic infection from the small intestines of clinically ill birds, especially Psittaciformes and Passeriformes exhibiting clinical signs and pathologic lesions of hepatitis, lethargy, loss of appetite, weight loss, and yellow diarrhea with potential mortality.[44–46]

PUBLIC HEALTH SIGNIFICANCE

Campylobacter can exist in very high numbers in the intestines and feces of poultry and other food-producing animals. Foodborne infections with *Campylobacter* are estimated to affect over 800,000 people annually in the United States and infect 1% of the population in the European Union.[47,48] Infection by *Campylobacter* results in severe gastroenterocolitis in humans. During 2012, over 70,000 cases of human campylobacteriosis were reported in the United Kingdom, of which 90% of the cases were due to *C. jejuni*. While these cases were often genetically linked to production animals (including poultry), small proportions (2.1%–3.5% annually) were also linked to wild bird isolates, further complicating the epidemiology of the disease.[47]

The Centers for Disease Control and Prevention constantly ranks *Campylobacter* spp. as a major problem in food safety and continues to see increased rates of infection reported annually. With regards to poultry, several interventions with improved preharvest strategies and postharvest strategies, such as better storage and handling of poultry meat, will reduce the risk of campylobacteriosis in humans.[1]

CHAPTER 18

Avian Chlamydiosis—Beyond *Chlamydia psittaci*

INTRODUCTION

Chlamydiaceae are a group of obligate intracellular, gram-negative bacteria that can infect a wide variety of birds and mammals, with some having zoonotic potential. This family comprises two genera. The first genus, named *Chlamydia*, includes the species *C. trachomatis*, *C. pneumoniae*, *C. pecorum*,[1] *C. abortus*, *C. felis*, *C. caviae*, *C. muridarum*, *C. suis*, *C. psittaci*, *C. avium*, *C. gallinacea*,[1,2] *C. poikilothermis*,[3] *C. buteonis*,[4] and *C. serpentis*,[5] as well as the candidate species, *Candidatus* (*Ca.*) *C. ibidis*,[6] *Ca. C. sanzinia*,[7] *Ca. C. corallus*,[3] and *Ca. C. testudines*.[5] The other genus, recently described as *Chlamydiifrater (Cf.)*,[8] includes two new species that have only been detected so far in flamingos, namely *Cf. phoenicopteri* and *Cf. volucris*.

Until very recently, *C. psittaci* was considered to be the main *Chlamydia* species infecting birds. However, recent research has identified new *Chlamydia* species in domestic bird populations, captive birds, and wild avian species, albeit frequently without clinical signs in the host animals. These discoveries have led to the identification of novel species that appear to be globally distributed. Notable among these are *C. gallinacea*, which appears to be endemic in poultry species, and *C. avium*, frequently detected in pigeons (Columbiformes) and psittacine birds (Psittaciformes). Additionally, other emerging species, such as *C. buteonis*, initially misclassified as *C. psittaci* M56 and as *C. abortus*, were delineated using advanced molecular techniques. These breakthroughs were made possible by using polymerase chain reaction (PCR) methods targeting the Chlamydiaceae family and the development of whole-genome sequencing techniques applicable to this obligate intracellular bacterium.

Because of their wide host range, Chlamydiaceae species have a significant impact on human and animal health worldwide.[9,10] The discovery of new species within this family from avian hosts highlights how much we still have to learn about the biology and pathogenicity of the Chlamydiaceae as a whole. The continued identification of novel chlamydial organisms provides evidence that some may be pathogenic to birds, humans, or other animals, thereby posing new zoonotic risks.[11] The intensification of farming and the widespread popularity of companion animals also present ongoing opportunities for emerging zoonoses.[9,11]

In this chapter, we will provide an overview of current knowledge regarding *C. avium* in pigeons and psittacine birds, *C. gallinacea* in poultry, as well as novel *Chlamydia* species circulating in avian wildlife. Furthermore, we report on an outbreak of *C. psittaci* in Sphenisciformes as little documentation about *Chlamydia* in this bird order is available.

CHLAMYDIA AVIUM IN PIGEONS AND PSITTACINE BIRDS

A retrospective analysis of chlamydial strains isolated from asymptomatic feral pigeons *(Columba livia)* in Italy and France, as well as from clinically affected psittacine birds in Germany, led to the identification and description of a novel chlamydial species that was designated *C. avium* in 2014.[12] This new agent was clearly distinguished from *C. psittaci* through phylogenetic analysis based on 16S rRNA and whole-genome analysis, and it was found to be phylogenetically closest to another novel chlamydial species, *C. gallinacea*, which was isolated from poultry birds.[12] Within the Chlamydiaceae family, *C. avium* and *C. gallinacea* represent a distinct clade alongside *C. psittaci*, *C. abortus*, *C. felis*, and *C. caviae* (Figure 18.1).

The Agent

C. avium has primarily been detected in pigeons and psittacine birds, although its presence in other birds is assumed and has anecdotally been shown. There is evidence for the existence of host-specific genotypes,[12,13] although data on this topic remain limited. Currently, there are two complete *C. avium* genome assemblies available: one from the type strain 10DC88^T, isolated from a parrot in Germany, and the other from the strain PV 4360/2, which was isolated from a feral pigeon in Italy. When compared, these genomes of about 1 Mbp differ by 3696 single nucleotide polymorphisms (SNPs), resulting in a nucleotide identity of 99.64%.[14]

C. avium can be grown in cell culture or embryonated chicken eggs. Electron micrographs of the designated type strain 10DC88^T in infected cells (Figure 18.2) show multiple inclusions of variable size (2–10 μm)[12] inside infected cells. These inclusions typically consist of small, electron-dense elementary bodies (EBs) measuring 240 to 330 nm in diameter, alongside larger, more translucent reticulate bodies (RBs) with a diameter ranging from 450 to 1100 nm. These observations

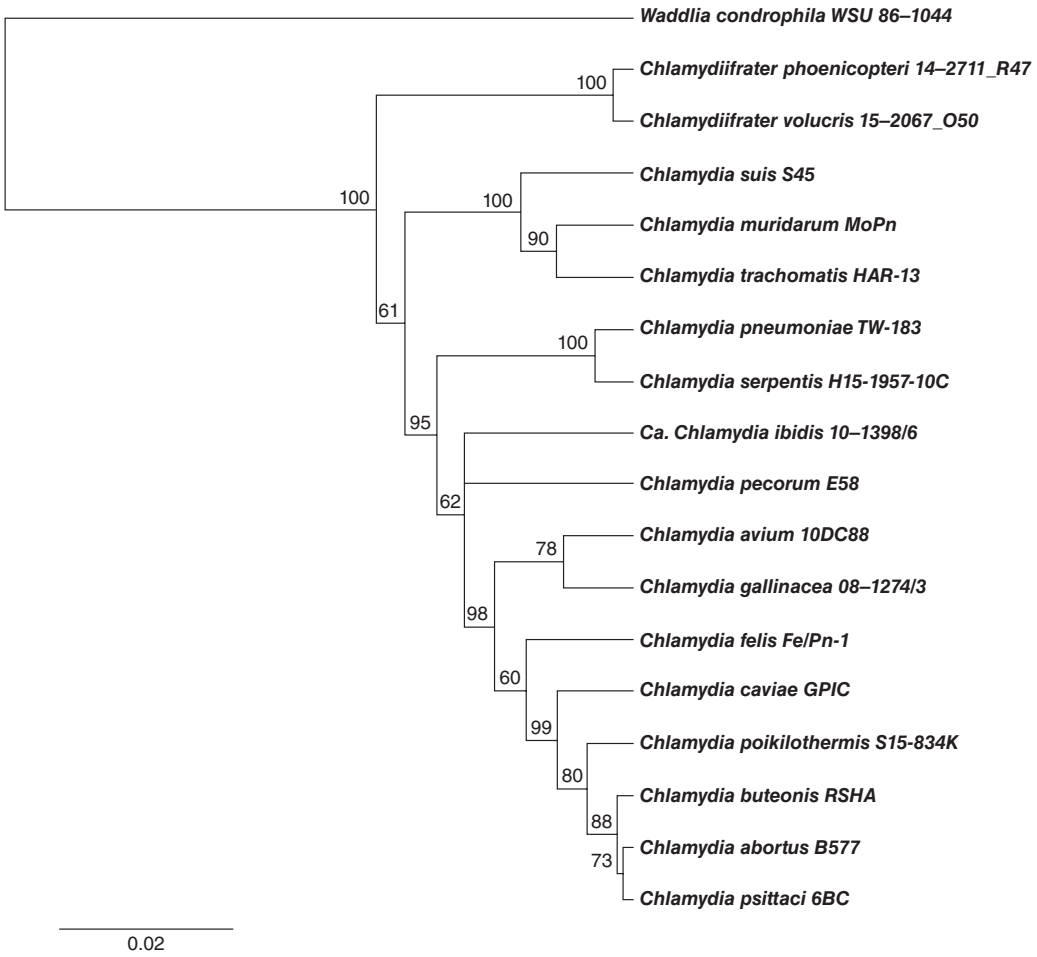

FIGURE 18.1 Phylogeny of the family Chlamydiaceae including the type strains of all currently valid members and those of *Waddlia condrophila* as an out-group. The phylogenetic tree was reconstructed based on a ClustalW alignment of 16S RNA gene sequences with the Geneious Tree Builder using the Jukes-Cantor model and unweighted pair group method with arithmic mean algorithm. Bootstrap values are based on 1000 replicates. The scale bar indicates percentage of sequence divergence.

indicate that *C. avium* has a binary life cycle, which is typical for all Chlamydiaceae. Unlike some fast-growing *C. psittaci* strains that take 36 to 48 hours to complete a developmental cycle, *C. avium* strains take longer, around 60 to 72 hours.[12]

From the limited epidemiological data available, it appears that *C. avium* is widely disseminated, particularly among pigeons. Investigations of feral pigeon populations in different European cities have identified the agent in a range of 0.6% to 28.4% of total samples and in 3.1% to 85.2% of Chlamydiaceae-positive samples (Table 18.1).[15–18] In domestic or racing pigeon flocks, *C. avium* was detected in 5.9% to 7.4% of total samples and in 17.4% to 41.6% of Chlamydiaceae-positive samples (Table 18.1).[16] In most studies, *C. psittaci* appeared as the predominant chlamydial agent in pigeons, but there were instances where *C. avium* outcompeted *C. psittaci* in feral pigeon populations in two Dutch cities.[15] Co-infections with both *C. psittaci* and *C. avium* in individual birds appear also to be common.[15,17] In psittacine birds, assessing the prevalence and impact of *C. avium* is challenging, as reported findings are often individual cases associated with chlamydiosis outbreaks. There have been limited systematic epidemiological investigations conducted so far.[19] Due to limited reports and information, the worldwide distribution of *C. avium* remains unknown.

Detection and isolation of *C. avium* have mainly been reported in European countries, including France,[16,21] Belgium,[19] Germany,[18] Italy,[14] Switzerland,[17] The Netherlands,[15] and Poland.[22] There have also been reports of *C. avium* detection in an asymptomatic feral pigeon in Thailand[23] and in two asymptomatic psittacine birds in Argentina.[24]

Transmission

The transmission pathway of *C. avium* is not specifically documented, but it is likely to be similar to that of *C. psittaci*, involving direct bird-to-bird transmission or airborne transmission through inhalation of aerosolized dried fecal particles or ocular and nasal secretions containing the bacteria.[25] Chlamydial shedding is supposed to be intermittent and may depend on the virulence of strains and the host's immune status. For *C. psittaci*, stressors such as nutritional deficiencies, overcrowding, chilling, breeding, transport, and handling have been identified as important factors influencing both increased shedding

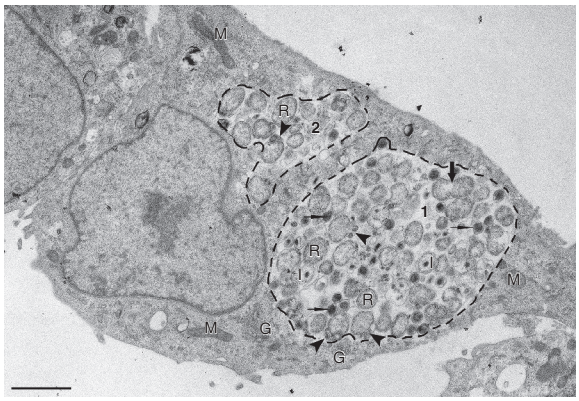

FIGURE 18.2 Electron microscopic image of Buffalo green monkey (BGM) cell culture infected with *Chlamydia avium* strain 10DC88, bar = 1.5 μm. Two inclusions are indicated by *dashed lines*. They contain reticulate bodies *(R)*, elementary bodies *(thin arrows)*, and intermediate bodies *(I)*. Binary fission and budding events are marked with a *thick arrow* and *arrowheads*, respectively. Mitochondria *(M)* and stacks of Golgi membranes *(G)* are closely associated with the inclusion's membrane. (Courtesy Elsevier Ltd. From Sachse K, Laroucau K, Riege K, et al: Evidence for the existence of two new members of the family Chlamydiaceae and proposal of *Chlamydia avium* sp. nov. and *Chlamydia gallinacea* sp. nov., *Syst Appl Microbiol* 37(2):79–88, 2014. http://dx.doi.org/10.1016/j.syapm.2013.12.004.)

and susceptibility to infection,[25] and these factors are assumed to apply to *C. avium* as well. Other potential transmission pathways, such as transmission through feeding, blood-sucking ectoparasites, or vertical transmission have not been documented but cannot be ruled out. So far, only individual cases of *C. avium* infection inside groups of captive psittacine birds have been investigated, suggesting a limited spread of the bacterium in aviaries.[13] Susceptibility to *C. avium* infection appears to vary significantly between different bird species, as well as within the same avian species.

The zoonotic potential of *C. avium* is unknown. The fact that it has never been isolated from or detected in human samples could merely be a consequence of limited diagnostic approaches targeting only traditional chlamydial agents rather than indicate a lack of bird-to-human transmission. Therefore, a risk of transmission to humans in close contact to parrots and pigeons such as pet bird owners and breeders, staff in zoos and pet shops, pigeon fanciers, and veterinarians cannot be excluded.

Clinical Signs

The pathogenic role of *C. avium* has not been investigated through experimental infections to fulfill Koch's postulates. Current knowledge is primarily based on limited epidemiological data from natural infections. It appears that the majority of pigeons harboring *C. avium* do not develop clinical signs. In contrast, in parrots and parakeets, the agent can be associated with a range of clinical symptoms, including respiratory disease, enteritis, anemia, emaciation, and sudden death without prior symptoms.[12,21] At necropsy, pathological findings similar to acute *C. psittaci* infections were noticeable, including hepatosplenomegaly, thickened air sacs, congested lungs, and the accumulation of fibrinous exudate in respiratory organs and the liver. Histological examination showed lymphohistiocytic, moderate necrotizing hepatitis and moderate necrotizing splenitis with hyperplasia.[13] Co-infection with other *Chlamydia* spp. or pathogens could exacerbate the course of the infection with *C. avium* in birds.

Diagnosis

The choice of sample types for analysis depends on the clinical signs observed in the birds. In case of acute illness, samples should include inflammatory or fibrinous exudate in or around affected organs, ocular and nasal exudates, as well as tissue samples from the spleen, liver, and lungs. For cases with diarrhea, samples from colon contents and feces can also be included. In live birds, it is recommended to analyze pharyngeal, nasal, and cloacal swabs. Due to intermittent shedding, especially in asymptomatic carriers, it is advisable to perform repeated sampling on several consecutive days.

Nucleic acid amplification tests are recommended for fast, sensitive, and accurate diagnosis. A *C. avium*–specific PCR method, based on the *enoA* gene, is available.[26] For the detection and identification of *C. avium* in suspected birds,[27] it is advisable to follow a hierarchical approach. This one begins with an initial Chlamydiaceae-specific PCR screening.[28,29] Positive cases identified though this screening should then undergo both a *C. avium*–specific[26] and a *C. psittaci*–specific PCR assay.[30] In previous studies, *C. avium* may have been overlooked or misidentified with *C. psittaci* due to the lack of appropriate diagnostic tools.

Proper handling and storage of samples is essential for successful culture of *C. avium*. Samples should be stored in a special preservation medium consisting of sucrose/phosphate/glutamate (SPG) with a cocktail of antibiotics/antifungals (streptomycin, vancomycin, gentamicin, and amphotericin)

and stored at −80°C if they cannot be processed immediately.[27] For the isolation and cultivation of *C. avium*, both embryonated chicken eggs and Buffalo green monkey (BGM) cells have proven to be suitable methods. Detection of *C. avium* can be accomplished through direct or indirect immunofluorescence using antibodies targeting the family-specific lipopolysaccharide (LPS) or using relevant staining techniques (Gimenez, Giemsa, Ziehl-Neelsen, or Macchiavello stain).

Treatment and Prevention

No vaccine is currently available for *Chlamydia* infections in birds. Sanitary measures must be implemented, in particular, the separation of sick animals and shedders, quarantine procedures for newly acquired birds, the separation of birds from multiple sources, and the application of strict hygienic practices (disinfection; see Chapter 11).[31]

Antibiotic treatment is only indicated by the onset of symptoms and laboratory confirmation of chlamydial infection. The primary choice of antibiotics for treatment includes tetracyclines, but quinolones, macrolides, and even rifamycins can also be administered.[32,33] Recently, psittacine birds with respiratory troubles and confirmed *C. avium* infection have been successfully treated with doxycycline administered at 20 mg/kg orally every 24 hours for a duration of 6 weeks. This treatment was completed with hepatoprotectors, vitamins, and tube feeding.[13] In racing and fancy pigeons, a shortened treatment period of 25 days with doxycycline at 40 mg/kg in drinking water has proven effective against *C. psittaci*/*C. avium* co-infections. However, achieving complete elimination of infection may be challenging, as reported in other animal and human chlamydial infections, due to the potential for persistence and resistance.[32] Therefore, laboratory testing after treatment is advisable, with at least two posttreatment analyses, typically 7 and 14 days after therapy completion.

While the zoonotic potential of *C. avium* has not been established, it is advisable to implement preventive measures similar to those used in case of *C. psittaci* infection. Wearing personal protective equipment when handling infected animals or samples, as well as during cleaning activities, is crucial for reducing the risk of aerosol exposure of people. This precaution is essential to minimize the possibility of inhaling infectious particles in confined environments.

CHLAMYDIA GALLINACEA IN POULTRY BIRDS

While an investigation was underway in France in 2009 at a poultry slaughterhouse in response to reports of unusual pneumonia cases among its workers, atypical *Chlamydia*, different from *C. psittaci*, was primarily isolated from chickens, the predominant avian species slaughtered at this facility.[34] This led to the identification and description of a novel chlamydial species that was designated *Chlamydia gallinacea* in 2014.[12] These atypical bacteria were clearly differentiated from *C. psittaci* through phylogenetic analysis based on 16S rRNA and whole-genome analysis, and they found to be phylogenetically closest to another novel chlamydial species, *C. avium*. Although *C. gallinacea* was suspected to be the cause of the pneumonia cases, this was never confirmed. Furthermore, the fact that ducks carrying *C. psittaci* also passed through this slaughterhouse suggests a potential *C. psittaci* infection in these individuals.

The Agent

C. gallinacea has primarily been detected in poultry, although its presence in other birds is assumed and has only been shown anecdotally.[35] Genome analysis has revealed that *C. gallinacea* constitutes a separate species, as it exhibits an average nucleotide identity of less than 81% when compared to its closest relative, *C. avium*.[34] Several complete genome assemblies are available for different *C. gallinacea* strains. Strain 08-1274/3^T,[12,36–38] isolated from a chicken in France, is considered the type strain.[12] Multilocus sequence typing (MLST) conducted on two complete genomes and 23 Chinese samples from nine farms has revealed 15 sequence types (STs) and two main clades. All Chinese STs clustered within one clade, further subdivided into 14 lineages, highlighting the genetic diversity of *C. gallinacea*.[39] Currently, it is unknown if these genetic differences have functional implications for host adaption or virulence.

C. gallinacea has been successfully isolated in cell culture and in embryonated eggs through yolk sac inoculation.[12,38,40] When cultivated in cell culture, it takes 60 to 72 hours to complete one developmental cycle, and serial passaging is more challenging compared to *C. avium* or *C. psittaci* strains.[12] In infected cells, single and multiple inclusions of variable size can be observed, containing small EBs and larger RBs. Within RBs, different stages of division through binary fission have been observed, indicating a binary life cycle typical for *Chlamydiaeceae*.[12]

C. gallinacea is mainly detected in poultry but has been found in other species such as pigeons, woodcocks (*Scolopax* spp.), a parrot, ultramarine grosbeak (*Cyanoloxia brissonii*), and cattle.[2,38,41–44] Its presence is widespread, with reports from various regions, including Asia,[38] Australia,[44] Europe,[15,22,45–47] North America,[48] and South America.[49] Most studies have focused on chickens, where *C. gallinacea* is highly prevalent (Table 18.2). Interestingly, it is more frequently detected in layers than in broilers, possibly due to differences in age and breeding systems.[49] Among layers, those within the age of 40 to 60 weeks appeared to have the highest risk of infection. This may be influenced by factors such as the timing of introduction, the duration of *C. gallinacea* infections, and the acquisition of immunity.[15]

A higher risk of *C. gallinacea* infection has also been reported in backyard chickens or chickens in open-sided poultry houses compared to commercial breeding farms with stricter biosecurity measures.[49] Furthermore, an association with certain bedding materials has been found.[50] These associations suggest that the environment plays a crucial role in the introduction and survival of *C. gallinacea*. This hypothesis is further supported by partial *ompA* gene sequence data, which have shown that individual farms, regardless of the flock, harbor their own unique *C. gallinacea* strain.[51]

Co-infections with both *C. gallinacea* and *C. psittaci* have been documented in chickens, but they seem to be sporadic.[46,52] In one case, co-infected chickens were traced back to a farm that also bred ducks.[52] It is likely that the ducks were the source of the *C. psittaci* infection through environmental contamination. While *C. psittaci* is considered to be the main chlamydial species in ducks and *C. gallinacea* in chickens,[45] there is a report of a high prevalence of *C. psittaci* and the absence of *C. gallinacea* in commercial Belgium chicken farms (18 out of 19).[53] A recent study has shown that experimental *C. gallinacea* infection in chickens does not provide protection against a subsequent experimental infection with *C. psittaci*.[54] Future research will help clarify the roles and possible interactions of *C. gallinacea* and *C. psittaci* in different poultry species.

TABLE 18.2

Transmission

C. gallinacea is shed in high quantities in fecal droppings, and environmental contamination appears to play an important role in transmission. The main route of transmission is the fecal-oral route, and unlike *C. psittaci*, airborne transmission through dried fecal material does not seem to occur.[55] Vertical transmission has been proposed based on the detection of *C. gallinacea* in the albumen and yolk of embryonated eggs. However, an alternative explanation could involve environmental contamination through penetration of the eggshell.[55] Cases of mechanical transmission through biting flies, lice, or mites have not been reported.

Currently, there is no conclusive evidence supporting the potential for zoonotic transmission of *C. gallinacea*. Initial concerns about transmission to humans arose when the first strains of *C. gallinacea* were isolated, notably in a French slaughterhouse where workers displayed signs of pneumonia.[40] However, this has never been confirmed, and it is more likely that contamination with *C. psittaci* through duck exposure was the probable source. In a recent prevalence study involving 69 Dutch poultry farmers and workers, testing failed to detect any *Chlamydia* DNA in human samples.[50] Additionally, during an outbreak of human psittacosis, in which eight women were exposed to chickens infected with both *C. gallinacea* and *C. psittaci* during plucking, no *C. gallinacea* DNA was found in their samples.[52] More recently, an investigation among Italian commercial or backyard poultry farmers identified 12 positive *C. gallinacea* cases out of 16 farmers in farms where the bacteria was also detected.[56] Notably, there were no associated clinical cases, indicating a low potential for *C. gallinacea* to induce disease in exposed individuals.

Clinical Signs

In chickens and turkeys, *C. gallinacea* infections are mainly asymptomatic, although reduced weight gain has been observed in chicken broilers.[37,44,49,56] Experimental data on the pathogenesis of *C. gallinacea* in poultry show that *C. gallinacea* mainly resides in the gut,[57] although it has been detected in blood, lung, heart, liver, trachea, kidney, pancreas, and spleen samples.[38,51,55] In contrast, experimental infections with *C. psittaci* in poultry birds can lead to severe clinical outcomes, although chickens are relatively resistant to *C. psittaci* infections.[58,59] The clinical signs and pathogenesis of *C. psittaci* infections depend on both the avian host and the *C. psittaci* strain.[60]

Diagnosis

A cloacal swab is the preferred sample for detecting *C. gallinacea* in poultry birds, as cloacal shedding of the bacterium is often high.[43,57] Additionally, *C. gallinacea* can also be detected in oropharyngeal swabs and, in lower amounts, in samples of lung, heart, kidney, liver, pancreas, trachea, spleen, and whole blood.[38]

PCR-based detection is considered the gold standard for *Chlamydia* diagnostics.[27,61] It is advised to first run a broad Chlamydiaceae PCR that targets the 23S rRNA gene.[28] Other 23S rRNA–based assays have also been described.[29,38] For the specific detection of *C. gallinacea*, PCR or sequence-based approaches can be used.[43,50]

Isolation can be performed using various cell culture systems, including Human Epidermoid carcinoma-2 (HEP-2) cells, BGM cells, and embryonated eggs via yolk sac inoculation.[12,37,38,40] Proper handling and storage of samples are crucial for successful isolation. In cases where immediate processing is not possible, samples should be stored at −80°C in a preservation medium consisting of SPG containing a cocktail of antibiotics and antifungals (streptomycin, vancomycin, gentamicin, and amphotericin).[27] For identification in cell culture or pathology, standard staining techniques, immunofluorescence, or immunohistochemical protocols for other *Chlamydiae* can be applied.[27] These last techniques mainly rely on the cross-reaction of antibodies targeting the LPS of chlamydial organisms.

Indirect detection of *C. gallinacea* can be challenging and is not recommended, as specific serological assays are not readily available. Generic serological assays for *Chlamydia* can be used, based on cross-reactive chlamydial antigens. For example, Stokes et al. reported the use of the ImmunoComb solid-phase ELISA (enzyme-linked immunosorbent assay) (Biogal, Israel) with serum samples of *C. gallinacea*–positive chickens.[44] However, it is essential to interpret results with caution, as cross-reactivity with other *Chlamydia* species and even gram-negative bacteria can occur when using generic serological assays. The development of peptide-based assays offers a promising solution to address issues related to cross-reactivity but requires further validation.[62,63]

Treatment and Prevention

The clinical relevance of *C. gallinacea* is questionable, and a zoonotic potential has not been established. Infections in poultry appear to be mostly asymptomatic. It is advised to only consider treatment when clinical symptoms are noticed, *C. gallinacea* infection is confirmed, and other possible infectious causes are excluded. There is no reason to believe that *C. gallinacea* responds differently to treatment than other Chlamydiaceae. Therefore treatment guidelines for *C. psittaci* can be applied.[31]

While there is no evidence of a zoonotic potential, it is advisable to use a flow cabinet when isolating or propagating the bacterium in cell or egg culture as high loads of the bacterium can be achieved during isolation.

Environmental contamination is thought to play an important role in transmission, so general cleaning and disinfection measures should be implemented. *Chlamydia* is susceptible to heat and most disinfectants, including 1:1000 dilutions of quaternary ammonium compounds, 70% ethanol, and a 1:32 preparation of household bleach. The bacterium is resistant to both acid and alkali.[31]

CHLAMYDIA BUTEONIS IN FREE-RANGING BIRDS OF PREY

The Agent

Chlamydiaceae DNA has been consistently detected from raptors for years.[64–71] A unique chlamydial isolate was identified from a cluster of four clinical cases of juvenile red-tailed hawks (RTHA, *Buteo jamaicensis*) in California, and partial sequence analysis of the 23S rRNA and the *ompA* genes indicated that this strain was closely related to, but distinct from, the *C. psittaci* M56 genotype, which had previously been detected in snowshoe hares and muskrats. At that time, it was designated as "*C. psittaci* strain G."[72] Interestingly, *C. psittaci* M56 was recently identified by PCR in samples from five raptors in Switzerland that were also tested with *C. buteonis* primers.[73] The same authors re-evaluated cases from falcons in the United Arab Emirates that had originally been identified as intermediate to *C. psittaci* and *C. abortus* and found they were all positive using *C. buteonis* primers.[74] Additional studies are necessary to evaluate whether avian chlamydiosis identified from raptors is attributed to a single or multiple species.

The prevalence of Chlamydiaceae DNA detection in apparently healthy, free-ranging wild *Buteo* species in California was found to be 1.4% (4/291).[71] Prevalence of 1.6% for *C. psittaci* DNA was identified among raptors in wildlife rehabilitation centers in Oregon.[75] A spatial cluster of seropositive *Buteo* raptors and raptors testing positive for *C. buteonis* was detected between Sacramento and San Francisco in California.[76] An isolate was cultured from a hatch-year red-shouldered hawk (RSHA, *Buteo lineatus*) from California and designated as the reference strain of the new *Chlamydia buteonis* species.[4] Chlamydial DNA was isolated from a juvenile Swainson's hawk *(Buteo swainsoni)* and an adult RTHA, and the full genetic sequences aligned 100% with each other and 99.97% with the recently described C. *buteonis*.[4] A retrospective study of all raptors admitted to the University of California, Davis Veterinary Medical Teaching Hospital from 2000 to 2019 identified chlamydial DNA in 1.7% of all raptors and 5.1% of all RTHAs presented (M.G. Hawkins, unpublished data, November 8, 2023). Sixty-one raptors were identified as confirmed or probable clinical cases: 57/61 cases were RTHAs; 2/61 were Swainson's hawks; 1/61 a rough-legged hawk *(Buteo lagopus)*; and 1/61 a ferruginous hawk *(Buteo regalis)*.

Transmission, Signalment, and Clinical Signs

To date it is unclear how *C. buteonis* is transmitted, but this organism is expected to be similar in transmission to *C. psittaci* and *C. abortus*.[4,25] The zoonotic potential of *C. buteonis* has not yet been evaluated. Human cases have been linked to other chlamydial species in free-living raptors.[77,78] There was suspected *C. psittaci* genotype B zoonotic transmission between a long-eared owl (Asio otus) and volunteers at a rehabilitation center.[78] Chlamydial organisms can be transmitted horizontally to other birds via ingestion or inhalation of ocular and nasal discharges, feces, urine, and fomites, increasing the potential risk of an outbreak at a rehabilitation center.[25,79,80] Enhanced surveillance and control measures should be in place in wildlife rehabilitation centers in order to minimize the risk of both zoonoses and of reintroduction of infection back into wildlife populations.

To date, *Buteo* raptor species seem to be the most affected of the raptors; however, a number of falcons have tested positive with *C. buteonis* PCR primers,[74] so much more testing is necessary to determine the global host range. Positive birds were significantly more likely to present during winter months (December–February) in California, and hatch-year

RTHAs were more frequently diagnosed (M.G. Hawkins, personal communication). Clinical signs observed were similar to those described in *C. psittaci*–infected psittacine birds and included lethargy, dehydration, emaciation, weakness, conjunctivitis, diarrhea, and biliverdinuria. Respiratory signs have been uncommon.

Diagnosis

Diagnosis of chlamydial infections is challenging due to the variability of nonspecific clinical signs, thus multimodal diagnostic testing is always recommended for confirmatory diagnosis.[31]

Culture requires specialized handling in the United States due to the zoonotic potential of *C. psittaci* and very few laboratories offer this testing. The most commonly available antemortem molecular testing modality available today is PCR for *C. buteonis*. This organism also cross-reacts with *C. psittaci* PCR primers, so, if suspected, it should be tested for specifically. For screening purposes, conjunctival-choanal-cloacal combination swabs are commonly obtained. Samples are collected from commonly infected tissues including the liver, lung, air sac, gastrointestinal tract, kidney, and spleen at postmortem examination.[31,81,82] Separate swabs from the conjunctiva and choana can support infection whereas cloacal swabs may detect a chlamydial organism passing through the gastrointestinal tract. Two non-*Buteo* raptors, one great horned owl (*Bubo virginianus*) and one prairie falcon (*Falco mexicanus*) tested positive via PCR for *C. buteonis*[76] and falcons originally identified as having chlamydial infections with an organism between *C. psittaci* and *C. abortus* were retested and found to be infected with *C. buteonis*.[74] Additional work is needed to further evaluate whether the organism affects additional raptorial species. Amplicons from swab samples from raptors did not identify as *C. psittaci* and were reported as "atypical" positives based on the amplitude of the detected amplicon.[71,82] If there is no commercially available specific PCR assay for *C. buteonis*, it is advised to run a broad *Chlamydia* PCR for raptor samples, then perform further subtyping. A commonly used *Chlamydia* PCR detects all Chlamydiaceae and targets the 23S rRNA gene.[28]

Paired acute- and convalescent-phase serum samples, obtained at least 2 weeks apart, are ideal and should be tested in the same laboratory at the same time.[31] Elementary body agglutination (EBA) detects chlamydial IgM antibodies, while the indirect fluorescent antibody test (IFA) detects IgY antibodies at the genus level for any *Chlamydia* spp.[31] The *C. psittaci* EBA serologic assay available in the United States is specific and does not detect host antibody response to *C. buteonis*.[71] An EBA assay specific for *C. buteonis* was utilized in a recent study;[76] the test is now commercially available in the United States.

Ancillary testing includes imaging, a complete blood count (CBC), and a biochemistry panel. The most consistent radiographic finding was splenomegaly (M.G. Hawkins, personal communication; Figure 18.3). Anemia with a moderate-to-severe leukocytosis were the most reported CBC abnormalities, characterized by heterophilia, bands, monocytosis, and eosinophilia—extraordinarily like those found in parrots with *C. psittaci*. Hyperfibrinogenemia was also commonly identified (M.G. Hawkins, personal communication; Table 18.3). The most significant changes on plasma biochemistry panels were elevations in creatine kinase (CK), aspartate aminotransferase (AST), uric acid, globulins, and hypoalbuminemia (Table 18.4).

FIGURE 18.3 Lateral radiograph of a red-tailed hawk (*Buteo jamaicensis*) with avian chlamydiosis. Hepatosplenomegaly and cranial thoracic air sac lines are evident. Splenomegaly is the most common radiological finding in raptors with *Chlamydia buteonis*.

Histopathological evaluation of postmortem tissues from *Buteo* hawks found lesions like those of *C. psittaci* in psittacines in the liver, spleen, air sac, heart, lung, and kidney (M.G. Hawkins, personal communication). Chlamydial immunofluorescent IHC testing has been recently reported to be nonspecific and therefore not useful for diagnosis.[31] However, many cases have tested positive by IHC and have been correlated with tissue PCR and in situ hybridization, suggesting that pathologists familiar with chlamydial lesions can use IHC staining in the diagnosis of this disease (M.G. Hawkins, personal communication).

