CHAPTER 26

Anatomy and Physiology of the Respiratory System

Susan E. Orosz

INTRODUCTION

The primary function of the respiratory system is to provide oxygen to the tissues and remove carbon dioxide. In addition, the respiratory system is involved with thermoregulation by evaporative losses and for vocal communication. Moreover, the lungs are the site for the conversion of angiotensin I to angiotensin II for the maintenance of blood pressure.

The anatomy of the respiratory system has several unique anatomic features. These features most likely result from evolutionary consequences that allowed for flight. In birds, ventilation uses one-way parabronchial valving and air sacs, which segregate ventilation from gas exchange.[1] The separation of these functions provided a more efficient system for gas exchange compared to mammals in which gas exchange and ventilation both occur at the level of the alveoli.

Interestingly, when the two functions are separated, it allows the lungs to be smaller. As such, the lungs of birds have a reduced volume, which ranges from 1% to 3% compared to 7% for mammals. However, the lungs and air sacs combined have a total volume of 15%, which is much higher than mammals. As the fixed lungs do not change in volume during the respiratory cycle, the paired air sacs act as a bellow to move air through the parenchyma in a unidirectional manner. This allows for a greater surface area for gas exchange between the air capillaries and blood, when compared with the movable alveoli of mammals.

Another important difference between mammals and birds is the thoracic cage and its dynamics. Birds do not have a diaphragm that separates the thoracic cage from the abdominal cavity as in mammals. As a result, the pressure within the thorax of birds is essentially atmospheric without the possibility to create differences in pressure, as is the case in mammals, which have subatmospheric pressures in their thoracic cage, thereby allowing air to rush into the lungs.

The specialized respiratory system of birds is extremely efficient when the patient is healthy. However, when ill, respiratory signs are often pronounced, and respiratory distress is a common reason for birds to be presented to the veterinarian. The first step in assessing birds with respiratory signs is to determine whether the signs are localized to the upper or lower respiratory tract or whether both components are affected (see Chapter 27). Moreover, a basic understanding of the anatomy and physiology of the avian respiratory system is required to successfully manage the patient. This chapter aims to provide an overview of the anatomical and physiological characteristics of the avian respiratory tract that are relevant for the veterinary clinician dealing with birds with respiratory distress.

UPPER RESPIRATORY SYSTEM

Nasal and Sinusal Cavities

The cere is the area around the most dorsal surface of the maxillary rhamphotheca or upper bill. It may be feathered or nonfeathered, depending on the species of bird involved. In addition, ceres in each species have their own characteristic size and shape. In adult male budgerigars *(Melopsittacus undulatus)* of the wild phenotype, the cere is usually blue (Figure 26.1); in adult females it is usually brownish pink. Changes in the cere's normal color pattern are suggestive of gonad tumors in this species.

Air moves into the nasal cavity through the nares or nostrils, which are located dorsally within the area of the cere at the base of the beak (Figure 26.2). In several species, the nares are covered by feathers making them hard to visualize. Examples of birds with feathered nares include Eclectus parrots *(Eclectus roratus)*, some species of cockatoos (e.g., *Callocephalon fimbriatum*, *Cacatua ducorpsii*, *C. goffiniana*, *C. haematuropygia*, *C. leadbeateri*, *C. pastinator*, *C. sanguinea*, *C. tenuirostris*, *Eolophus roseicapilla*, *Probosciger aterrimus*) and macaws (e.g., *Anodorhynchus* spp., *Ara ambiguus*, *Ara militaris*, *Ara rubrogenys*), crows (*Corvus* spp.), and grouse (Tetraonini). Some may be perforated as in Gruiformes and Cathartiformes; closed as in Pelecaniformes; tubular in shape as in Procellariiformes; or located at the tip of the bill as in kiwis (*Apteryx* spp.).[2–4] In

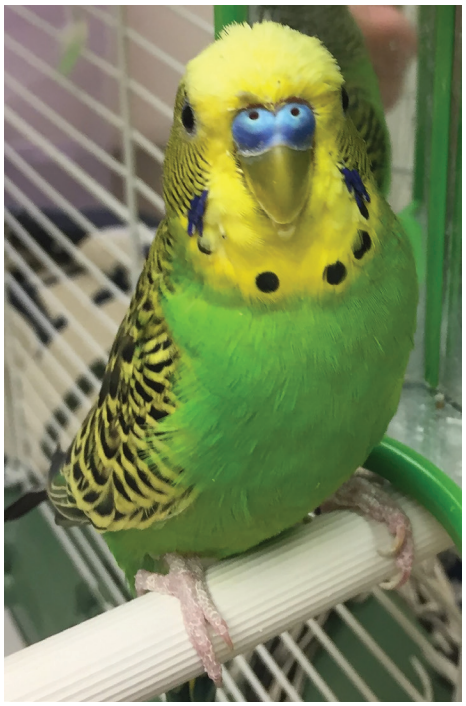

FIGURE 26.1 Budgerigar *(Melopsittacus undulatus)* with a blue cere that signifies a male with the wild phenotype green coloration. (Photo courtesy Susan Orosz.)

FIGURE 26.2 Orange-winged Amazon parrot *(Amazona amazonica)* head. Note the location of the nostrils at the base of the beak, at the cere, with the presence of opercula inside. (Photo courtesy Susan Orosz.)

many parrot species, including grey parrots *(Psittacus erithacus)*, Amazon parrots (*Amazona* spp.), and Galliformes, there is a rounded, keratinized structure called the operculum, which is found in the rostral-most extent of the nasal cavity. It acts as a baffle to deflect and prevent inhalation of foreign bodies.[3] The openings of the nares may be shaped abnormally as a result of a chronic upper respiratory infection. Therefore,

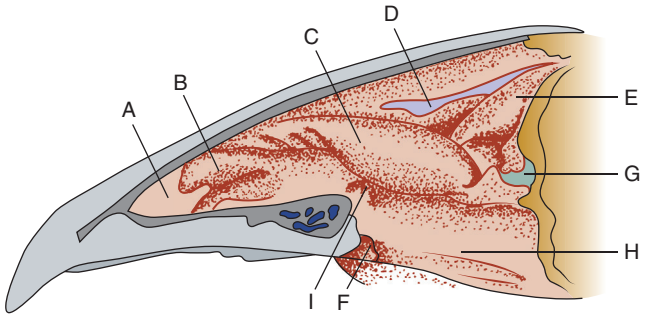

FIGURE 26.3 Anatomical structure of the nasal cavity through a vertical sectional view of a chicken's *(Gallus gallus domesticus)* skull. *(A)* Nostril, *(B)* concha nasalis rostralis, *(C)* concha nasalis media, *(D)* continuation of the nasal meatus, *(E)* concha nasalis caudalis, *(F)* vomer, *(G)* opening into sinus cavity, *(H)* choanal cleft, *(I)* opening of ductus nasolacrimalis. (Reprinted from Kang H, Yan M, Yu Q, Yang Q: Characteristics of nasal-associated lymphoid tissue (NALT) and nasal absorption capacity in chicken, *PLoS One* 8(12):e84097, 2013.)

clinicians should be familiar with the normal shape and size of the nares of the species that is presented. Changes from normal, as well as possible occlusions obstructing airway passage, should be noted during the physical examination.

The nasal cavity in most species is divided by a nasal septum. Within the lateral walls of the nasal cavity are highly vascularized nasal conchae. Most birds have three scroll-like cartilaginous nasal conchae, that is, the rostral, middle, and caudal nasal conchae (Figure 26.3). The middle nasal concha is the largest of the three.[3]

The rostral portion of the nasal cavity (Figure 26.4) can have a vestibule that is lined by a squamous epithelium. This epithelium continues over the rostral nasal conchae. Distally, the epithelium changes to a mucociliary epithelium over the middle nasal conchae. The caudal nasal conchae, which is absent in grey parrots,[2,4] have an olfactory epithelium for sensing smell. In all aquatic birds, there is a mucosal fold that acts as a valve to deflect the water from the caudal conchae where olfaction is detected. This sense of smell is highly developed in a number of species, including albatrosses (Diomedeidae), which can discern bacon up to 10 miles away on the ocean surface. Some species with increased scrolling of the caudal nasal conchae include vultures (Cathartidae, Aegypiinae, Gypaetinae,), crows and ravens (Corvidae), hummingbirds (Trochilidae), and kiwis. The increasing amounts of scrolling of this concha in those species are hypothesized to be linked to a greater sense of smell, most likely as a result of the increased surface area. It is thought that this may be important for location of food.

The nasal gland, or formerly the salt gland, often has two lobes—a medial and lateral—with a duct that opens into its own ostium at the vestibular region of the rostral nasal cavity. In marine birds, the gland concentrates salt from the salt water ingested and secretes it, helping to maintain the osmolality of the blood. It serves a similar function in other species of birds that have access to a limited water supply including some of those in deserts, such as the ostrich *(Struthio camelus)*.[3]

A clinically important anatomic feature is the relationship of the middle nasal conchae to the openings of the infraorbital sinus, which is the only true paranasal sinus of birds. The infraorbital sinus in various publications has been referred to

FIGURE 26.4 Photographs of the transverse sections of the nasal cavity at the level of the rostral vestibular region of a Muscovy duck *(Cairina moschata)* (A), Egyptian goose *(Alopochen aegyptiaca)* (B), laughing dove *(Spilopelia senegalensis)* (C), and Japanese quail *(Coturnix japonica)* (D) showing the rostral *(RC)* and middle *(MC)* nasal conchae and the nasal septum (*asterisk*). (From Madkour F: Anatomical descriptions of the nasal cavity of the aquatic and non-aquatic birds, Int J Vet Sci 2(2):101–110, 2019. https://journals.ekb.eg/article_44862.html.)

as the "subocular sac," "orbital sinus," "maxillary sinus," and several other terms. As the infraorbital sinus is located within the antorbital fossa, the term "antorbital sinus" has also been proposed.[5] For the purposes of uniformity, this sinus is referred to as the infraorbital sinus in this book, as this is the most common name used in the veterinary literature. The infraorbital sinus opens dorsally into both the middle and caudal nasal conchae (Figures 26.5 and 26.6). The caudal nasal concha drains only into the nasal cavity by its dorsal opening into the infraorbital sinus. As a result, the only passageway for drainage of mucopurulent material in the infraorbital sinus is through the dorsal opening of the caudal nasal concha, or over the middle nasal concha, into the nasal cavity. This is important from a clinical perspective as drainage of materials from infections of the infraorbital sinus is limited due to these dorsal openings.