Treatment and Prevention

To our knowledge, treatment of *C. buteonis* or other chlamydial organism infections in wild raptors has not yet been reported. As modes of transmission are also not known yet for this organism, it is challenging to predict which preventative protocols may be successful in minimizing this infection. The severity of chlamydiosis in *Buteo* raptors raises the question of whether this disease could also threaten raptors at a population level. From November, 2021, through March, 2022, increased admissions and mortalities of free-ranging red-tailed hawks into rehabilitation centers throughout the state of California were reported to the California Department of Fish and Wildlife. Fifty of 76 bird carcasses tested were positive for chlamydiosis on IHC and tissue PCR during this outbreak. Of the four species that have shown clinical signs and have tested positive, the RTHA, rough-legged hawk, and ferruginous hawk populations are considered stable, whereas the Swainson's hawk is listed as a threatened species in California due to loss of nesting grounds. Additionally, non-endangered species may be a reservoir for the disease with the potential for spillover into less stable populations, such as the California condor *(Gymnogyps californianus)*, a federally listed endangered species in the United States. More work is needed to determine the host range of this chlamydial species to gain better understanding of the potential threat it poses to wildlife populations.

TABLE 18.3

Median ± SE Complete Blood Count Values of 28 Red-Tailed Hawks *(Buteo jamaicensis)*, 1 Ferruginous Hawk *(Buteo regalis)*, and 1 Swainson's Hawk *(Buteo swainsoni)* With *Chlamydia buteonis*

Parameter	Median ± SEM	Range	Reference Interval (Mean ± SD)[83]

AST, aspartate aminotransferase; *CK*, creatine kinase; *SD*, standard deviation.

CHLAMYDIA ABORTUS

Avian strains of *C. abortus*, originally detected during a 2014–2015 study in Poland, have recently been identified alongside the well-established ruminant strains primarily associated with ruminant abortions.[22] These avian strains share a close genetic resemblance to ruminant *C. abortus* strains but possess distinctive traits, notably a plasmid similar to those found in *C. psittaci* strains.

These avian *C. abortus* strains have been detected in cloacal swabs collected from various healthy wild bird species in Poland, including swans, mallard ducks (*Anas platyrhynchos*), Eurasian teals (*Anas crecca*), Eurasian coots (*Fulica atra*), magpies (*Pica pica*), and hooded crows (*Corvus cornix*).[22] They have also been found in crows in Italy[85] and cormorants (*Phalacrocorax* spp.) in the Galapagos islands. PCR tools have been developed to identify all *C. abortus* strains, encompassing both avian and classical ruminant strains. This discovery challenges the initial classification of some strains as *C. psittaci*.[86] For example, strains such as 84/2334, isolated from an Amazon parrot (*Amazona* spp.) in Germany, and Prk/Daruma, isolated from a parakeet in Japan, exhibit notable differences from classical[87] *C. psittaci* strains. These strains have been recently reclassified as avian *C. abortus* strains.

CANDIDATUS CHLAMYDIA IBIDIS

While investigations were being conducted in the wild fauna due to the significant presence of *C. psittaci* in duck farms in France, ibises observed in the areas visited by these ducks were sampled to assess their potential role in transmission and contamination of the ducks. This is how atypical strains, distinct from *C. psittaci*, were isolated alongside the typical strains of *C. psittaci* commonly found in ducks.[6] This study led to the isolation and description of strains later identified as *Ca. C. ibidis*. Notably, the study also indicated the potential for the risk to be reciprocal, suggesting that farmed animals could present a contamination threat to wild fauna as well.

Ca. C. ibidis was isolated from cloacal swabs from healthy feral African sacred ibises *(Threskiornis aethiopicus)* in western France.[6] More recently, 20.2% of fecal samples from crested ibis *(Nipponia nippon)*, an endangered species with a very limited population, were found positive for Chlamydiaceae DNA and were related to *Ca. C. ibidis*, with the co-existence of *C. psittaci* in one positive sample. In this study, the samples positive for *Ca. C. ibidis* displayed substantial genetic diversity, with only 77% identity for the *ompA* gene sequence when compared to those of the French 10-1398/6 *Ca. C. ibidis* strain.[4]

OTHER CHLAMYDIACEAE IN WILD BIRDS

The Agents

In wildlife, the first chlamydial infections were recorded in the 1930s, when juvenile fulmars (*Fulmarus* spp.) were hunted for food. Human infections from preparing and cooking the fulmars prompted a ban on their hunting for human consumption in the United States until 1954.[88] To date, most of the attention has been on wild birds acting as reservoirs for *C. psittaci*, with little consideration given for disease manifestation in wildlife species for this or other new chlamydial species.[89] However, there is evidence for the zoonotic and/or cross-species transmission potential of bacteria within the order Chlamydiales, with an increasing number of reports suggesting contact with wildlife and/or livestock is a risk factor for these infections.[9,11]

As such, Chlamydiaceae species in wildlife could have higher impact on human and animal health worldwide than currently recognized.[10,11] The discovery and description of novel species in avian hosts highlights how much we still must learn about the biology and pathogenicity of the Chlamydiaceae as a whole. Throughout the continued identification of novel chlamydial organisms there is growing evidence that some of these novel organisms may be pathogenic to birds, humans, or other animals, thereby posing new zoonotic risks.[11] The intensification of farming and the widespread popularity of companion animals also present ongoing opportunities for emerging zoonoses.[10,11]

Thus far, chlamydial infections have been identified in over 70 species of wild birds.[89] In addition to the more traditional hosts (most notably Columbiformes), birds from the Corvidae and Accipitridae families seem to be emerging as chlamydial hosts.[22,90–92] Other species in which Chlamydiaceae have been isolated include Anatidae (ducks and geese[22,34,93–96]), Rallidae (rails[95]), Alcidae (auks[97]), Laridae (gulls[97,98]), Sulidae (gannets and boobies[34]), Procellariidae (fulmars[99]), Gruiformes (cranes[94]), Threskiornithidae (ibises[100]), Phoenicopteriformes (flamingos[8]), Sphenisciformes (penguins[98]), Strigiformes (owls[90–92]), Apodidae (swifts[101]), and various species of Passeriformes (songbirds, e.g., Paridae [tits], Turdidae [thrushes[96,102–105]]). Aside from the traditional members of the genus *Chlamydia*, including *C. psittaci*,[78] *C. trachomatis*,[94] and avian strains of *C. abortus*,[106] newly identified Chlamydiales are also regularly discovered in wild birds. These novel species likely represent the "tip of the iceberg" in terms of diversity of *Chlamydiae* (and their hosts) present in wild birds.[97]

Prevalence estimates also greatly vary between studies, even if focusing on the same host lineages (see Stokes et al., 2021 for an overview[89]). For example, in a study conducted in Oregon, 3 out of 82 choanal and cloacal swabs from raptors (1.6%) from wild bird rehabilitation centers in Oregon were positive for chlamydial DNA using PCR,[75] suggesting that the carriage rate of *C. psittaci* in this region is low. However, in a Belgian wildlife facility, 26% (11/42) of pharyngeal swabs were culture positive in sampled wild birds, suggesting prevalence can vary greatly according to the region involved. Additionally, molecular characterization of the isolates from these birds revealed *C. psittaci* genotypes A, B, D, and E/B, reflecting multiple distinct infections and highlighting the endemic nature of *C. psittaci* in avian wildlife.[78] However, as the reported prevalence estimates in free-ranging birds are based on detection of Chlamydiaceae DNA in cloacal and fecal swab samples,[18,64,71,97] these rarely provide a definitive diagnosis of infection.[103]

Transmission, Clinical Signs, and Zoonotic Potential

There are few reports to date documenting transmission and clinical disease associated with chlamydial organisms in wild birds.[41,65,67,68,72,78,94,103,107] Similarly, little data is available on the influence of chlamydial infections on the reproductive success of wild birds, although one study in crimson rosellas *(Platycercus elegans)* found that breeding birds were less likely to be infected than nonbreeding birds,[108] suggesting that chlamydial infections may reduce the likelihood of breeding in this and potentially other species of wild birds as well. Some preliminary evidence also exists that in some wild bird populations (e.g., white-winged doves, *Zenaida asiatica*), young birds are more susceptible to *C. psittaci* infection than adult birds,[108,109] yet further studies are needed to confirm these findings.

Many *Chlamydia*-positive birds are believed to harbor chlamydial organisms without showing clinical signs. Nevertheless, there are some reports of wild birds showing clinical signs associated with chlamydiosis (e.g., emaciation, diarrhea, and, less commonly, respiratory signs), as well as reports on suspected epizootics in white-winged doves and various gull species in the United States,[109,110] which suggest that chlamydial disease can affect wild bird populations.[111] A postmortem study investigating tissues from wild bird mortalities in Great Britain that showed histopathologic lesions characteristic for chlamydial infection such as hepatitis were evaluated using *C. psittaci* PCR and ArrayTube microarray assays. Twenty-one of the 40 birds tested positive: 8 dunnocks *(Prunella modularis)*, 7 great tits *(Parus major)*, 3 blue tits *(Cyanistes caeruleus)*, 2 collared doves (*Streptopelia decaocto*, order Columbiformes), and 1 robin *(Erithacus rubecula)*.[103] Of the 21 *C. psittaci*–positive birds, 10 had histological lesions consistent with chlamydiosis and colocalizing *Chlamydia* spp. antigens on immunohistochemistry.[103] *C. psittaci* genotype A was identified in all positive passerines and in a further three dunnocks diagnosed with chlamydiosis from a previous study. Two collared doves had genotype E.

Zoonotic transmission of chlamydial infections is mostly thought to result from contact with infected captive birds, but there are also cases where infection is suspected to be contracted through direct or indirect contact with wild birds. While in most cases this seemed to involve feral pigeons,[112–115] other species have been implemented in human-transmitted psittacosis as well.[116,117] Close contact with or handling of wild birds is a common source of zoonotic infection, but in some cases, infections have been linked to cleaning of bird feeders or mowing of lawns[117–119] without a grass catcher. Suspected zoonotic transmission between a long-eared owl and volunteers at a rehabilitation center highlighted that wildlife rehabilitation workers were unaware that signs of chlamydiosis were similar to cold and flu symptoms.[78] These findings demonstrate that chlamydial infections in wild birds may be problematic for contact individuals, including rehabilitation center workers, wildlife biologists, banders, veterinarians, and falconers.

Diagnosis

As the majority of wild birds are not diagnosed antemortem; instead, diagnosis is often made from postmortem tissues using qPCR or in situ hybridization. Care must be taken in the design of PCR primers for the phylum *Chlamydiae* such that insect infestation is not mistaken for an infection by known chlamydial pathogens.[75] Immunohistochemistry can be utilized as a tool to diagnosis but in the United States, it is not considered highly diagnostic because of indiscriminate staining.[31] Culture can be used to identify chlamydial species from fresh tissues, if a willing laboratory can be found to perform the culture. Tissue qPCR has confirmed infection in a number of wild bird species.[69,94,103,107] If heart blood can be collected, the blood can be centrifuged and serology performed for IgM/IgY antibodies. Seroprevalence in wild birds has been identified from 1% to 63%.[70,120–122] While both IgM and

IgY chlamydial antibodies are differentiated serologically, the presence of one or both does not confirm active infection.

Treatment and Prevention

There are no reports to our knowledge of successful treatment of a wild bird documented with chlamydiosis. As the pathogenesis and zoonotic potential of the disease is mostly undefined in wild birds, methods of prevention should follow those outlined for *C. psittaci*.

Chlamydial infections of wildlife may pose a threat to conservation.[9] Perhaps the most well-known example of this is the devastating effect *C. pecorum* and *C. pneumoniae* have had on koala *(Phascolarctos cinereus)* populations in Australia[123] As *C. psittaci* can cause severe disease in highly susceptible hosts (e.g., immunocompromised individuals) or when exposed to additional stressors (e.g., human-induced habitat destruction) or concurrent infections (e.g., beak and feather disease virus [BFDV]), chlamydial infections may potentially result in population declines in wild birds.[89] However, the pathogenicity can differ greatly across species, whereby the strain may cause severe disease in one species but no clinical signs in another.[89] This poses additional concerns as a particular host may introduce a novel chlamydial strain in a naïve population or alternative host, thereby potentially inducing severe disease and species decline. Detailed studies are thus required to assess whether the new chlamydial species have the capacity to cause serious disease and/or zoonosis in wild birds and to be transmitted to humans or other animals.

AN OUTBREAK OF *CHLAMYDIA PSITTACI* IN SPHENISCIFORMES

The Agent

C. psittaci is a well-documented agent of disease in captive avian populations, but few reports of clinical disease associated with chlamydial species have been described in Sphenisciformes. Positive *Chlamydia* antibody titers have been documented in several wild species in Argentina, the Galapagos, and Antarctica.[98,124–126] In addition, a large survey of Antarctic seabirds and penguins showed that the prevalence of *C. psittaci* is low but another Chlamydiaceae-like bacterium is widespread.[98] These studies suggest that *Chlamydia* spp. may be wide-ranging in penguin species but are not known to commonly cause disease. The one confirmed outbreak of *C. psittaci* has been described in Magellanic penguins (*Spheniscus magellanicus*) and was successfully treated in a captive care facility in California.[127]

Transmission

The source of infection for the outbreak in Magellanic penguins was never discovered. The outbreak occurred in an outdoor flock with frequent trespasses by gulls and pigeons, which are documented carriers[128] and may have served as a source of exposure. Alternatively, wild caught birds or birds from other zoological institutions within the colony may have been latently infected and served as the source of infection. Banked serum samples from the effected colony were submitted for serology and showed positive antibody titers from samples taken up to 9 years earlier. Possible predisposing factors in this colony included overpopulation, as the colony was approximately 10 birds more populated than historical levels. The outbreak also occurred during breeding season, which may have added additional stress leading to emergence of latent infections.

An aggressive quarantine protocol was established to protect other species of birds in the collection and the caretakers. Zoonotic spread likely occurred in one human caretaker during this time, but diagnostics were not performed to confirm infection.

Clinical Signs

Initial clinical signs emerged in 14% of the colony and were nonspecific including acute lethargy, inappetence or anorexia, and green urates. As clinical signs were vague, aspergillosis or malaria, which had previously been diagnosed in the colony, were top differentials and birds were prophylactically treated as such. Three of these birds died before a diagnosis of avian chlamydiosis was made. During the outbreak and treatment period, four birds presented with seizures, of which two died. Fifty birds exhibited severe keratoconjunctivitis with blepharospasm (Figure 18.4A), serous to purulent conjunctival exudate, chemosis, and varying degrees of corneal edema while undergoing treatment. An additional five of these birds presented with dermatitis of the legs and dorsal feet in varying degrees of severity (Figure 18.4B,C). The dermatitis developed within days after completion of treatment with doxycycline. The keratoconjunctivitis and dermatitis of the legs and feet were attributed to light sensitivity secondary to doxycycline administration.

Diagnosis

A variety of diagnostic modalities were employed in the outbreak investigation. Clinical signs were nonspecific initially and *C. psittaci* was not high on the differential list when signs first appeared. Histopathology and immunohistochemical staining of mortalities were the first diagnostics to suggest *C. psittaci* infection and lesions observed were consistent with avian chlamydiosis. PCR of tissues confirmed the diagnosis. PCR of choanal-cloacal/fecal swabs and environmental swabs was most useful in determining presence of the bacteria and shedding in live birds. PCR of environmental and choanal-cloacal/fecal swabs was also used as a monitoring and follow-up tool. Fecal samples collected randomly remained positive for 2 weeks following the start of treatment after which they tested negative.

Blood work, conducted on nine individuals, showed nonspecific abnormalities including leukocytosis, heterophilia with toxic change, and hyperproteinemia. A moderate increase in AST and uric acid was observed in a subset of these birds. Rising or persistently elevated titers to *C. psittaci* were not observed in the colony in monthly serologic tests over a 3-month period.

Treatment and Prevention

Treatment with doxycycline at 100 mg/bird (17–33 mg/kg depending on the weight of the bird) PO q24h for a minimum of 30 days was effective in treating the disease. Initially, a dose increase to 200 mg/bird was attempted but a significant number of birds exhibited side effects and the dose was lowered again to 100 mg/bird. Loss of appetite was the most common side effect and often occurred within 5 days of starting oral

FIGURE 18.4 Clinical signs exhibited in Magellanic penguins (*Spheniscus magellanicus*) with avian chlamydiosis included keratoconjunctivitis with (A) blepharospasm and (B, C) dermatitis of the legs and dorsal feet in varying degrees of severity.

treatment. In those cases, oral medications were assist-fed or long-acting doxycycline injections 50 to 75 mg/kg IM q7d were given in alternating sites in combination with subcutaneous fluids. Some birds received combinations of injectable and oral doxycycline. Fluconazole was also given (100 mg PO q24h) as prophylaxis for fungal infections and was continued for 30 days after completion of doxycycline. Avian malarial prophylaxis with primaquine was maintained for the first 2 weeks of the treatment period.

Light sensitivity was a side effect of treatment with doxycycline and birds with dermatitis and ocular lesions received nonsteroidal antiinflammatory drugs (NSAIDs), either ketoprofen at 2 mg/kg IM PRN or carprofen 2 mg/kg PO q12h and zinc oxide topically. Topical ocular treatments included saline flush, followed by ophthalmic lubricant. Dermatitis resolved over an average of 3 to 4 weeks after beginning treatment. Anorexia and weight loss were also side effects of the treatment and in cases with pronounced weight loss, assist feeding oral doxycycline in fish was used to maintain caloric consumption. Behavioral side effects occurred as well, with birds spending time in unusual places or hiding more in dens. Abnormal swimming patterns occurred in a quarter of the birds. These were characterized by birds swimming in small circles with heads pointed to the sky and eyes held tightly shut. Behavioral side effects resolved with the completion of treatment.

Death due to *C. psittaci* only occurred prior to diagnosis and targeted treatment. Additional deaths occurred and were attributed to a variety of cofactors or complications from treatment. Other diagnoses included visceral gout, myocardial degeneration and insufficiency, and severe esophagitis leading to esophageal perforation and sepsis. Caution is recommended in pilling doxycycline and this medication should be given in a whole fish or gavage fed. The majority of birds recovered fully.

CHAPTER 19

Erysipelas in Wild Birds

Manjula Jayasinghe • *Brett D. Gartrell*

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Erysipelas is the infectious disease caused by the opportunistic pathogen *Erysipelothrix rhusiopathiae* in a wide range of mammals, birds, some reptiles, and fish.[1,2] Erysipelas is a zoonotic disease and usually causes mild dermatitis in humans, but in rare cases can cause systemic disease and endocarditis.[3,4] Confusingly, in humans, the term erysipelas refers to skin infection due to *Streptococcus* spp.,[5] while cutaneous disease caused by *E. rhusiopathiae* in humans is known as erysipeloid.[6] In birds, erysipelas can be an acute, fulminating infection or, more rarely, a chronic infection of the reproductive tract causing infertility in male birds and reduced egg production in females.[1] However, many avian infections of *E. rhusiopathiae* are subclinical. It is possible that erysipelas in wild birds is underrecognized and underdiagnosed.[7] The disease has been reported as individual cases or in isolated clusters of cases in over 60 species of wild birds, including little blue penguins *(Eudyptula minor)*,[8] laughing kookaburras *(Dacelo novaeguineae)*,[9] rainbow lorikeets *(Trichoglossus moluccanus)*,[10] eclectus parrots *(Eclectus roratus)*,[10] and the endangered Hawaiian crow (*Corvus hawaiiensis*; Table 19.1).[11]

Mass mortality events associated with *E. rhusiopathiae* have been reported in some wild bird populations.[7] For example, an erysipelas outbreak in the Great Salt Lake in Utah, USA, killed more than 10,000 eared grebes *(Podiceps nigricollis)*. Similar events at the same location have also affected California gulls *(Larus californicus)*.[7] An estimated 600 brown pelicans died in another outbreak of erysipelas in California.[7] A mass mortality event due to *E. rhusiopathiae* killed little swifts *(Apus affinis)*, nesting in South Africa.[12] Erysipelas has also been recorded in Southern Ocean albatrosses and is suspected to have caused outbreaks of mortality in these birds in the mid-1980s.[13] The prevalence of *E. rhusiopathiae* in dead seabirds on New Zealand offshore islands used for intensive conservation varied from 3.4% to 11.4% and was most commonly found in sooty shearwaters (*Puffinus griseus*; 5.9%), mottled petrels (*Pterodroma inexpectata*; 2.7%), and Cook's petrels (*Pterodroma cookii*; 13.5%). These burrowing seabirds are possible reservoirs of *E. rhusiopathiae* and may be a source of spillover to other species managed on the islands.[14]

ETIOLOGY: *ERYSIPELOTHRIX RHUSIOPATHIAE*

E. rhusiopathiae is a gram-positive, rod-shaped bacillus, ubiquitous in nature, and both a commensal and pathogen in diverse species of animals, wild or domestic, from mammals and birds to reptiles and fish.[2] Transmission of *E. rhusiopathiae* is thought to be through the gastrointestinal tract by the intake of contaminated food or water or through breaks in the mucous membrane or skin.[1] Asymptomatic carriage of the organism in animals with subsequent dissemination into the environment and other animals has been suggested as an important mechanism for maintenance of *E. rhusiopathiae* in nature.[15] The organism may persist in aquatic and soil environments, meat products, and decomposing animal remains. The bacteria may also be spread through insect vectors, ticks, mites, and flies; however, the role of these vectors in the epidemiology of *E. rhusiopathiae* remains unclear. There is no evidence to support vertical or egg transmission of the bacterium. Control of infections is challenging because of the organism's ubiquitous nature in the environment and its ability to survive asymptomatically within reservoir hosts.

The genus *Erysipelothrix* consists of five species, and the differentiation of *Erysipelothrix* species was historically based on their serovar, which is determined by the cell wall peptidoglycan antigens. Serovars 1a, 1b, 2, 4 to 6, 8, 9, 11, 12, 15 to 17, 19, 21, 23, and N were characteristic of the only pathogenic species, *E. rhusiopathiae*.[16] Disease in pigs, poultry, and humans is mostly associated with *E. rhusiopathiae* serovars 1a, 1b, and 2. Serotypes 1b, 5, 6, 8, 14, and 21 have been isolated from *E. rhusiopathiae* isolates from captive native Australian birds.[17] Although serotyping is important as a diagnostic technique in diagnosing *E. rhusiopathiae* infection, the ability of horizontal exchange of capsule-specific genes in many bacterial species has reduced its use as a technique to detect evolutionary relatedness among isolates.[18,19] Recent genomic studies revealed that there is, as yet, no indication of geographic or host specificity of the *E. rhusiopathiae* isolates, suggesting that the mammals and birds are infected by phylogenetically similar strains either through a common reservoir or indirect transmission between animal orders.[20]

TABLE 19.1

A summary of published reports of the clinical and pathologic features of wild bird mortality due to *Erysipelothrix rhusiopathiae*

Avian Species	Clinical Signs	Gross Lesions	Means of Diagnosis	References
Little swifts *(Apus affinis)*	High mortality	Moderate splenomegaly	Bacterial culture from liver, spleen, and heart blood	12
Bald eagle *(Haliaeetus leucocephalus)*	Sudden death	Little subcutaneous fat and a slight reduction of the pectoral musculature, diffusely pale heart with light streaks. The atrioventricular valve leaflets were thickened with numerous vegetations (proliferative outgrowths) on their surfaces. Irregular cream-colored 1- to 2-mm foci were observed on the surface and within the parenchyma of the liver	Bacterial culture from liver	36
Hawaiian crow *(Corvus hawaiiensis)*	Found dead	Partially scavenged and loss of tissues, moderate atrophy of the left pectoralis, and the absence of abdominal and subcutaneous fat	Culture of the kidney	11
Indian yellow-nosed albatross *(Thalassarche carteri)*	Chick mortality, apparently healthy well-fed chicks died within a few minutes after convulsions	Not recorded	Necropsy, bacterial culture, histopathology	13
Little blue penguins *(Eudyptula minor)*	Anorexic for 1 day, found acutely recumbent and moribund the next day	Pulmonary hemorrhage, edema of the lungs and intestine and with clotted blood in bronchi, and mucosal petechiation of the proximal third of the small intestine with clotted blood in the lumen	Bacterial culture from liver, lungs, and intestine. Histopathology	8
Laughing kookaburras *(Dacelo novaeguineae)*	Weakness and weight loss over 2 weeks	Moderately atrophied pectoral muscle, edematous red lungs	Bacterial cultures of lung, liver, heart, and cloacal swabs. Pulsed-field gel electrophoresis (PFGE)	9
Kakapo *(Strigops habroptilus)*	Lower level of activity than commonly seen posttranslocation. Mortality within 1–4 days post translocation	Congested, slightly swollen and mottled liver and a congested and swollen spleen, variable degree of enteritis. All birds were in good body condition with good fat reserves and food still present in the crop	Clinical findings, gross necropsy changes, cytology, histopathology and bacterial culture	33
Takahe *(Porphyrio hochstetteri)*	Found dead	Not recorded	Bone marrow culture from the frozen carcasses and then PCR	35
Rainbow lorikeets *(Trichoglossus moluccanus)* and eclectus parrots *(Eclectus roratus)*	Died with no premonitory signs	Moderately atrophied adipose tissues, moderate to severe dehydration, severe hepatomegaly, a large area of dark red discoloration in the left ventricle, mild accumulations of yellowish transparent fluid in the coelomic and pericardial cavities, mild splenomegaly, and mild bilateral thyroid enlargement	Histopathology, Gram staining, bacterial culture and sequencing, immunohistochemistry, and real-time PCR	10
North Island brown kiwi *(Apteryx mantelli)*	Moderately swollen right hock joint for 1–2 weeks	Moderate body condition. Loosely adhered clumps of gelatinous dull yellow material in the reddened and thickened synovium of the hock joint. Multiple areas of dull yellowing, softening, and pitting of the articular cartilage from both the right distal tibiotarsus and proximal tarsometatarsus	Bacterial culture	Unpublished

PCR, Polymerase chain reaction.

Clinical Signs

With the exception of lethargy, there have been no specific clinical signs associated with *E. rhusiopathiae* infection in wild birds. Death of one or more birds in a flock is generally the first clinical sign in acute septicemia.[7] In chickens, the main clinical signs include general weakness, depression, diarrhea, and sudden death.[1]

Pathogenesis

The pathogenesis of erysipelas in wild birds or in animals in general is not well known, and while the organisms can be found in large numbers in endothelial cells and macrophages, there is often little host inflammation or cellular damage present. Capsule antigens, neuraminidase, surface adhesion molecules, hemolysins, and hyaluronidase are considered important in the pathogenicity of the organism. Neuraminidase releases sialic acid residues from glycoproteins, glycolipids, and oligosaccharides expressed on host cells leading to vascular damage and hyaline thrombus formation.[16] It has been found that the capsule is associated with resistance to phagocytosis and intracellular survival of the bacteria.[21] However, experimental studies have shown that hyaluronidase is not associated with the virulence of *E. rhusiopathiae*.[22]

Diagnosis of Erysipelas

Gross lesions of erysipelas include signs of septicemia, such as hepatomegaly and splenomegaly (Figure 19.1), similar to other infectious diseases in birds including avian chlamydiosis, fowl cholera, *Escherichia coli* infections, and salmonellosis. Most field cases of erysipelas have been diagnosed with necropsy examination including culture and identification of *E. rhusiopathiae*. Demonstration of the presence of clumps and segregated gram-positive, beaded, slender, and pleomorphic rods in smears prepared from liver, spleen, heart blood, or bone marrow provide rapid tentative diagnosis (Figure 19.2). The organism is more readily isolated from birds that died of the disease rather than ill birds that are killed for sampling. Sampling from multiple organs, including bone marrow, is necessary in order to detect the organism from carrier birds. Packer's medium, which contains sodium azide-crystal violet, and the tryptose phosphate broth medium with 5% horse serum plus kanamycin, neomycin, vancomycin, and novobiocin are two inhibitory culture media routinely used to isolate *E. rhusiopathiae*.[1]

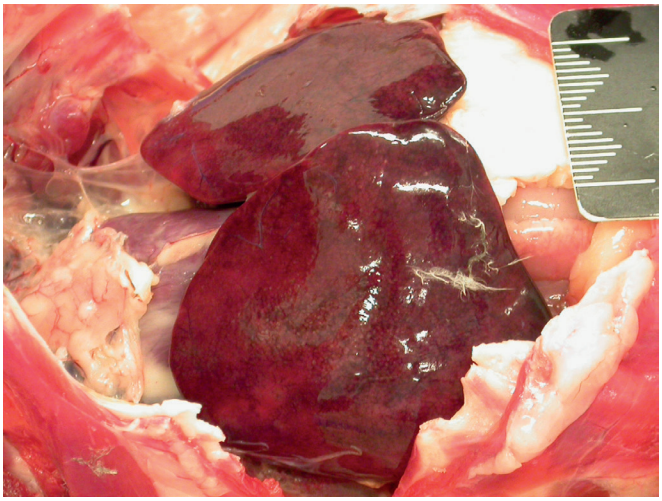

FIGURE 19.1 A postmortem image of the swollen liver of a young kakapo *(Strigops habroptilus)* that died suddenly in good condition due to erysipelas.

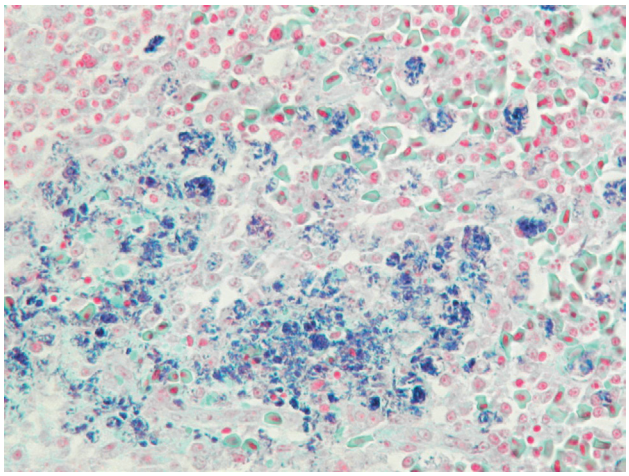

FIGURE 19.2 Gram-stained section of the spleen of a young kakapo *(Strigops habroptilus)* that died due to erysipelas (400× magnification). The aggregation of *Erysipelothrix rhusiopathiae* organisms is evident as blue staining material within macrophages and endothelial cells.

Morphological and biochemical identification of *Erysipelothrix* species colonies is based on Gram stain, cultural morphology, motility, hemolytic characteristics, and biochemical properties. Colonies are clear, circular, and very small, with a diameter of 0.1 to 0.5 mm after 24-hour incubation at 37°C or 0.5 to 1.5 mm after 48 hours. They may be either smooth colonies with bluish, transparent, and convex appearance or rough colonies that are larger and have a flat rough surface with irregular edges. Microscopically, smooth colonies contain small, slightly curved, slender rods with rounded ends, while rough colonies have long filaments rods up to 60 mm or more, in chains. Alterations in pH and incubation temperature can result in these morphological differences. *Erysipelothrix* species are relatively inactive biochemically and negative for catalase, oxidase, methyl red, indole, esculin, and nitrate. The majority of *Erysipelothrix* species produce hydrogen sulfide (H_2S) as demonstrated in triple sugar iron (TSI) agar. Acid is produced from glucose, fructose, galactose, and lactose but not from maltose, xylose, and mannitol. The ability of *E. tonsillarum* to ferment sucrose differentiates it from *E. rhusiopathiae*.[2]

Polymerase chain reaction (PCR) has been used to diagnose *E. rhusiopathiae* from tissue samples of swine, poultry, and other animal species. A PCR technique has also been used to diagnose *E. rhusiopathiae* using the DNA extracted from formalin-fixed, paraffin-embedded liver tissues[23] and for the rapid diagnosis of *E. rhusiopathiae* in chicken blood.[24] Restriction fragment length polymorphism analysis[25] and pulsed-field gel electrophoresis[26] are two types of molecular methods alternative to PCR and DNA sequencing that have been used to diagnose and characterize *E. rhusiopathiae* isolates. In addition, the use of MALDI-TOF-MS (matrix-assisted laser desorption/ionization with time-of-flight mass spectrometry) for diagnosis of *E. rhusiopathiae* in tissue samples, blood, and tissue

fluids has been demonstrated recently.[27–29] For the confirmation of diagnosis in a postmortem investigation any of these techniques may be sufficient. However, for the investigation of the mortality clusters of erysipelas in wild birds, culture of *E. rhusiopathiae* from affected individuals with subsequent confirmation by PCR and whole-genome sequencing is recommended. The best way for us to understand the epidemiology of erysipelas is by phylogenetic comparison of field strains with published sequences.

Treatment and Control

Treatment for erysipelas in wild birds has not been formally reported due to the acute nature of the disease and most of the affected birds were found dead. However, *E. rhusiopathiae* is susceptible for many antibiotics such as penicillin, cephalosporin, clindamycin, and the fluoroquinolones.[1,7] At the time of a cluster of mortality in kakapo *(Strigops habroptilus)*[30] the remaining birds were captured, placed in temporary pens, and treated with amoxicillin and clavulanate at 125 mg/kg PO bid for 5 days. There were no further deaths once this treatment commenced, but it is uncertain if that was a result of treatment (B. Gartrell, personal communication, 2021). During an outbreak in domestic poultry, it has been recommended to treat and vaccinate all the birds in a flock.[1,30] Treatment of choice is a rapid-acting form of penicillin given intramuscularly. Penicillin can be administered via drinking water for 4 to 5 days to control an infection when a presumptive diagnosis has been made.[1] Prompt removal of carcasses and incineration has been recommended to control an infection during an outbreak.[1] In addition, adequate sanitation, stress reduction, and health monitoring are important in controlling and eradicating the diseases in captive birds.

Prevention of erysipelas in intensively managed wild populations can be achieved through vaccination[30,31] and by reducing management actions during harsh seasonal periods, for example, not translocating susceptible birds in winter.[30,31] However, for most wild bird populations, control of erysipelas is not a feasible option.