The infraorbital sinus acts to pneumatize the head and neck and is suggested to lighten the head for flight. It is located ventromedial to the orbit and has numerous diverticula. In psittacine birds, the diverticula are well developed, whereas they are absent in other species such as cormorants (*Phalacrocorax* spp.). In most birds, a rostral diverticulum of the infraorbital sinus extends into the maxillary rostrum or bill, which is unpaired (Figure 26.7), but in macaws there appear to be two unpaired rostral diverticula with a transverse canal. In Amazon parrots and macaws, at least there are eight paired diverticula that are distal to the rostral one. These include paired preorbital diverticula, which lie on either side of the skull rostral to the orbit; paired postorbital diverticula, which may be subdivided to surround the opening of the ear; and paired mandibular diverticula, which extend into the mandibular rostrum.[6,7] In addition to its communication with the nasal conchae dorsally, the infraorbital sinus also communicates with the

cervicocephalic diverticulum at its caudal-most extent. This diverticulum is the largest of the diverticula in psittacines and may extend to the thoracic inlet. While it has been classified as an air sac due to its large size, it is not connected to the air sacs that are associated with the lungs.[4,6]

The infraorbital sinus extends out from the skull in various locations so that its lateral walls underlie soft tissues and skin (Figure 26.7). In case of an infection of inflammatory response, this can result in swellings that are noticeable on the exterior surface of the head, as is commonly seen in Psittaciformes and Galliformes. Several bones of the skull, including the quadrate bone, articular bone, and bones of the braincase, are pneumatized through its connection with the tympanic cavity.[5] The infundibular cleft is a slit-like opening just caudal to the choanal slit. This cleft is the opening of the right and left Eustachian or pharyngotympanic tubes that connect to the middle ear cavity. The opening of this tube at the cleft is without folds to quickly equalize pressures during a dive or when flying at higher altitudes and then descending.[3] Knowledge of the relationship of the infraorbital sinus and its diverticula in relation to the bones of the skull is important during examination of the upper respiratory system, during irrigation/flushing of the infraorbital sinus, and for surgical (drainage) procedures.

The Larynx, Trachea, and Syrinx

While anatomists often describe the upper respiratory tract extending from the nares to the choanal slit, others include the larynx through the trachea. The larynx is composed of four partially ossified cartilages with an overlying mucosa or laryngeal mound (Figure 26.8A). The median cricoid cartilage articulates dorsally with a small median comma-shaped procricoid cartilage. This procricoid cartilage has a gliding contact with the paired arytenoid cartilages. The glottis is the opening between these two arytenoid cartilages. They are abducted by a dilator muscle and adducted by a constrictor muscle, regulating the size of the opening (Figure 26.8B,C). The larynx is not involved in the production of sound in birds. However, it may alter the sound produced, as has been observed in parrots.[8–10]

The mucosa covering the laryngeal cartilages is a pseudostratified epithelium with unicellular mucus glands. There are cilia associated with the areas where the ridges project.[3] This entrance to the trachea is not covered by an epiglottis as it is in mammals, making it easier to intubate a bird compared with a mammal. In addition, birds do not have a thyroid cartilage. In some species of birds, including but not limited to pelicans (*Pelecanus* spp.), hornbills (Bucerotidae), kiwis, penguins (Spheniscidae), and some ducks,[4,10] there is a median crest *(crista ventralis)* that comes off the cricoid cartilage ventrally, thereby reducing the opening of the glottis in that location. This should be taken into consideration when intubating these species, and care should be taken to examine the opening in others as they may have one like it or another complication.

The *rima glottidis* and trachea are wider in diameter on a per weight basis than they are in mammals, being up to 1.3 times the radius of that of a mammal of similar size. This principle provides another reason why it is easier to intubate birds than mammals. This increased diameter directly reflects one physiologic adaptation of birds: the use of their beaks for the manipulation of objects. The increased length of the trachea (2.7 times that of a mammal of similar size) is part of an adaptation in birds whereby the increased length of their necks allows the use of their beak to manipulate objects. However, the increase in length also causes an increased air resistance. A wider *rima glottidis*, as well as a wider trachea, is necessary to reduce this resistance. This results in an increased dead space, which is four times that of a similarly sized mammal.[3] To compensate for the wider and longer trachea and its corresponding increase in dead space, the respiratory rate of birds is less than that of mammals of similar size with a larger tidal volume. These anatomic and physiologic differences are important when selecting endotracheal tubes and ventilating birds for anesthetic procedures.

The tracheal rings of birds are complete (Figure 26.9) and shaped like a signet ring. The shape is fairly constant across species.[3] The cartilages that make up the tracheal rings overlap to form a more rigid trachea compared with mammals. These adaptations are important to reduce the possibility of tracheal kinking when moving the neck. The risks of overinflation of a cuffed endotracheal tube are potentially greater in birds because of the less expansive nature of the trachea and

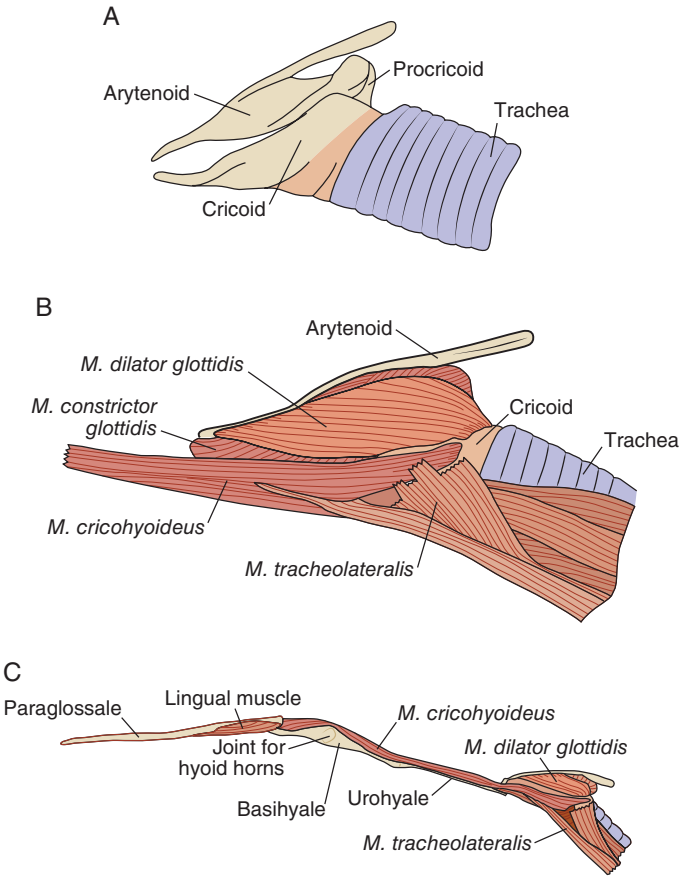

FIGURE 26.8 Lateral view of the larynx and upper end of the trachea in a snowy egret *(Egretta thula)*: (A) skeletal elements, (B) extrinsic and superficial intrinsic laryngeal muscles, and (C) the laryngeal apparatus with its muscular connections to the hyoid apparatus. (Reprinted from Homberger DG: The avian tongue and larynx: multiple functions in nutrition and vocalisation. In Adams NJ, Slotow RH, editors: *Proceedings of the 22nd International Ornithology Congress*, Durban, Johannesburg, 1999, BirdLife South Africa, pp 94–113.)

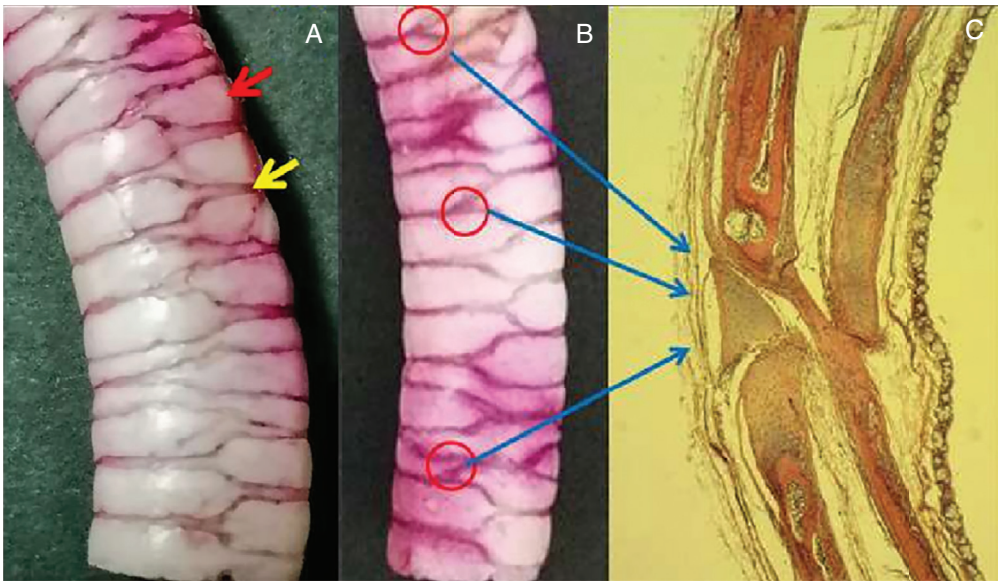

FIGURE 26.9 (A) and (B) Dorsal view of the trachea of a female peacock *(Pavo cristatus)* demonstrating the shape of the tracheal cartilages and the way they overlap; *red arrow*, wide part of tracheal ring; *yellow arrow*, narrow part of tracheal ring. can lead to mucosal edema, bleeding, necrosis, scarring, stricture formation, and respiratory compromise. Thus, whenever possible, uncuffed endotracheal tubes should be used, or the cuff should be left deflated. In addition, when intubating a bird, the tube should not be inserted too deep as in several species (e.g., domestic fowl, macaws, cockatoos) up to 45% decreases in the distal tracheal diameter have been reported, which can significantly increase the risk for trauma and stricture formation following deep endotracheal intubation.[3,11]

The location of the trachea varies with the species. In passerines (Passeriformes) and chickens *(Gallus gallus domesticus)*, the trachea initially sits in the midline but moves to the right side of the neck before returning to the midline at the thoracic inlet. In spoonbills (*Platalea* spp.) and curassows (Cracinae), the trachea forms coils under the skin and pectoral muscles. In swans (*Cygnus* spp.) and cranes (Gruidae), these coils are excavated into the sternum. In penguins, the trachea bifurcates at the cranial neck into right and left halves that are separated by a cartilaginous septum that is continuous with the tracheal rings. There is a tracheal sac that is an inflatable diverticulum in the ruddy duck *(Oxyura jamaicensis)* and the emu *(Dromaius novaehollandiae)*. In many male Anseriformes, the trachea expands at its distal end into a tracheal bulb (Figure 26.10).[3]

The trachea often bifurcates into a right and left bronchus immediately after entering the thoracic inlet. The syrinx, which is the voice box of birds, is located at this bifurcation. The syrinx is a complex structure and is unique to birds. While it is highly variable among species, it is composed of several cartilages, which may be (partially) ossified, and of syringeal muscles and membranes. The derivation of the cartilages—from the trachea and/or bronchi—determines its

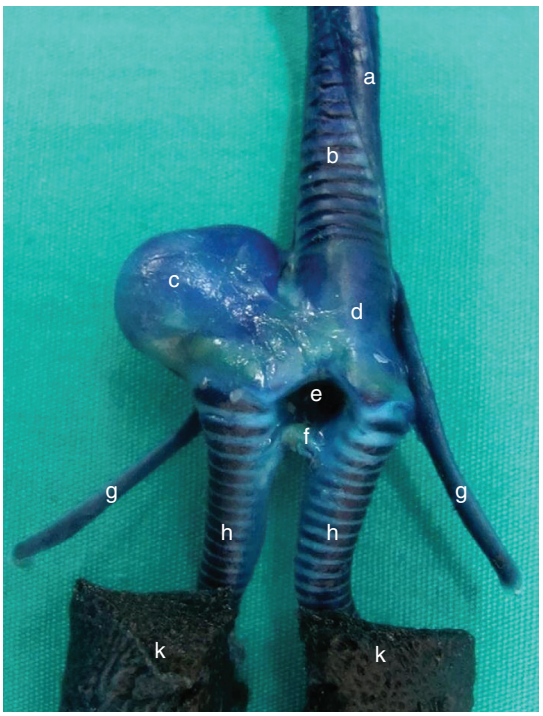

FIGURE 26.10 Dorsal view of the syrinx in the male mallard (*Anas platyrhynchos*): tracheolateral muscle (*a*), trachea (*b*), syringeal bulla (*c*), tympanum (*d*), interbronchial foramen (*e*), interbronchial ligament (*f*), sternotracheal muscle (*g*), right and left primary bronchi (*h*), and lungs (*k*). (Reprinted from Yilmaz B, Yilmaz R, Arican I, Yildiz H: Anatomical structure of the syrinx in the mallard *(Anas platyrhynchos)*, *Harran Univ Vet Fak Derg* 1(2):111–116, 2012.)

classification (tracheal, tracheobronchial, or bronchial), although this may be difficult to determine. New-world vultures (Cathartidae) lack a syrinx. The location of the syrinx can vary widely across bird groups. In most species, including all songbirds, the syrinx is classified as tracheobronchial as the syrinx covers both the lower end of the trachea and the upper parts of the bronchi, suggesting that both elements are involved in the syrinx, with partially ossified cartilages. In other, nonpasserine birds, notably owls (Strigiformes), cuckoos (Cuculidae), and nightjars (Caprimulgidae), the syrinx may be restricted to the bronchi, or to the trachea, as can be observed in a very small number of bird groups that are collectively known as tracheophonae. This group of tracheophonae comprises a subset of the suboscine Passeriformes that includes ovenbirds (Furnariidae), woodcreepers (Dendrocolaptidae), ground antbirds (Formicariidae), typical antbirds (Thamnophilidae), tapaculos (Rhinocryptidae), and gnateaters (Conopophagidae).

The syringeal muscles are important for sound production as they modulate the sound shape by changing the tension of the membranes and the bronchial openings. The muscles to the syrinx are supplied by the 12th (hypoglossal) cranial nerve (CN XII). Most syringeal muscles are external to the tracheal bifurcation (Figure 26.11).[3] However, depending on the species, birds may also have internal syringeal muscles that are located within the lumen of the trachea and/or bronchi. Passerines, for example, can have up to five pairs of internal muscles of the syrinx. Psittacines have two pairs of short syringeal muscles, that is, a superficial and deep pair. In addition, parrots lack a pessulus that is an upright bar of cartilage in the midline between the dividing bronchi (Figure 26.12).[4,12,13] The narrowed internal diameter of the syrinx is a common site for tracheal granulomas and foreign bodies.

The syrinx functions to produce voice. How that happens is not well understood and may vary with the species examined. It is thought that the tympaniform membranes vibrate to produce sound. Another alternative is that the membranes form two slots that produce two streams of turbulent air like in a whistle. It is thought that the vibration of the membranes results from the changes in the pressure of the clavicular air sac, the syrinx, and its lumen. At the onset of expiration, an elevation in pressure in the clavicular air sac closes the syrinx momentarily as the tympanic membranes are forced into the lumen. Tension is applied to the membranes, which results in vibration as air flows past these partially tightened membranes, thereby producing sound.[3] While it is generally believed that sound is produced only during expiration, some of the warblers may be able to use mini breaths to trill and produce pulsed sounds that are unbroken for long periods of song. Breathing and vocalization are coordinated through nuclei in the midbrain of the brainstem.[3]

LOWER RESPIRATORY SYSTEM

Large Airways

The main stem or primary bronchus represents the continuation of the syrinx. Each perforates the septal surface of the lung and continues into the lung parenchyma as the intrapulmonary primary bronchus. That portion of the bronchus is long as it continues to the caudal extremity of the lung (Figure 26.13). Its diameter is variable among species but is widest at its entrance into the lung and then tapers progressively. The epithelium of the primary bronchus is pseudostratified with goblet cells and there are areas with ridges carrying cilia. There are four groups of secondary bronchi that arise from the primary bronchus. Their anatomy will be described with the description of the air sacs and lung parenchyma.[3]

Lung—Pulmonary Air Sacs

The lungs are paired and attached firmly to the ribs and dorsal body wall. They extend from the thoracic inlet at the first rib to the cranial border of the ilium (Figure 26.7). In storks (Ciconiidae) and geese (*Anser* spp., *Branta* spp.), the lungs extend caudally to the hip joint.[3,13] Each lung is often quadrilateral in shape depending on the species, rather than being lobed as in mammals. The lungs appear spongy on radiographs and are best visualized using a lateral view. In this view, the lungs have a honeycomb appearance. The lungs on their dorsolateral margins or costal surfaces are deeply seated against the vertebral ribs. The hilus is where the primary bronchus and the pulmonary artery and veins enter each of the paired lungs. The dorsomedial surface is in contact with the vertebrae and is termed the vertebral surface. Interestingly, while the weight of the lung in relation to total body weight is similar to mammals, its volume per gram of body weight is about 25% smaller.[3]

There are four groups of secondary bronchi that branch off the primary bronchus and they are named according to the region that they supply (Figure 26.14). The mediodorsal and medioventral secondary bronchi connect to form a functional unit. The medioventral secondary bronchi connect with the mediodorsal secondary bronchi in rows of parallel tubes from the primary bronchus. These and their branches form the thick medial portion and the cranial part of the lungs. Some of these bronchi terminate at the cranial pulmonary air sacs and form the basis of the paleopulmonic respiratory system. The cranial pulmonary air sacs are expandable sacs that are connected to the lungs by these bronchial arrangements and include the cervical, clavicular, and cranial thoracic air sacs.