Epidemiology of Erysipelas

The prevalence of erysipelas among poultry or wild birds is not well understood. Two studies have reported the prevalence of antibodies to *E. rhusiopathiae* in domestic poultry as 5.5% (200 samples) and 39.8% (545 samples).[32,33] Stephenson and Berman (1978) estimated that 30% to 50% of healthy swine harbor *E. rhusiopathiae* in their tonsils making them the most important reservoir for other domestic livestock. Infected pigs can transmit the organism indirectly by contaminating soil, bedding, and water.[34] However, the reservoirs and host species in wild ecosystems are far less well studied; *Erysipelothrix* spp. has been isolated from the cutaneous slime of both fresh and saltwater fish and can persist long periods in marine locations.[2] In addition, these bacteria may persist on insects, mollusks, and crustaceans.[2,16] Rodents can be infected and have been suggested as a possible source of infection for other animals. It is believed that more than 30 species of wild birds can harbor the organism and act as reservoirs in natural ecosystems. The source of infection is often not identified in many erysipelas outbreaks. Stress or various other factors that weaken the host defense mechanisms may lead to clinical disease in *E. rhusiopathiae* carriers. In wild birds, extreme weather conditions during winter are suspected to increase susceptibility to infection with *E. rhusiopathiae*.[7]

Effects of Erysipelas on the Conservation of Wild Birds

Erysipelas is a sporadic cause of mortality in a range of species, but clusters of mortality have been reported in a number of seabirds and erysipelas may be of special concern for these birds. *E. rhusiopathiae* has been identified as a potential cause of chick mortality causing population decline in yellow-nosed albatross *(Thalassarche carteri)* in Amsterdam Island. The presence of this bacterium has also been detected in oropharyngeal swabs of Amsterdam albatross *(Diomedea amsterdamensis)* and sooty albatross (*Phoebetria fusca*) and in cloacal swabs of Northern rockhopper penguin *(Eudyptes moseleyi)* through PCR.[35]

E. rhusiopathiae has killed endangered New Zealand fauna on offshore islands used for conservation purposes. The species affected have included kakapo, takahe *(Porphyrio hochstetteri)*, and kiwi (*Apteryx* spp.). An outbreak of erysipelas affected the success of translocation of group of juvenile kakapo from Codfish Island to Chalky Island killing 3 of the 19 birds translocated,[30] and subsequent studies have shown that most kakapo living on offshore islands have antibodies to *E. rhusiopathiae*.[31] A vaccination program is in place for kakapo and takahe using a commercial killed bacterin for turkeys,[31] but this was controversial among conservation managers who were concerned about the possible side effects of vaccination. Initially, the kakapo team vaccinated all remaining birds,[30] but management has subsequently decided that only juvenile birds will be vaccinated, based on antibody studies that show older birds are exposed naturally.[31] Unfortunately, there has been a subsequent death due to erysipelas of an old male kakapo who was not vaccinated in the preceding 2 years (B. Gartrell, personal communication, 2021).

The formalin-inactivated, aluminum hydroxide-adsorbed *E. rhusiopathiae* bacterins are the most used vaccine types for the immunization of turkeys *(Meleagris gallapavo)* against erysipelas and have been used to good effect in takahe and kakapo in New Zealand.[31] These bacterins may contain either whole or lysed bacterial cells. Two vaccine doses have been recommended for turkeys at 4-week intervals. The first dose can be administered at 16 to 20 weeks of age. Live erysipelas vaccines have been used for swine over 50 years and now becoming available for turkeys as well.[1]

Our knowledge on the effect of this disease on the conservation of other free-living wild bird populations is limited due to the opportunistic nature of the pathogen and the problems associated with detecting the disease in those populations. It is believed that some environmental factors predispose avian species to *E. rhusiopathiae*. However, it is not fully understood and outbreaks are related to rainy, cold weather in many species.[1,30] Feeding on contaminated feed, soil, or decaying matter has been considered as the source of infection for some outbreaks in wild birds.[8,12] Immunity to this pathogen in wild birds is not studied, and it has been suggested that young and stressed birds are more likely to be infected than older or less stressed individuals in domestic species.[7] There is a need for epidemiological studies of this disease that go beyond identifying erysipelas as a cause of mortality. In the southern hemisphere at least, this research should be prioritized for endangered seabird species.

CHAPTER 20

Mycoplasmosis

Luisa Fischer • *Teresa Y. Morishita*

Visit eBooks.Health.Elsevier.com for a complete set of references.

Mycoplasma spp. are bacteria that can affect a wide variety of avian species. Most documentation of *Mycoplasma* infections in birds have been reported in poultry, psittacines, and raptorial species due to their economic and/or human-animal bond connection. While the infection is usually subclinical in most birds, it can be exacerbated with concurrent infections. The lack of cell wall and fragile nature of this bacteria necessitates the need for close bird-to-bird contact. This organism is susceptible to most disinfectants as the bacteria does not survive long in the environment. Moreover, *Mycoplasma* is not affected by those antibiotics, which disrupt cell wall development since it lacks a cell wall. As a pathogen, due to its poor survival in the environment, one of its strategies is to be transmitted vertically. Hence, infection is spread from hen to chick besides direct horizontal infections.

MYCOPLASMA IN POULTRY

There are four species of *Mycoplasma (M.)* that are pathogenic to poultry: *M. gallisepticum*, *M. synoviae*, *M. meleagridis*, and *M. iowae*. These species generally affect the respiratory system (Figure 20.1), but other bodily systems can also be affected.[1–3]

M. gallisepticum infection (also known as chronic respiratory disease [CRD] or infectious sinusitis in turkeys [*Meleagris gallopavo*]) causes respiratory illness primarily in chickens (Gallus gallus domesticus) and turkeys. Infection has also been reported in other poultry species including pheasants, partridges, quail, peafowl, guinea fowl, ducks, and geese.[1] Clinical signs in affected birds include coughing, sneezing, rales, snicks, and discharges from the eyes and nares. Affected turkeys have a swollen infraorbital sinus (Figures 20.2 and 20.3). Signs can be more severe if there is concurrent respiratory disease, poor management conditions, and/or stress placed on the birds.[1–3] Mortality can be increased in severe cases. Necropsy of affected birds often reveals thickened air sacs with occasional caseated debris, pneumonia (Figure 20.4), and salpingitis.[1–3]

Mycoplasma synoviae infection (also known as infectious synovitis) often occurs subclinically in poultry. However, the infection can become systemic and result in lameness due to inflammation of the synovial membranes. Often, there is caseated exudate within the joint, especially the hock joint, and tendon sheath. Chickens are most often affected. Mortality is minimal unless there are other diseases present and/or if management conditions are poor.

While *M. gallisepticum* and *M. synoviae* are the primary pathogenic species involved in chickens and turkeys, the two remaining pathogenic species, *M. meleagridis* and *M. iowae*, affect turkeys. These two *Mycoplasma* species tend to have a greater impact on the reproductive system. *M. meleagridis* infection is primarily associated with poor hatchability, often occurring late in the incubation period. Moreover, airsacculitis can be observed in newly hatched turkey poults, as early as day 1 of the hatch. Affected poults may show severe respiratory signs and/or sinusitis. In addition, skeletal abnormalities have been reported, often with osteomyelitis in the cervical vertebrae. This can lead to deformation and a crooked neck in some poults. Other birds may have leg deformities as a result of chondrodystrophy. There may also be a unilateral or bilateral varus deformity.[1,2]

M. iowae causes a venereal disease in turkeys. Affected adults rarely display any clinical signs but will have reduced reproductive performance due to poor hatchability and late embryonic mortality.[1,2]

Since *Mycoplasma* spp. are vertically transmitted, disease monitoring in the commercial poultry industry often includes

testing whereby infected breeders are removed to maintain *Mycoplasma*-free flocks.[3] However, among backyard poultry and small poultry flocks, *Mycoplasma* spp. may be highly prevalent. On-farm biosecurity, preventing other concurrent respiratory diseases, maintaining good management practices, and reducing stress can help to minimize the impacts of *Mycoplasma* in these flocks.[3]

MYCOPLASMA IN CAPTIVE BIRDS

Mycoplasma spp. may also play a role as a causative agent in respiratory disease in captive birds. In companion birds, cases of mycoplasmosis in psittacines and finches are described, especially when there is close contact between these bird species and backyard poultry.[4] Therefore biosecurity

FIGURE 20.4 Pneumonic lung from a turkey *(Meleagris gallopavo)* with *Mycoplasma gallisepticum* isolated. (Photo courtesy Robert E. Porter, Jr.)

and hygienic measures should be kept in mind when keeping these bird species within one household. In pigeons (*Columba livia*), *Mycoplasma* spp. were long suspected to be the cause of severe respiratory disease. However, *M. columbinum*, *M. columborale*, and *M. columbinasale* are also found in healthy individuals. Hence, these organisms seem to be part of the commensal bacterial flora in pigeons.[5,6] In cases of mycoplasmosis, clinical signs are not pathognomonic since infection is often associated with other bacterial pathogens. Generalized respiratory signs such as rhinitis, tracheitis, swollen infraorbital sinuses, airsacculitis, and bronchopneumonia, as well as serous conjunctivitis and blepharitis, may be seen (Figures 20.1). The latter may lead to starvation due to blindness especially in smaller bird species like finches.[7]

In birds of prey, *Mycoplasma* spp. were first thought to be obligatory pathogens as they were isolated from different individuals showing respiratory signs due to tracheitis, airsacculitis, and pneumonia.[8,9] Subsequently, Poveda et al. (1994)[10] described novel *Mycoplasma* spp. isolated from different birds of prey species: *M. buteonis* isolated from a buzzard *(Buteo buteo)*, *M. falconis* isolated from a saker falcon *(Falco cherrug)*, and *M. gypis* isolated from a griffon vulture *(Gyps fulvus)*. However, as Morishita et al.[11] and Lierz et al.[12] isolated these species regularly from the respiratory tract of clinically healthy individuals, these species were no longer interpreted as obligate pathogens but to be more likely part of the physiological bacterial flora of these bird species. However, as some *Mycoplasma* spp. were found to be associated with pathological alterations, their role as a pathogen needs to be further investigated (e.g., *M. corogypsi* found in a bumble foot lesion of a black vulture [*Coragyps atratus*][13] or *M. vulturii* from dead found white-backed vultures [*Gyps bengalensis*][14]).

MYCOPLASMA IN WILD BIRDS

The knowledge on the occurrence of *Mycoplasma* spp. in different wild birds is limited. In some bird species *Mycoplasma* spp. are regularly found in healthy individuals, hence, considered apathogenic. However, as *Mycoplasma* spp. are absent in healthy individuals of some other wild bird species, they might play a role as a respiratory pathogen in these bird species.[15]

There are two main aspects, which are important regarding the occurrence of mycoplasmas in wild birds. On the one hand, wild birds may play a role as potential reservoir or vector for mycoplasmas infecting poultry and humans. On the other hand, mycoplasmas may represent pathogens for wild birds, potentially leading to population declines.

Wild birds are direct and indirect vectors for multiple pathogens, which are transferred to farm animals and humans. Migratory birds can spread pathogens over long distances.[16] In particular, *M. gallisepticum* can be transferred by wild birds between poultry farms.[17] *M. gallisepticum* has been found in various wild bird species, including wild turkeys,[18] thin-billed murre *(Uria aalge)*,[19] mallards *(Anas platyrhynchos)*, grey harrier *(Ardea cinerea)*, wood pigeon *(Columba palumbus)*,[20] peregrine falcon *(Falco peregrinus)*,[21] and various passerines (Passeriformes).[22] Meanwhile, passerine birds and corvids, which are regularly found nearby poultry farms, are classified as transient carriers of *M. gallisepticum*.[23] In addition, *M. gallisepticum* was found to be responsible for severe disease outbreaks in house finches (*Haemorhous mexicanus*) in North America, firstly reported in 1994.[24,25] Infected birds often suffer from conjunctivitis and may subsequently die due to starvation, predation, or trauma.[7]

Systematic studies investigating the occurrence and role of mycoplasmas in wild birds are rare.[26,27] Due to the ease of collection, many studies include collection of samples from injured or diseased birds. However, the significance of such studies needs to be discussed carefully, as preexisting health conditions may increase the possibility of disease or accidents occurring in individual birds.[28] Wild birds being kept in rehabilitation centers are stressed too, so that an immunosuppressive effect also needs to be considered.[29] Furthermore, these injured and diseased wild birds are preselected, therefore not reflecting a true representation of the free-ranging population and its microbial flora. In a study investigating the occurrence of mycoplasmas in corvids, two groups of birds were sampled: (1) individuals originating from hunting bags (group 1) and (2) juveniles or injured birds that were presented in a veterinary clinic (group 1). In sum, 7% of the healthy, adult birds from group 1 versus 32% of the birds presented in the veterinary clinic were positive for *M. sturni*.[30] These findings support the assumption of bias introduced by the chosen selection method and warrant cautious interpretation of study results. Moreover, the pathogenic relevance of *Mycoplasma* spp. isolated from diseased wild birds remains uncertain. To be able to interpret their relevance, studies on the prevalence of *Mycoplasma* spp. in healthy individuals from free-ranging populations are therefore highly needed.

Summarizing several studies focusing on mycoplasmas in wild birds, there are clear differences in the occurrence of mycoplasmas in the physiological flora in the respiratory tract. While *M. buteonis*, *M. gypis*, and *M. falconis* are regularly found in the respiratory tract of birds of prey, there were no mycoplasmas found in clinically healthy tits and nightingales.[31] To date, 28 avian *Mycoplasma* spp. have been described (Table 20.1), and new species are isolated on a regular basis.

TABLE 20.1

Twenty-eight Validly Described Avian *Mycoplasma* species (Published in and/or Approved by the *International Journal of Systematic and Evolutionary Microbiology*)

Mycoplasma Species	Host Species, Other Affected Species	Clinical Signs
M. anatis	Ducks[a]	Sinusitis, airsacculitis, pneumonia, central nervous signs in adult ducks; decreased clutch size and hatching rate, weak chicks; also found in clinically healthy wild duck species[32]
M. anseris	Geese[a]	Inflammation of the cloaca and the phallus[33]; also found in clinically healthy geese[34]
M. anserisalpingitidis	Geese[a]	Inflammation of the phallus[35]
M. buteonis	Accipitrids,[a] falcons	Found in clinically healthy birds of prey[36]; also found in birds of prey showing respiratory signs[11,37]
M. ciconiae	White storks (*Ciconia ciconia*)[a]	Found in clinically healthy nestlings[38]
M. cloacale	Galliforms,[a] turkeys (*Meleagris gallopavo*), waterfowl, songbirds	Found in clinically healthy chicken[39]; also found in clinically healthy turkeys, ducks, geese, and song birds[34,40,41]; inflammation of the cloaca and the phallus in geese[33]
M. columbinasale	Pigeons (*Columba livia*)[a]	Found in clinically healthy pigeons[39]; also found in pigeons showing respiratory signs[42]
M. columbinum	Pigeons[a]	Found in clinically healthy pigeons[39]; also found in pigeons showing respiratory signs and conjunctivitis[43]
M. columborale	Pigeons,[a] crows, peregrine falcon	Found in clinically healthy pigeons[39]; also found in pigeons showing respiratory signs and conjunctivitis[44]; also found in crows and a peregrine falcon showing pneumonia[21,45]
M. corogypsi	Falcons,[a] vulture	Found in clinically healthy falcons[46]; also found in a vulture showing pododermatitis, polyarthritis and tendovaginitis[47]
M. falconis	Falcons[a]	Found in clinically healthy falcons[11,12]; also found in falcons showing sinusitis[21]
M. gallinaceum	Galliforms,[a] turkeys, ducks, peregrine falcon, hoopoe	Found in clinically healthy chicken[39]; also found in chicken showing tracheitis and sinusitis; also found in clinically healthy wild turkeys[48]; also found in ducks and a peregrine falcon showing respiratory signs[49]; also found in a hoopoe showing central nervous signs[21]

TABLE 20.1

Twenty-eight Validly Described Avian *Mycoplasma* species (Published in and/or Approved by the *International Journal of Systematic and Evolutionary Microbiology*)—cont'd

Mycoplasma Species	Host Species, Other Affected Species	Clinical Signs
M. gallinarum	Galliforms,[a] turkeys, waterfowl, crows, peregrine falcon	Found in clinically healthy chicken, turkeys, ducks, and geese[39]; also found in crows and a peregrine falcon showing respiratory signs[21]
M. gallisepticum	Galliforms,[a] turkeys, passerines, crows, peregrine falcon	Chronical respiratory signs, decreased laying and hatching rate, synovitis and arthritis in chicken[50]; found in clinically healthy wild turkeys[18], also found in turkeys showing respiratory signs, sinusitis and conjunctivitis; respiratory signs, sinusitis, conjunctivitis and central nervous signs in passerines, crows, peregrine falcons[37,51]
M. gallopavonis	Turkeys,[a] crows	Found in clinically healthy wild turkeys[52]; also found in turkeys showing airsacculitis[53]; also found in crows showing respiratory disease[45]
M. glycophilum	Galliforms[a]	Found in clinically healthy chicken; also found in chicken showing decrease in laying, increased embryonal mortality; also found in pheasants showing respiratory signs[39,54,55]
M. gypis	Accipitrids,[a] falcons, vultures	Found in clinically healthy birds of prey; also found in vultures showing respiratory signs[12,21]
M. hafezii	Falcons[a]	Found in clinically healthy falcons[56]
M. imitans	Water fowl[a]	Found in ducks and geese showing respiratory disease[57]
M. iners	Galliforms,[a] pigeons, peregrine falcon	Found in clinically healthy chicken[39]; also found in pheasants, partridge, pigeons, and a peregrine falcon showing respiratory signs[37,58]
M. iowae	Turkeys,[a] chicken	Increased embryonic death, dwarfism, chondrodystrophy, edemas, feather disorders and airsacculitis in poults; increased embryonic death, skeletal deformations, and malformations of chicks[59,60]
M. lipofaciens	Galliforms,[a] turkeys, ducks, geese, Eurasian goshawk (*Accipiter gentilis*)	Found in clinically healthy chicken, turkeys, and ducks[39]; also found in an infertile egg of a Eurasian goshawk (increased embryonic mortality in chicken and turkey after experimental infection)[61,62]
M. meleagridis	Turkeys[a]	Found in clinically healthy turkeys and turkeys showing airsacculitis; increased embryonic death, skeletal deformations, malformations, and immunosuppression in poults[63,64]
M. nasistruthionis[b]	Ostriches (*Struthio camelus*)	Respiratory signs in ostriches[65]
M. neophronis	Vultures[a]	Found in dead found vultures without specific alterations[66]
M. pullorum	Galliforms,[a] pigeons	Found in clinically healthy chicken and pigeons; also found in pheasants and partridges showing respiratory signs[39,58]
M. seminis[b]	Hierofalcons	Found in the respiratory tract and semen of clinically healthy hierofalcons[67]
M. sphenisci[b]	African or Jackass penguin (*Spheniscus demersus*)	Found in jackass penguins showing respiratory signs[68]
M. struthionis[b]	Ostriches	Found in ostriches showing respiratory signs[65]
M. sturni	Songbirds,[a] cliff swallows (*Petrochelidon pyrrhonota*)	Found in clinically healthy songbirds (crows, fieldfares, and starlings)[30]; also found in other songbird species and cliff swallows showing rhinitis, sinusitis, and conjunctivitis[51,69,70]
M. synoviae	Galliforms,[a] turkeys	Synovitis, tendovaginitis, airsacculitis in broilers, egg-pole shell defects or without clinical signs in laying hens[71]; synovitis and tendovaginitis in turkeys[72]
M. tullyi	Humboldt penguin (*Spheniscus humboldti*)	Found in clinically healthy Humboldt penguins[73]
M. vulturii[b]	White-backed vulture (*Gyps africanus*)	Found in a white-backed vulture dying from intoxication (showing mild inflammation in its respiratory tract)[14]

[a]Host species.
[b]Some species are also described in the literature (published in other journals and not approved by *IJSEM* yet).

Diagnostics

The gold standard for diagnosing the presence of *Mycoplasma* spp. is cultivation. Due to the small genome size and associated limited biosynthetic potential, *Mycoplasma* spp. are strongly dependent on their metabolism. Therefore cultivation media need to provide all components for growth. The composition of the fluid and solid media, as well as the general procedure for the cultivation of avian mycoplasmas, is well described by Hayflick[74] and Bradbury.[75] The main advantage of cultivation is the possibility of differentiating between multiple *Mycoplasma* species within one sample. After performing several single-colony subcultures, each isolate can be further investigated by different diagnostic methods (e.g., molecular biological, antigenetic, or biochemical tests). Due to different growth rates, some slowly growing *Mycoplasma* species may easily get overgrown in mixed infections. For example, in samples collected from chickens, pathogenic species such as *M. gallisepticum* and

M. synoviae may become overgrown by commensal species like *M. gallinarum*.[76] This impedes the possibility of detecting these pathogenic *Mycoplasma* species via culture. Other advantages include the possible isolation of novel, undescribed *Mycoplasma* spp. and the ability to perform antibiotic sensitivity tests, which is only possible following the culture of the mycoplasmal organisms.[77] Newer diagnostic tools allow the differentiation of *Mycoplasma* spp. within a few hours. The MALDI-TOF MS (matrix-assisted laser desorption/ionization with time-of-flight mass spectrometry) is currently established for the common avian *Mycoplasma* species. However, this diagnostic depends on the successful culturing process as colony material is needed for testing. Furthermore, colonies need to be pure cultures as this may result in inaccurate species-level identification. Nevertheless, MALDI-TOF MS is a promising tool for reliable species identification of avian *Mycoplasma* species.[78,79]

Besides a broad range of biochemical tests focusing on different metabolic characteristics of *Mycoplasma* spp., antigenetic test methods can also aid in the differentiation of *Mycoplasma* spp. Such tests include the immunobinding assay, growth inhibition test, and immunofluorescence test. However, cross-reactivity may occur between some *Mycoplasma* spp.[80] Therefore monoclonal antibody tests such as the enzyme-linked immunosorbent assay (ELISA) test are regularly used, as these provide a higher specificity.[81]

Currently, molecular biological methods are also becoming increasingly relevant as test methods, as these tests provide a reliable differentiation of *Mycoplasma* spp. based on multiple gene segments. The 16S rRNA gene is used as *Mycoplasma* genus-specific polymerase chain reaction (PCR) protocol,[82] while sequencing the 16S-23S intergenetic transcribed spacer region (ISR) allows distinction between each *Mycoplasma* spp.[83] Moreover, gene segments such as RNA polymerase beta subunit (rpoB) and RpoB protein sequences may be used, as well as whole-genome sequencing.[84] There are multiple PCR protocols detecting specific *Mycoplasma* species (e.g., *M. gallisepticum*–specific PCR[85]). For the detection of *Mycoplasma* spp. in companion birds, this may be the first-line diagnostic tool. Relying on the bird species affected, the *Mycoplasma* species should be differentiated in case of a positive result by the sequencing of the amplicon and the subsequent comparison with the help of reference databases.[86] Diagnostic tools like amplified fragment length polymorphism (AFLP) or restriction fragment length polymorphism (RFLP) are based on specific restriction enzymes digesting DNA samples in fragments, producing a specific restriction fragment pattern through gel electrophoresis. Each of these methods can aid in the typing of different strains of *Mycoplasma* spp.

Serological tests are the most common diagnostic tool used in poultry due to their efficiency and manageable costs for larger production flocks.[87] With these diagnostic tests, antibodies against a specific *Mycoplasma* spp. can be detected. Hemagglutination inhibition test, antibody-ELISA, and serum agglutination tests are commercially available for the detection of antibodies against pathogenic *Mycoplasma* spp. such as *M. gallisepticum*, *M. synoviae*, *M. meleagridis*, and *M. iowae*. Serum agglutination provides rapid results, but due to the possibility of cross-reactions (leading to false-positive results), positive results need to be confirmed with additional tests such as species-specific PCR testing, respectively.[88]

In wild birds, the detection of *Mycoplasma* spp. should be interpreted with caution, even if these birds are showing clinical signs suggestive of mycoplasmosis and *Mycoplasma* spp. are isolated upon performing further diagnostics. Unidentified *Mycoplasma* spp. could represent commensal bacteria found widely in association with mucous membranes. Therefore differentiation of *Mycoplasma* spp. is considered essential for understanding their role as a pathogen in a single bird species.

Treatment and Control

Since *Mycoplasma* spp. can both be spread horizontally and transmitted vertically from infected hen to chick, the primary method for the control in poultry is to start a new flock with *Mycoplasma*-free birds. This implies obtaining hatching eggs and/or chicks from a *Mycoplasma*-free breeder hen to obtain *Mycoplasma*-free progeny. Poultry should be obtained from a hatchery and/or breeder flock that participates in a program such as the National Poultry Improvement Plan (NPIP) in the United States or similar international program that routinely monitors for the presence of *Mycoplasma* sp. in poultry flocks through serological testing and culture.

If a poultry flock is found to be positive for the pathogenic species of *Mycoplasma*, including *M. gallisepticum*, *M. synoviae*, and *M. meleagridis* or *M. iowae*, there are three options available to move forward: depopulation, vaccination, or no action (expectative). In a commercial poultry operation, depopulation of the infected flock is the option of choice, especially in all-in/all-out production management systems. If clinical signs are nonexistent to mild, birds may be sent to the slaughterhouse and/or further processed instead of treated through the administration of medication. In commercial poultry flocks that keep birds of multiple ages on the premises (e.g., commercial laying flocks), vaccination of replacement pullets prior to introducing them to the *Mycoplasma*-infected layer flock is acceptable in certain US states. For poultry, vaccination can be accomplished via spray or eyedrop method during the growth phase and prior to placing them in the layer houses. However, one should establish first whether there are state, regional, provincial, or national laws that prohibit vaccine usage.

While eradication and/or vaccination are exercised in commercial flocks, in backyard poultry, hatching eggs, chicks, and adult birds of different ages may be obtained from a variety of non-NPIP (United States Department of Agriculture) sources. Many owners prefer not to take any action and will simply allow the birds to live with the infection in their backyard flocks. Under these circumstances, it is important that flock owners maintain proper management and ensure proper environmental conditions. This includes the reduction of the amount of dust and ammonia in the enclosure through adequate ventilation and the routine removal of moist and caked litter from the floors as these can all lead to irritation of the respiratory tract hence increasing the risk of the birds developing a clinical *Mycoplasma* infection. If a backyard flock owner wishes to maintain a specific genetic line (e.g., in case of exhibition poultry), vaccination practices such as those employed in the commercial industry may need to be utilized.

Since mycoplasmas have no cell walls, they do not survive in the environment for extended periods of time. Hence, routine cleaning and disinfection should help to eliminate the bacterium from the farm premises. If possible, the building should

be kept isolated and devoid of birds for a minimum of 2 weeks following disinfection before the location is repopulated.

Treatment of *Mycoplasma* infections can be attempted but will generally not result in clearance of the infection. Relapses are common. If treatment is attempted, this usually comprises the use of tylosin or tetracycline, delivered via drinking water. As with any medication usage in poultry, caution is warranted as withdrawal times need to be adhered, especially if the bird and/or eggs are to be used for human consumption (http://www.usfarad.org/poultry.html).

For *Mycoplasma* spp. that cause venereal disease, specifically *M. meleagridis* and *M. iowae* in turkeys, medications such as lincomycin or spectinomycin, delivered via the drinking water, can be used to control the infection. However, long-term use of antibiotics can lead to increased antimicrobial resistance (see also Chapters 6 and 7). Dipping of hatching eggs in an antibiotic solution has been used in the commercial turkey industry, but this method does not seem practical in backyard flock situations unless the flock is a strain or variety from a specific genetic breeding line that the backyard flock owner wishes to continue to perpetuate (e.g., in case of exhibition and ornamental poultry).

For the treatment of individual companion birds or small flocks with respiratory disease (e.g., pet birds or small flocks), systemic antibiotic treatment (direct per os or through drinking water) using tetracyclines or gyrase inhibitors may be considered. In addition, antibiotic-containing ophthalmic preparations (ointment or drops) can be administered topically in case of conjunctivitis. Treatment of wild birds in rehabilitation centers is not advised, as treatment will not clear the infection and only pose a risk for these birds to become permanent shedders of the bacteria when released back into the wild.

Public Health and Zoonotic Potential of *Mycoplasma* spp.

Avian mycoplasmas are generally not known to cause disease in humans. However, as there is one report of the accidental airborne transmission of *M. lipofaciens* (strain ML64) causing mild respiratory signs (rhinitis), transmission of avian mycoplasmas to humans needs to be considered in some *Mycoplasma* species.[89]

CHAPTER 21

Cryptococcosis

Anne E. McDonald

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Fungal diseases are anything but dull. Fungi are innovative, tenacious, and motivated. They are masters of genetically driven change. Fortunately, comparatively very few are animal pathogens, but the genus *Cryptococcus* is one of those.[1] It is an ancient, highly adaptive, invasive fungus whose genome dates back millions of years. It is a formidable pathogen in the arena of infectious disease. It is the Harry Potter of contagious disease, complete with a multifunctional cloak or capsule (Figure 21.1). It is an adaptive organism and when caught in a foreign environment, such as an animal host, fights with all its adaptability to survive (McDonald AE, personal observations, 2010-2020).[2–6,7] Luckily, infections in mammals and birds are rare,[7,8] except in humans in association with HIV and AIDS with *Cryptococcus neoformans*.[9]

There are over 50 species of *Cryptococcus*,[5] but only a few are considered animal pathogens.[5] The initial named species was *C. neoformans*, a pathogen, which in time became known as *C. neoformans neoformans*. Over 10 million years ago, the first split occurred, yielding a separate pathogenic species *C. gattii*.[5] This set the foundation for cryptococcal classifications as we know it today.[5,10,11] Collectively, they are known as the *C. neoformans-C. gattii* species complex and are responsible for almost all mammalian and avian cryptococcal infections.[7–10]

Both complexes have gained attention in recent medical history and, in doing so, exemplified a major difference in their pathogenicity.[9,12] These pathogenic traits have also ended any medical complacency regarding *C. neoformans-C. gattii* species complex in causing disease.[10]

Globally, the *C. neoformans* complex species has been strongly associated with host immunodeficiency, emerging as a global epidemic in HIV/AIDS patients in the 1980s.[13] Prior to the HIV/AIDS pandemic, there were fewer than 200 human cases of cryptococcosis in the literature.[9] In 2009, Park et al. estimated the global burden of the disease (HIV/AIDS/cryptococcosis) to be close to 950,000 cases, with approximately 625,000 deaths annually.[9] However, with the development of antiretroviral therapeutics for AIDS patients, antifungal treatment became highly successful, enabling successful cryptococcal treatment, extending and saving many lives.[9] While it was initially thought that a negative HIV status would exclude one from *C. neoformans* cryptococcosis, in New York City, interestingly many children have antibodies to *C. neoformans*.[9] However, it is now recognized that other factors causing immune suppression, such as cancer chemotherapy, steroid medication, and some comorbidities, can activate dormant *C. neoformans* causing secondary infection.[9] Quite differently, *C. gattii* acts as a primary pathogen, apparently not requiring immune compromise to invade an animal host and primarily affecting immunocompetent individuals.[5,7] In 1999, cryptococcosis caused by *C. gattii* appeared unexpectedly, causing a novel epidemic on Vancouver Island, British Columbia, Canada. The Vancouver Island outbreak qualified as a true epidemic among humans.[14,15]

By 2000, cryptococcosis was well established as an emerging disease on Vancouver Island, and by 2004 was considered endemic. The locations of disease were mapped, and the organism's environmental range was found to encompass the east coast of Vancouver Island, the southern Gulf Islands, Washington, and Oregon states.[5,14,16] It is now recognized that *C. gattii* had been present silently in the Parksville area silently of Vancouver Island, prior to the onset of the epidemic.[15]

This pathogen caused illness and mortality in humans and animals, including wild and exotic birds.[15] Although the disease incidence has declined in recent years, *C. gattii* has remained endemic to the Pacific Northwest geographic niche.[5,7,15,17] The author's avian practice has treated nine psittacine cases (2000–2020) from this endemic area. Only two are documented

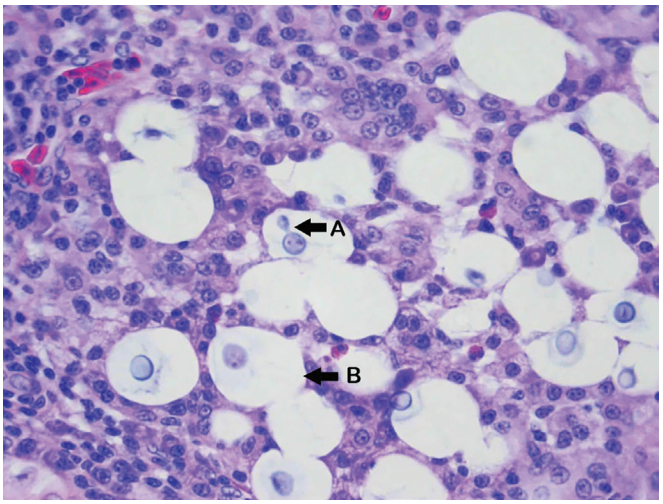

FIGURE 21.1 Cryptococcal infection in brain tissue. *Arrow A* identifies the narrow-based budding yeast, and *arrow B* identifies the polysaccharide capsule; depending on environmental conditions, capsular size can be highly variable.

survivors, who are both asymptomatic but require maintenance with oral medications (McDonald AE, personal observations, 2010-2020).

Human literature points out the sentinel value of nonhuman clinical cases.[7,11,15,18] The fact that these organisms can produce epizootics had led to extensive surveillance of both the pathogen's environmental distribution and its biological behavior.[7,12,14,15,19]

CLASSIFICATION

Pathogenic cryptococcal classification has been revised extensively to reflect morphology, biological characteristics involving serotyping (A, B, C, and D), and genotyping *C. neoformans neoformans* (VN1V), *C. neoformans* var. *grubii* (VN1, VN11), the AD hybrid (VN111), and *C. gattii* (VG1, VG11, 111, and 1V) (McDonald AE, personal observations, 2010-2020).[5]

More recently, the high molecular discriminatory power of the amplified fragment length polymorphism genotyping method has been used, defining the current nomenclature. The *C. neoformans* species complex is currently composed of four species, whereas the *C. gattii* species complex is composed of five molecular types, which are argued to be five distinct species.[4]

However, revision is continual.[10] As of 2018, cryptococcal nomenclature was revised again, suggesting that nomenclature goes back to *C. neoformans* species complex and *C. gattii* species complex, and the Latin names for individual species of *C. gattii* be removed.[10]

C. neoformans species complex:

1. *neoformans neoformans* or VNIV
2. *neoformans* var. *grubii* VNI
3. *neoformans* var. *grubii* VNII
4. *AD hybrid* var. *neoformans/gattii* VNIII

C. gattii species complex:

1. AFLP4NGI (*C. gattii* sensu stricto)
2. AFLP7NGII *(C. deuterogattii)*
3. AFLP5NGIII *(C. bacillisporus)*
4. AFLP7NGIV *(C. tetragattii)*
5. AFLP410NGIV *(C. decagattii)*

Genotypes VG1 and VG11 are prevalent worldwide, whereas VGIII and VGIV are less common. *C. gattii* V11a, recognized as highly virulent, was the most common animal isolate involved in the Vancouver Island outbreak.[15] It had devastating consequences on the inadvertently affected psittacine birds (McDonald AE, personal observations, 2010-2020).

LIFE CYCLE

Cryptococcus spp. are free-living environmental microbes, with a life cycle that does not appear to require an animal host.[4,9,14,20] They are diphasic environmental yeasts; the most basic form is the asexual phase that utilizes budding for reproduction. However, with the appropriate environmental factors (substrate, warmth, and dryness), hyphae grow to form blasidioform arms that may produce basidiospores: these undergo meiosis to form haploid spores. These spores are believed to be the infective organisms or propagules. Hyphae growth signifies development of the sexual phase or teleomorph, which is characteristic of all biphasic fungi. Sexual reproduction appears to have the potential to boost cryptococcal spore numbers to aid in the survival of the organism.[10] The sexual form is responsible for pathogenic animal host involvement. Inhaled yeast can also cause illness.[7,11]

C. neoformans mycelia grow commonly in bird excreta, especially when desiccated, using its high creatinine content as a nitrogen source.[21] The mycelial growth of *C. gattii* is strongly tree-associated, growing in decaying tree hollows and much less commonly in bird excreta.[3,9,15,16,20] This difference is the most defining ecological characteristic that distinguishes *C. neoformans* species complex from *C. gattii* species complex.

DISTRIBUTION

Pathogenic *Cryptococcus* spp. have been recognized on every continent.[2,6,8,15] Until recently, Antarctica was exempt. However, studies on Antarctic volcanic interior ash have identified viable *C. laurentii* organisms, which have recently become recognized as an emerging human pathogen associated with a rising number of meningitis cases.[22,23] There is one documented case report in a glossy starling *(Lamprotornis chalybaeus)*, with dermal pathology related to *C. laurentii*.[24] The organism isolated in this case was not particularly virulent. The bird in that case exhibited patchy feather loss around the back and beak area, and grayish crusts were noted, which were firmly adhered to the underlying skin. *C. laurentii* has been isolated from Canada goose droppings in New York state,[25] from feral pigeon *(Columba livia)* droppings in Sweden,[26] from crop and fecal samples from pigeons in Grand Canary Island,[27] and from captive pet bird droppings in pet shops in Brazil.[28]

In the literature, one of the problems recognized in determining geographical distribution of pathogenic *Cryptococcus* species has been the lack of reported differentiation between pathogenic and nonpathogenic species and between the pathogenic species. Historically, this resulted from the lack of ready access to sophisticated, rapid, and affordable diagnostics. The importance of pathogenic species identification globally was not appreciated until the AIDS virus/*Cryptococcus* relationship was realized.[9]

Several researchers emphasize the importance of further clinical studies to define differences between *C. gattii* and *C. neoformans*, to define potential differences in disease syndromes, treatments, outcomes, and potentially the management of potential outbreaks of cyrptococcosis.[4,29]

C. neoformans and *C. gattii* have both been found in the excreta of many wild and captive avian species, including birds kept indoors and outdoors, in private homes, churches, pet stores, zoos, and private collections.[15,30,31] The avian species documented to be affected are numerous and include canaries *(Serinus canaria)*, lovebirds *(Agapornis roseicollis)*, raptors, and kiwis (*Apteryx* sp.).[10,15,30,29–32]

Taxonomic orders in which *Cryptococcus* infections have been reported include Anseriformes, Accipitriformes, Apterygiformes, Charadriiformes, Columbiformes, Passeriformes, Psittaciformes, Galliformes, Strigiformes, and Spheniscifor mes.[2,7,30,31,32] *Cryptococcus* spp. have also been found in the environment in association with vegetation (trees, fruit, and vegetables), avian droppings and skin, commercial bird seed, soil, fresh and saltwater.[7,8,14,15,30,20,29]

Surprisingly, the presence of cryptococcal organisms environmentally, even in avian droppings, does not necessarily

correspond to the prevalence or incidence of avian or mammalian disease, and when noted, such a correlation seems to be more the case with *C. gattii* than with *C. neoformans*.[20,22,33] Environmental presence in excreta as opposed to cloacal samples may reflect environmental contamination, especially if the dropping sample is dry.[9] *C. gattii* tends to be more fastidious and found in specific biogeoclimatic niches as compared to the more ubiquitous, *C. neoformans*.[12] Cryptococcal environmental survivability can be long. A culture of *C. gattii* was documented to be viable after 20 years.[34]

Historically, *C. neoformans* was said to favor temperate climatic zones, while *C. gattii* favored (sub)tropical zones. This simplistic climatic classification system is no longer considered valid for predicting the distribution of pathogens and likelihood of pathogenicity.[5,10,11,15] Recently, the concept of ecological niche modeling has emerged.[14,15,35] Using this model, climatologists and epidemiologists work together to predict public health impact and identify areas with similar ecologies at risk for pathogen spread. The model considers ecosystems, meteorology, and the presence of environmental pathogens and has been utilized successfully for *C. gattii* to predict the presence of the organism, including human and animal involvement.[12,15,16] Hopefully, the information from these models can eventually be used to advance disease prevention and treatment.[36,37]

TRANSMISSION

Spores and yeast are carried by air currents, especially when soil is disrupted.[14,29] *C. gattii* has been found in high traffic areas, vehicle wheel wells, and footwear and is associated with forestry activities such as wood chipping.[4,14,15,18] Spore counts are higher in summer months and drop precipitously after rainfall.[14,15]

The source and method of arrival of *C. gattii* to Vancouver Island are still unknown. Possibilities proposed include soil contamination by flooding contaminated sea water, tourism, importation of wood or trees, dispersal via infected bird droppings, and water currents.[10,14,15] *C. gattii* is capable of long-term survival in freshwater lakes and streams and in salt water.[10,14,29] It is a lethal marine mammal pathogen.[7,38]

C. neoformans is strongly associated with pigeons and, less so, with chickens *(Gallus gallus)*, where it causes intestinal colonization without systemic illness.[9,39,29] The digestive tract of these species provides a nutritionally rich environment for yeast replication and physical distribution.[9,22,] The thick exterior capsule of the *Cryptococcus* organisms is highly protective, enabling successful travel via fomites and within the digestive system. Singh et al. have cited evidence for rodents as reservoirs and passenger hosts, akin to pigeons and chickens for *Cryptococcus* spp.[10]

PATHOGENICITY

Cryptococcus is a virulent organism that has evolved very refined self-protecting survival mechanisms. The rare ability of *Cryptococcus* to replicate at warmer temperatures is the basic factor permitting successful animal invasion.[34,37] Cryptococci will grow at 37°C (98.6°F) (human body temperature) and even up to 40°C (104°F) but prefer temperatures less than 40°C (104°F).[7,21] These temperatures, which are lower than typical avian core body temperatures, are consistent with the more peripheral temperatures of the beak and upper respiratory system. This probably explains the predilection of these sites for cryptococcal growth and possibly eventual tissue invasion (Figures 21.2–21.4).[11,30,23]

Bielska has presented an extensive review of the role of cryptococcal pathogenic characteristics, including the ability to grow at mammalian temperatures, up to 37°C (98.6°F).[7] Three important virulence factors are the production of the polysaccharide capsule, melanin synthesis that combats oxidative stress damage by the host, and cell invasion.[7,11] The capsule swells in response to contact with host serum, initiating excessive polysaccharide production.[7] This biofilm has immune-modulating effects on host cells.[7] The capsular factors can upregulate and downregulate immune modulation.[7] As the organisms age within a lesion, they undergo a phenotypic switching related to increased capsule size, increased resistance to phagocytosis, and increased drug resistance.[11] Cryptococcal cell wall–associated virulence includes the presence of capsular channels, which allow expulsion of internally produced toxic products in "bags," called extracellular vesicles (EVs), into host cells, as well as the transportation of melanin to coat the cell membrane for protection against ultraviolet irradiation and reactive oxygen species (ROS).[7]

The effects of cellular invasion include the yeast's ability to survive in the bloodstream but also to survive phagocytosis.[7] The engulfed yeast can reduce the host systemic inflammatory response within the host macrophage allowing its multiplication.[7] The macrophage then delivers the yeast to other body sites where vomocytosis can, without harm to either the host or engulfed organism, deliver the yeast to other tissues or back into the blood.[7] This aids in deep dissemination of the fungus.[7] The virulence of the cryptococcal strain is based in part on fertility or the number of propagules (infectious particles) produced. Probability of infection is believed to be related to the number of inhaled spores, called the inoculum.[6,11,34,35]

The period of incubation (IP) is the period between contact with the organism and the development of disease. In humans, the IP ranged from 2 to 11 months, and in animals, it was as short as 1 month and up to 12 to 13 months after exposure. The period between phagocytosis and the production of disease is the period of latency, which occurs in birds, and may explain, in part, why recurrence of infection occurs after treatment.[5,10] The period of latency has been documented at up to 110 months in a human case and 8 years in a citron-crested cockatoo *(Cacatua sulphurea citrinocristata)*.[5,16]

CLINICAL SIGNS

There is comparatively a low number of clinical avian cryptococcosis cases reported in the literature. [5,11,14,30,21,31,38] These reports and the clinical cases treated at the Night Owl Bird Hospital have been used for the following discussion (McDonald AE, personal observations, 2010-2020). Every clinical case has the potential of providing valuable information.

Cryptococcus spp. have been associated with three distinct clinical syndromes, which are characterized by dermal, peripheral, and deep involvement.[9] Dermal involvement is rare in birds and usually results from traumatic injury. Lesions may be granulomatous and, with immune competency, local and oral treatment, carry a fair but guarded prognosis.[11]

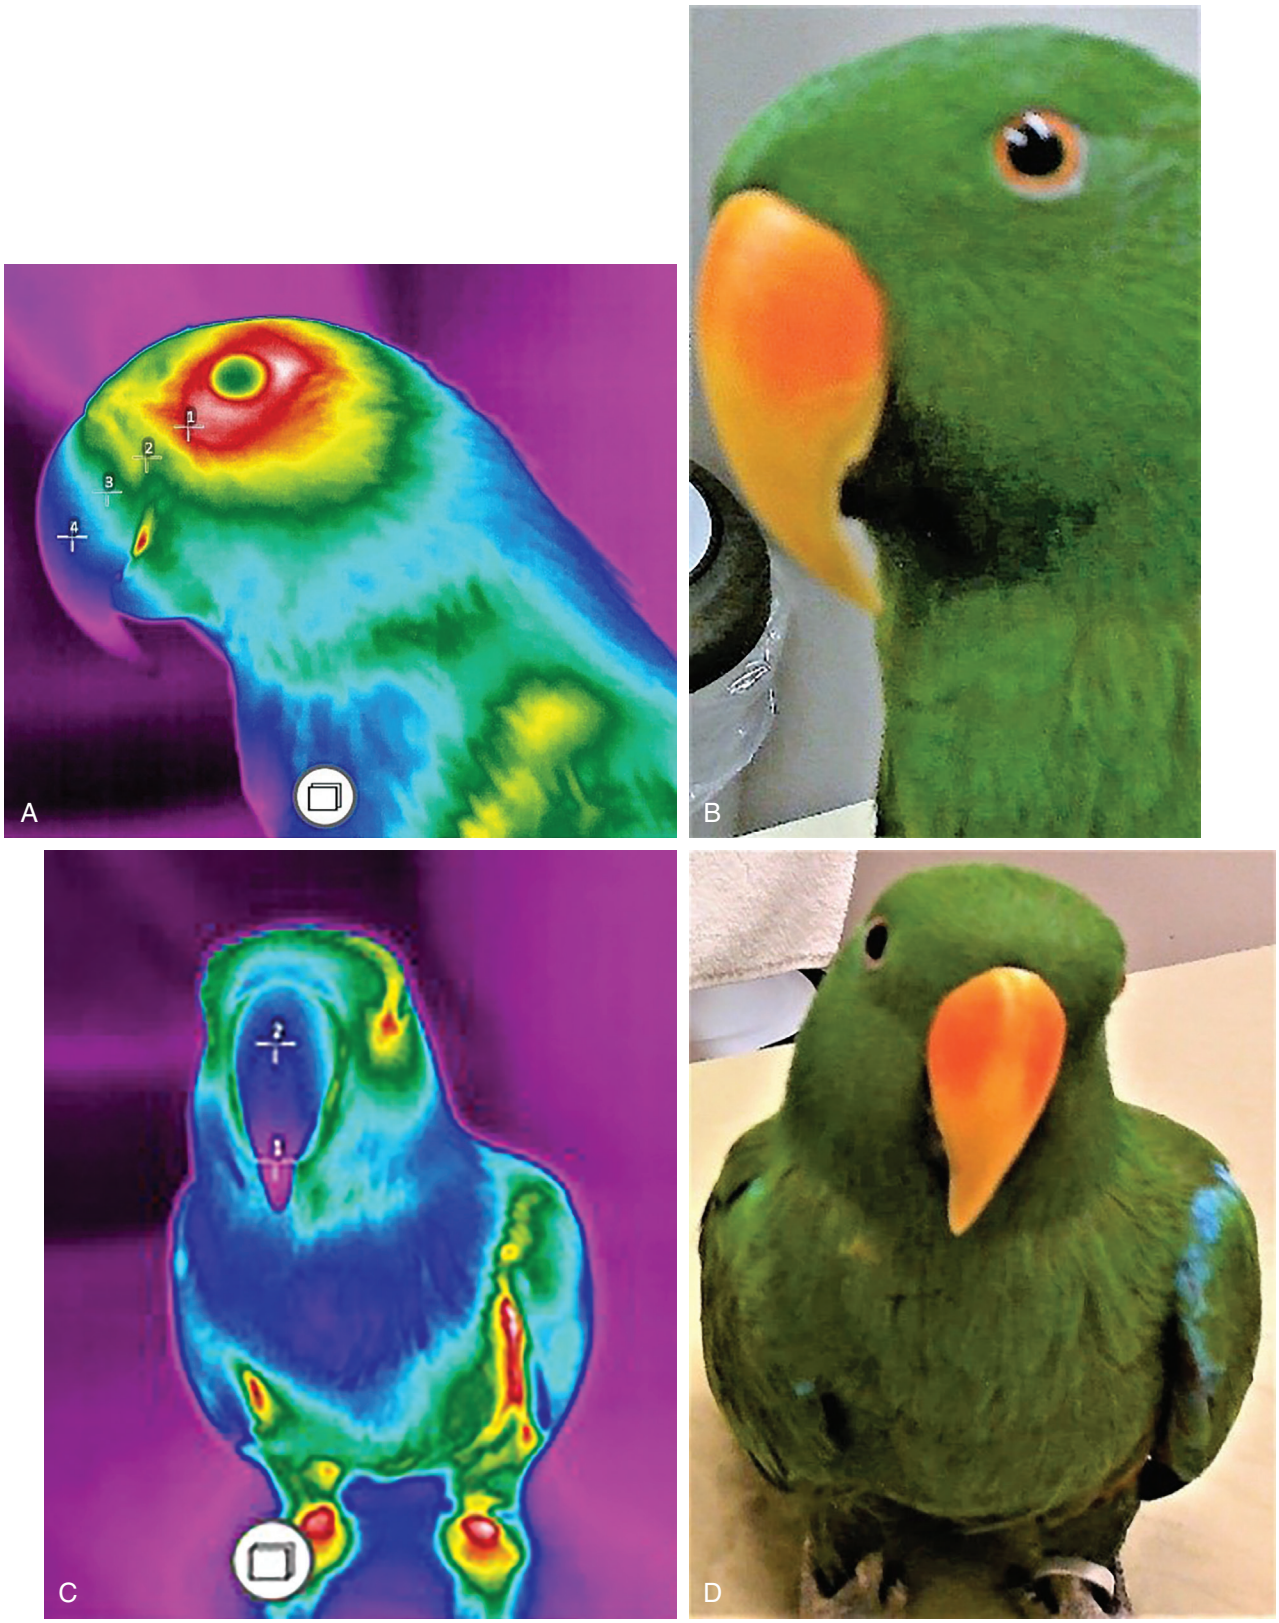

FIGURE 21.2 Lateral thermographic (A) and plain (B), and frontal thermographic (C) and plain (D) images of a fully feathered male grand Eclectus parrot *(Eclectus roratus roratus)*. Using the thermographic legend shown in Figure 21.4, and comparing these thermographic images to those of the female grand Eclectus parrot with feather destructive behavior in Figure 21.3, the difference in temperature of the beak and head as opposed to core body temperature is demonstrated, thereby helping to visually explain why the beak and head comprise the most common sites of cryptococcal lesions in avian species, and possibly also any further tissue invasion.

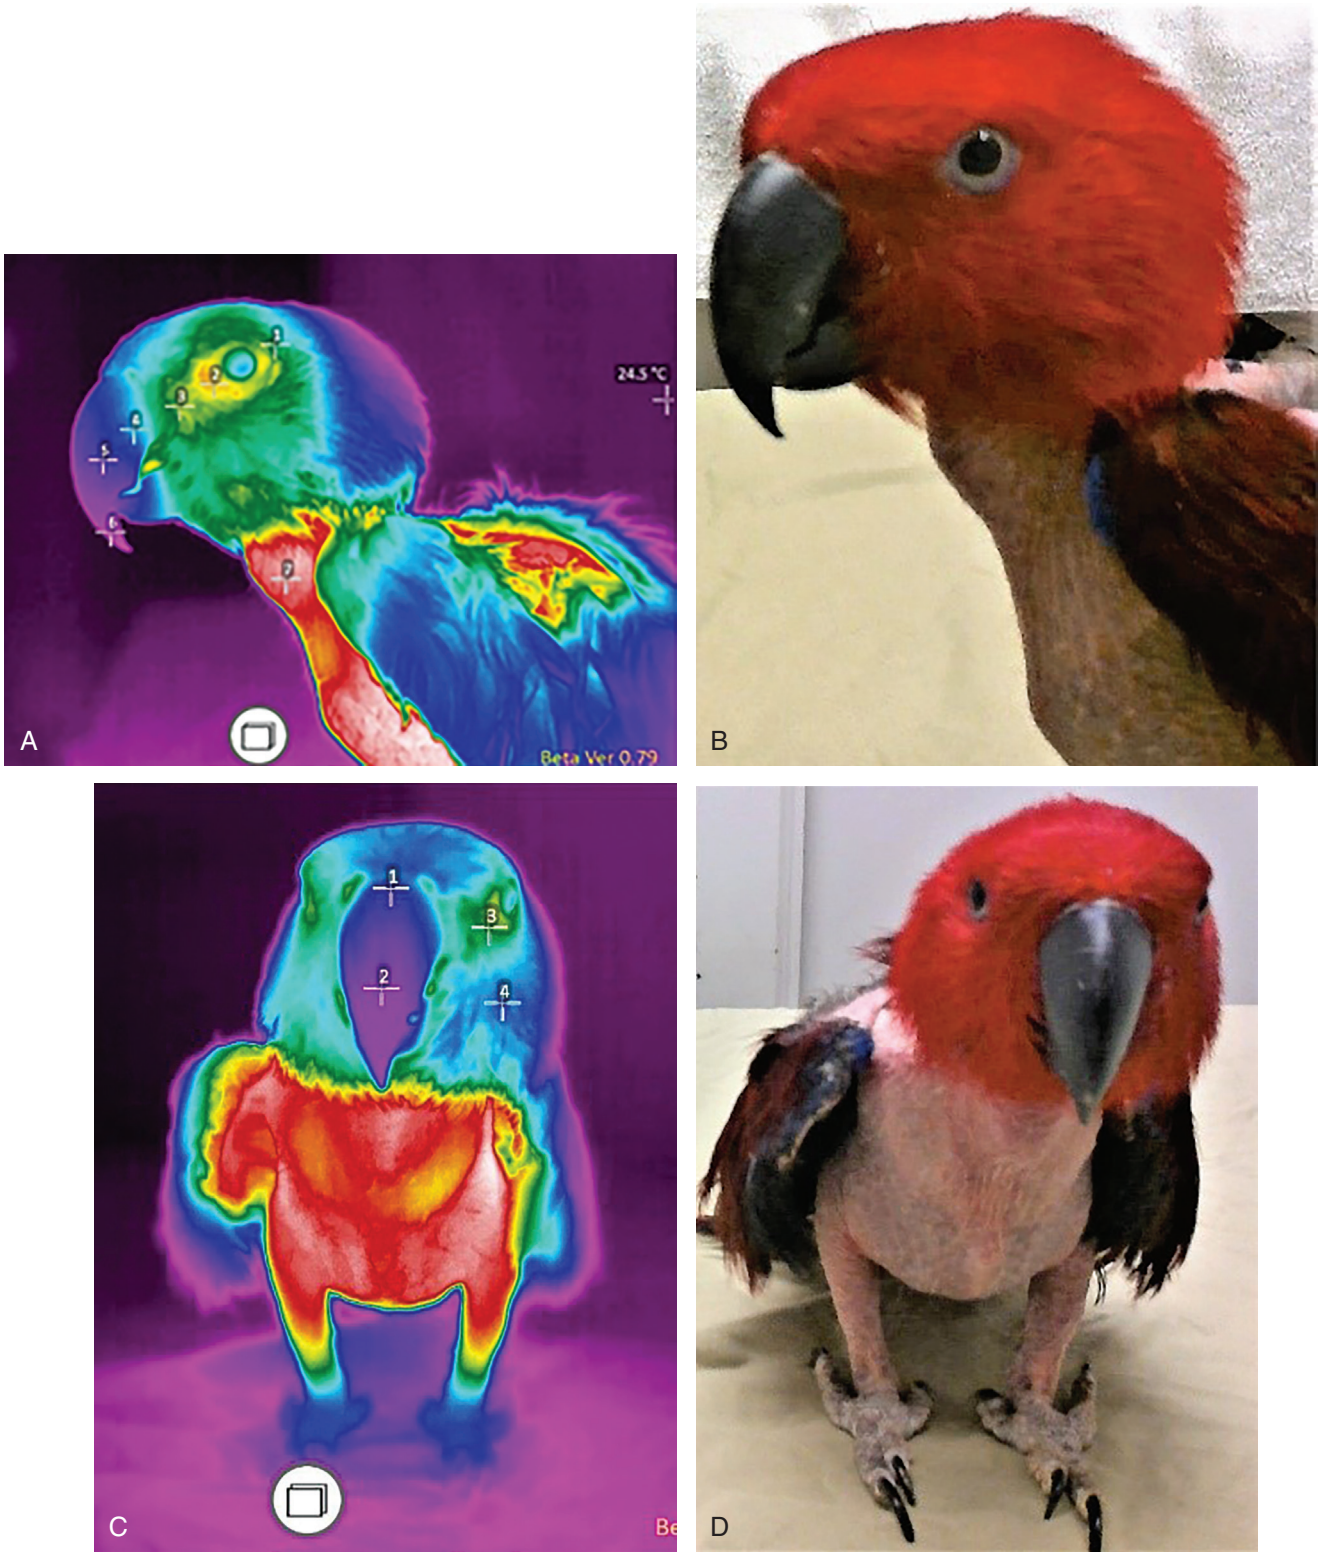

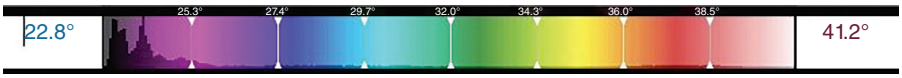

FIGURE 21.3 Lateral thermographic (A) and plain (B), and frontal thermographic (C) and plain (D) images of a female grand Eclectus parrot *(Eclectus roratus roratus)* with severe feather destructive behavior. These images can be compared against the thermographic images of the fully feathered male grand Eclectus parrot in Figure 21.2 to help visualize differences in core body temperature to those of the beak and head, thereby explain the predilection sites for cryptococcal lesions in avian species.

Site	Temp	Color
1	32.8°C	
2	36.8°C	
3	34.6°C	
4	30.4°C	
5	27.9°C	
6	26.7°C

FIGURE 21.4 Temperatures and gradient by color, used to interpret thermographic images.

This is different from secondary extension to the skin from a deeper-seated lesion, which does not carry a good prognosis (Figure 21.5).

Peripheral involvement refers to lesions located in areas of lower temperature such as the beak and head (nares, nasal sinuses, and perhaps choana). These infections start with nasal tissue colonization and invasion, with their lower, non-core body temperatures favoring fungal growth.[7,35,40] The developing lesions are commonly granulomatous and usually progress slowly but may disseminate in time. Initial surgical treatment and continued local and oral medication may help to control and possibly resolve the infection, but relapses are known to occur (McDonald AE, personal observations, 2010-2020).[5,30,41]

Particularly in the choana, the lesions may appear more as a solid tissue mass; often these lesions are referred to as a cryptococcomas.[40] Such cryptococcomas can foster exuberant mucous production, leading to extreme sinus distension over a few weeks' time, which despite treatment can markedly interfere with life quality (McDonald AE, personal observations, 2010-2020).[30] Both *C. gattii* and *C. neoformans* can cause the development of cryptococcomas. They are inflammatory, tumor-like masses representing areas of fungal invasion and multiplication.[40] They can occur in many tissues.[30,20,40,41] They can be solitary or diffuse and of variable size. In humans, surgical removal is the treatment of choice for single masses.[5] Surgical debulking is thought to decrease antigen load and facilitate recovery (Figure 21.5).[5]

Singular, choanal polyps, when noted in birds, carry a good prognosis with excision (McDonald AE, personal observations, 2010-2020).[30] Local head lesions may present with ocular and/or retrobulbar involvement and/or blindness (Figure 21.6). In avian species, ocular lesions may result from a peripheral lesion, but they can also result from disseminated disease. Invasion and spread to adjacent tissues may lead to brain involvement.[14,19]

C. neoformans is more commonly associated with central nervous system (CNS) signs.[9] In psittacine birds, *C. gattii*–caused CNS lesions may present as a flock outbreak with birds displaying ataxia or difficulty flying, which can rapidly progress

FIGURE 21.5 *Cryptococcus neoformans* right-sided sinusitis in a long-billed corella *(Cacatua tenuirostris)*. Note the rostral-ventral distention of the infraorbital sinus region and dried exudate about the right nare (A). Successful treatment included sinusotomy and debulking of the cryptococcoma (B), followed by a total of 4 months of systemic itraconazole treatment. (Photos courtesy Bob Doneley.)

to seizure activity and death.[38] Neurological involvement carries a poor prognosis.[9,31]

Anatomically, involvement of the trachea and syrinx can be seen. Initially, the patient may sneeze but otherwise appear healthy. However, over the course of several days to weeks and without treatment the patient's condition can quickly deteriorate, with clinical signs such as exercise intolerance and inspiratory dyspnea being noticeable. Tracheal lesions can start with a mucoid tracheitis, following which cryptococcoma development may occur, which will require surgical removal or debulking. The infection can reoccur at other tracheal sites. Pulmonary involvement may also take place and dissemination can occur from there.

Infection involving the respiratory system should be treated aggressively as a systematic disease, in which intravenous (IV) antifungal medications, nebulization/topical treatment, and long-term oral medication for at least a year should be considered.[11] Ensuring exposure to excellent air quality is important.

Patients with systemic dissemination may present in critical condition. Cryptococcemia is reported to produce shock proteins and cryptococcal capsular proteins can provoke severe oxidative stress.[40] Deeper infections start with lung invasion, following which all body tissues become vulnerable.[1,38] These deeper syndromes tend to progress quickly and aggressively and may lead to lung lesions with necrosis, encephalitis, and meningitis with associated CNS signs, coelomic involvement with focal organ involvement, osteomyelitis, and occasionally myxedematous peritonitis.[11,14,19,38] Stimulated cryptococci increase their mucoid capsular layer, which physically impedes effective treatment.[7,11,40] The organism can be found in lesions of the brain, sinuses, lungs, coelom, and even vertebrae.[14,38] In peritonitis, its bulk may cause respiratory distress (McDonald AE, personal observations, 2010-2020).[36]

DIAGNOSIS

Diagnosis usually begins with clinical suspicion based on the history of patient exposure to an endemic area (originated from or visited), woodland exposure via hiking, or exposure to accumulated bird droppings (e.g., city squares). This, in addition to the clinical signs, may lead to a suspicion of cryptococcal involvement.[14,15]

The initial diagnostic tool is often cytology "done in-house," on nasal/choanal swabs, secretions, tissues, or tracheal wash. Effective stains for identifying the characteristic capsule include India ink, Wright-Giemsa and modified Wright stain (Figure 21.1).[10,11,34] Recognition on cytology of the characteristic capsule is considered a sensitive point-of-care diagnostic test for pathologic *Cryptococcus* species.[10,11,34] It is easy, fast, and inexpensive. However, organism size and number, capsular development, and budding characteristics can be variable (Figure 21.7).[7,9–11]

The gold standard for distinguishing *C. gattii* from *C. neoformans* is by fungal culture and isolation, utilizing different growth characteristics on CBG or Pal media.[8,10,34] The use of molecular diagnostics is revolutionizing fungal species identification, and although, at present time, these tests largely remain

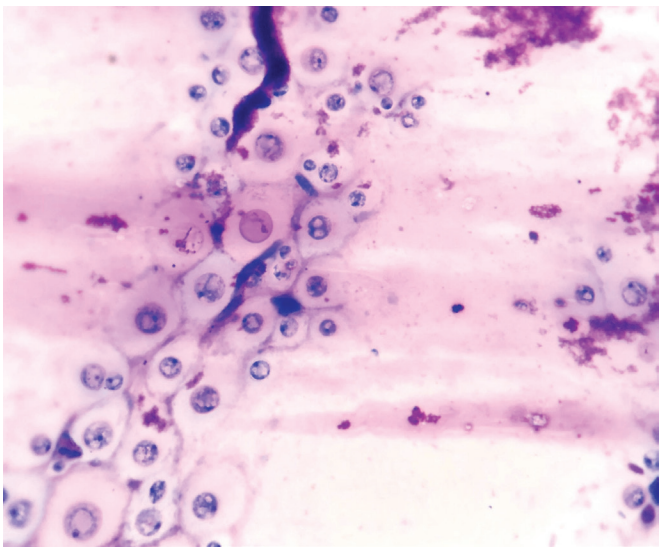

FIGURE 21.7 Modified Wright stain showing the characteristic myxedematous capsule of *Cryptococcus,* and its narrow-based budding.

a research tool, they may be available in some regions for use as a diagnostic tool.[5,9] *Cryptococcus* spp. grow rapidly, appearing in 48 hours on blood agar and Sabouraud dextrose media.[11] This rapid growth enables drug sensitivity testing, which can be used to guide ongoing treatment plans, particularly for those patients that survive the initial 2 weeks of treatment and will need long-term medication.[5,11] Drug sensitivities and minimum inhibitory concentration (MIC) values can vary with the cryptococcal species involved and their geographic origin.[5] It is recognized that in vitro drug sensitivities may not translate into in vivo efficacy.[5] Only a few laboratories offer fungal drug sensitivity testing. For those interested in having such test performed, it would be advised to contact university-associated diagnostic labs (e.g., Texas A&M, Cornell University), the CDC, medical school pathology laboratories, or regional agriculture laboratories.

Other diagnostic options involve cryptococcal antigen serology, or CrAg testing. The CrAg indicates the amount of cryptococcal capsular antigen that has gained access to patient circulation (antigenemia).[11] It does not necessarily indicate severity of infection. The capsular antigen is highly specific to *Cryptococcus* spp. but does not differentiate *C. neoformans* from *C. gattii* or quantitate live versus dead organisms.[11] Any titer elevation can be significant, as circulating antigen implies tissue invasion.[11] The CrAg antigen tests commonly used are the latex agglutination (LAT) and the enzyme-linked immunoassay (EIA). Both provide comparable results. False negatives and positives are rare but can occur.[11] Either test requires approximately 500 μL of serum, limiting its usefulness in small or anemic patients. CrAg testing is available through commercial and university veterinary laboratories.

ADDITIONAL DIAGNOSTIC TOOLS: IMAGING AND ENDOSCOPY

Noninvasive diagnostic imaging tools are in general less challenging for the compromised patient. Advanced imagining techniques (magnetic resonance imaging [MRI], computed tomography [CT]) are preferential for detection of small cryptococcomas of the lung and CNS. CT usage is much more readily available and clinically adapted (see Chapter 2 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 14, Advances in Diagnostic Imaging).

Digital radiography aids in patient evaluation for general health status including cryptococcal lesions, particularly of the beak, sinuses, trachea, and coelomic cavities (Figure 21.8). Fluoroscopy or a swivel head generator can also be used for radiographic body screening in patients whose condition is considered too critical for anesthesia and standard radiographic positioning (see Chapter 2). Attention to patient positioning, imaging modalities chosen, magnification, and adjustment of contrast can make a great difference in identifying the presence of these lesions (see Chapter 2).

In a female Eclectus parrot *(Eclectus roratus)* that had resided on Vancouver Island for several years prior to presentation for lethargy, poor appetite, and marked inspiratory distress at the author's practice, radiography suggested presence of a tracheal lesion (Figure 21.8). Based on the presence of a seropositive CrAg result, a tracheal cryptococcoma was suspected, which was subsequently removed via endoscopy and confirmed cytologically (Figure 21.7). Sixteen

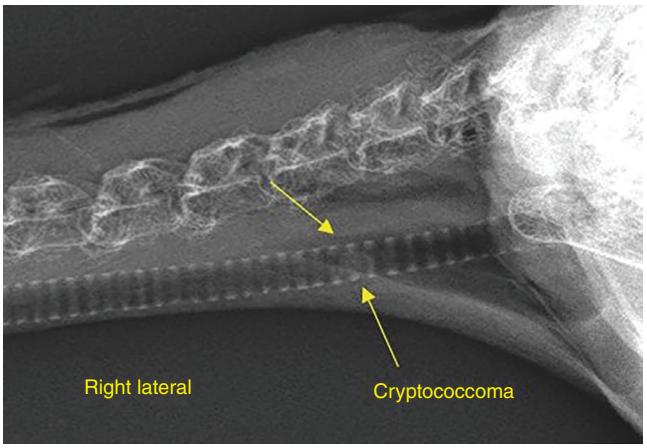

FIGURE 21.8 Lateral radiographic image of a female Eclectus parrot *(Eclectus roratus)* with a proximal obstructive tracheal lesion due to cryptococcoma development. This lesion was successfully debrided; however, clinical signs reoccurred in this patient.

months after this initial cryptococcoma was removed, clinical signs recurred due to the development of another lesion deeper in the trachea. A second endoscopic surgery was more difficult, as the base was congruent with the tracheal wall, allowing only a debulking of approximately 60% of its overall size. Due to comorbidities, the patient was eventually euthanized 6 weeks later, with postmortem histopathology of the affected tracheal wall confirming recurrence of the cryptococcoma (Figure 21.9).

Ultrasound and CT imaging can be particularly valuable for identification of comorbidities of the cardiovascular system and liver and suspect cryptococcal masses within the respiratory tract and coelomic cavities (Figures 21.10–21.12). Gross coelomic distension can result from exuberant capsular material.[36] In cryptococcal peritonitis, the echogenicity of the myxedematous gel is that of water; however, on centesis, its consistency makes aspiration and drainage potentially more difficult (McDonald AE, personal observations, 2010-2020).

Endoscopy plays an important role, especially in tracheal lesions (see Chapter 30). Air sac cannulation anesthesia facilitates examination, diagnostic sampling, and treatment. Tracheal cryptococcoma removal or biopsy (debulking) may require basket type biopsy forceps to successfully grasp the lesion (see Chapter 30 for further information on endoscopic removal of masses). The mass may be firmly attached to the tracheal wall, making removal challenging and time consuming, or it may require tracheal surgical resection and anastomosis (see Chapter 29 for afurther information on tracheal resection and anastomosis).

An air sac tube can also be used for limited laparoscopy and/or therapeutics (see Chapters 29 and 34), although great care should be taken to avoid any further cryptococcal contamination of the respiratory or coelomic cavities. If the air sac tube insertion wound does not heal quickly following tube removal, it may indicate a compromised patient and perhaps a more guarded prognosis. While the tube is in place, it is recommended to perform maintenance cleaning every 2 to 4 hours using a Calgi-sized swab moistened with a tissue-compatible (ophthalmic) dilution of IV amphotericin B or voriconazole (McDonald AE, personal observations, 2010-2020).