The parabronchi of the lateroventral secondary bronchi connect with the laterodorsal secondary bronchi, and they in turn are connected to the last few mediodorsal secondary bronchi. The laterodorsal and lateroventral secondary bronchi and their terminations form the thin lateral region of the lungs. The lateroventral bronchi are connected to the caudal air sacs of the lungs. These caudal air sacs are the caudal thoracic and abdominal air sacs. This latter arrangement represents the neopulmonic respiratory system. The paleopulmonic and neopulmonic pulmonary air sac systems are best defined physiologically rather than anatomically.[3]

Pulmonary air sacs, in general, are similar histologically to a peritoneum, with squamous to columnar epithelium, a basement membrane, and an underlying connective tissue support. Their interrelationship with the coelomic cavities is discussed in depth in *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 8, Pleura, Pericardium, and Peritoneum: The Coelomic Cavities of Birds and Their Relationship to the Lung–Air Sac System. Only in the area immediately surrounding an opening of a parabronchus does the tissue change to ciliated columnar epithelium. Pulmonary air sacs have limited blood vessels and do not provide for gas exchange.[2]

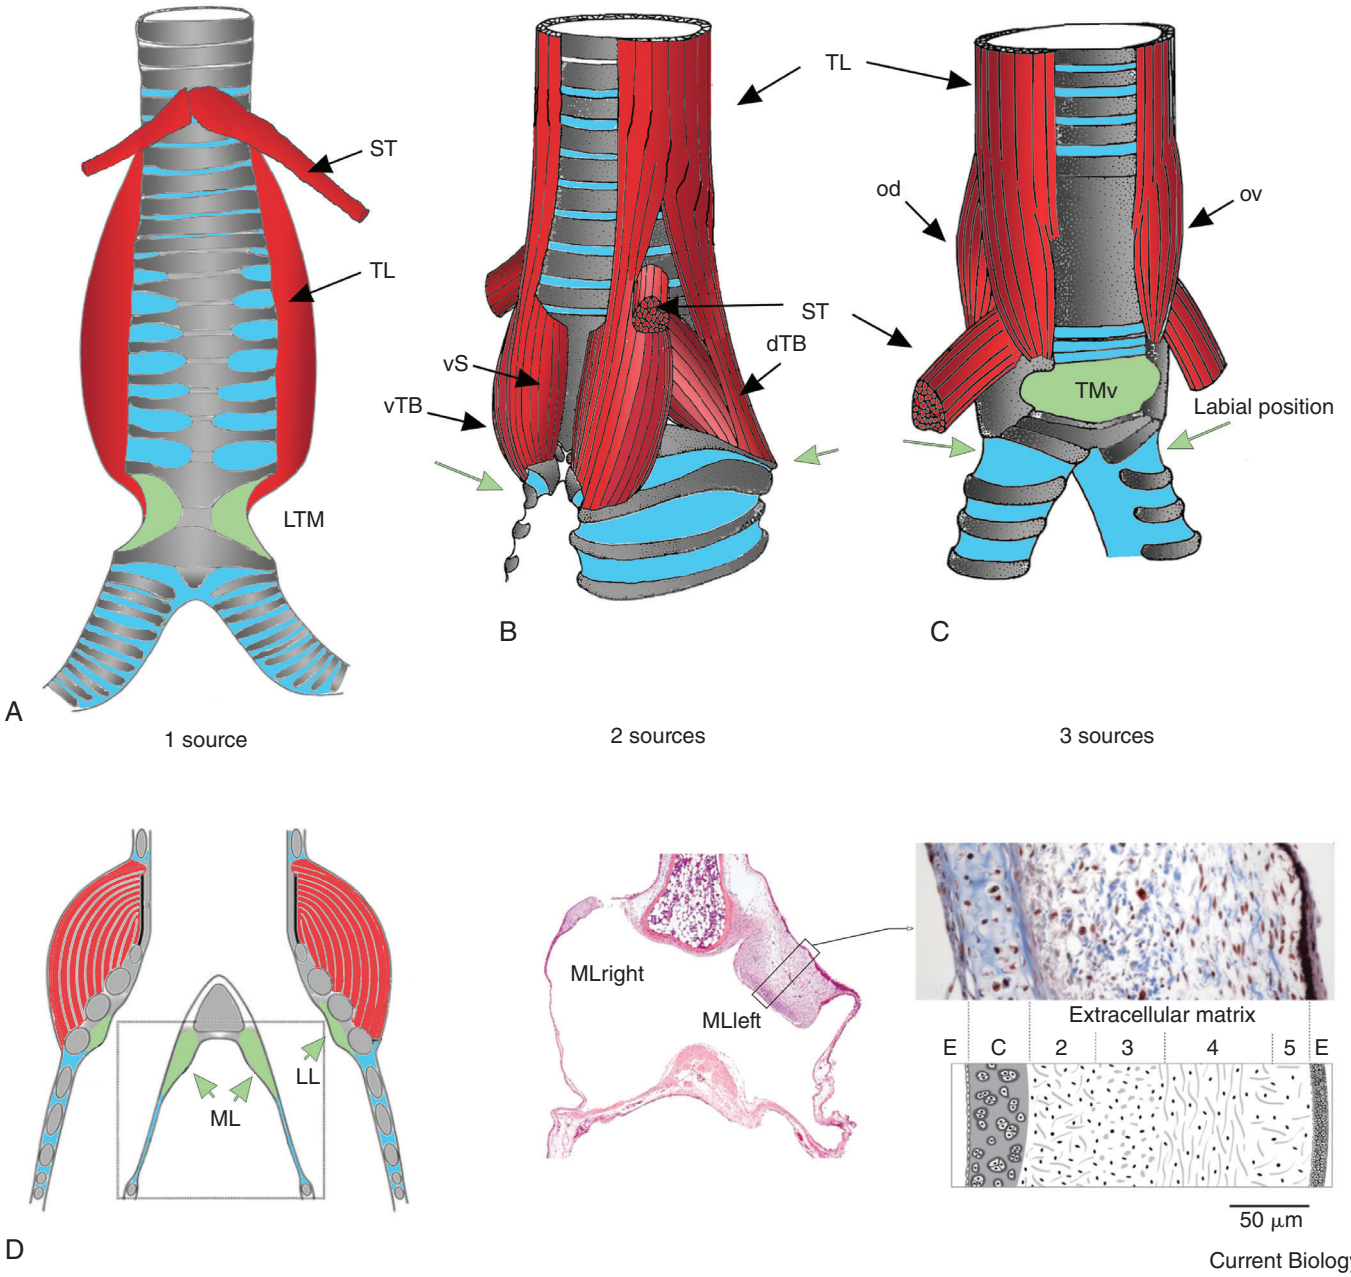

FIGURE 26.11 Schematic illustration showing the overall morphology of the cartilage framework *(grey)* and musculature *(red)* of the syringeal area for a dove (a), oscine (b), and tracheophone suboscine songbird (c). Depending on the location of the sound-generating structures (membranes or labia) along the tracheobronchial juncture, the syrinx contains one, two or, in the case of tracheophone suboscine birds, three sound sources (green membranes and green arrows point at the location of labia in the lumina of the bronchi). *LTM*, lateral tympaniform membrane; *Od, m. obliquus dorsalis; Ov, m. obliquus ventralis; ST, m. sternotrachealis; dTB, m. tracheobronchialis dorsalis; TL, m. tracheolateralis; TMv*, ventral tracheal membrane; *vS, m. syringealis ventralis; vTB, m. tracheobronchialis ventralis*, the dorsal counterpart of which is not visible in this view.The frontal transsectional image (d) illustrates the location of the two pairs of sound generating labia in an oscine songbird (schematically, *LL*, lateral labium; *ML*, medial labium). FIGURE 26.14 (A) Ventromedial view of the plastic cast of the left lung of the Japanese quail *(Coturnix japonica)*. *a*, Extrapulmonary part of the primary bronchi, *b*, intrapulmonary part of the primary bronchi, *c*, medioventral secondary bronchi, *d*, mediodorsal secondary bronchi, *e*, parabronchus. (B) Line drawing (modified from King, 1966) showing the arrangement of the airways in the avian lung. The first secondary bronchi to arise from the primary bronchus are the four medioventral secondaries *(MV1–MV4)*. Additionally, eight mediodorsal secondary bronchi (e.g., *MD3* and *MD8*) arise from the dorsal aspect of the caudal half of the primary bronchus, and eight lateroventral secondaries (e.g., *LV2*) arise from its ventral aspect. The air sacs connect to the lung at six sites, known as ostia. Four of these occur on the costoseptal border of the lung; the fifth, for the cervical sac, is in the craniomedial region of the lung. The sixth is somewhat cranial to the center of the septal surface, and consists of two large direct connections, one to the clavicular and one to the cranial thoracic sac. (A, Reprinted from Cevik-Demirkan A, Kürtül I, Haziroglu RM: Gross morphological features of the lung and air sac in the Japanese quail, *J Vet Med Sci* 68(9):909–913, 2006. B, Modified from King AS: Structural and functional aspects of the avian lung and air sacs. In Felts WSL, Harrison RJ, editors: International review of general and experimental zoology, vol 2, New York, London, 1966, Academic Press.)