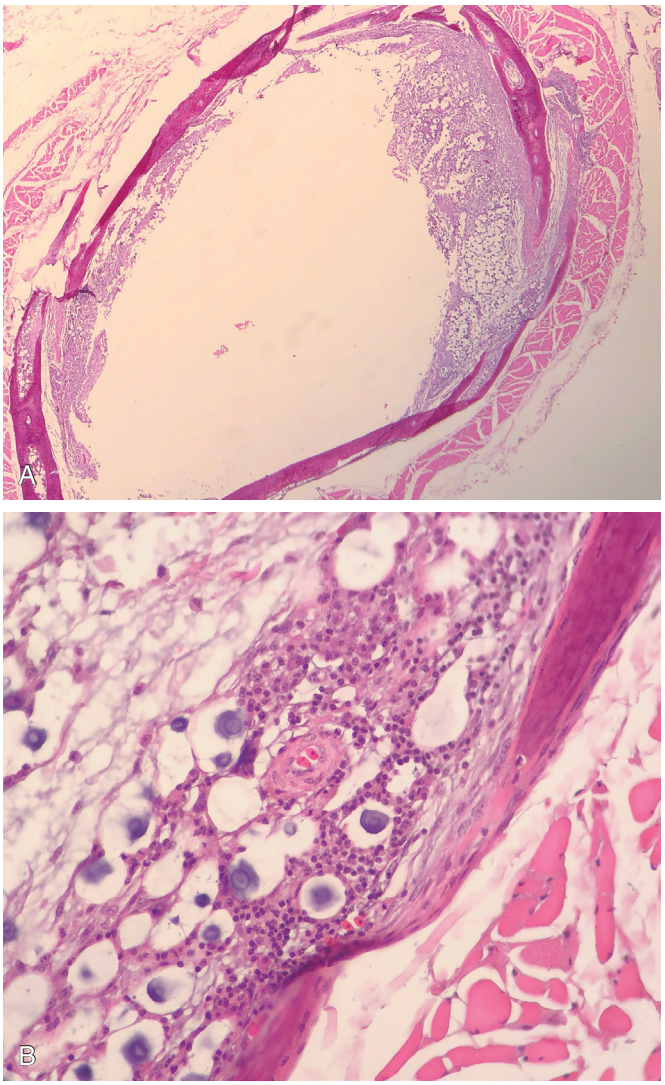

FIGURE 21.9 (A) Postmortem section of affected tracheal ring of the Eclectus parrot *(Eclectus roratus)* from Figure 21.8 with recurrence of clinical disease 16 months after endoscopic removal of the initial tracheal lesion. (B) Magnified view of tracheal ring with cryptococcal invasion.

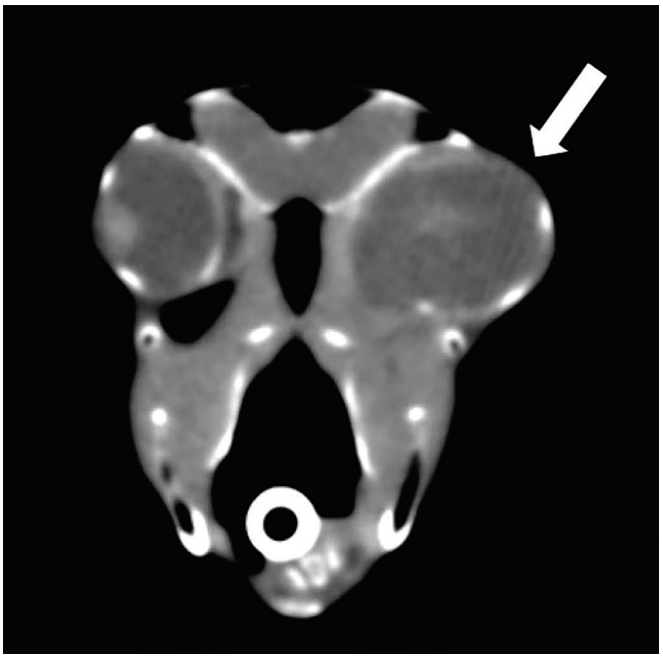

FIGURE 21.10 Computed tomography image of a Grey parrot *(Psittacus erithacus)* with multicentric cryptococcosis. In this image, exophthalmos and buphthalmos of the left eye are apparent, as well as loss of normal intraocular architecture *(arrow)*. Cytologic examination of fluid aspirated from the eye showed extracellular yeast, 4–15 μm in diameter, with narrow-based budding and a thick, nonstaining capsule, consistent with *Cryptococcus*. TREATMENT

Initial treatment is divided into general patient support and targeted antifungal therapy, which is largely drug oriented (see Chapter 8). Supportive care includes the use of antiinflammatory medication (NSAIDS, colchicine), antioxidant therapy (silymarin, glutathione), analgesics (butorphanol, tramadol, NSAIDs, gabapentin), anxiolytics, and antiseizure medication (midazolam, gabapentin).

Ideally, perhaps through the Center for Disease Control, historical local geographic information exists as to which species of *Cryptococcus* prevails, its antifungal drug sensitivities, and its MIC values. Unfortunately, drug sensitivities and MIC values vary geographically.[5,11,30] Regardless, fluconazole and voriconazole are generally good first choices.[5] In addition, new antifungal drugs are being developed, one of which is the drug T2307, which in future may provide novel, effective therapeutic options for treatment of cryptococcosis.[6,42]

Induction of targeted therapy for systemic infections often starts with IV amphotericin B combined with fluids, especially in cases involving the CNS (see Chapter 8). After induction, ongoing therapy combined with a long-term oral antifungal (fluconazole or voriconazole) (McDonald AE, personal observations, 2010-2020). Itraconazole and terbinafine may not be effectively absorbed orally to reach adequate plasma levels to treat infection. In humans, IV amphotericin B is given every 24 hours for a variable period depending on the response to treatment. Midazolam/butorphanol sedation has made IV administration much safer and easier in birds (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 19, Anesthesia). Both fluconazole and voriconazole are well tolerated by avian patients for continued monotherapy (McDonald AE, personal observations, 2010-2020). Fluconazole pediatric suspension as Diflucan (Pfizer, Kirkland, Quebec, Canada) is palatable and can be given once a day; it is also more economical than voriconazole. It is less likely to produce significant side effects than itraconazole and has the additional advantage of reaching higher concentrations in the eye and CNS.[30]

All three drugs are available in IV formulations and cross the blood-brain barrier. They are usually readily available from human hospital–associated pharmacies. The IV form of amphotericin B and voriconazole can also be used for

nebulization and can be compounded into ophthalmic or nasal drops or used topically (intratracheal lesion spray). Drug toxicity from topically used, tissue-compatible (ophthalmic) dilutions is unlikely (see Chapter 8). If multiple modalities or multiple antifungal drugs are used together, great care needs to be taken to ensure patient safety from adverse drug interactions.

Nebulization with IV voriconazole produces drug levels in the lungs but does not achieve therapeutic blood levels (pigeons).[43] Nebulization with antifungals has been utilized for lower respiratory involvement with questionable efficacy.[43] The concerns and potential for variability relate to the length of nebulization time and the resultant uneven distribution of particles deposited within the respiratory system with nebulization. Aerosol exposure periods of 0.5 or 1 hour did not result in a readily observable distribution of 1.0-μm fluorescent microspheres to the cranial thoracic, caudal thoracic, or abdominal air sac membranes. The 2- and 4-hour exposure periods resulted in readily observable deposition of the 1.0-μm fluorescent microspheres in the cranial thoracic, caudal thoracic, or abdominal air sac membranes, with the 4-hour exposure period resulting in the greatest number of particles on the membrane surfaces.[43]

Another factor to consider is the mucinous gel found in upper airway cryptococcosis.[30] Acetylcysteine is a powerful mucolytic that also reduces host oxidative stress (see Chapter 28).[44] As such, the author hypothesizes that nebulization of the upper airways with acetylcysteine, directly before nebulizing with an IV antifungal, may enhance treatment efficacy (McDonald AE, personal observations, 2010-2020).

To minimize the potential for renal damage, concurrent use of IV amphotericin B with nephrotoxic drugs (NSAIDs or

aminoglycosides) should be avoided. In addition, adequate fluid therapy should be provided, even if IV amphotericin B is used as a monotherapy (see Chapter 8). Other potential adverse drug effects to consider are adrenal suppression from ketoconazole and itraconazole hepatotoxicity in Grey parrots (*Psittacus erithacus*; see Chapter 8).

If treatment of a comorbidity such as bacterial conjunctivitis or cloacitis is indicated, selection of an immune-modulating antibacterial or an antibiotic that also has anticryptococcal activity should be considered. Several "natural" substances have been studied in vitro as antifungal drug enhancers. These include cinnamic and benzoic acids, which have been tested as effective synergistic adjunct treatment for fluconazole, itraconazole, and amphotericin against *C. neoformans*.[3] Similarly, the avian microbiome is reported to have an inhibitory effect on survival of *Cryptococcus* in the gut and lungs.[30] As such, fecal translocations from healthy birds could potentially assist in patient immune support. Currently there is no vaccine available for prevention of cryptococcosis[42].

The longest still living case of *C. gattii* in the author's experience is a male Eclectus parrot, who developed a choanal cryptococcoma 19 years ago, with infection acquired and identified at age 3. The mass self-amputated within 24 hours of the initial presentation. The patient has maintained a positive CrAg titer since but appears normal (McDonald AE, personal observations, 2010-2020). Initially, the patient was medicated with a succession of antifungals, but over the last 11 years, the patient has received voriconazole (monotherapy) orally every 12 hours and has an excellent quality of life (McDonald AE, personal observations, 2010-2020).

MONITORING RESPONSE TO TREATMENT

In veterinary medicine, the CrAg has been of value in monitoring patient response to therapy. Repeat testing should be delayed for 8 weeks after initiation of treatment to avoid confusion from rising titers from degenerating organisms, rather than treatment failure.[11] If the titer is positive, treatment should be maintained, as even low-level titers indicate active infection.[11] Titers typically decline with successful treatment, although the drop in titer generally lags the clinical improvement.[10]

Therapy should be continued for at least 2 months, but possibly longer (years) post–negative titer results. At this time, the CrAg should be remonitored every 2 months, following which the intervals can gradually be increased to every 6 to 12 months. A negative titer is not a guarantee that relapse or reinfection will not occur.[11] Nasal tissue may remain colonized despite a negative antigen titer and a lack of clinical signs. In such cases, culture, polymerase chain reaction (PCR), or cytology may be helpful in determining if the organism has been effectively eliminated.[11]

For identified imaging abnormalities, such as skull, sinus, visceral, tracheal, or pulmonary lesions, long-term monitoring is advisable at appropriate intervals for each pathological area and modality. Initially, radiographic imaging is recommended to be repeated every 1 to 2 weeks where relevant while gradually extending that to monthly or greater intervals.[5,11,30] Periodic biochemical monitoring for hepatic function or cellular damage is also advisable with long-term drug administration.

CLIENT COMMUNICATION

The client needs to be informed in a timely manner of the public health implications of cryptococcosis, pointing out that it is an environmental organism with potential for serious human illness. Emphasizing that their bird has acted as a sentinel and that their environment rather than their bird is a disease risk to them is important.[11] Also, encourage owners to visit their family doctor to discuss the human illness with them.[11]

Educating the owner on the latency period, clinical presentations, life cycle of the organism, and disease prevention methods, as well as the low incidence of disease in people and birds, can help manage their expectations and engage them in their potential role of monitoring and day-to-day care.[11] Clients also need to be prepared both financially and emotionally for the initial and long-term care that are required to manage these cases, as well as be aware of the prognosis (which is often "uncertain" at best) and possibility for relapses or reinfection. Life quality as always needs to be considered. Birds that survive the initial critical period of 2 weeks are candidates for long-term care, which is often the basic tenet of long-term survival.[9,11]

PREVENTION OF DISEASE RECURRENCE IN THE HOST

There are at least two main factors involved in recurrence of disease. One is reinfection when exposed to the infective organisms, whereas the other is reactivation of latent, preexisting (dormant or latent) organisms within the host, which can occur several years later due to exposure to environmental stressors.[8,9,30,40]

Minimizing exposure to sources of spore production and maintaining good air quality is a key to reduction of the potential for reinfection. Poor air quality negatively impacts respiratory tissues, causing inflammation, and increases the susceptibility to fungal invasion. The use of air purifiers is recommended as these will help improve air quality, desiccate the spores, and negatively impact their viability. Owners and caretakers should furthermore be advised to avoid bringing in tree branches, leaves, and old cut wood to use as perches, and so on, particularly if sourced from endemic areas for the organism. In outdoor aviaries, wire enclosures should be kept free of organic debris, whereas access to wild birds, rodents, and especially their droppings should be avoided. Additionally, it is important to avoid landscaping with trees, particularly mature trees, or exposure to soil from outdoor construction, gardening, and pressure washing enclosures.[29]

Prevention of recurrence also depends on avoiding host stress. Avoid any female reproductive activity, including egg production, to curb the associated physiologic and behavioral changes. Similarly, nesting and incubation should be avoided as these promote inactivity, with the bird spending weeks to months in an enclosed dark place (nest box).

Exposure to airborne particles from sources such as books, carpeting, and unwashed toys should also be minimized as cryptococcal organisms have been isolated from regular house dust. The use of an inline vacuum system or a vacuum with filtration will help to trap spores and avoid their further

dissemination. Daily cage cleaning is essential to avoid any build-up of avian droppings in cages, especially in conjunction with fruit or vegetable debris. Peach juice, tomatoes, and other fruits and vegetables will support and possibly enhance cryptococcal mycelial growth.[5,10,14,15] Chlorhexidine, 70% ethyl alcohol, and quaternary ammonium disinfectants are effective against *Cryptococcus* and their implementation in routine hygiene and disinfection protocols should therefore be recommended.[33,45]

CONCLUSIONS

Cryptococcus spp. are fungal pathogens that are far more widely distributed geographically than historically thought. The organism has developed the means to manipulate the potential host's defense mechanisms such as the inflammatory response and utilizes host phagocytosis to further its pathogenesis. It can adapt to adverse conditions in the host, and remain and survive in a latent form for years. While it rarely causes disease in birds, it can lead to severe clinical disease in individual or outbreaks in larger groups if given the right environmental circumstances. *Cryptococcus* spp. can alter its genome for better self-protection and propagation and amazingly can harness other organisms such as amoeba to alter their behavior to evoke environmental changes that benefit the fungus. It needs no animal host to survive. Due to its unique characteristics and ability to induce long-term infections that are difficult to treat, researchers and medical professionals have been forced to continue to search for key determinants of its pathogenicity, which will hopefully aid in identifying novel therapeutic approaches to manage and hopefully in future cure clinically affected individuals[42].

CHAPTER 22

Trichomoniasis

Hamish R. Baron • Jolianne M. Rijks • Yuko Sato

Visit eBooks.Health.Elsevier.com for a complete set of references.

Trichomoniasis is a parasitic disease affecting a range of avian species. The disease, also known as canker in pigeons or frounce in raptors, is the clinical form of an infection of the upper digestive tract of birds by protozoa of the *Trichomonas* genus. It causes significant economic losses for aviculturists and commercial pigeon producers and is responsible for several spillover and mortality events resulting in population declines in avian wildlife.

ETIOLOGY

Trichomoniasis in birds is caused by infection with single-celled parabasalids belonging to the genus *Trichomonas*. The trophozoites of these protozoa are small, measuring 6 to 20 μm in length and 3 to 8 μm wide, and have four anterior flagella, a fifth recurrent one that forms an undulating membrane, and a distinct nucleus (Figure 22.1). Trichomonads have a direct life cycle and reproduce by binary fusion; they are present in two life stages—motile trophozoites and nonmotile pseudocyst stages that are only encountered under suboptimal growth conditions in vitro.[1]

It is currently still unclear if the etiology of trichomoniasis in birds concerns one species of *Trichomonas*, specifically *Trichomonas gallinae*, or several distinct *Trichomonas* species. Some studies suggest that the genetic differences among isolates, together with morphology and host species predilection, are sufficient to consider them taxonomically distinct species such as *Trichomonas stableri* and *Trichomonas gypaetinii*.[2–4] Others consider that the partial genetic characterization of isolates with evidence for hybrid lineages, make it premature to conclude the disease is caused by multiple *Trichomonas* species, and classify the different genotypes as *T. gallinae* types, alphanumerically based on the combination of the internal transcribed spacer (ITS) ribotype sequences (A, B, …) and subtypes based on the Fe-hydrogenase (FeHyd) gene sequences (1, 2, …).[5] Regardless, all studies do corroborate that genotypes are evolving in different metapopulations and that genotypes are often associated with specific host species (Figure 22.2). Classically, *T. gallinae* has been associated with the rock pigeon *(Columba livia)*. A recent phylogenetic study showed that all *Trichomonas* genotypes are highly likely to have originated from columbid host species and are evolving along at least four lineages: a specific lineage for mesocarpal fruit doves, an old-world lineage (which includes *T. gallinae* ribotypes A and B, *T. tenax*, and *T. brixi*), a new-world lineage (which includes *T. stableri*, *T. gypaetinii*, and *T. vaginalis*), and an Australasian lineage.[6] For simplicity, *Trichomonas* species or strains causing trichomoniasis in birds are, from this point forward, referred to as *Trichomonas* spp.

EPIDEMIOLOGY

While the ancestral parabasalid from which avian *Trichomonas* spp. arose was possibly a symbiont of the lower gastrointestinal tract of Columbiformes,[6] these species have found a niche in the oral cavity, ingluvies, and esophagus of a range of avian species. They do not survive passage through the lower gastrointestinal tract and therefore rely on direct or indirect oral transmission (Figure 22.3). Direct transmission is particularly favored in Columbiformes because pigeons and doves feed their young with the desquamated lining of their ingluvies known as "crop milk." This feeding method enables highly effective transmission of *Trichomonas* and explains the high prevalence of infection reported in these species.

Both in the wild and in an avicultural setting, infected birds have been confirmed to transmit *Trichomonas* spp. through billing, courtship feeding, or via contaminated food or drinking

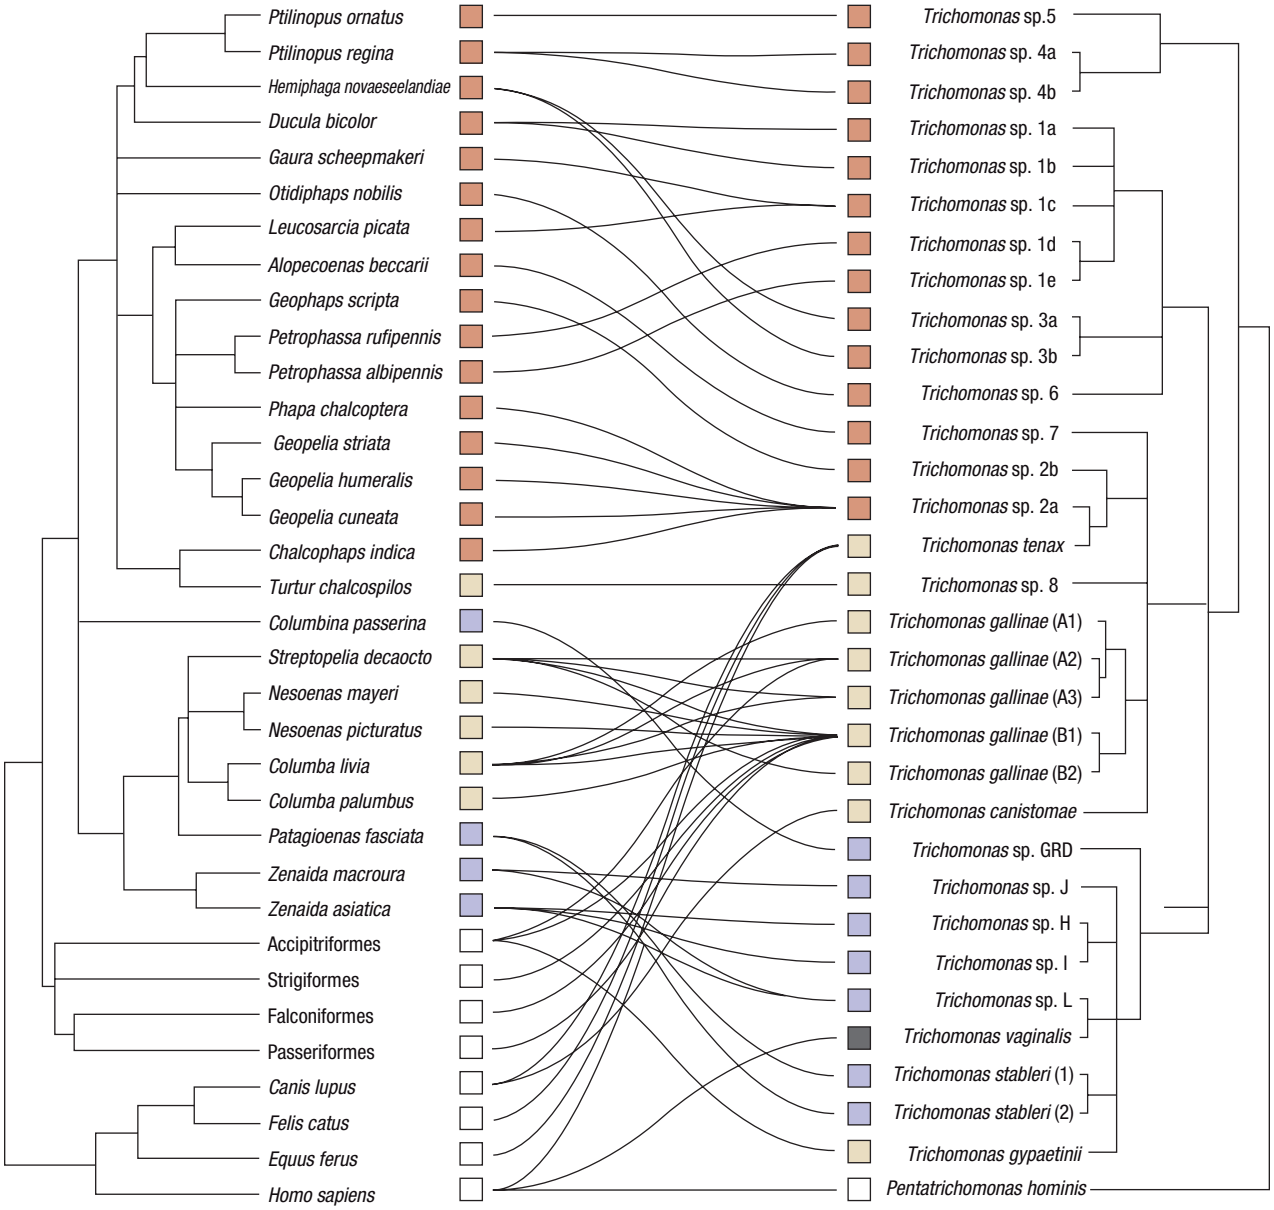

FIGURE 22.2 Cophylogram of all known *Trichomonas* genotypes and their associated host taxa. *Bold branches* and *text* indicate columbid or *Trichomonas* species. Cladogram topologies are based on multigene and nicotinamide-adenine-dinucleotide (NADH) dehydrogenase subunit 2 gene phylogenies (host) and ITS1/5.8S/ITS2 rRNA gene consensus phylogenies *(Trichomonas)*. Associations are indicated by *lines*. *Square boxes* accompanying columbid and *Trichomonas* taxa indicate geographic distribution (*orange,* Australasia; *yellow,* Eurasia; *blue,* Americas; *black,* cosmopolitan). *Circles* indicate geographic origin (>50% support) for a host or *Trichomonas* clade. (Reprinted with permission from Peters A, Das S, Raidal SR: Diverse *Trichomonas* lineages in Australasian pigeons and doves support a columbid origin for the genus *Trichomonas*, *Mol Phylogenet Evol* 143:106674, 2020.)[6]

water. While the direct transmission of trophozoites in infected saliva or regurgitated food material may be the most common route of conspecific infection, direct infection via predation, carrion feeding or cannibalism on infected carcasses, and indirect infection via contaminated water sources or birdseed, all represent possible transmission routes within and between species (Figure 22.3).[7–10]

Columbiformes act as a reservoir host, and transmission to other species occurs as a result of spillover events. In some populations it is likely that the *Trichomonas* spp. persist, with infected birds transmitting the organism within and between members of that population. These populations, in which *Trichomonas* spp. are endemic, act as a primary source of infection for birds of prey (raptors and owls) that either hunt,

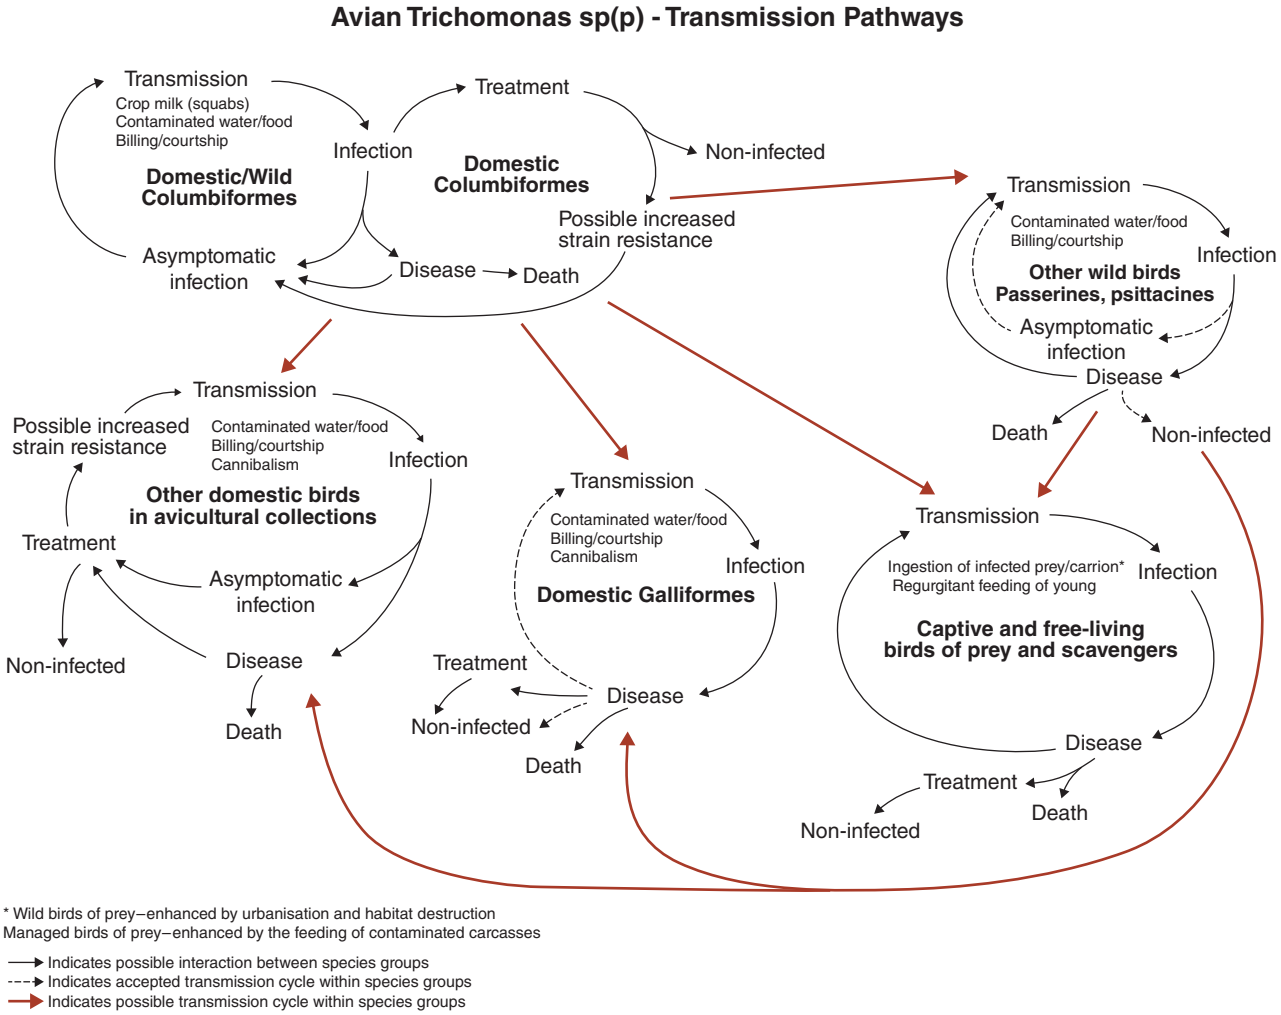

FIGURE 22.3 Avian *Trichomonas* spp. transmission pathways, outlining the most commonly encountered species groups and the possible and accepted transmission pathways between and within these groups.

feed on, or are fed carrion from doves and pigeons. Trophic transmission of *T. gallinae* has been documented in raptors that feed heavily on infected prey such as mourning doves *(Zenaida macroura)* and rock pigeons. Raptor nestlings may then become horizontally infected with trichomonads from infected parents or from being fed infected prey (by their parents).

Spillover is also reported in Passeriformes that share feeding stations or water sources with Columbiformes. Such spillover is presumably enhanced by unnaturally high stocking densities. Recently, a specific *T. gallinae* A1 subtype has caused mortality in finches in the United Kingdom and continental Europe. In these outbreaks, there appears to be a prominent seasonal pattern, which starts in July and peaks in late summer or early autumn.[11–13] To date, no studies have examined long-term climatic data and its association with *Trichomonas* infections, but dry weather and warmer temperatures have been identified as risk factors for the emergence of trichomoniasis in finches and doves.[14,15] During times of drought or stress, when activity at water sources becomes more concentrated and water becomes contaminated, infection rates in species such as the band-tailed pigeon *(Patagioenas fasciata)* have risen, causing mass mortality events.[16] *Trichomonas* spp. survival outside the host is temperature dependent. *Trichomonas vaginalis* survives exposure at temperatures near the freezing point for 96 to 144 hours and at 24°C to 25°C (75.2°F–77°F) for 120 to 154 hours. Exposure to −72°C (−97.6°F) for 1 minute destroys the organisms. The thermal death time for temperatures above 43°C (109.4°F) has been recorded. At 50°C (122°F) it is 4 minutes. The lowest temperature consistent with multiplication is 25°C (77°F); the upper limit 41°C (105.8°F).[4] The minimum time required for cell division is 5 to 8 hours and was observed over a broad range from 34°C to 39°C (93.2°F–102.2°F). Because of this, transmission via an indirect route is far less likely to occur during seasons or in climates where temperature precludes the survival of the parasite in water sources or in carcasses being scavenged. It stands to reason that niche sharing with Columbiformes, geographical distribution, and stressors during major life events (e.g., breeding, migration, molting) increase transmission opportunities and may contribute to the successful transmission of the *Trichomonas* parasite.

PATHOGENESIS

Infection with *Trichomonas* spp. results in various disease syndromes that depend on the host-pathogen interaction. Many columbid species are asymptomatic carriers of *Trichomonas* spp. and these birds are often infected by the parents with the endemic strain of the parasite as day-old chicks. Several studies indicate a wide spectrum of virulence in *Trichomonas* spp. Birds can succumb to infection with a single, highly virulent trichomonad isolate within 14 days postinfection, whereas they fail to seroconvert when exposed to 1×10^6 organisms of avirulent strains. Clinically normal pigeons can harbor both avirulent and virulent strains, although naive doves and pigeons challenged with mixed strains will succumb to infection.[17] With highly virulent strains, mortality may be as high as 50% before sufficient protective immunity develops and can become as high as 80% to 90% in young squabs that have not yet fully developed a functional immune system.[18] Analysis of clones of strains of variable virulence shows that there is significant variation in the cell membrane proteins expressed; in strains with the highest virulence, proteins related to cell adhesion were more abundant, whereas the strains with the lowest virulence displayed large numbers of proteins associated with carbohydrate metabolism.[19]

The variability in virulence is likely related to a multitude of factors, but recent work has identified that genetically different *T. gallinae* isolates caused a diverse magnitude of a cytopathogenic effect on permanent chicken liver cell and permanent quail fibroblast monolayers. The damage to these monolayers in vitro is thought to be the result of cysteine peptidases produced by the parasite.[20] This pathogenesis is well documented in the closely related *T. vaginalis*, the causative agent of a human sexually transmitted infection. Cysteine peptidases have been associated with nutrient acquisition, hemolysis, and evasion of the host immune response; they have been implicated in the virulence, the cytotoxicity, the adherence to host cells, and the detachment of host cells. *T. vaginalis* cysteine peptidases found extracellularly (as has been shown to occur in *T. gallinae*) are involved in the degradation of the mucin layer covering epithelial cells and in the subsequent apoptosis of epithelial cells, indicating an important role in the virulence of this parasite.[20]

CLINICAL SIGNS

Clinical signs associated with trichomoniasis vary across species. In Columbiformes, lesions and clinical signs largely depend on the virulence of the infecting strain and the age of the pigeon. Most endemic strains are of low virulence, and the majority of pigeons infected with *Trichomonas* spp. do not show macroscopic lesions. Early gross lesions in the oral cavity consist of irregular yellow plaques and exudate on the mucosa of the soft palate. Small, yellowish, circumscribed areas can increase in number and become progressively larger, finally developing into very large, caseous masses that may invade the roof of the mouth and even extend to the sinuses (Figure 22.4A). Early lesions in the esophagus and crop may be visible via endoscopy and may be palpable if they have progressed to thick necrotic masses. Squabs may be failing to thrive, show poor growth rates and weakness, and, in addition to previously mentioned lesions, show yellow plaques in the umbilical region (Figure 22.4B). Infected nests may be wet when compared with an uninfected nest—the result of the parents developing polydipsia and consequently regurgitating more watery feed to their young.