In the embryo, there are six pairs of air sacs but these are reduced in the adult. Commonly, there are paired cervical air sacs, fused clavicular, paired cranial thoracic, paired caudal thoracic, and paired abdominal air sacs (Figure 26.15). In passerines, the cranial thoracic air sacs fuse to the clavicular air sac. In chickens, the cervical air sacs fuse, and in turkeys *(Meleagris gallopavo)*, the caudal thoracic air sacs are absent while the cervical air sacs fuse to smaller clavicular paired air sacs.[3]

The cervical air sacs often have diverticuli on each side of the vertebral column, one inside the neural canal and one outside, stretching from the transverse foramina to the axis. The clavicular air sac takes origin from four primordial sacs, that is, the paired medial and paired lateral sacs. The medial pair most often fuses to form a single large sac that surrounds the heart, great vessels, and nerves. In addition, the esophagus, trachea, and syrinx are suspended in folds of the clavicular sac or between it and the cervical sac. The extrathoracic diverticula arise from the lateral sacs and extend between the bones and muscles of the thoracic girdle and the shoulder joint. The paired cranial thoracic air sacs are large in chickens and small in parrots. In contrast, the paired caudal thoracic air sacs are small in chickens but large in parrots. Both do not have diverticula.[3] The abdominal air sac is paired in all species examined. There are three paired perirenal diverticula that separate the kidney from the pelvis and the synsacrum, to then invade the vertebrae and the pelvic girdle. There can be femoral diverticula that travel into the medullary cavity of this bone as well as into some of the muscles to the pelvic limb. In general, all of these air sacs are often compressed and form potential spaces.[3]

Birds do not have a diaphragm and therefore rely on changes in pressure between their air sacs relative to the atmospheric pressure to move air through the nonexpandable lungs. The pressure changes within the air sacs are the result of volume changes in the thoracoabdominal or coelomic cavity (Figure 26.16). On inspiration, the ribs move cranioventrally, thereby increasing the thoracoabdominal space. This results in a lowering of the pressure in the air sacs.[3] On expiration, the ribs move caudodorsally, thereby reducing the space in the thoracoabdominal space and increasing the pressure in the air sacs. Expiration is an active process requiring skeletal muscle contraction. For this reason, it is extremely important when holding a bird that the sternum can move freely, as otherwise the bird may suffocate. Alternatively, to ventilate an apneic bird, the sternum can be compressed and then allowed to recoil into its resting position.

Gas exchange occurs in the walls of the parabronchi, the atria, and more importantly in the air capillaries, which are the avian equivalent of alveoli (Figure 26.17). These air capillaries branch and anastomose freely. Their size varies among species but in general they are smaller than the alveoli in mammals. However, unlike in mammals, the size does not vary during the respiratory cycle, which allows a higher number of air capillaries per volume compared to mammals. Additionally, the small diameter of air capillaries suggests that the pressure gradient for the diffusion of oxygen is greater in birds than in mammals.[3] Due to their small size, there is an increase in the number of air capillaries per lung, and hence an increase in the total surface area that is available for gas exchange in birds compared with that in mammalian lungs.

The blood-gas barrier of birds is like that in mammals in that it consists of an endothelial capillary cell, a common basal lamina, and an air capillary epithelium of squamous cells (Figure 26.18). The difference is that the blood-gas barrier is much thinner in birds than in mammals due to the

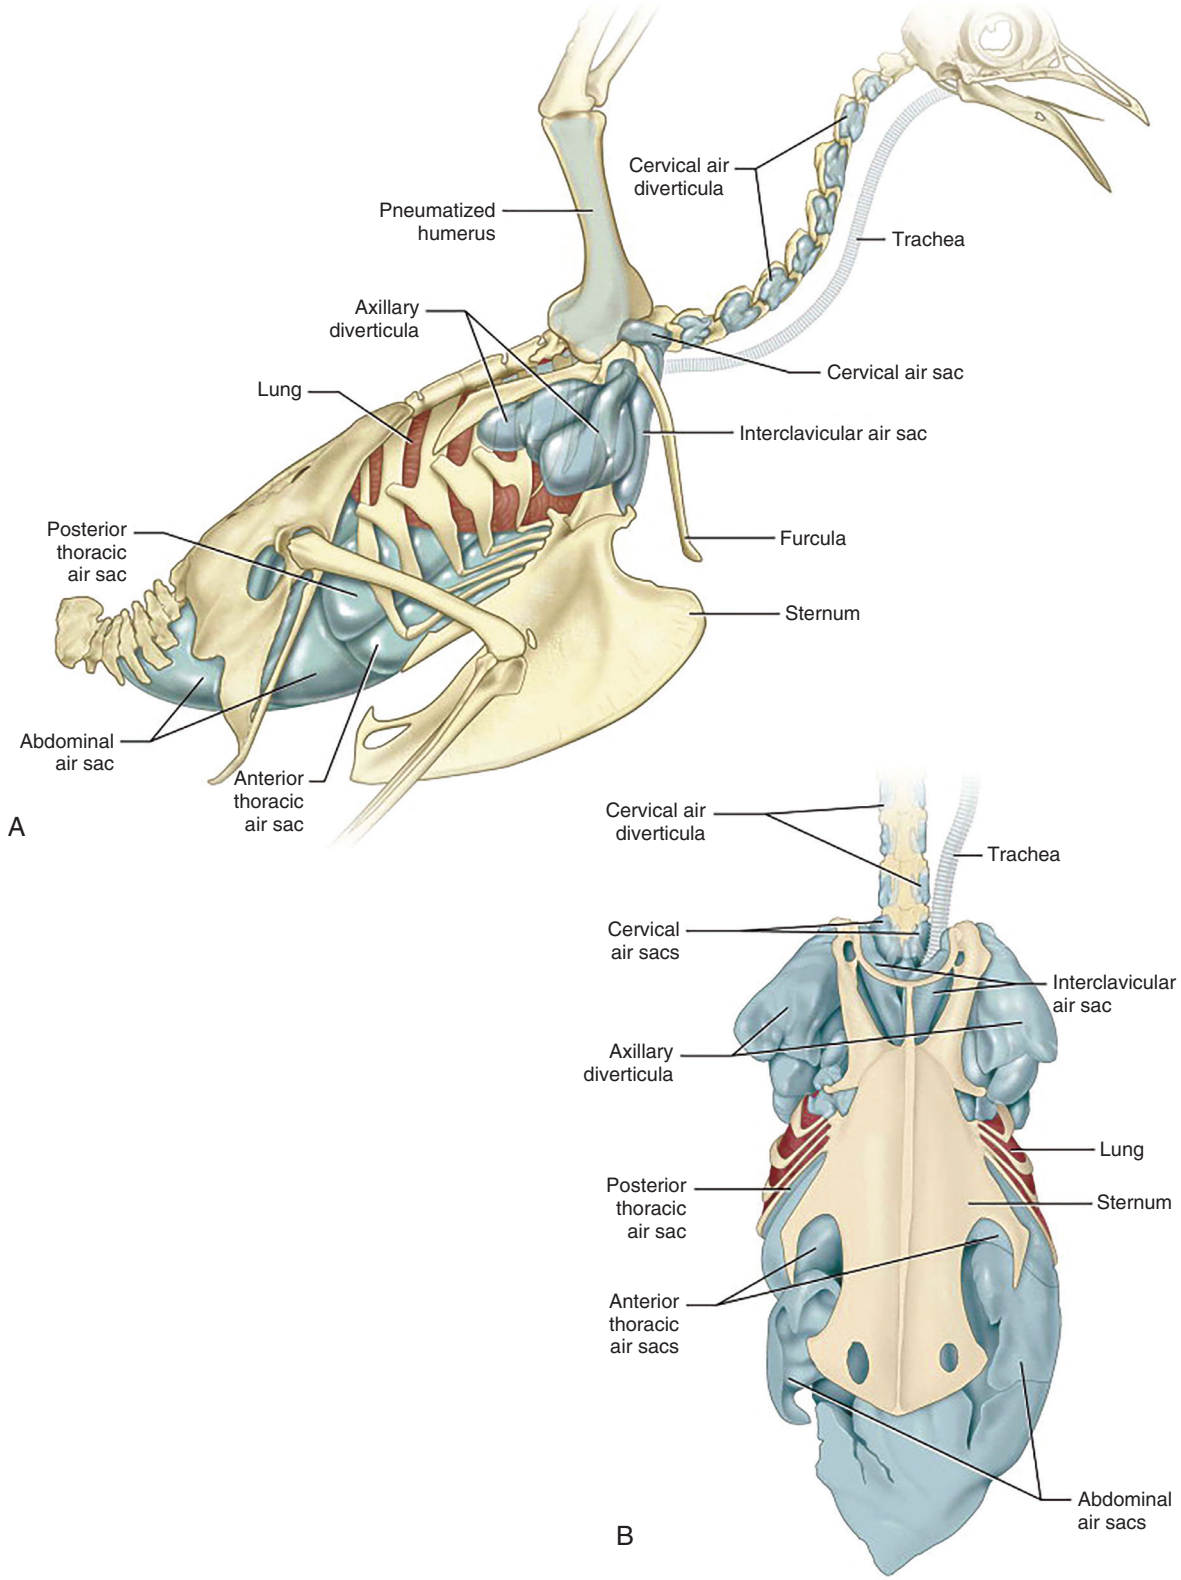

FIGURE 26.15 Diagram of the air sac system of the pigeon *(Columbia livia domestica)* in (A) left lateral and (B) ventral views. There are six primordial pairs of air sacs. The first pair, the cervical air sacs, is fused across the midline. The second and third pairs are fused to each other and across the midline, forming a single median sac, the interclavicular air sac. The cranial thoracic, caudal thoracic, and abdominal air sacs are paired in the pigeon, like in most birds. (Reprinted from De Iuliis G, Pulerà D: Chapter 9: the pigeon. In De Iuliis G, Pulerà D, editors: *The dissection of Vertebrates*, ed 2, 2011, Academic Press, pp. 287–310. https://doi.org/10.1016/B978-0-12-375060-0.00009-7.)

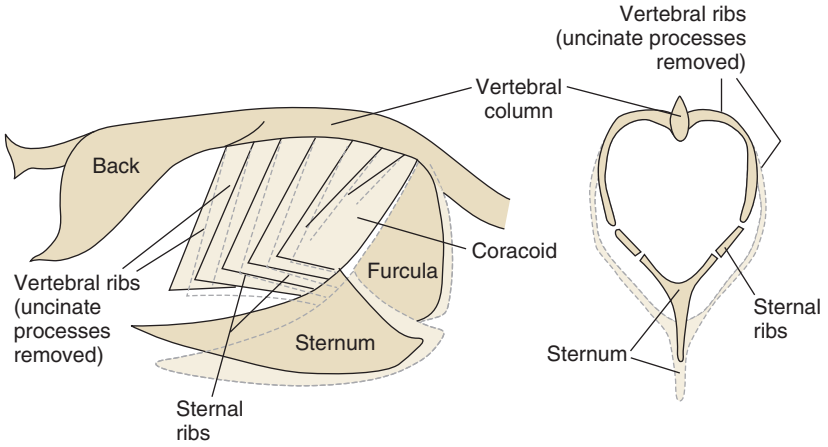

FIGURE 26.16 The movements of the thoracic cage during breathing: (A) cranial view; (B) lateral view. (*Solid lines*, position at the end of expiration; *dotted lines*, position at the end of inspiration.) The inspiratory muscles move the ribs craniolaterally during inspiration, pushing the sternum ventrally and cranially. These inspiratory movements increase the dorsoventral, transverse, and craniocaudal diameters of the thoracic cage. (Reprinted from Powell FL: Chapter 20: respiration. In Scanes CG, Dridi S, editors: *Sturkie's Avian Physiology*, ed 7, 2022, Academic Press, pp 445–484. https://doi.org/10.1016/B978-0-12-819770-7.00033-5.)

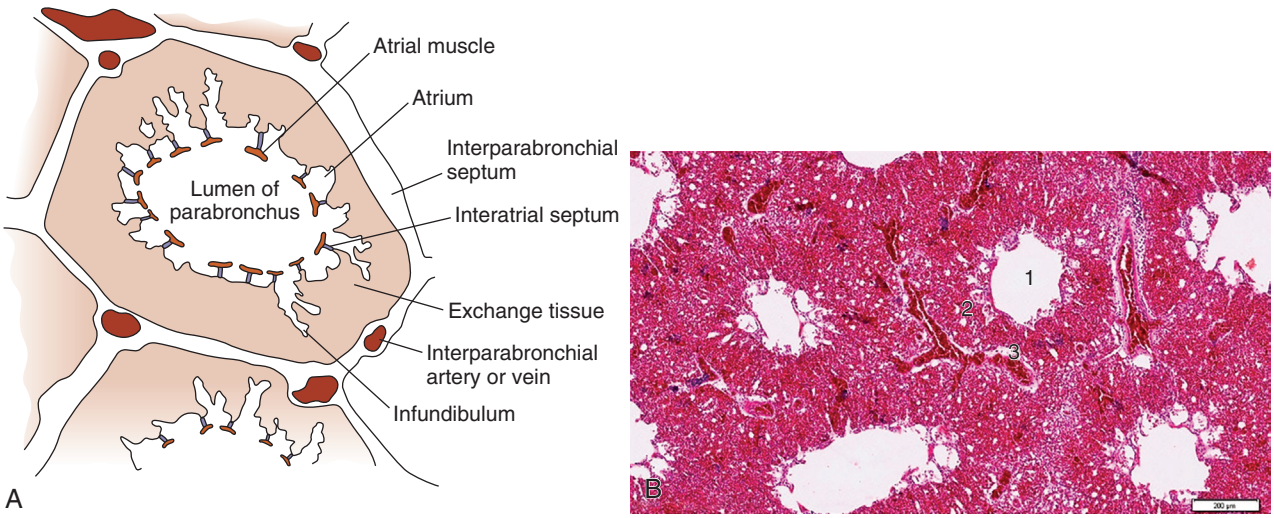

FIGURE 26.17 A drawing (A) and photomicrograph (B) of a histological section showing parabronchi of the domestic fowl *(Gallus domesticus)* in transverse section. The photograph (B) further depicts the tertiary bronchi and parabronchial structures of the domestic fowl. 1 represents the lumen, 2 exchange tissue, and 3 an interparabronchial artery or vein. (Figure A adapted from King AS, McLelland J: Respiratory system. In Birds: their structure and function, 2nd ed, Eastbourne, UK, 1984, Baillière Tindall; Figure B (reprinted from https://histology-of-birds.com/galleries.php?id=20&v=3. reduced thickness of the air capillary. The resistance of the barrier to oxygen diffusion is less with this reduced thickness. There are cells in the lining of the air capillary that have osmophilic bodies that produce surfactant. It is thought that the surfactant produced in birds restricts the diffusion of fluid from the blood capillary across the blood-air barrier.[3] This would promote normal function for oxygen and carbon dioxide exchange. However, due to this reduced barrier thickness, when there is increased pressure on the blood capillary side, for example, due to high blood pressure in the lungs (right-sided heart failure) and/or changes in the lungs from chronic or acute infections, there is increased leakage with faster crashing of the system compared to mammals.

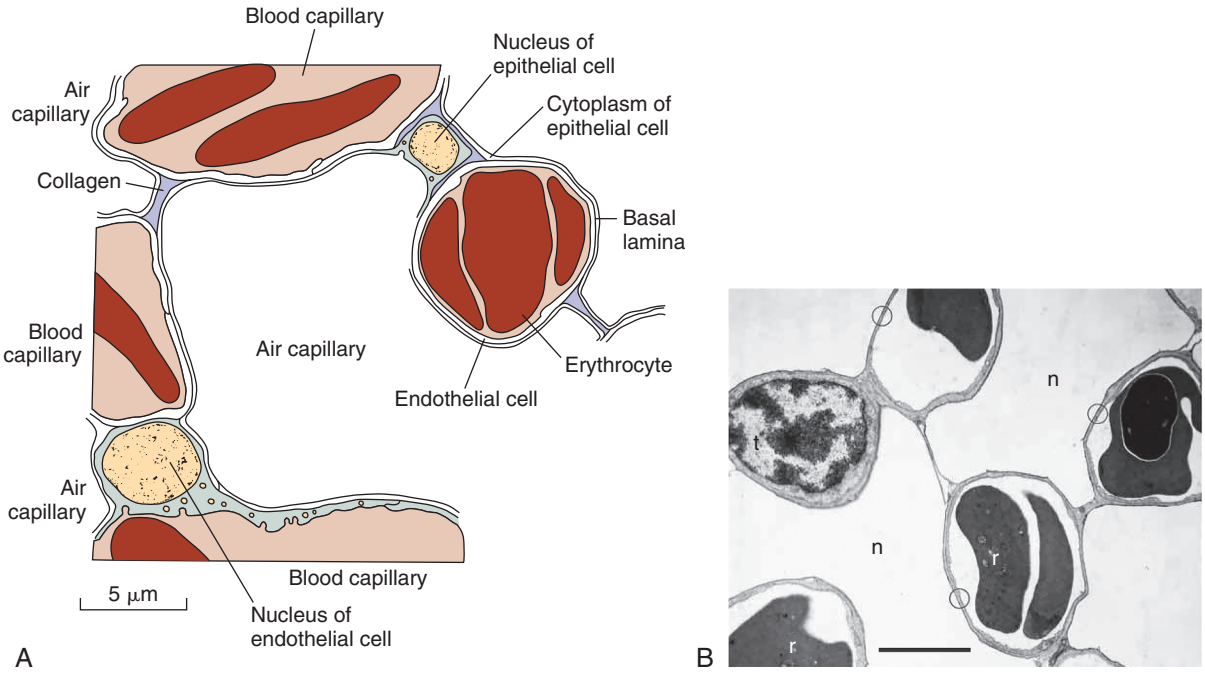

FIGURE 26.18 A drawing (A) of a photomicrograph of the exchange tissue of the lung of the domestic fowl and a transmission electron microscopy (TEM) photomicrograph (B) showing the structure of the lung of a Japanese quail (Coturnix japonica). Air capillaries (n) are alternately situated between erythocyte-containing capillaries (r) with a very thin blood-gas barrier in between. Magnification 3500×. (Reprinted from Rombout PJA, Dormans JAMA, van Bree L, Marra M. Structural and biochemical effects in lungs of Japanese quail following a 1-week exposure to ozone, *Environ Res* 54(1):39–51, 1991. https://doi.org/10.1016/S0013-9351(05)80193-8.)

The epithelial cells lining the lungs act as fixed macrophages and transfer engulfed material to interstitial macrophages. Air that enters the caudal air sacs is filtered less than that of the cranial air sacs, making the caudal air sacs more susceptible to disease. This is due to the anatomic arrangement of origin of the lateroventral secondary bronchi, which arise from the ventral wall of the primary bronchus.[3] If infectious or other particles are able to travel down the primary bronchus, as they reach its terminal end, these particles are more likely to fall ventrally into lateroventral secondary bronchi. The secondary bronchi from the paleopulmonic system, on the other hand, arise dorsally from the primary bronchus making them less susceptible. This can be observed radiographically as opacities in the most caudal (i.e., caudal thoracic and abdominal) pulmonary air sacs.

Because of the unidirectional continuous flow of air of the paleopulmonic system through the series of parabronchial tubes, birds are more efficient than mammals in capturing oxygen (O_2) and removing carbon dioxide (CO_2). The nonoxygenated blood enters at an approximately 90° angle from the parabronchus. This cross-current gas exchange enhances the ability to oxygenate the blood. There is abundant smooth muscle in the walls of the interparabronchial arteries, as well as smooth muscle in the walls of the parabronchi and the atria that allows altering of the air flow into this system by regulating their diameters.[3] These muscles are innervated by nerves of both the sympathetic and parasympathetic nervous systems and would most likely respond to bronchodilators (see Chapter 28).