Raptors suffering from trichomoniasis develop similar signs to those mentioned previously but may also present with flicking food and regurgitating because of the inability to swallow. Birds of prey appear to be particularly susceptible to *Trichomonas* sinusitis with invasion of the choanal cleft and sinuses leading to open-mouth breathing, nasal discharge, decreased flying performance, and respiratory distress. There have also been reports of vultures presenting with clinical signs including disorientation and depression, as well as emaciation due to dysphagia.[4]

In passerines infected with *Trichomonas*, diseased birds will often be fluffed up and perching in a huddled position with signs including gagging, regurgitation, stretching of the neck, and greenish to yellow nasal and oral discharge (Figure 22.4C). In advanced cases, respiratory distress, emaciation, weakness, and death may be seen. There is evidence of asymptomatic infection in some passerine species.[21] Similar signs are reported in psittacine birds, with budgerigars *(Melopsittacus undulates)* being the most commonly infected species. Diseased birds often present with thick, mucus-covered feathers over the top of

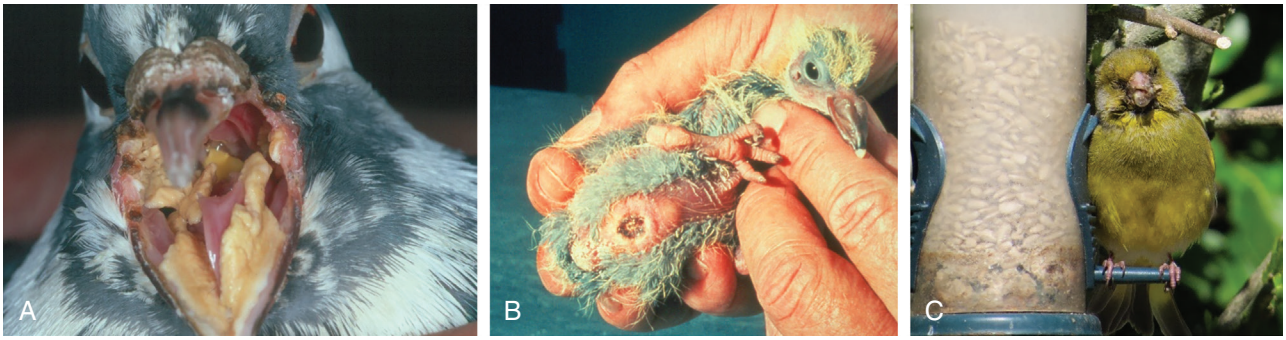

FIGURE 22.4 Clinical signs of trichomoniasis. (A) Characteristic caseous plaques in the oral cavity and glottis of a stray homing pigeon *(Columbia livia)* caused by *Trichomonas* spp. (B) A pigeon squab showing an umbilical lesion caused by *Trichomonas* spp. (C) Fluffed-up European greenfinch *(Chloris chloris)* showing greenish-yellow mucous discharge and bubbles, huddled on a backyard seed feeder. (A, B, Photos courtesy Nico Schoemaker/Yvonne van Zeeland. C, Photo courtesy Yne ten Wolde.)

their head from vomiting/regurgitation, bubbles, or viscous clear mucous from the lateral aspects of the beak with white or yellow plaques occasionally visible within the oral cavity. In budgerigars, there often is palpable thickening of the crop mucosa present on examination. If the budgerigar was infected as a young bird, it may show poor growth and will often have green diarrhea and show signs of ataxia and emaciation depending on the stage of disease progression.

In summary, in severe infections, all species may develop large caseous granulomas in the upper gastrointestinal tract, choanae, or extending into the periorbital sinuses, leading to partial or complete obstruction of the upper gastrointestinal tract and respiratory distress, and causing severe halitosis, emaciation, and starvation.

PATHOLOGY

Gross Lesions

The preferred site for *Trichomonas* spp. is the upper digestive tract including the mouth, pharynx, esophagus, and crop (Figure 22.5). The flagellate is also able to enter the respiratory sinuses and invade the neck, nasopharynx, brain, and infraorbital sinus and its periorbital diverticula (Figure 22.5B). Systemic trichomoniasis involving the liver, lung, heart, pancreas, air sacs, and pericardium, as well as focal trichomoniasis of the umbilicus, has been documented. It is likely that infection with and severity of these atypical lesions are attributed to co-infections or secondary infections with other etiologies such as bacteria or viruses. Degenerative lesions have also been documented in the kidney and genitalia of pigeons infected with a virulent strain.[22] In one incident, pigeons had trichomoniasis with bacterial co-infections in the trachea and lung, presenting as necrotizing and hemorrhagic tracheitis with an obstructive, tracheal plug and fibrinopurulent pneumonia, but a lack of gross and microscopic lesions in the upper digestive tract.[23] The severity of pathologic lesions of *T. gallinae* strains with moderate virulence in the upper digestive tract ranges from a mild catarrhal inflammation of the oral mucosa, throat, and crop to caseous necrosis of the proximal esophagus, crop, and thoracic esophagus that may progress to obstruct and occlude the esophageal lumen, often resulting in weight loss or starvation. Birds infected with avirulent strains will often develop no visible signs in gross pathology.

Experimental infection of pigeons with the virulent *T. gallinae* Eiberg strain created necrosis of the epithelial cells and submucosa of the oropharyngeal regions by day 5 postinfection.[22] Purulent exudates containing mainly heterophils were noticed in the oropharynx, crop, and lungs after 1 week. The authors also noted that this virulent strain also resulted in diphtheritic membranes and fibrinous lesions in internal organs such as the liver, lungs, and peritoneum, resulting in high mortality.[22] Liver lesions are uncommon but typically superficial and can extend into the parenchyma as solid, white to yellow circular or spherical masses.[18]

There are significant differences in the pathology seen in columbid populations in which a *Trichomonas* strain is endemic and species that are naive to the parasite. The pathology present in the naive species can be so severe that it results in mortality, while columbids that appear to be infected by the same strain are seemingly healthy.[13] In greenfinches *(Chloris chloris)*, goldfinches (*Carduelis* spp.), house finches *(Haemorhous mexicanus)*, and other passerines, some birds have been found to have no macroscopic lesions after being infected and dying with virulent *T. gallinae*.[24,25]

Trichomonas infections may readily be confused with some other pathological conditions that result in similar plaques in the oral cavity. Conditions resulting in similar lesions include infections with avian poxviruses, fungi (*Candida* sp., *Aspergillus* sp.), and nematodes (*Capillaria* sp.), salmonellosis, mycobacteriosis, nonspecific bacterial or fungal pharyngoesophagitis, oral neoplasia (squamous cell carcinoma), and vitamin A deficiency (especially in young passerines). Systemic spread of trichomonads, involving multiple organ systems should be differentiated from pigeon herpesvirus, avian paramyxovirus, or fowl adenovirus, while navel *Trichomonas* should be differentiated from bacterial infection.

Histopathology

Histopathological changes associated with *T. gallinae* in the upper digestive tract include hyperplastic mucosa with necrotic pseudomembranes and multifocal, superficial erosions (Figure 22.5E) to deep, ulcerative necrosis of the epithelium. Macrophages and plasma cells predominate the inflammatory response, but in acute phases, when tissue invasion by the organisms occurs, there may be a marked heterophilic response. Numerous pale eosinophilic, ovoid to piriform trichomonads with a round basophilic nucleus may be present in secretions and on the mucosal surface of the oropharynx (Figure 22.5F). Ulceration of the mucosa with a severe transmural heterophilic inflammation is well established by the fourth day of experimental infection with a virulent strain.[22] Caseous granulomas may also be present in the lung, liver, in the intestinal mesentery, and around the heart. A mixed population of inflammatory cells predominated by heterophils surrounds necrotic areas with occasional epithelioid macrophages and giant cells. In granulomatous lesions, trichomonads appear to be most numerous at the periphery. Passerines such as greenfinches that have died from trichomoniasis may have no macroscopic lesions but will have microscopic lesions similar to those described previously, resulting in obstruction or hemorrhagic diathesis.[24]

In tissues, hematoxylin and eosin (H&E) and periodic acid-Schiff (PAS) stains were proven to be of limited use for identification of the flagellates, especially in organs that contained only a few protozoal cells.[26] Although the technique is complex and interpretation may be unreliable, Bodian silver stain may potentially be used to facilitate detection of the organism, as this stains the organism purple to black.[23]

DIAGNOSIS

History, signalment, clinical signs, and salient gross lesions are highly suggestive of trichomoniasis and can be confirmed by microscopic observation of organisms in direct wet smears from the mouth or crop. Finding characteristic motile trophozoites, moving briskly in a jerky, spastic motion in fresh wet preparations, is diagnostic. Samples include swabs obtained from the crop, oral cavity, or conjunctiva. Organisms are most readily observed when examined immediately following collection, ensuring the stage diaphragm is down. Examination at 100× and 400× will facilitate the best opportunity for visualization.

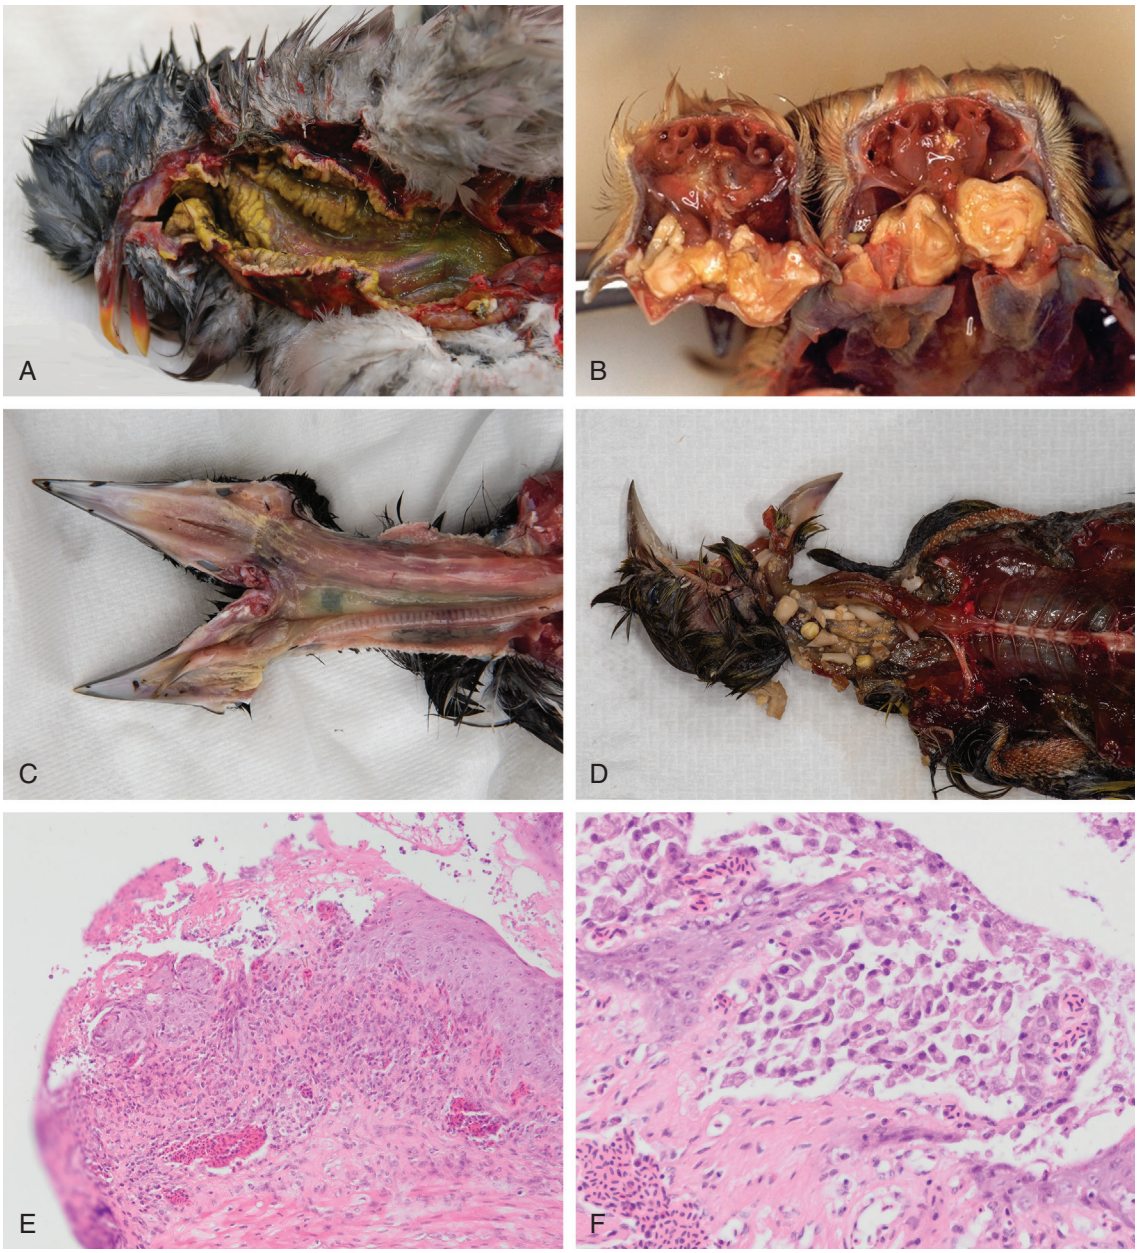

FIGURE 22.5 Trichomoniasis gross pathology and histology. (A) Severe necrotic lesions in the upper digestive tract of a wild woodpigeon *(Columba palumbus)*. However, the sensitivity to detect trichomonads in wet mount preparations is significantly lower than culture techniques, especially if the number of parasites in the host is marginal. When suspected cases are negative for motile trophozoites, or during research and disease investigations, a variety of molecular and microbiological techniques can be used to further characterize the pathogenic organisms.

Samples collected for culture should be inoculated into an appropriate culture media and stored at room temperature; common commercial media include InPouch TF (Biomed Diagnostics, White City, OR, USA) or Diamond's commercial media (Thermo Fisher Scientific, Scoresby, Australia). Culture of *Trichomonas* spp. is carried out using trypticase-yeast extract-maltose and various other *Trichomonas*-specific media, with or

without the addition of antibiotics. Optimal growth conditions include a water bath temperature of 35.5°C, but lower temperatures prolong sample viability. Culturing *Trichomonas* facilitates further molecular analysis and DNA extraction with a higher concentration of organisms and higher-quality parasite DNA.

Polymerase chain reaction (PCR) to detect trichomonads is common. The most readily available reactions include the ITS1/5.8S rRNA/ITS2 region used for species confirmation in a diagnostic setting, the *FeHyd* gene used for strain variability in research settings and nested PCR for the small subunit *(SSU)* rRNA gene. Rapid detection kits, developed for the identification of positive *T. vaginalis* samples, have been used in the diagnosis of *T. gallinae*. The OSOM Trichomonas Rapid Test (SEKISUI Diagnostics, Kent, UK) has been demonstrated as being sensitive and specific for *Trichomonas* spp. However, while suitable for the rapid detection of trichomonads, the test is not able to distinguish between *Trichomonas* spp.[27]

Immunohistochemistry using a rabbit polyclonal antibody that targets the outer membrane of *Trichomonas* genus with antigen-specific antibody has been described in literature. Although this stain is not specific for *T. gallinae*, staining correlated with areas with trichomonad regions observed on H&E.[23] In situ hybridization was found to be more sensitive than histochemical staining (such as PAS and H&E), especially in tissues with small numbers of the parasite. The protozoa were clearly visible as dark blue cells, which allowed the demonstration of cells in different organs and locations within the affected tissue, helping to correlate the histological changes with the presence of the protozoon.[26]

TREATMENT

Various nitroimidazoles, including metronidazole (10–30 mg/kg PO BID for 10 days), dimetridazole (666 mg/L drinking water for 7–12 days), ronidazole (1 g/L drinking water for 6 days), and carnidazole (20–30 mg/kg tablet PO once) are the standard treatment for trichomoniasis in birds (see Chapter 9). Historically, these therapeutic options have been used effectively against flagellate infections, but several have subsequently been banned (see Table 24.1). Metronidazole is the drug of choice for the treatment of *T. gallinae*, but in some countries the law prohibits its use. Advanced clinical cases may require surgical debridement of caseous lesions. Surgical excision using a curette to remove granulomas from the choanae, or oral cavity, should be carried out with extreme care, as these lesions are prone to hemorrhage. An ingluviotomy approach can be performed to allow for surgical debulking of lesions in the esophagus or crop. Following opening of the crop, the affected mucosa can be exteriorized and isolated to facilitate the debulking. Once resected, the crop wall can be closed using simple continuous sutures before the skin is closed. While the success rate is not documented, treatment of advanced disease states, which may lead to complete occlusion of the esophageal lumen, carries a poor prognosis.

Treatment in young pigeons is usually limited to those showing clinical disease in the nest. These birds can be treated using carnidazole tablets by mouth. In severe cases where granulomatous lesions preclude the administration of oral tablets, a dimetridazole or ronidazole "paste" can be prepared using the in-water medication that can be applied topically onto the oral cavity lesions with a cotton tip. In infected squabs, it is common practice to also treat the nest-mate and the parents using oral carnidazole tablets.

There is an increasing body of evidence, as well as anecdotal reports, indicating nitroimidazole resistance, with resistant isolates of *T. gallinae* having been reported in Belgium, Spain, the United States, and Iran (see Chapter 9).[8] To prevent subclinical disease-causing decreased racing performance, nitroimidazole drugs are routinely administered to racing pigeons for 3 to 4 days each month during the racing season. This prolonged exposure to potentially subtherapeutic doses of nitroimidazole creates a suitable environment for resistant strains to develop; a phenomenon that is well documented in related trichomonads, *T. vaginalis*.[28] This resistance is now documented in budgerigars and racing pigeons, where clonal cultures of *T. gallinae* obtained from each species had significantly different minimal lethal concentrations (MLCs) against four 5-nitroimidazoles (Table 22.1).[29]

Development of resistance is a concern; not only because the nitroimidazoles provide the mainstay for current therapy but also because of the husbandry practices of racing pigeons that are most likely to carry resistant strains of *Trichomonas*. These birds are driven long distances and released during races, and also released from their loft twice daily during training. If they do not return to their loft, they will sometimes join groups of feral pigeons in city parks or areas of high avian density, where food is readily available. Here, the potential for spread of resistant strains to wild birds increases. *T. gallinae* isolates, with similar nitroimidazole resistance profiles detected in racing pigeons and wild pigeons in Belgium, provide support for the exchange of resistant strains.[30]

In wild birds, treatment is much more problematic and not recommended.[31,32] Studies have shown variable success with in-water medications with possible suboptimal dosing, which increases the risk for the development of resistance.[33,34] Variable intake of food and water may have detrimental effects on nontarget bird species that share the feeding stations. This is especially true for dimetronidazole, where intake of high doses is also potentially toxic to birds.[35] In practice, treatment is only feasible when individual wild birds are presented for veterinary assessment.

Despite nitroimidazole-resistant strains of *T. gallinae* becoming more frequently reported, there is only a small body of research investigating alternative treatment modalities.[36] There has been recent work evaluating various essential oils and natural remedies in vitro and in vivo. There is evidence that essential oil of *Artemisia sieberi* or *Pelargonium roseum*, wild rue *(Peganum harmala)* alkaloid extract, and aqueous extract of garlic *(Allium sativum)* may act as potent natural antitrichomonal agents in vitro and in vivo in pigeons.[37–40] Essential oils of East Indian lemongrass *(Cymbopogon flexuosus)* were tested in quails.[41] Based on in vitro results, other possibly promising extracts and pure compounds include some from the curry leaf tree *(Murraya koenigii)*, pitanga *(Eugenia uniflora)*, pepper fruit *(Dennettia tripetala)*, the fool's curry leaf tree *(Clausena lansium)*, ginger *(Zingiber officinale)*, lavender *(Lavandula angustifolia)*, and other Lamiaceae.[36,42] Pure compounds of Lamiaceae plants with good antitrichomonal activity and limited cytotoxicity in vitro, included linalyl acetate, thymol, 4-terpinenol, γ-terpinene, *p*-cymene, or D-fenchone.[42] Further work is required to establish whether safe and therapeutic doses of treatments based on

TABLE 22.1

Minimal Lethal Concentrations of Metronidazole, Dimetridazole, Ornidazole, and Ronidazole for the Six Different Cloned Xenic *Trichomonas* Cultures Investigated in the Present Study

Cloned Cultures	Minimal Lethal Concentrations (MLC) of the Test Compounds (μg/mL)				Classification After Phylogenetic Analyses
	Metronidazole	Dimetridazole	Ornidazole	Ronidazole

Values are given as mean ± Standard error of mean of three independent experiments performed in duplicate. Values (in columns) having no common superscript are significantly different at $p \leq 0.05$; values in bold indicate resistance (= MLC ≥ 50 μg/mL) of the isolate to the respective drug.

Modified from Zimre-Grabensteiner E, Arshad N, Amin A, Hess M: Genetically different clonal isolates of *Trichomonas gallinae*, obtained from the same bird, can vary in their drug susceptibility, an in vitro evidence, *Parasitol Int* 60(2):213–215, 2011. https://doi.org/10.1016/j.parint.2011.02.003.

natural products from such plants can be consistently effective against trichomonads.

PREVENTION

The prevention of clinical disease outbreaks should be considered as an essential aspect of treatment. Identification and elimination or treatment of carrier birds in avicultural collections, alongside regular cleaning and disinfection of drinkers and drinking water, will help to prevent disease spread. The provision of a dry environment and preventing moisture buildup in the aviary will assist in preventing transmission. This may be achieved by using nipple drinkers, covered water containers, or by natural or artificial ventilation and heat. Wild birds should have no access to water or unfinished seed (especially spoiled or moist seed where *Trichomonas* can survive for up to 24 hours) from the avicultural collection. To prevent infection in raptors or birds of prey, the feeding of frozen or parasite-free pigeon carcasses, or seeking alternative food sources, is the most effective course of prevention. Feeding farmed quail, chickens, or rodents as a less susceptible protein alternative will help to prevent the introduction of disease. Where there is a history of disease, or in collections that are highly susceptible to infection, routine health checks and prophylactic treatment with in-water ronidazole during breeding, weaning, and at other susceptible times of the year are recommended.

Management of trichomoniasis in avicultural collections depends on reducing stress in birds and removing severely affected birds from the flock. In Columbiformes, establishment of carrier states and humoral immunity has been shown to have a protective effect postexposure in adults. There is no vaccine available for this parasite; however, future studies looking into immunity may be of help due to potential protective effects from humoral immunity. Murine model studies looking at *T. vaginalis* vaccines for humans have been explored. However, despite some success in controlling symptoms or duration, none of them were able to achieve clearance of the parasite. Since the organism is an extracellular parasite, cell-mediated immunity will likely be less effective than a humoral response in triggering immunoglobulin-dependent elimination of the parasite,[43] hence rendering the development of an effective and successful vaccine challenging. For a related parabasalid, *Trichomonas foetus*, there is a commercial vaccine (TrichGuard; Boehringer Ingelheim Animal Health USA, Duluth, GA, USA). However, while routine vaccination strategies in asymptomatic bulls help to reduce shedding, it does not protect the animals from infections with the organism.[44]

To prevent disease outbreaks in wild birds, limiting the unnatural congregation and mixing of species at feeding stations or communal watering points will help to limit transmission of disease. However, such congregations may not always be preventable, for example, during times of drought, which will result in birds congregating at the few remaining water sources. Under these conditions, providing supplementary watering points with clean water may help to maintain sanitary conditions and limit transmission between and within species. Similarly, if feed must be supplied, it should be done in moderation (equivalent to daily consumption) and any feeder cleaned and disinfected daily. If different types of feed are offered, these should be supplied in different locations to avoid unnatural mixing of species.[32]

CONSERVATION AND ONE HEALTH CONSIDERATIONS

Trichomoniasis can be a leading cause of death in wild avian species, whether columbids[45,46] or finches.[23,24] It can contribute to the decline of a species, as likely seems to be the case for the threatened turtle dove *(Streptopelia turtur)* and the

band-tailed pigeon.[47,48] The parasite may even drive population declines in naive populations of novel host species. Numbers of greenfinches are declining in North and Western Europe since *T. gallinae* was first detected in the species in 2005, and this trend shows no indication of leveling off yet.[32,49] Models have shown that endangered populations can be driven to extinction by repeated exposure to a pathogen from the reservoir host species,[50] and such a scenario is not to be excluded for species exposed to trichomonads.

Besides contributing to or causing species decline, trichomoniasis can also be a substantial threat to the recovery of species, as exemplified with the endangered pink pigeon *(Columba mayeri)* in Mauritius. In this species, *T. gallinae* was demonstrated to be the most significant pathogen hampering species' recovery by reducing both reproductive success (being a prime cause of squab mortality) and adult survival (the more persistent the infection, the shorter the adult bird survival).[46,51,52] This led to initiation of (preventive) treatment during the initial recovery phase to ensure pink pigeon squab survival.[51] Treatments have also been used to ensure the local survival of raptor nestlings, such as golden eagle *(Aquila chrysaetos)* nestlings.[53]

The trichomoniasis context is constantly evolving, partly through anthropogenic influence. The effects of human perturbation of host habitat and food sources on *Trichomonas* transmission and trichomoniasis occurrence have been documented to some extent. The practice of supplementary feeding of game birds, which promotes the congregation of columbids, has been shown to increase the risk of *Trichomonas* infection and the occurrence of trichomoniasis outbreaks in these species.[31,54] The year-round feeding of garden birds with multiple types of seed, which supports aggregation and bird species mixing, has most likely altered *Trichomonas* transmission dynamics and promoted cross-species disease transmission events from columbids to finches.[32] The advent of a more urban environment and the loss of native habitat and prey have caused some raptor populations to substantially increase the proportion of synanthropic columbids in their diet, and with this the probability of *Trichomonas* infection.[53,55,56] The translocation of columbids from aviaries into the wild for restocking purposes has introduced novel *Trichomonas* strains into habitats, such as occurred in a raptor recovery program.[57]

Should *Trichomonas* infecting birds, humans, and mammals be shown to be more of a continuum as perceived by some authors,[6,58] then disease emergence risk and the development of nitroimidazole resistance require closer collaboration among human, animal, and ecosystem health scientists. This would, among others, require better insight into the scale of nitroimidazole treatments in (racing) pigeons and surveillance for nitroimidazole-resistant strains.

CHAPTER 23

Diplomonad Protozoal Diseases: Giardiasis, Spironucleosis

Lauren V. Powers

Visit eBooks.Health.Elsevier.com for a complete set of references.

PROTISTS

Protists are a diverse group of unicellular eukaryotes that are taxonomically considered separate from animals, plants, and fungi. Protists include protozoa, unicellular algae, and slime molds. The protist supergroup Excavata contains species that are morphologically asymmetrical and have a feeding groove that is "excavated" on one side. Most excavates are flagellated protozoa that are either free-living or parasitic and feed on organic matter such as organic debris, other microorganisms, or host tissues.[1]

FORNICATES

Excavates in the clade Fornicata possess one or two karyomastigonts per cell. A karyomastigont system consists of a single nucleus with four basal bodies (kinetosomes). Each basal body is typically associated with a single flagellum, and therefore there are generally four flagella per karyomastigont and eight per cell.[1,2] All fornicates are anaerobic or microaerophilic.[1] Fornicates lack classical mitochondria but possess mitochondria-related organelles (MROs), which are organelles that are believed to have evolved from mitochondria in certain eukaryotes that live in low-oxygen environments.[1–4] The Fornicata clade consists of four lineages: free-living *Carpediemonas* and *Dysnectes*, the retortamonads (almost exclusively parasitic), and the diplomonads.[1,2,5]

DIPLOMONADS

Diplomonads are mostly parasitic, but some species are free-living.[1,2,5] Most diplomonads ("two units") are diplozoic, meaning their cells contain two apparently symmetrical karyomastigonts.[1–3] Based on morphologic features such as the presence or absence of cytostomes (cell "mouth" supported by microtubules), diplomonads have been divided into the monophyletic groups Giardiinae and Hexamitinae.[1,2]

Giardiinae Diplomonads

Giardiinae diplomonads consist of the genera *Giardia*, *Brugerolleia*, and *Octomitus*.[1] These diplomonads lack cytostomes, and their recurrent flagella pass through the cytoplasm as naked axonemes.[1,2] Among the Giardiinae, the ventral adhesive disc is unique to *Giardia*.[2] *Giardia* has been widely reported in birds, but to date there are no confirmed reports of infection with *Brugerolleia* or *Octomitus* in avian species.

Giardia

Giardia trophozoites are pear-shaped with a convex dorsal and a concave ventral side (Figure 23.1).[3] Trophozoites range from 10 to 20 μm in length and 5 to 15 μm in width.[3,6] The *Giardia* cytoskeleton contains several important microtubule structures including the ventral disc, three pairs of dorsal flagella, one pair of ventral flagella, the funis, and the median bodies.[3,6] The morphological appearance of the median bodies has historically been used to assist with the taxonomic classification of different *Giardia* species.[6,7] Cysts are oval to egg-shaped and range from 10 to 14 μm in length and 8 to 10 μm in width.[2,3,6,8] Cysts have a thick wall that contains a double membrane and contain 2 to 4 nuclei.[2,3,6] Cysts from almost all *Giardia* species appear similar by light microscopy.[9]

A total of eight *Giardia* species are currently recognized: *G. duodenalis* (syn. *G. intestinalis*, *G. lamblia*), *G. psittaci*, *G. ardeae*, *G. muris*, *G. agilis*, *G. microti*, *G. peramelis*, and *G. cricetidarum*.[3,10] The major hosts for *G. duodenalis* are mammals, and *G. duodenalis* is the only *Giardia* species known to infect humans.[10,11] All other *Giardia* species are found in animal species including birds, amphibians, and mammals.[10] *G. duodenalis*, *G. psittaci*, and *G. ardeae* are the only *Giardia* species currently known to infect birds.[10–12] There are no confirmed reports to date of zoonotic transmission from birds to humans for any *Giardia* species.[10,13]

Giardia duodenalis. *G. duodenalis* is a species complex that consists of eight genotypes with specific host preferences, categorized as assemblages A through H (Table 23.1).[3,11] Assemblages A and B are the most dominant assemblages in humans.[2,10,14] Assemblages A and B are also found in other vertebrate species and therefore have zoonotic potential.[2,3,10] Assemblages A and B have been reported in point prevalence studies of fecal shedding in wild birds including the mallard duck *(Anas platyrhynchos)*, European quail

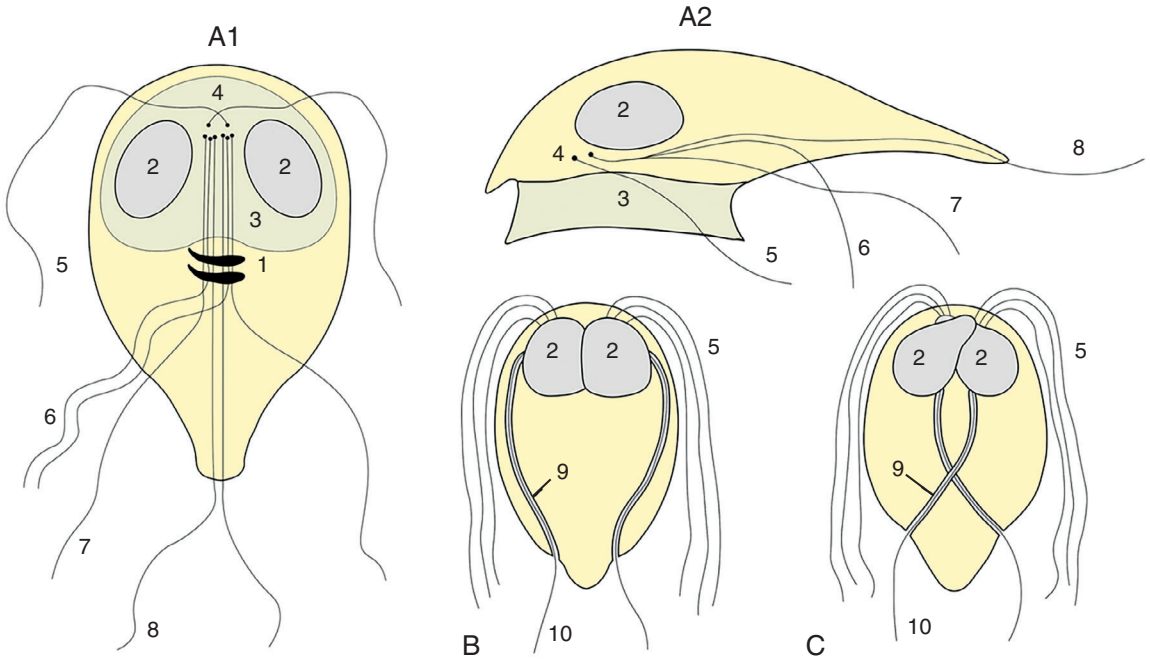

FIGURE 23.1 Morphological differences between *Giardia* (A1, A2), *Hexamita* (B), and *Spironucleus* (C). *1*, Median bodies. In *G. duodenalis* and *G. ardeae*, the median bodies appear as a "clawhammer" shape. In *G. psittaci*, the median bodies are rod-shaped and pointed but similar in appearance to *G. duodenalis* and *G. ardeae* by light microscopy. *2*, Nucleus. The nuclei in *Hexamita* are generally round, while the nuclei in *Spironucleus* are somewhat spiral-shaped. *3*, Ventral disc. The marginal groove (not illustrated here) around the ventral disc is incomplete in *G. psittaci* but complete in *G. duodenalis*. *4*, Basal bodies. *5*, Anterior flagellum. *6*, Ventral flagellum. *7*, Posterior flagellum. *8*, Caudal flagellum. *9*, Cytostome (cell "mouth"). *Giardia* species lack cytostomes. *10*, Posterior (or recurrent) flagellum. The posterior flagella and associated cytostomes travel laterally caudal to the nuclei in *Hexamita* and medially caudal to the nuclei in *Spironucleus*. (Illustration by Lily Baine © 2020, courtesy Lauren Powers.)

(Coturnix coturnix), European turtle dove *(Streptopelia turtur)*, European nightjar *(Caprimulgus europaeus)*, Eurasian magpie *(Pica pica)*, and common buzzard *(Buteo buteo)* in Spain[15,16]; a gadwall *(Anser strepera)* from a lake catchment in Hungary[14]; and gulls (*Larus* spp.) from Dennis, MA, USA, and from Appledore Island in Maine.[17] Assemblages A and B have also been reported in surveys of domestic birds including ducks and chickens *(Gallus gallus domesticus)* living in closed enclaves in the Ivory Coast[18]; domestic graylag geese *(Anser anser)* and domestic ducks from farms and a lake catchment in Hungary[14]; and birds kept in zoological collections including a toco toucan *(Ramphastos toco)* in Brazil.[19] Assemblages D, F, and H have been reported in surveys of wild aquatic and nonaquatic birds, including the mallard duck and the Eurasian jay *(Garrulus glandarius)* in Spain[12,15] and a herring gull *(Larus argentatus)* from Dennis, MA.[17]

Assemblages A and B have been identified in psittacine birds kept as pets or in zoological collections in fecal shedding surveys, including a blue-and-gold macaw *(Ara ararauna)*, scarlet macaw *(Ara macao)*, blue-fronted Amazon parrot *(Amazona aestiva)*, and white-bellied caique *(Pionites leucogaster)* in Italy.[11] In this report, 5.3% of fecal samples from psittacine birds were positive for *G. duodenalis* by polymerase chain reaction (PCR).[11] *G. duodenalis* was also identified in sick wild-caught sulfur-crested cockatoos *(Cacatua galerita)* from Victoria, Australia, in a report published prior to the establishment of *Giardia* assemblages.[20] In this report, axenically cultured *G. duodenalis* trophozoites from cockatoos established infection in experimentally infected mice *(Mus musculus)*, affirming the concern for zoonotic potential.[20]

Giardia psittaci. The first report of *Giardia* in a psittacine bird was published in 1962 and described postmortem findings in a 2-year-old budgerigar *(Melopsittacus undulatus)* with poor body condition and chronic diarrhea.[21] In 1981, based on morphologic findings by light microscopy of *Giardia* isolated from sick budgerigars, it was suggested that budgerigar *Giardia* be classified as *G. duodenalis* race *psittaci*.[13] Trophozoites possess rod-shaped, pointed median bodies that are similar in light microscopic appearance to the clawhammer-shaped median bodies of *G. duodenalis*.[13,22] However, in 1987 it was proposed that the *Giardia* isolated from budgerigars be classified as its own species, *G. psittaci*, based on scanning electron microscopy morphologic findings including the lack of a complete marginal groove around the ventral disc.[22] More recently, partial molecular sequencing of *G. psittaci* from budgerigars[23,24] and lineolated parakeets *(Bolborhynchus lineola)*[23] supports the current taxonomic classification of *G. psittaci* as its own species. *G. psittaci* was also isolated and partially sequenced from 12 asymptomatic adult psittacine

TABLE 23.1

Giardia duodenalis Assemblages Referenced in This Text

Assemblage	Species Affected	Human Reports	Reports in Avian Species and Geographic Area
A	Mammals, birds[10]	Human reports are common.[10] Zoonotic potential	Four species of psittacine birds (blue-and-gold macaw [*Ara ararauna*], scarlet macaw [*Ara macao*], blue-fronted Amazon parrot [*Amazona aestiva*], white-bellied caique [*Pionites leucogaster*]) kept as pets or in zoos in Italy[11] Gadwall (*Mareca strepera*) from a lake catchment in Hungary[14] Mallard ducks (*Anas platyrhynchos*), common buzzard (*Buteo buteo*), and a European nightjar (*Caprimulgus europaeus*) from a wildlife center in Spain[15] Gulls (*Larus* spp.) from Cape Cod, MA, USA[17] Domestic duck (*A. platyrhynchos;* mixed A+B assemblage) and chickens (*Gallus gallus domesticus*) in the Ivory Coast[18] Toco toucan (*Rhamphastos toco*) kept in a zoo in Brazil[19]
B	Mammals, birds[10]	Human reports are common.[10] Zoonotic potential	Domestic graylag geese (*Anser anser*) and domestic ducks from farms in Hungary[14] Mallard ducks (*A. platyrhynchos*), European turtle dove (*Streptopelia turtur*), Eurasian magpie (*Pica pica*), and European quail (*Coturnix coturnix*) from a wildlife center in Spain[15] Aquatic birds (mixed population of 17 different avian species) from the Salburua wetlands in Álava, Northern Spain[16] Gulls (*Larus* spp.) from Dennis, Massachusetts, and Appledore Island, Maine[17] Domestic duck (*A. platyrhynchos;* mixed A+B assemblage) and chickens (*Gallus gallus domesticus*) in the Ivory Coast[18]
C	Mammals (e.g., dogs, cattle)[10]	Human reports in China and Slovakia[10]	None reported
D	Mammals (e.g., dogs, cattle, chinchillas), birds[10]	Single human report in German travellers[10]	Eurasian jay (*Garrulus glandarius*) from a wildlife center in Spain[15]
E	Mammals (e.g., hoofed animals, cats)[10]	Several reports[10]	None reported
F	Mammals (e.g., cats, pigs), birds[10]	Single report in Ethiopia[10]	Mallard duck (*A. platyrhynchos*) from a wildlife center in Spain[15]
G	Rodents[10]	None reported[10]	None reported
H	Pinnipeds (e.g., gray seal), birds	None reported[10]	Herring gull (*Larus argentatus*) from Dennis, Massachusetts[17]

birds from 6 genera after fecal sampling during a bird exhibition in Brazil.[12] In this report, 93/359 (25.9%) of psittacine birds were positive for *G. psittaci* by nested PCR including 2/18 (11.1%) cockatiels *(Nymphicus hollandicus)*.[12]

To date, *G. psittaci* has only been reported in psittacine birds.[12,13,21,22,24,25] Attempts at the transmission of budgerigar *G. psittaci* to canaries *(Serinus canaria domestica)* and mice were not successful in one report.[13] In a separate study, inoculation of budgerigar *G. psittaci* failed to produce infection in chicks, ducklings, Mongolian gerbils *(Meriones unguiculatus)*, or neonatal mice.[9]

Giardia ardeae. *G. ardeae* also has clawhammer-shaped median bodies, but the long axis of the clawhammer shape is parallel to the caudal flagellar axonemes rather than perpendicular as seen with *G. duodenalis*.[9,26] Ultrastructural imaging and partial molecular sequencing have been performed for *G. ardeae*, which support *G. ardeae* as a unique species.[7] *G. ardeae* has been reported in aquatic birds including the aquatic great blue heron *(Ardea herodias)*,[26] gray heron *(Ardea cinerea)*,[27] and straw-necked ibis *(Threskiornis spinicollis)*.[7,28] Inoculation of great blue heron *G. ardeae* failed to establish infection in chicks, budgerigars, Mongolian gerbils, and neonatal mice in one report.[9]

Giardiasis

Giardia is a common cause of gastroenteritis (giardiasis) in humans, livestock, and companion animals worldwide.[3,10,24,29–31] Infection occurs almost exclusively through the ingestion of cysts.[2,3,10,14,24,29] Cysts are immediately infectious when excreted in feces and are remarkably stable in the environment.[2,3,32] Excreted cysts can contaminate drinking water sources and recreational bodies of water.[10,14,29,32] After ingestion, excystation occurs after exposure to gastric acids and peptidases.[2,3] Excyzoites then divide into trophozoites that colonize the small intestine.[2,3] After disrupting the local microbiome and mucus layer barriers, trophozoites adhere to the intestinal epithelial microvilli using the ventral adhesive disc.[2,3,22,30]

Infections with *G. duodenalis* in humans and animals can be asymptomatic or result in acute illness or chronic disease associated with malabsorption. Symptoms in humans with acute illness include abdominal pain, watery diarrhea, vomiting, and weight loss.[2,3,10,30] Pathologic findings are variable but can include blunting of intestinal brush border microvilli, villous flattening, hyperplasia of the crypts of Lieberkühn, and intraepithelial lymphocyte accumulation. Trophozoites are often visible within the crypts and may extend to the villi. There is no intracellular form, and mucosal and submucosal invasion are not typical of infection.[2]

Giardiasis in birds. As stated earlier, *Giardia* has been widely reported in wild and managed populations of birds worldwide, including domestic birds and species kept as pets such as psittacine birds. Most reports of *G. duodenalis*, *G. psittaci*, and *G. ardeae* are point prevalence studies of shedding in apparently asymptomatic wild and managed bird populations, particularly in aquatic birds.[33] However, there are also reports of morbidity and mortality associated with *Giardia* in birds, such as in managed breeding populations of straw-necked ibis infected with *G. ardeae*.[7,28]

Giardiasis in psittacine birds. Giardiasis has been reported in psittacine birds. Several wild-caught sulfur-crested cockatoos from Victoria, Australia, succumbed to infection with *G. duodenalis* despite treatment with ronidazole in the drinking water.[20] Giardiasis caused by *G. psittaci* was reported in a pet 4-year-old male gray-hooded parakeet *(Psilopsiagon aymara)* that died despite treatment with ronidazole orally and in the drinking water.[25]

Numerous sources state that *Giardia* is common in budgerigars and cockatiels.[6,34–38] Although there are many confirmed reports of *G. psittaci* and giardiasis in budgerigars (see section on Giardiasis in Budgerigars), only one published report documented *Giardia* shedding in cockatiels by electron microscopy or molecular sequencing.[12] In fact, other *Giardia* prevalence studies that included cockatiels did not identify *Giardia* in this species.[11,19,32,38,39] It has been proposed that a flagellated protozoan commonly observed in fecal samples from cockatiels is not *Giardia*,[40,41] but rather possibly *Spironucleus*.[41] While cockatiels appear susceptible to infection with *Giardia*,[12] *Giardia* and giardiasis may not be as common in cockatiels as widely believed.

Clinical signs of giardiasis in birds include lethargy, inappetence, weight loss, ruffled feathers, regurgitation, diarrhea, and death, especially in young birds.[6,20,23,25,42,43] Many anecdotal sources state that *Giardia* infection may be associated with rough plumage and self-harm to feathers and skin in pet birds,[6,8,10,34,36–38,43–46] particularly in cockatiels, perhaps associated with a micronutrient malabsorption syndrome. However, evidence is lacking for a definitive causal association.

At necropsy there may be few visible gross changes in birds infected with *Giardia*, although thickening of the gastric intermediate zone and hyperemia and distension of the small intestine have been reported.[12,25,35,42] Microscopic changes include intestinal villous atrophy and mononuclear inflammatory cell infiltration into the lamina propria.[21,35,39,47] *Giardia* trophozoites can be found within the intestinal crypts, often in large numbers, and may extend the entire length of the villi.[12,21,35,39,42] Secondary bacterial and yeast enteritis may be present.[12,47]

Giardiasis in budgerigars. The first report of *Giardia* in the budgerigar was published in 1962 and described postmortem findings in a 2-year-old budgerigar with poor body condition and chronic diarrhea.[42] Since then, a number of other reports of *Giardia* in budgerigars have been published.[9,13,21,23,25,31,38,39,47–55] Prevalence rates of fecal *Giardia* shedding in asymptomatic adult budgerigars ranged from 36.5%[55] to 90.3% in several studies.[31,52,53] Mortality rates of 20% to 50% in affected commercial budgerigar flocks have been described, particularly during hot summer months.[49,50]

While budgerigars are often inapparently infected,[12,23,25,37,47–49] acute and chronic forms of giardiasis have been described in this species.[23,25,47,49] The acute form is more common in nestling, juvenile, and young adult birds. Clinical signs in budgerigars are similar to those in other avian species and include lethargy, ruffled feathers, dehydration, regurgitation, inappetence or polyphagia, weight loss ("going light"), emaciation, diarrhea, and death.[6,7,10,13,25,47,49,50,53] Poor growth and high mortality can be seen in nestlings.[6,12,53] Inappetence, weight loss, lethargy, and diarrhea can also be seen with chronic infections in budgerigars.[47] Comorbidities, including concurrent infection with *Macrorhabdus ornithogaster* or circovirus, can exacerbate the disease and worsen the prognosis.[12,25,37]

Diagnosis. *Giardia* is most commonly identified through the direct observation of trophozoites or cysts in fecal samples (Table 23.2; Figure 23.2A).[6,12,19,30,37,42,45,47] Shedding can be intermittent, and therefore repeat sampling of feces over several days is recommended when possible.[12,37,44,45,47,48] Trophozoites can also be identified in small intestinal contents sampled surgically (e.g., duodenal aspirates) or at necropsy.[6,8,22,35,42] Aspirates or scrapings of small intestinal mucosa should be collected during the gross necropsy since trophozoites are often washed away after tissue processing.[8,35] Microscopic inspection of feces or intestinal contents should be performed as soon as possible, ideally within 10 minutes of collection,

TABLE 23.2

Diagnostic Methods for the Detection of *Giardia* in Birds in Feces or Intestinal Contents

Test	Sample Type	Trophozoite Detection	Cyst Detection
Wet mount (e.g., saline, LRS), no stain	Very fresh (<10 minutes after leaving host)	Yes, motile	Yes, but easily mistaken for yeasts
Wet mount (e.g., saline, LRS) with iodine stain (e.g., Lugol's)	Fresh	Yes, nonmotile	Yes
Flotation concentration (e.g., saturated zinc sulfate, sucrose, sodium nitrate)	Fresh	No	Yes
Biologic stains (e.g., carbol fuchsin, trichrome, modified Wright-Giemsa)	Dried or fixed (e.g., 10% neutral buffered formalin)	Yes	Yes
Antigen detection techniques and molecular diagnostics (e.g., ELISA, IFA, DFA, ICT, PCR)	Fresh, dried, or fixed	Yes (antigenic or genetic material)	

DFA, Direct fluorescent antibody; *ELISA,* enzyme-linked immunosorbent assay; *ICT,* immunochromatographic dipstick test; *IFA,* immunofluorescence assay; *LRS,* lactated Ringer's solution; *PCR,* polymerase chain reaction.

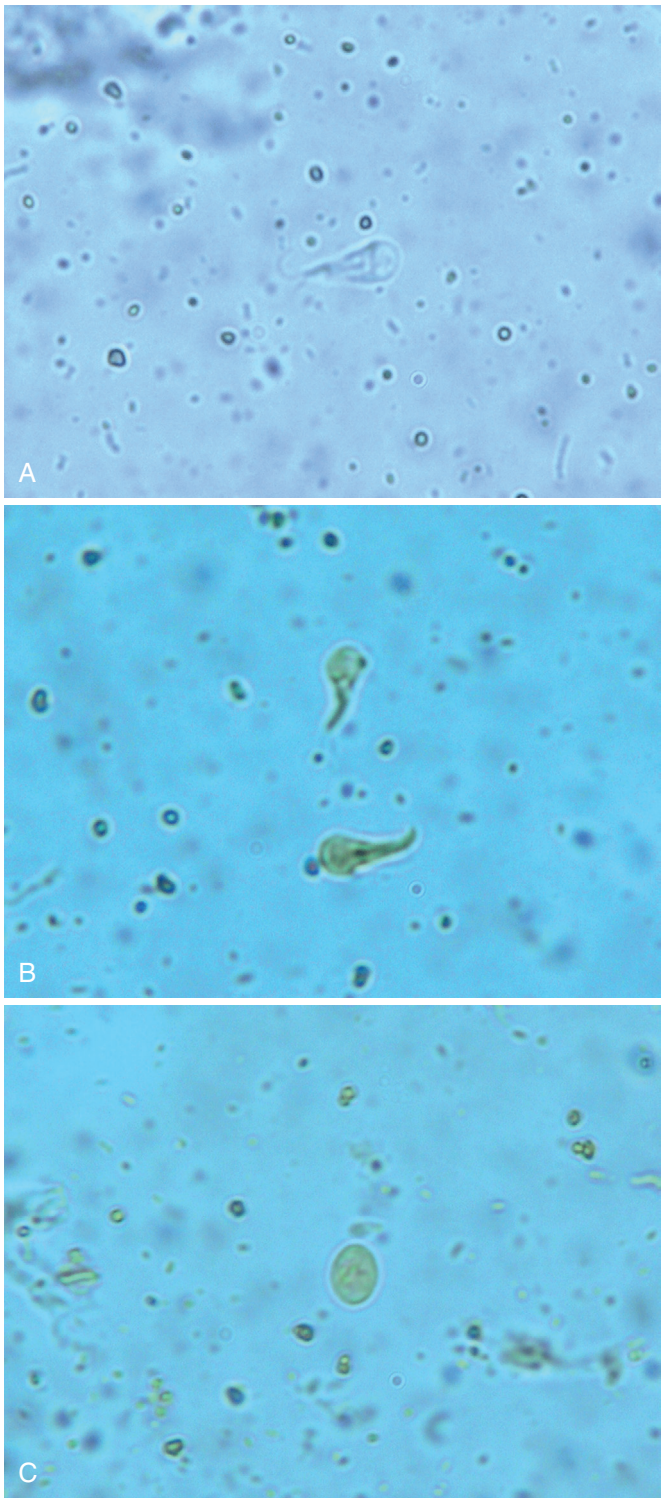

FIGURE 23.2 Saline wet mount appearance of *Giardia psittaci* in feces from an asymptomatic adult budgerigar (*Melopsittacus undulatus*) (magnification ×400). *G. psittaci* trophozoites without stain (A) and with the addition of a small amount of Lugol's iodine (B). *G. psittaci* cyst with the addition of a small amount of Lugol's iodine to the saline solution (C). (Courtesy Lauren Powers.)

BOX 23.1 PRACTICAL TIP

Preparation of the wet mount for direct microscopic observation of *Giardia* and *Spironucleus* trophozoites and cysts.

- Collect fecal samples over a period of several days to increase the likelihood of identifying cysts.
- To evaluate for motile trophozoites, examine samples (feces, intestinal contents) within 10 minutes of leaving the host.
- Use a balanced electrolyte solution such as normal physiologic saline or lactated Ringer's solution instead of tap water.
- Mix the sample thoroughly into solution—no chunks!
- The wet mount should be thin enough so that paper print can be read through it.
- Lower the microscope condenser to its lowest position in order to enhance contrast.
- If no motile trophozoites are observed, consider adding a small amount of Lugol's iodine to aid in the detection of trophozoites and cysts.

since trophozoites cease movement soon after leaving the host (Box 23.1).[6,8,45,56] A balanced electrolyte solution such as normal physiologic saline or lactated Ringer's solution should be used instead of tap water for preparing the wet mount.[6,45] The sample should be mixed well with the solution and should be thin enough so that paper print can be read through the sample. The microscope condenser should be dropped to its lowest level to enhance contrast. Viable *Giardia* trophozoites swim in a "falling leaf" pattern.[6,8,45] A small amount of iodine stain such as Lugol's iodine or D'Antoni's aqueous iodine solution can be added to the wet mount to aid in the detection of cysts and nonmotile trophozoites (Figure 23.2B,C).[12,44] Cysts can also be observed after concentration with saturated zinc sulfate, sucrose, or sodium nitrate solutions.[6,8,30] However, the delicate trophozoites will be destroyed if placed in saturated salt or sugar solutions.[6,8,44,45] Biologic stains such as carbol fuchsin (found in some acid-fast staining kits),[57] trichrome, and modified Wright-Giemsa can be used to aid in the detection of trophozoites and cysts in dried or fixed samples (Table 23.2).[6,8,30,47] *Giardia* cysts are similar in size and shape to yeasts and can be misidentified by light microscopy.[8,30]

Antigen detection techniques including enzyme-linked immunosorbent assay (ELISA),[58] immunofluorescence assay (IFA),[58] direct fluorescent antibody (DFA), and immunochromatographic dipstick tests (ICT) have been developed for the detection of *Giardia* in humans and domestic animals (Table 23.2).[30]

In one report, two commercially available antigen capture reagent tests (Color-Vue Giardia Kit [ELISA test, since discontinued; Seradyn Inc., Indianapolis, IN, USA] and Merifluor Cryptosporidium/Giardia [DFA test; Meridian Diagnostics, Cincinnati, OH, USA]) correctly identified birds that were positive for *Giardia* by fecal microscopic observation.[58] A commercially available ICT for the detection of *G. duodenalis* in veterinary patients including birds (Primagnost Giardia H+K; Albrecht GmbH, Aulendorf, Germany) and a commercially available ELISA (ProSpecT Giardia Microplate Assay; ThermoFisher Scientific, Lenexa, KS, USA) were both positive in two budgerigars and a gray-hooded parakeet with confirmed *Giardia* infection in a separate report.[25] PCR assays and molecular sequencing techniques can also be used for diagnostic and research purposes.[25,30]

Treatment, prevention, and control. Giardiasis in humans is generally treated with nitroimidazole drugs including metronidazole and tinidazole, acridine derivatives such as quinacrine, or monoamine oxidase inhibitors such as furazolidone.[30] In veterinary medicine, the nitroimidazoles metronidazole and dimetridazole are commonly used and are the most widely reported drugs used in birds (Table 23.3; see also Chapter 9).[8,20,51,52,56] Metronidazole can be effective when administered orally to birds.[8,37] Although drinking water dosages have been published for metronidazole, the drug has poor palatability and birds may be reluctant to drink medicated water.[8,37,43,47,51,52] Dosing of metronidazole in the drinking water may not be effective or safe in birds. Dimetridazole has been reported to be used in birds by gavage or in the drinking water. Dimetridazole has been shown to be effective in budgerigars when delivered in the drinking water,[49,50,52] although reportedly this drug may be toxic in finches and other birds.[42,46] Dimetridazole dosages of 0.1% in the drinking water were well-tolerated in adult cockatiels but resulted in high morbidity in nestling chicks in one report.[46] At 0.5% drinking water, all age groups of cockatiel nestlings showed severe morbidity. The authors of this report advised that dimetridazole not be used in the drinking water for cockatiels during the breeding season.[46] Effective treatment with ronidazole has been reported in budgerigars when administered orally once to twice daily or in the drinking water.[26,37] Tinidazole delivered in the drinking water was effective in budgerigars and lineolated parakeets in a separate report.[23] Drinking water dosages for any medication may need to be reduced during hotter summer months due to the potential for increased water intake.[49] Of the nitroimidazole drugs described here, only metronidazole is approved for use in the United States by the Food and Drug Administration (FDA).

In dogs, benzimidazole drugs such as oxfendazole, albendazole, and fenbendazole have been shown to eliminate cyst excretion and improve clinical signs.[8,56] Fenbendazole may be an effective treatment in birds.[8] However, benzimidazole drugs may potentially cause life-threatening radiomimetic bone marrow suppression,[30] which is uncommon but has been reported in birds.[35] Other less-widely studied and utilized treatments for avian giardiasis include nitazoxanide (a thiazolide), azithromycin (a macrolide), and paromomycin (an aminoglycoside).[23,30] Paromomycin was effectively used to treat budgerigars and lineolated parakeets with giardiasis in one report.[23] Relapses and reinfections are common with *Giardia*, suggesting that acquired immunity may be short-lived.[6,12,30,47] Published treatment durations may be inadequate to prevent reinfection from contaminated environments.[30]

Prevention of *Giardia* infection in birds is best accomplished through sound husbandry, hygiene, and biosecurity practices.[12,45,47] Physiologic stressors such as overcrowding, competition for food and water resources, and temperature extremes should be avoided.[6,43] Screening of at-risk birds prior to entry into breeding collections should be considered.[12,47] Food and water containers should be placed in elevated positions in the enclosures and cleaned regularly.[47] Trophozoites are sensitive to most disinfectants, but cysts can remain infectious for many months in water and soil.[12] Cysts may survive in chlorinated water, although quaternary ammonium compounds may be effective disinfectants.[30,45]

Hexamita *and* Spironucleus

The Hexamitinae diplomonads *Hexamita* and *Spironucleus* have very similar morphologic characteristics by light microscopy. Older reports that lacked ultrastructural details by electron microscopy placed some *Spironucleus* species that affect birds and fish into the genus *Hexamita*, or even *Octomitus*.[1,5,63,64] Ultrastructurally, *Hexamita* and *Spironucleus* both possess cytostomal canals (flagellar pockets) that pass through the whole cell and open posteriorly, whereas *Octomitus* (a Giardiinae diplomonad) lacks cytostomal canals.[1,2,64] *Hexamita* and *Spironucleus* differ from each other in the shape of their nuclei and in the position of their basal bodies (Figure 23.1).[1] *Hexamita* species have round nuclei, whereas the nuclei of *Spironucleus* species are spiral-shaped and subapical in location.[2,64] Despite the differences in nuclear structure and other distinctive features, molecular sequencing has placed *Spironucleus* phylogenies into three different clades that differ as much from each other as they do from *Hexamita* species.[2,5] The third clade of *Spironucleus* consists of *S. muris* from the mouse and *S. meleagridis* from turkeys *(Meleagris gallopavo)*.[65] A cyst form is present for many, but not all, *Spironucleus* species.[2,64]

Spironucleus species are primarily intestinal organisms and are parasitic in a wide range of vertebrates from fish to birds and mammals including primates.[59] *Spironucleus* species are significant pathogens to economically important Atlantic salmon *(Salmo salar)*, rainbow trout *(Oncorhynchus mykiss)*, cichlids, and other fish.[2] To the author's knowledge, the only Hexamitinae diplomonads known to infect birds are *S. meleagridis* and *S. columbae* and none has documented zoonotic potential.

Spironucleus meleagridis *S. meleagridis* was initially classified as *Hexamita meleagridis* but was later reassigned to the genus *Spironucleus* based on ultrastructural morphologic findings as determined by scanning and transmission electron microscopy.[60,64] Trophozoites range from 5.5 to 9.0 μm in length and 1.0 to 6.0 μm in width, and cysts range from 4.5 to 7.0 μm in length and 3.5 to 5.5 μm in width.[64]

S. meleagridis is the cause of avian infectious catarrhal enteritis, or avian spironucleosis, in turkeys and other birds.[64–68] The terms "hexamitiasis" and "hexamitosis" are still occasionally used to describe this disease.[64,65] Spironucleosis has had considerable economic impact on the commercial turkey industry in the United States since the late 1930s, although the incidence of the disease in turkeys has declined dramatically in recent decades due to changes in commercial production management.[42,65,66,67,69] However, spironucleosis remains a disease of considerable economic importance in farm-reared game birds such as chukar partridges *(Alectoris chukar)*,[66] red-legged partridges *(Alectoris rufa)*,[70,71] ring-necked pheasants *(Phasianus colchicus)*,[64,70,71] quail (*Coturnix* spp.), and guinea fowl *(Numida meleagris)*. Mortality rates of up to 80% have been observed in some chukar partridge broods.[66] *Spironucleus* has also been identified in non-galliform avian species including ducks, sandhill cranes *(Grus canadensis pratensis)*,[72] demoiselle cranes *(Anthropoides virgo)*,[73] ostriches (*Struthio camelus*),[74] rheas *(Rhea americana)*, and a Gouldian finch *(Erythrura gouldiae)*,[39] among others.[6,61]

Both cysts and trophozoites may be capable of infecting the host through direct ingestion or ingestion of contaminated

TABLE 23.3

Some Published Drug Dosages for the Treatment of Giardiasis and Spironucleosis in Psittacine Birds and Pigeons

Drug and Dosage	Species	Protozoan	Efficacy and Safety	References
METRONIDAZOLE				
25–30 mg/kg PO q24h × 10 days	Various	*Giardia*	Some birds may require 25 mg/kg PO q12h up to 30 days	8
25 mg/kg PO q12h × 5 days; 50 mg/kg PO q24h × 5 days	Various	*Giardia*		37
50 mg/L DW × 5 days	Budgerigar (*Melopsittacus undulatus*)	*Giardia*	Not considered effective in a group of four birds	52
200 mg/L DW × 5 days	Budgerigar	*Giardia*	Not considered effective in a group of four birds	52
800 mg/L DW × 5 days	Budgerigar	*Giardia*	No further shedding at day 5	47
1000 mg/L DW × 7 days	Budgerigar	*Giardia*	3/6 birds died and all lost weight, no trophozoites found on necropsy of surviving birds	51
15–50 mg/kg IM single dose	Various	*Giardia*	Reportedly safe in budgerigars, cockatiels, and lovebirds but relapses occurred	56
1.5 mg per bird q8h × 5–7 days	Australian king parrot (*Alisterus scapularis*)	*Spironucleus*	Followed by 250 mg/L DW × 10–21 days. Considered effective	59
DIMETRIDAZOLE				
50 mg/kg PO, three doses total, q12h	Budgerigar	*Giardia*	Virtually cleared all birds of infection. Administered via gavage	52
200 mg/L DW × 5 days	Budgerigar	*Giardia*	Partially effective in a group of four birds	52
200 mg/L DW × 5 days	Budgerigar	*Giardia*	Treatment considered effective. Dosage should be reduced to 100 mg/L on hot summer days. Treatment can be repeated	13, 49
2000 mg/L DW × 10 days	Budgerigar	*Giardia*	Cleared shedding and no further mortality	53
4000 mg/L DW × 10 days	Budgerigar	*Giardia*	1/6 birds died and all lost weight, no trophozoites found on necropsy of surviving birds	51
3000 mg/L DW × 5 days	Australian king parrot	*Spironucleus*	Followed by 5 mL of 3000 mg/L via crop lavage. Most birds failed to respond to treatment	60
RONIDAZOLE				
6–10 mg/kg PO q24h × 6–10 days	Various	*Giardia*		36
100–200 mg/L DW × 7 days	Various	*Giardia*		36
2000 mg/L DW × 10 days	Budgerigar, gray-hooded parakeet (*Psilopsiagon aymara*)	*Giardia*	Effective in two budgerigars but an adult gray-hooded parakeet died on day 3 of treatment	25
4000 mg/L DW	Sulfur-crested cockatoo (*Cacatua galerita*)	*Giardia*	Not considered effective, treated birds died	20
1111 mg/L DW	Pigeon, (*Columba livia*), cockatiel (*Nymphicus hollandicus*)	*Spironucleus*	Considered effective following a single oral dose of carnidazole	61
DW for 7–10 days	Pigeon	*Spironucleus*	Treatment considered effective. Drinking water dosage not reported	62
TINIDAZOLE				
800 mg/L DW × 7–14 days	Budgerigar, lineolated parakeet (*Bolborhynchus lineola*)	*Giardia*	Treatment considered effective	23
CARNIDAZOLE				
10 mg single PO dose	Pigeon, cockatiel	*Spironucleus*	Considered effective followed by ronidazole in drinking water	61
PAROMOMYCIN				
100 mg/kg PO q12h × 7 days	Budgerigar, lineolated parakeet	*Giardia*	Treatment considered effective	23
FURALTADONE				
1778 mg/L DW	Pigeon	*Spironucleus*	Considered effective following single oral dose of metronidazole 50 mg	61

DW, Drinking water.

drinking water or food sources.[45,64] Cysts contained within fecal material were capable of infecting turkey poults for up to 6 weeks after storage at room temperature in one report.[60] Cysts in the mucus in the cloaca of carrier hens could potentially adhere to eggshell surfaces as eggs are laid and potentially result in infection of newly hatched chicks.[64]

Although *Spironucleus* can be found in apparently healthy birds,[71] the protozoan can also be associated with significant clinical disease, particularly in young birds.[6,59,75] In turkeys, the incubation period is short at 4 to 7 days.[8] Mortality begins to occur from 1 to 21 days after the onset of clinical signs in an affected flock.[8] Clinical signs of avian spironucleosis in galliform birds include lethargy, poor feathering, reduced appetite, weight loss, diarrhea, and death.[8,65,67,71,76] Diarrhea is often watery and yellow in affected turkeys and pheasants.[65,76] Concurrent infection with other intestinal pathogens may increase the pathogenicity of *S. meleagridis*.[32,73,68]

Gross necropsy findings may include small intestinal distension with watery luminal contents.[64] Microscopically, large numbers of trophozoites can be observed within the lumen of the duodenum and jejunum and within the intestinal crypts (Figure 23.3).[59,65] Cysts are almost exclusively seen within the luminal mucus and are rarely observed within the intestinal crypts. Varying degrees of intestinal congestion, goblet cell hyperplasia, mononuclear inflammatory cell infiltration within the lamina propria, and necrosis are observed.[39,59,65]

Spironucleosis in psittacine birds Spironucleosis has been documented in several psittacine species including juvenile wild Australian king parrots *(Alisterus scapularis)*,[59] an emaciated splendid grass (scarlet-chested) parakeet *(Neophema splendida)*,[61] an emaciated wild sulfur-crested cockatoo,[75] and cockatiels.[41,54,61,77] The organism was identified as *S. meleagridis* in several of these reports by molecular analysis.[77] Partial genomic sequencing of a flagellated protozoan isolated from cockatiel feces demonstrated a 98% molecular identity with *S. meleagridis* isolated from turkeys in one report.[77] Prevalence of infection in asymptomatic birds was found to be 70% and 86% from two unrelated cockatiel breeding facilities using a diagnostic PCR assay on fecal samples in this same study.[77]

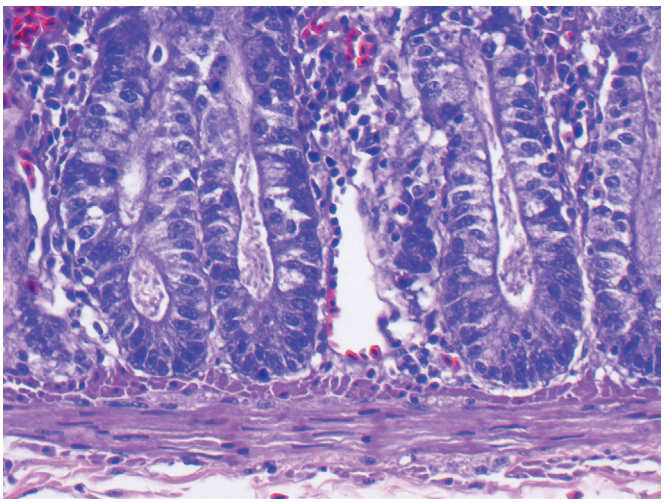

FIGURE 23.3 *Spironucleus meleagridis* trophozoites visible within hyperplastic intestinal crypts in a cockatiel *(Nymphicus hollandicus)*. (Courtesy Michael Garner.)

Clinical signs of spironucleosis in psittacine birds are similar to those described in galliform birds, including listlessness, anorexia, weight loss, emaciation, diarrhea (Figure 23.4), and death.[59,61] In one report, five 3- to 4-month-old cockatiels in one aviary and juvenile birds from four separate aviaries with spironucleosis were described as having lethargy, changes in the appearance of feces, and emaciation.[61] In one retrospective report, 8/83 (9.6%) juvenile cockatiels submitted for necropsy demonstrated a flagellated protozoal enteropathy consistent with spironucleosis.[54] Necropsy findings in psittacine birds are similar to those for galliform birds.

Spironucleus columbae In 1923, a report of catarrhal enteritis in young pigeons *(Columba livia)* in Germany associated with a flagellated protozoal parasite was published and the protozoan was classified as *Octomitus columbae* nov. spec.[64] Trophozoites measured 5 to 9 μm in length and 2.5 to 3.5 μm in width, similar in size to *S. meleagridis*.[64] Since then, the protozoan has been reclassified as *S. columbae* and reported in other pigeon collections.[44,78–80] Clinical signs in pigeons include reduced or selective appetite, slow crop emptying, weight loss, emaciation, reduced flight performance, and death.[61,79] In one report, clinical signs were highest in birds 7 to 10 weeks of age and in loft imports.[61] The morbidity rate was 15% to 25%, and the mortality rate was about 5% in this report.[61] Immunosuppression caused by circovirus co-infection may affect susceptibility to disease.[78] Postmortem findings included a characteristic dilatation of the duodenum.[66] Attempts at infecting turkey poults with *S. columbae* were unsuccessful in one report.[80] However, to the author's knowledge, no ultrastructural imaging by electron microscopy or molecular sequencing has been performed to date for *S. columbae* to confirm that it should continue to be taxonomically classified as a separate species from *S. meleagridis*.

Diagnosis Techniques for the detection of *Spironucleus* are similar to those for *Giardia*, although commercial antigen detection techniques are not currently available. Motile trophozoites and cysts can be observed by wet mount observation of fresh feces or intestinal contents.[8,44,45,59,65] *Spironucleus* trophozoites can easily be confused with those of *Giardia* by light microscopy.[42] However, viable *Giardia* trophozoites move in a "falling leaf" pattern, whereas viable *Spironucleus* trophozoites move in a rapid, linear, darting motion.[44,45,59,65] As with *Giardia*, *Spironucleus* trophozoites are motile for only a very short time after exiting the host, and so diagnostic samples should be evaluated soon after collection.[44,59] *Spironucleus* cysts are similar in appearance to those of *Giardia* but somewhat smaller.[71] Biologic stains described for detecting *Giardia* such as modified Wright-Giemsa can also be used to detect *Spironucleus* trophozoites and cysts in dried or fixed samples. As with *Giardia*, PCR can be used for diagnostic and research purposes. In one report, a diagnostic PCR assay was developed and used to evaluate the fecal shedding of *S. meleagridis* in cockatiels.[77]

FIGURE 23.4 Chronic diarrhea in an adult cockatiel *(Nymphicus hollandicus)* with spironucleosis. (Courtesy Lauren Powers.)