Respiratory Cycle

In birds, respiration does not rely on changes in the volume of the thorax that create negative pressures as in mammalian lungs. Instead, pressure changes in the air sacs move the air through a nonexpanding lung. These pressure changes result from volume changes in the thoracic and abdominal space, and require muscular exertion during both inspiration and expiration.[3,14]

On inspiration, the ribs and sternum are drawn cranially and the more caudal portion of the thoracoabdominal wall is drawn ventrally.[3,14] This action can be compared to that of a bellows. The junction of the coracoid and sternum corresponds to the fixed end of the bellows, whereas the distal end of the sternum corresponds to the more movable end. When the thoracoabdominal space is expanded, the air rushes into primarily the caudal sacs (caudal thoracic and abdominal) as a result of the reduced pressure and inspiratory aerodynamic valving (Figure 26.19). On expiration, the ribs and sternum move caudodorsally, closing the "bellows" and reducing the thoracoabdominal space. Consequently, the pressure in the caudal air sacs is increased, moving the air by expiratory aerodynamic valving into the paleopulmonic system. In those birds with both neopulmonic and paleopulmonic systems, air enters and exits the respiratory system in a two-breath cycle.[14] This two-breath cycle allows a continuous flow of air through the parabronchi to the gas exchange surfaces (Box 26.1), whereas the less efficient mammalian breathing cycle allows gas exchange to occur only at the end of inspiration.

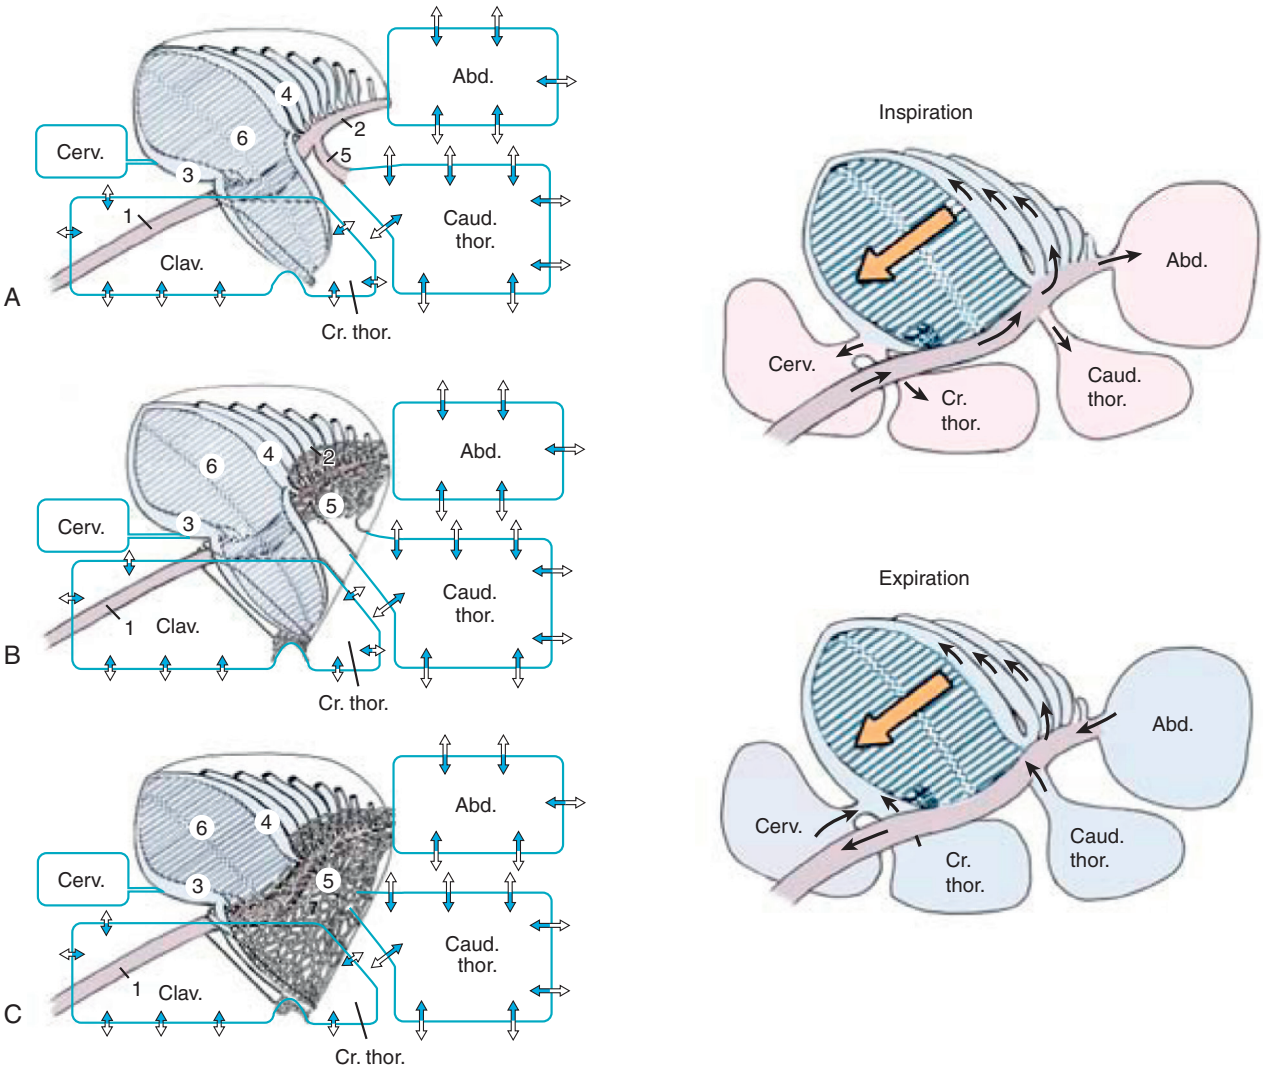

FIGURE 26.19 (A) and (B) *Left panels*, Successive stages in the division of the lung into a paleopulmo and neopulmo. (A) Lungs composed only of the paleopulmo such as observed in Sphenisciformes; (B) moderate development of the neopulmo forming the caudal part of the lungs such as observed in Anseriformes; (C) highly developed neopulmo occupying the entire lateroventral aspect of the lungs, such as occurring in Passeriformes. *1*, Trachea; *2*, primary bronchus; *3*, medioventral secondary bronchi; *4*, mediodorsal secondary bronchi; *5*, lateroventral secondary bronchi; *6*, paleopulmo; *7*, neopulmo. The length of the *white arrows* in A, B, and C indicates the estimated dilatation of the air sacs in inspiration; the length of the *shaded blue arrows* indicates the estimated compression in expiration. *Right panels*, The orange arrows indicate the flow of air across the gas exchange tissues of the lungs, in inspiration and in expiration. The *black arrows* indicate the flow of air within the trachea and to and from air sacs, in inspiration and expiration. *Abd*, Abdominal air sac; *Caud thor*, Caudal thoracic; *Cerv*, Cervical air sac; *Clav*, Clavicular air sac; *Cr. Thor*, Cranial thoracic. (Modified and reprinted with permission from McLelland J: Anatomy of the lungs and air sacs. In Mitchell MA, Tully TN, editors: *Current therapy in exotic pet practice*, ed 1, 2015, St. Louis, Elsevier.)

Defense Mechanisms of the Lower Respiratory Tract

One of the first lines of defense of the lower respiratory tract is the mucociliary escalator.[14] This anatomic and physiologic escalator uses mucus secreted from the goblet cells to trap foreign material, which is then swept away by cilia for removal from the respiratory tract. This defense mechanism can be overwhelmed by infection. When this happens, the mucociliary escalator cannot move infectious material and products of inflammation out of the lung quickly enough to keep the parabronchi clear.[14] Nebulization reduces the increased viscosity of the mucus associated with infection and

BOX 26.1 RESPIRATORY CYCLE IN BIRDS

First inspiration—Air flows into the trachea through the primary bronchi, and most of the air goes directly into the abdominal air sac and/or into the caudal thoracic air sac via the lateroventral secondary bronchi.

First expiration—Air travels back through the paleopulmonic parabronchi and is then shunted via aerodynamic valving into the mediodorsal secondary bronchi; the air moves through the parabronchi of this system and gas exchange occurs.

Second inspiration—Air is pulled from the mediodorsal secondary bronchi through the medioventral secondary bronchi and into the cranial pulmonary air sacs.

Second expiration—Air moves out of the cranial air sacs, into the opening of the medioventral secondary bronchi, and out of the trachea.