Treatment, prevention, and control Reported treatment options for the treatment of avian spironucleosis are similar to those reported for giardiasis.[43] Nitroimidazole drugs including metronidazole, dimetridazole, ronidazole, and carnidazole have been used to treat spironucleosis in turkeys, farm-reared game birds, pigeons, and psittacine birds (see also Chapter 9).[45,64,59,61,79] However, treatment failures and disease recurrences are common, and severely emaciated birds may not recover.[44,45,59] In one report, shedding of *Spironucleus* was reduced in Australian king parrots after treatment with dimetridazole, but only two mildly affected birds from one aviary clinically recovered.[59] Reports suggest that pheasants with spironucleosis respond better to a combination of dimetridazole and oxytetracycline than to dimetridazole alone.[76] However, the addition of neomycin and oxytetracycline to the drinking water was not considered effective for chukar partridges.[66] Treatment with a single oral dose of carnidazole followed by ronidazole in the drinking water for 7 days was considered successful in pigeons and cockatiels in another report.[61] Furaltadone in the drinking water following a single oral dose of metronidazole was considered successful in pigeons.[61] Effective control and prevention measures have not yet been standardized for *S. meleagridis* in farm-reared game birds, psittacine birds, and pigeons.[8,64] In the absence of evidence-based information, control measures recommended for the management of *Giardia* in birds appear to be reasonable options for the control and prevention of *Spironucleus*.

CHAPTER 24

Histomoniasis

Yuko Sato

INTRODUCTION

Histomoniasis (blackhead disease) is a protozoal disease that affects mainly the liver and ceca of turkeys *(Meleagris gallopavo)* and other gallinaceous birds, including chickens *(Gallus gallus domesticus)*, peafowl (*Pavo* spp.), and quail (*Coturnix* spp.). This disease causes high mortality in turkeys and game birds. In chickens, mortality usually is 10% to 20%, although the morbidity is very high, as they could serve as asymptomatic reservoirs of disease.[1] Currently, there are no efficacious drugs for treatment or prevention that are approved for use in poultry in the United States, Europe, and many other countries. There are no vaccines for this disease, and management practices are key in reducing outbreaks. Severe outbreaks may potentially lead to loss of entire flocks or euthanasia to relieve bird suffering.[2]

ETIOLOGY

The causative agent of blackhead disease is the protozoal parasite *Histomonas meleagridis*. *H. meleagridis* is a member of the family Dientamoebidae, order Trichomonadida.[3] It is a pleomorphic, single flagellated protozoa in the cecal lumen, approximately 3 to 16 μm in diameter, and can also exist in an amoeboid form (tissue form), 6 to 20 μm in size, in the liver and other tissues during infection. Recently, a cyst-like stage was discovered, perhaps explaining the resistance of the organism in the environment.[2] Histomoniasis was first described in turkeys in Rhode Island by Cushman in 1893 and has since been reported across the country and soon in many other countries.[4] The organism itself is not resistant to environmental conditions, and variables such as temperature extremes, drying, and lack of oxygen will destroy the organism outside of its host.[2] However, control of the intermediate host is key to controlling the disease. Bacterial flora in the gut is shown to be important in development of the disease, although little is affected by the course of the disease with the administration of antibiotics.[5]

There are two known methods for transmission: (1) ingestion of embryonated ova or adult worms of the intermediate host, *Heterakis gallinarum*, also known as cecal worms, containing the histomonads, and (2) direct transmission of histomonads through "cloacal drinking."[1] Although the most significant disease in turkeys, blackhead has been reported to infect all gallinaceous birds and others such as ostriches *(Struthio camelus)*, rheas *(Rhea americana)*, and a variety of game birds, including pheasants *(Phaesianus colchicus)*, quail, grouse (*Tetraonini* spp.), ducks (*Anas* spp.), guinea fowl (*Numida* spp.), and chukar partridges *(Alectoris chukar)*. Blackhead is sometimes reported from zoo birds such as peacocks.[6] Species such as ducks and ostriches show a high resistance to disease and may become asymptomatic carriers.[3]

EPIDEMIOLOGY AND PATHOGENESIS

Histomoniasis is typically a seasonal disease that occurs mostly in late spring and summer (e.g., April through June in the United States). The intermediate host, the cecal worm, is the most common vector of the histomonads, and according to a study by Hauck and Hafez, the coinfection rate is 50.8% and could be up to 60% to 91% in chickens.[7] The hosts of *H. gallinarum*, the cecal worm, include birds that are maintained in soil or litter, which include the chicken, turkey, duck, goose, grouse, guinea fowl, partridge, pheasant, and quail. Birds become infected with blackhead by ingestion of the embryonated eggs of *H. gallinarum*, and chickens are the best host and the best reservoir for infection. Thus biosecurity is a critical control method when it comes to housing turkeys and other susceptible species from chickens. Since worm eggs may remain infective up to 3 years in soil and remain positive for *H. meleagridis* after 150 weeks, care must be taken when overlapping housing environments with chickens for the susceptible population. Other *Heterakis* worms, such as *Heterakis bonasae* found in bobwhite quail *(Colinus virginianus)* and ruffed grouse *(Bonasa umbellus)*, do not have the ability to act as a vector for *H.* gallinarum.[8] However, further investigations on other vectors including *Heterakis isolonche*, which infects ducks and other gallinaceous birds, as well as *Heterakis dispar*, which infects ducks and geese, have not been performed.[7]

Additional studies show that earthworms can harbor cecal worm larvae for long periods of time and transmit blackhead disease. There have been reports of outbreaks of histomoniasis following heavy rains in commercial turkeys, which could be due to a surge in earthworm population indoors, which are subsequently ingested by turkeys. Other vectors such as houseflies, grasshoppers, and sow bugs have been reported to cause low rates of mechanical transmission of cecal worms.[2]

Direct transmission by "cloacal drinking" has now been adopted as the main method of inoculation and infection due to its high reproducibility and reliability.[7] The histomonads

are taken inside the cloaca by retrograde movement caused by reverse peristalsis following muscular contractions of the cloacal lip during normal cecal function. This method is important in explaining the rapid and explosive spread of blackhead throughout turkey flocks in the absence of intermediate hosts and vectors. By the same token, contaminated litter or paper has been shown to spread blackhead within a floor pen.[2] In contrast to its major contribution to transmission in turkeys, studies have shown that infection does not spread by direct contact in chickens. Possible theories include the difference in behavior and the water composition in chicken droppings versus turkey droppings.[9]

The relationship of histomonads with bacteria and other organisms to create pathology has been debated. Some studies show that histomonads are avirulent in gnotobiotic poults and only fully virulent when certain bacteria such as *Escherichia coli*, *Clostridium perfringens*, and *Bacillus subtilis* are present.[10] However, most lesions from turkeys infected by *H. meleagridis* are sterile, and treatment with therapeutic levels of antibiotics has had little to no effect on disease lesions in chickens.[11] Although cecal coccidiosis in chickens can potentially affect the severity of gross lesions, there seems to be no significant effect of concurrent infection on pathogenicity or mortality in chickens. In contrast, *Eimeria adenoides* infection in turkeys appears to interfere with blackhead infection and cause lessened severity of cecal lesions.[5]

Pathogenesis begins when histomonads penetrate through the cecal wall, multiply, and enter the bloodstream to eventually parasitize the liver. Clinical signs can be visible in birds from 7 to 12 days and death may occur 11 to 14 days postinfection. The incubation period varies with the size of the infective dose and the route of infection. Indirect infections from *H. gallinarum* eggs require longer than those from direct transmission. Experimentally, lesions in turkeys develop about 3 days earlier with cloacal inoculation compared with infection via *H. gallinarum* eggs.[2,9]

CLINICAL SIGNS

Clinical signs in birds depend greatly between species of gallinaceous birds, ranging from high mortality and severe hepatitis/typhlitis in turkeys, while in chickens, the clinical signs are milder and pathology is mostly restricted to ceca.[1]

Clinical signs in turkeys include:

- Anorexia and emaciation
- Bowing of the head and wings
- Depression and drowsiness
- Yellowish green (sulfur-colored) droppings
- Huddling together
- Ruffled feathers
- Death

By 6 to 12 days postinfection, turkeys will start to become emaciated.[3] The yellow-green droppings are observed because of liver necrosis and the excreta contains bile pigments. Birds exhibiting this clinical sign often succumb to death. Clinical signs in chickens can range anywhere from asymptomatic, mild depression, and loss in production to mortality. Mortality may be low (10%–20%), but morbidity is high.[9] Disease is more commonly seen in young pullets or layers and broiler breeders in early stages of egg production.[2] Droppings may be bloody in chickens and resemble cecal coccidiosis.[1]

GROSS AND HISTOPATHOLOGIC LESIONS

Gross lesions in turkeys and game birds are characterized by severe caseous typhlitis with a fibrinonecrotic core (cecal cores) and necrotic foci in the liver (Figures 24.1 and 24.2). Characteristic bull's-eye liver lesions and cecal lesions, including caseous cores, serosal inflammation, and occasional ulceration and hemorrhage, are almost pathognomonic with matching history and signalment. The ulcerative cecal lesions may perforate and lead to secondary peritonitis. Cecal contents often have a foul-smelling odor. The liver is often enlarged with pale tan to yellow, crater-like lesions with depressed centers and well-demarcated edges.[12] Severity of the lesion depends on multiple factors but may be up to 4 cm in diameter and can involve parts or the entire organ.[3] Atypical lesions have been reported in the kidney, spleen, pancreas, and lungs of turkeys, presumably due to the histomonads being

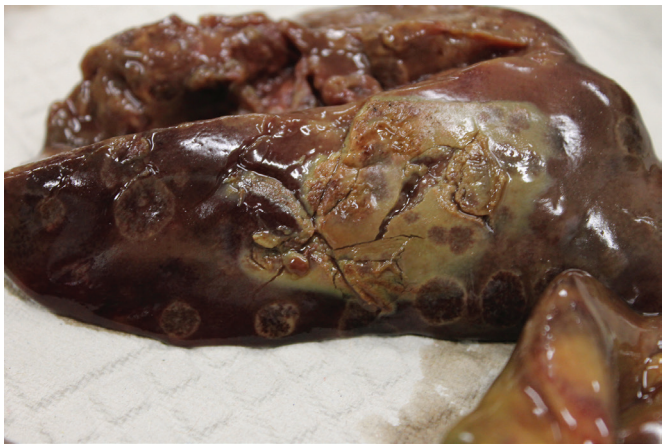

FIGURE 24.1 Gross liver lesions from a turkey *(Meleagris gallopavo)* with histomoniasis. Note the prominent, multifocal circular necrotic lesions on the liver surface.

FIGURE 24.2 Caseous typhlitis from the turkey *(Meleagris gallopavo)* pictured in Figure 24.1. Note sloughing of the mucosal epithelium into a thick caseous mass in the lumen of the ceca.

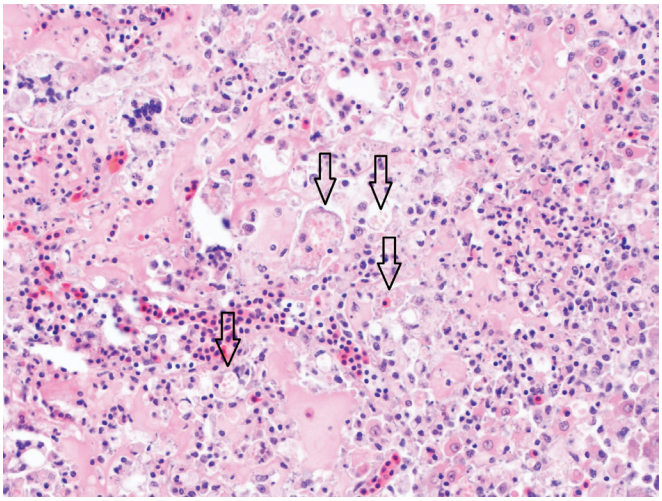

FIGURE 24.3 Histopathologic lesions from the turkey *(Meleagris gallopavo)* liver pictured in Fig. 24.1 with coagulative necrosis, hemorrhage, and inflammatory cell infiltrates. Note numerous clusters of histomonads *(arrows)* within necrotic centers and digestive chambers of histiocytes that are taking up weak eosinophilic to brown staining. (40× magnification, hematoxylin and eosin stain.)

carried from infected tissues in the ceca to the liver and other tissues via the bloodstream. Histomonads can also reach the bursa of Fabricius without entering the bloodstream.[9,13] In chickens, lesions are often restricted to the ceca and liver lesions may be present but occur less frequently.[3]

Microscopic lesions correlate with gross lesions and result in multifocal necrosis and granulomatous inflammation in the liver, ceca, and other tissues. Necrosis is typically coagulative and extensive, with loss of normal tissue architecture, hemorrhage, and presence of inflammatory cells. Invasion of the cecal wall results in hyperemia and heterophilic infiltration in early stages. By 5 to 6 days postinfection, numerous histomonads are visible as weakly brown to pale eosinophilic staining, ovoid, intracellular organisms in clusters approximately 10 μm (3–16 μm) in diameter within necrotic centers and lacunae in the mucosa (Figure 24.3).

Live organisms may be observed with phase-contrast microscopy. Organisms may be seen as clusters in the liver, ceca, and other sections stained with hematoxylin and eosin (H&E), with some aid in visualization by periodic acid-Schiff (PAS) and Grocott methenamine silver (GMS) stain to distinguish from molds and other fungal infections.[9]

DIAGNOSIS

Blackhead in turkeys and game birds is easily diagnosed by salient gross lesions with or without histopathologic lesions. Coupled with potential clinical history of sulfur-colored urofeces, having (1) dilated ceca with a necrotic core characterized by sloughed mucosa, blood, and other debris, and (2) necrotic liver lesions (target or bull's-eye lesion) is almost pathognomonic. Histomonads can also be isolated in vitro from the ceca and liver in suspected cases using Dwyer medium.

Polymerase chain reaction (PCR) methods have recently been used using primers based on published sequence of *H. meleagridis* small subunit ribosomal RNA gene using the ITS (internal transcribed spacer) region, the 18S RNA gene, and a conserved region of the β-tubulin gene.[14] Many of the other described assays comprise mostly conventional gel-based assays except for a qPCR for *H. meleagridis*. While qPCR is generally more sensitive and much less time-consuming compared to conventional PCR, this previously developed qPCR for *H. meleagridis* was found to be less sensitive.[15] Analysis by Clarke et al. revealed that the PCR specific for the ITS region had higher sensitivity using pooled ceca and liver samples versus cloacal swabs and PCR of other organs.[14]

TREATMENT, PREVENTION, AND CONTROL

Blackhead disease has been historically controlled by efficacious drugs and chemicals. The first set of compounds used were arsenicals such as tryparsamide, atoxyl, nitarsone, and roxarsone. The mode of action of these drugs involves interference with DNA repair processes and cellular energy metabolisms in the parasite. Early in vitro studies by Tyzzer in 1923 and others have repeatedly shown curative effects.[16] The benefit of this class of chemicals is the ability for it to be used for both prophylaxis and treatment, depending on the dosage. However, arsenicals have never been registered in the European Union (EU), and all arsenicals have been either banned or withdrawn by the Food and Drug Administration (FDA) in the United States since 2016.[12,17]

Nitroimidazoles such as dimetridazole and ipronidazole were used for a long time in the turkey industry for both prophylaxis and treatment (see Chapter 9). In addition, the medications were useful for increased weight gain and improved feed efficiency. However, due to concerns with food safety and illegal drug residues following the use of nitroimidazoles in food animals, the drugs were banned or voluntarily withdrawn.

The last available prophylactic product against blackhead was nitarsone (Histostat-50, Zoetis, Parsippany, NJ) but FDA approval was withdrawn in January 2016, which now creates a situation where all effective therapeutic and prophylactic medication are banned in the United States and several other countries such as Japan, Canada, Australia, and New Zealand.[10,17–19] A list of common treatment and prophylactic compounds for histomoniasis is listed in Table 24.1, some of which are historical archives and no longer available on the market.

With the loss of efficacious chemotherapeutics, three different approaches have been used to control histomoniasis: antibiotic therapy, phytogenics, and vaccine development.[18] Coupled with the movement toward antibiotic-free poultry production, phytobotanicals and alternative products have gained a lot of traction in recent years. There are numerous reports indicating in vitro efficacy to *H. meleagridis* using plant products including but not limited to plant extracts, prebiotics, probiotics, organic acids, essential oils, enzymes, and volatile fatty acids. Some of the more common compounds used in studies include oils such as cinnamaldehydes and terpene, ethanol and water extracts such as flavonoids and fatty acids, yeast products, alkaloids, and plant materials. Several challenges exist, including contradictory results, a lack of well-defined infection models in live animal trials, and the safety margins expressed in minimal lethal concentrations.

TABLE 24.1

List of Most Common Treatment, Prophylaxis, and Control Options for Blackhead Disease and Current Status of Availability

Type	Subtype	Product	Trade Name (Manufacturer)	Current Status (Organization and Year)
Treatment, prophylaxis	Nitroimidazole	Dimetridazole Ipronidazole	Emtryl (Solvay) Ipropran (Hoffman-La Roche)	Banned (FDA 1987, EU 1995–2001) Banned/withdrawn (FDA 1989)
Treatment, prophylaxis	Nitrofurans	Furazolidone Salfuride	Furox (Smith-Kline) Nifursol (Solvay)	Banned (FDA 1991) Banned EU 2002–2003)
Prophylaxis	Arsenicals	Carbarsone Nitarsone Roxarsone	Carb-O-Sep (Alpharma) Histostat-50 (Zoetis) 3-Nitro (Zoetis)	Not marketed Withdrawn (FDA 2016) Banned (EU 1999), withdrawn (FDA 2013)
Control	Phytogenics	Plant extracts	FitoTril (Ravet Sp. Zoo.)	Poland, on market
Control	Phytogenics	Essential oils	Protophyt (Phytosynthese)	France, on market
Control	Phytogenics	Combination	Natustat (Alltech)	United States, on market
Control	Phytogenics	Essential oils/acids	DeviSTAT (Devenish)	United States, on market
Control	Phytogenics	Oregano oil	Orego-Stim (Anpario)	United States, on market
Control	Antibiotics	Hygromycin	Hygromix 2.4 (Elanco)	Withdrawn (FDA 2014)
Control	Antibiotics	Paromomycin	Parofor (Huvefarma)	Italy, Bulgaria, on market
Control	Antibiotics	Tiamulin	Multiple companies	Extra-label, on market

EU, European Union; *FDA*, US Food and Drug Administration.

Modified from Clark S, Kimminau E: Critical review: future control of blackhead disease (histomoniasis) in poultry, *Avian Dis* 61(3):281–288, 2017. doi: 10.1637/11593-012517-ReviewR; Liebhart D, Ganas P, Sulejmanovic T, Hess M: Histomonosis in poultry: previous and current strategies for prevention and therapy, *Avian Pathol* 46(1):1–18, 2017. doi: 10.1080/03079457.2016.1229458.

Nonetheless, in vivo studies often failed to achieve efficacy, if not have contraindications in comparison to success in in vitro studies, further highlighting the complexity of the disease. A few products available commercially have been tested for efficacy and potential to prevent histomoniasis and subsequently published; however, none of the phytobotanicals tested so far seem to provide robust protection either in vivo or in field studies.[17,18,20]

Other alternative treatment strategies include the potential of anticoccidials as it pertains to controlling protozoal infections. However, anticoccidials had no effect in vivo, although studies in chickens with concurrent coccidiosis with *Eimeria tenella* showed reduction of liver lesions in broilers. In the same study, several other antibiotics including penicillin, chlortetracycline, tylosin, and sarafloxacin were tested with no effect on histomoniasis.[11] Prophylaxis with paromomycin, an aminoglycoside antibiotic, was reported to have effects in reducing mortality and severity of lesions in turkeys. The efficacy appears to be dose dependent and treatment must be applied prior to infection, rendering it ineffective as a treatment strategy for clinical disease. Field and experimental trials with tiamulin, a pleuromutilin class of antibiotic, have had mixed results when administered via drinking water for 5 days at 25 mg/kg body weight. Along with the risk for adverse reactions ("knockdown syndrome") due to the antibiotic potentiating the ionophores in the feed, when administered together combined with feed, it appears that its use as a blackhead treatment is limited.[9,17,18]

Vaccination is not a realistic option for prevention, as birds do not reliably become resistant to reinfection after suffering exposure. However, chickens and turkeys do produce antibodies against *H. meleagridis* antigens prepared from infected livers and ceca after natural or experimental infections.[6] In turkeys, these antibodies persist at least for up to 16 weeks postinfection. Some literature states partial immunity, which may or may not work for protection against reinfection. Until recently, vaccination against blackhead disease was, in most cases, contraindicated. Recent research showed complete protection of turkeys using vaccination with attenuated clonal culture containing clonal histomonads. In commercial settings, this may not be currently viable, although future research into vaccination using this method appears to be promising.[2,12,18]

Prophylaxis is therefore based mainly on biosecurity measures. One of the basic concepts is separation of species, especially chickens and turkeys. Hence, a free-range location used for chickens should not be used for turkeys. It is also advisable not to mix young poults and older turkeys. Deworming against intermediate hosts *(Heterakis)* is also recommended in a high worm burden environment, which could be checked with a simple fecal examination. Prevention of contamination of feed and especially water by infected droppings and proper litter management may also reduce the transmission of the parasite via cloacal drinking.[1,7,12,17]

ACKNOWLEDGMENT

The author would like to thank Dr. Mohamed El-Gazzar for his peer review of the chapter and his additions to the Epidemiology and Pathogenesis section.

CHAPTER 25

Cochlosomosis

Peter Sandmeier

CLASSIFICATION

The genus *Cochlosoma* includes intestinal flagellates in birds and mammals. *Cochlosoma anatis*, which causes disease in poultry and waterfowl, is the only species that has been described within this genus.[1] More distantly defined *Cochlosoma* spp. have been reported as pathogens in various nondomestic avian species.

Morphologically, the presence of an adhesive disk suggests a possible relationship to *Giardia*, whereas the presence of the parabasal apparatus and the axostyle suggests a relationship to trichomonads. For many years, the genus *Cochlosoma* was described as belonging to the family Cochlosomidae, distinct from the families Trichomonadidae and Hexamitidae.[2] More recently based on the 16S rRNA gene sequence the genus *Cochlosoma* has been placed in the family Trichomonadidae within the order Trichomonadida together with the genera *Trichomonas*, *Trichomonoides*, *Tetratrichomonas*, and *Pentatrichomonas*.[3]

MORPHOLOGY

C. anatis is an oval-shaped flagellate that measures between 6 to 12 μm long and 4 to 7 μm wide. It tapers from a broad, rounded anterior end to a narrow, tapered posterior end. In light microscopy it shows a characteristic ventral sucking disk, which opens to the left side.[4] In stained smears, a centrally located nucleus and an axostyle, which curves dorsally along the curvature of the body, are clearly visible.[5] *Cochlosoma* spp. are readily distinguished from other flagellates by their jerking spiral motion. The six flagella produce a whipping movement causing a jerking motion and rotation around the long axis (Figure 25.1).[6]

On transmission electron microscopy, *C. anatis* has a kinetosomal complex. The kinetosomes (or basal bodies) 1 to 4 of the anterior flagella are located below the adhesive disk. The kinetosome of the recurrent flagellum is oriented perpendicular to the kinetosomes 1 to 4. The sixth flagellum kinetosome is located outside the complex on the dorsal side of the body. The parabasal apparatus is situated anteriorly beneath the kinetosomal complex and includes the parabasal fiber as well as the parabasal body or Golgi complex. The nucleus is located at the broad anterior part of the cell and is surrounded by a double membrane with pores. *C. anatis* has no mitochondria. The cytoplasm contains various food vacuoles, cisterns of the rough endoplasmic reticulum, free ribosomes, and glycogen particles (Figure 25.2).[7] In hematoxylin and eosin-stained histological sections, little attachment of the ventral suction disk to epithelial cells is observed. Although the exact role of the ventral disk in the pathogenicity of *C. anatis* infections is unknown, its morphology suggests that it serves for the attachment to the intestinal mucosa (Figure 25.3).[6]

LIFE CYCLE

Like all trichomonads, *C. anatis* reproduces asexually by cell division (binary fission). Electron microscopy images have documented longitudinal binary fission of the trophozoite stage and pseudocyst formation. A pseudocyst is a cyst with a flexible membrane covering the trophozoites. This pseudocyst stage is presumed to be a mechanism for transmission of *C. anatis*.[8]

COCHLOSOMOSIS IN COMMERCIAL POULTRY AND WATERFOWL

Transmission

Transmission studies in turkeys (*Meleagris gallopavo*) have confirmed the fecal-oral route of transmission. In turkeys orally infected with 1×10^7 trophozoites, the development of the parasite occurred throughout the digestive tract, and they were detectable within 5 to 6 days.[9]

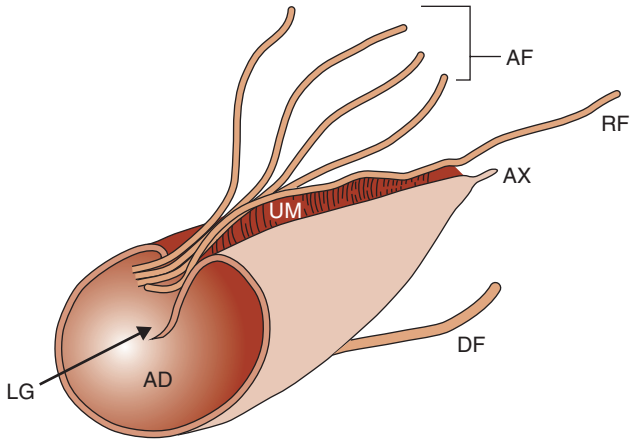

FIGURE 25.1 Schematic drawing of *Cochlosoma anatis* morphology features. *AD,* Adhesive disk; *AF,* anterior flagella; *AX,* axostyle; *DF,* dorsal flagellum; *LG,* lateral groove; *RF,* recurrent flagellum; *UM,* undulating membrane.

Note the ventral sucking disk *(S)*, the prominent grove *(G)*, anterior flagella *(arrow)*, undulating membrane *(double arrowhead)*, and recurrent flagellum *(arrowhead)*. (Magnification 6660×; bar = 5 μm.) (Reprinted with permission from Lindsay DS, Larsen CT, Zajac AM, Pierson FW: Experimental *Cochlosoma anatis* infections in poultry, *Vet Parasitol* 81(1):21–27, 1999. doi:10.1016/s0304-4017(98)00227-1.)

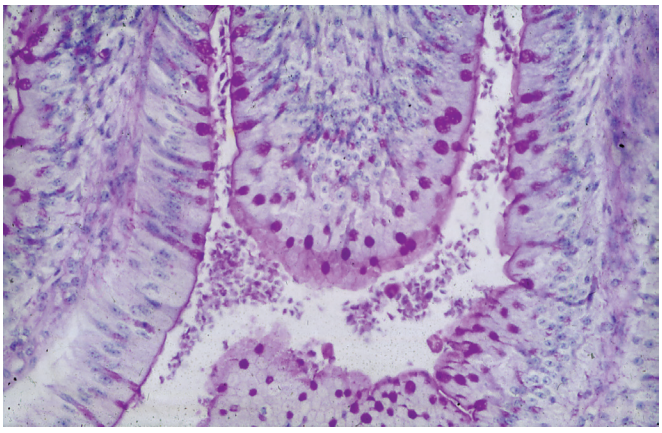

FIGURE 25.3 *Cochlosoma* spp. within the intestinal tract of a Gouldian finch (periodic acid-Schiff stain, 25×). (Reprinted with permission from Gerry M. Dorrestein.)

Trophozoites were readily destroyed by immersion in water. Trophozoites exposed to tap water or distilled water for 45 minutes at 37°C were nonmotile and appeared dead upon microscopy. None of the turkeys inoculated with trophozoites exposed to water for 5 minutes had demonstrable infections upon necropsy. This indicates that contamination of litter or feed is likely the primary means of transmission to other turkeys.[9] Only one of 12 turkeys became infected when placed on litter within 2 hours after the experimentally infected birds had been removed, whereas 7 of 8 turkeys became infected when placed in boxes together with experimentally infected turkeys that were excreting trophozoites. This suggests a lack of long-term survival of trophozoites in the environment.[9]

Cross-species transmission showed that four of six bobwhite quails (*Colinus virginianus*) and one of eight chickens (*Gallus gallus domesticus*) orally inoculated with *C. anatis* trophozoites from turkeys had demonstrable infections. Trophozoites were observed only in the ilea of quail and the ceca of positive chickens. Trophozoites collected from chickens and quails remained infectious to turkeys.[9] Over a 3-year period, 181/1996 tested houseflies collected from turkey farms were shown to be positive for *C. anatis* using a polymerase chain reaction (PCR) detection. Positive houseflies were collected inside and outside turkey facilities, proving that they potentially move the protozoan parasite to and from adjacent poultry facilities.[10]

Incubation Period

Experimentally inoculated 1-day-old Muscovy ducklings (*Cairina moschata*) were shedding *C. anatis* trophozoites by 7 days postinoculation.[11] Postmortem examination of inoculated turkeys showed that by 4 days postinoculation some turkeys were positive for *C. anatis* on intestinal scrapings and by 6 days postinoculation all were positive.[9]

Hosts

Naturally occurring *C. anatis* infections have been described in turkeys,[12,13] ducks,[11] and geese.[14] Experimental infections have been produced in chickens, turkeys, bobwhite quails, and ducks.[9,11,15]

Site of Infection

With the exception of infections in turkeys *Cochlosoma* spp. are found mainly in the large intestine, cecum, colorectum, and cloaca. *C. anatis* was first described in the cecum of the domestic duck (*Anas platyrhynchos*).[1] Similarly, in another study *C. anatis* was found in the large intestine below the junction of the cecum and in the cloaca.[6] In geese (*Anser anser domesticus*), *C. anatis* was also found primarily in the large intestine but also in the cecum.[7,14] In both natural and experimental infections in turkeys, *C. anatis* has been described in large numbers in the small intestine.[9,12]

Clinical Signs and Coinfections in Waterfowl and Poultry

Clinical signs described in affected turkeys included intense thirst, diarrhea, depression, ruffled plumage, loss of appetite, and death in chicks between 2 and 12 weeks of age.[5,12] In addition to infection with *C. anatis*, co-infections with *Trichomonas* spp., *Hexamita* spp. and other pathogens have been described. Stunted diarrheic turkey poults, 1 to 7 weeks of age, demonstrated a variety of intestinal parasites including *C. anatis* and concurrent co-infections with *Cryptosporidium* spp., *Hexamita* spp., *Coccidia* spp., *Chilomastix* spp., and *Trichomonas* spp.[13]

Co-infections with bacterial and viral pathogens are also described. In ducklings, a runting syndrome associated with *C. anatis* has been described.[11] In addition, small numbers of *Trichomonas* spp., *Hexamita* spp., and *Campylobacter jejuni* were isolated from the runted ducklings. In an experimental study, a combination of *C. anatis* and turkey coronavirus was proven more pathogenic than either agent alone.[16] In another study, a pure *C. anatis* infection in specific pathogen-free turkeys produced no clinical signs and only a mild decrease in production.[16] These results suggest that, although *C. anatis* can cause a decrease in productivity, clinical signs of disease should only be expected in waterfowl or poultry suffering from co-infections with other protozoa or bacteria or in juvenile birds.

Prophylaxis/Treatment in Commercial Poultry

Feeding young turkey poults inoculated with *C. anatis* with nitarsone or diclazuril did little to ameliorate production losses.

Although feeding nitarsone at US Food and Drug Administration (FDA)–approved levels (170.3 g/ton) decreases the severity of the infection and the number of positive poults, the production losses are not fully prevented. Feeding diclazuril (0.91 g/ton) had no significant efficacy in minimizing the infection or in decreasing the number of positive poults.[4]

COCHLOSOMOSIS IN FINCHES AND WAXBILLS

Classification

Cochlosoma spp. described in finches and waxbills were identified by microscopic identification of motile *Cochlosoma* trophozoites.[17,18] It is not known if these represent a new and different species or the only described species, *C. anatis* (Table 25.1).

Transmission

Although no information is available on the transmission of *Cochlosoma* spp. in finches and waxbills, it can be assumed that asymptomatic adult birds will transmit the parasite via fecal contamination to the nonimmunocompetent nestlings.

Hosts

Cochlosoma spp. infections have been reported in a variety of finches, mainly red-headed parrot finches *(Erythrura cyaneovirens)*, Bengalese or society finches *(Lonchura striata domestica)*, and Gouldian finches *(Erythrura gouldiae)*, but also in blue-faced parrot finches *(Erythrura trichroa)*, zebra finches *(Taeniopygia guttata)*, nutmeg mannikins *(Lonchura punctulata)*, double-barred finches *(Taeniopygia bichenovii)*,[17,19] and various waxbill species.[18]

Site of Infection

In Bengalese or society finches, serial sectioning of the digestive tract revealed presence of the flagellates within the colorectum and cloaca.[17]

Clinical Signs in Waxbills and Finches

In waxbills and finches, adult birds appear to be asymptomatic carriers. Clinical signs can be expected in young birds from 10 days to 6 weeks of age.[20] These signs include dehydration, diarrhea, whole seeds in the droppings, yellow staining of nestlings, and death.[21] Clinical signs classically occur in chicks hatched by asymptomatically infected Bengalese or society finches used as foster parents.[21]

Diagnosis

Diagnosis is made by demonstrating the jerking motion of the motile flagellates in saline smears from fresh warm feces.[21]

Prophylaxis and Treatment

Prophylaxis in finch and waxbill breeding facilities is best performed by screening fresh fecal smears of all newly introduced birds and of all breeding birds at the start of the breeding season.[21]

Cochlosoma spp. can be treated with the same medication as other flagellates such as *Trichomonas* spp. Ronidazole at 50 mg/L of drinking water and 50 mg/kg of soft food for 7 days has proven to be effective.[21] Dosages up to 400 mg/L of drinking water have been described but the lower dosages have been shown to be equally effective.[17] Metronidazole has also been proven to be effective at 30 mg/kg PO once only or 40 to 80 mg/L drinking water for 3 days.[17] Finally, dimetridazole at 100 mg/L drinking water for 5 days will also be effective against infections[21] with dosages up to 250 mg/L drinking water having been described. Be aware that overdosage can result in reversible central nervous system signs.[21] If bacterial co-infections are suspected, these drugs can be used in combination with antibiotics.

Differential Diagnosis

Other diseases causing similar signs in nestling birds include infections with *Isospora* spp., *E. coli* and other bacteria, infections with *Macrorhabdus ornithogaster*, and toxic enteritis.[21]

TABLE 25.1

Quick Reference: Cochlosomosis in Waxbills and Finches

Age Group	Young Birds 1–6 Weeks of Age
Clinical signs in juveniles	Dehydration, diarrhea, yellow staining of nestlings, death
Clinical signs in adult birds	Asymptomatic
Transmission	Asymptomatic adult birds to nonimmunocompetent nestlings
Diagnosis	Motile flagellates in saline smear of fresh warm feces
Prophylaxis	Screening of fresh fecal smears during quarantine and before breeding season
Treatment	Ronidazole, metronidazole, dimetridazole