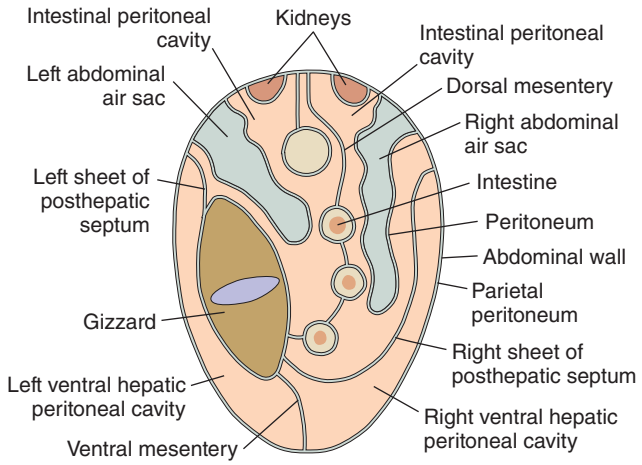

FIGURE 26.20 Diagrammatic transverse section through the peritoneal cavities of the bird, caudal view. The diagram shows three of the five peritoneal cavities, that is, the intestinal peritoneal cavity and the left and right ventral hepatic peritoneal cavities. The left and right dorsal hepatic peritoneal cavities, which are much smaller than the other three, are not shown. Note that the left and right ventral hepatic peritoneal cavities enclose the intestinal peritoneal cavity so that an incision anywhere in the abdominal wall at the level of this transverse section can only enter either the left or the right ventral hepatic peritoneal cavity; at a more caudal level of the body, immediately cranioventral to the vent, a ventral incision will enter the intestinal peritoneal cavity. (From McLelland J: Pericardium, pleura et peritoneum. In Baumel JJ, King AS, Lucas AM, Breazile JE, Evans RE, editors: Nomina anatomica avium, London and New York, 1979, Academic Press; with kind permission of the publisher. Reprinted from King AS, McLelland J: Coelomic cavities. In: *Birds: their structure and function*, 2nd ed., Eastbourne, UK, 1984, Baillière Tindall.)

helps the escalator work more efficiently.[14] In birds with vitamin A deficiency, cells undergo a change to a squamous type without mucus or cilia. This results in a breakdown of this fundamental system to remove foreign material.

A second line of defense involves the epithelial cells themselves. These cells of the lung parenchyma act as fixed macrophages,[14] engulfing foreign material and transferring it to interstitial macrophages for destruction. Because macrophages are involved early in defense, granulomatous reactions to infection are common in birds.

When defense mechanisms of the lower respiratory tract are overwhelmed, birds often exhibit a number of signs, including voice change (particularly when the syrinx is involved), increased abdominal/coelomic exertion (when the parabronchi are plugged with infection), tail bobbing (associated with increased respiratory effort), and clicks and wheezes (caused by air moving through a lumen that is reduced in size).[6] If lower respiratory tract infections obstruct the trachea, the abdominal or caudal thoracic air sac can be cannulated for oxygenation of the respiratory system (see Chapters 29 and 34). Oxygen can be administered into the clavicular air sac as well.

Extrapulmonary Factors

Because birds have air sacs that are connected to the lungs, extrapulmonary anatomic and physiologic factors can affect their ability to breathe normally. By understanding the anatomy of surrounding structures in relation to the respiratory tract, the clinician can make educated decisions regarding their patient. For example, structures in the neck that impinge on the trachea can cause difficulty breathing for the avian patient. An understanding of regional anatomy in the head, neck, and body cavity is also of particular importance when approaching the respiratory tract.

One important difference that must be understood clinically is the anatomy of the coelomic cavities of mammals compared to birds. The coelomic cavities of birds are similar between species; in general, there are eight coelomic cavities in the adult bird (*Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 8, Pleura, Pericardium, and Peritoneum: The Coelomic Cavities of Birds and Their Relationship To The Lung–Air Sac System). The mammalian coelomic cavities include the right and left pleural cavities, the intestinal peritoneal cavity, and the pericardial cavity. The four additional coelomic cavities of birds include the left and right ventral hepatic peritoneal cavities and the left and right dorsal hepatic cavities (Figure 26.13). The kidneys, adrenals, gonads and their ducts are found within the intestinal peritoneal cavity (Figure 26.20).

This anatomic arrangement is important to gain understanding of how and where an infection or neoplasia can spread or affect the function of other organ systems, in particular the function of the air sacs. For example, enlargement of the liver will reduce the size of the caudal thoracic and the abdominal air sacs, making it more difficult to move air through the parabronchi for oxygen exchange. Similarly, tumors or infections from the ovary will often seed into the intestinal peritoneal cavity; while being retained within it, this cavity will expand, thus reducing the ability of the abdominal air sac to expand and leading to respiratory distress (see also Chapter 28).

CHAPTER 27

Diagnostic Workup of Respiratory Problems

Nico J. Schoemaker • Yvonne R. A. van Zeeland

When evaluating the respiratory system of a patient, several steps need to be taken. First, an extended history should be collected focusing on issues that may affect the respiratory system. Subsequently, the patient should be evaluated and inspected from a distance with a special focus and emphasis on respiratory sounds and movements. Finally, a hands-on physical examination should be performed during which the separate parts of the respiratory system are examined, starting with the nares, and finishing with the coelom.

HISTORY

When taking the history of a patient with respiratory problems, questions need to be asked on the time of onset, duration, and clinical course of the disease, as well as any potential treatments that may have been initiated prior to the visit (including their effects). Additionally, information is warranted on presence of nasal discharge, respiratory sounds, and labored respiration (dyspnea). Other pertinent questions relate to the bird's living environment (including diet) as certain factors can predispose to respiratory issues. Occurrence of similar problems in other birds within the household can point toward infectious, toxic, and/or managemental causes. Gender and reproductive status are important to note as egg binding and yolk peritonitis are frequent causes of respiratory distress in hens.

In relation to *nasal discharge*, important features to evaluate include the type of discharge (i.e., watery/serous, mucus, exudate/purulent, blood, etc.), sidedness (i.e., unilateral or bilateral), pattern (i.e. continuous, intermittent, recurrent) and circumstances under which the discharge is produced (e.g., following exposure to certain fumes, smoke or aerosoles). Clear, serous discharge is often seen in the acute stages of chlamydiosis or viral infections, in case of allergies, or upon inhalation of dust or irritating agents. Chronic problems are usually associated with discharge that is more mucoid in nature. Once (secondary) bacterial infections are involved, the exudate often becomes purulent. Unilateral discharge often pinpoints a localized problem (e.g., aspergilloma or foreign body), while viral, fungal or bacterial infections more commonly lead to bilateral nasal discharge.

Respiratory sounds provide information on the location of the problem in the upper airways, as characteristic sounds may be heard if exudate or other material is present in the airways. A nasal stridor produces a typical "sniffing sound" and disappears as soon as the bird starts breathing with an open beak. As such it is important to inquire whether open beak breathing has been observed and whether the sound changes or disappears upon opening of the beak. Additionally, sneezing can be observed in birds with rhinitis or sinusitis. It is important to inquire about the frequency, duration, and moments at which this occurs. If a tracheal, syringeal, or laryngeal obstruction is present, a characteristic "sawing", "air racing", or "g"-sound can often be heard. Additional sounds that may be heard in birds with respiratory problems include the characteristic clicking sounds in case of an infectious tracheitis (e.g., tracheal mites, *Syngamus trachea*) or high-pitched squeaks as may be heard in budgerigars *(Melopsittacus undulatus)* in case of goiter. In addition to the presence of respiratory sounds, it is important to take note of changes (e.g., hoarseness) or loss of voice, as this is commonly heard in parrots with tracheal or syringeal obstructions.

Dyspnea (labored breathing) is characterized by forced respiratory movements, whereby auxiliary respiratory muscles are activated. The most frequently seen sign of labored breathing in birds is "tail bobbing" during which the tail is flexed ventrally in an effort to expel air out of the air sacs into the lungs. As such, tail bobbing can be considered as the avian counterpart of abdominal breathing in mammals. Other signs pointing toward labored breathing include inflation and deflation of the sinuses and cervicocephalic diverticulum, and open-beak breathing.

During the history taking it is vital to determine whether the dyspnea is acute or chronic. If the dyspnea is acute, inquiries should be made to inquire about events immediately preceding the dyspnea as this may reveal an underlying cause for the dyspnea (e.g., polytetrafluoroethylene [PTFE] toxicosis following cooking with recently purchased Teflon-coated pans; foreign body aspiration in a cockatiel *[Nymphicus hollandicus]* associated with consumption of millet seed; hypersensitivity/allergic pneumonitis in a macaw [*Ara* spp.] developing following exposure to the feather dust and dander of a grey parrot *[Psittacus erithacus]* or cockatoo [Cacatuidae]). In the early stages of dyspnea, dyspnea will mostly be observed following exercise or stress (while taking longer to recover), whereas it will often be present continuously in more advanced stages of disease.

Retrieving information on the *living environment* of the patient is essential to provide clues regarding potential causes and predisposing factors to respiratory disease. Details that are pertinent to collect include information on (recent) exposure or (in) direct contact with other birds (e.g., wild birds, new additions to

the household), outdoor versus indoor housing (including exact location), exposure to potentially irritating or toxic (aerosolized) substances (e.g., incense, hair spray, perfume, smoke, dust, fumes, etc.; see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 18, Advancements in diagnosis and management of toxicologic problems), and the climate conditions under which the bird is kept. Especially low environmental humidity can predispose to dry mucous membranes and associated irritation of the respiratory tract. Inquiries should also be made regarding the type of diet that is fed (including any supplements provided and consumed amounts), as vitamin A deficiency results in metaplastic changes of the mucous membranes along the respiratory tract, hence predisposing to infection (see also Chapter 28). When other birds are kept in the household, it is important to note whether these are also suffering from disease. Similarly, if diseases with zoonotic potential are expected, inquiries can be made in relation to illness of (other) members of the household as this may help narrow down the list of differentials and direct the focus of the further diagnostic work-up towards specific pathogens (e.g. *Chlamydia* spp., see Chapter 18).

OBSERVATIONAL ASSESSMENT FROM A DISTANCE

Prior to handling the bird, an observational assessment is made from a distance. Ample time should be taken to inspect the patient, starting when the client enters the examination room with the patient. In a new environment or when stressed, birds will often try to hide signs of disease but are commonly unable to maintain this during the examination. Hence, the bird should be allowed to acclimatize to the examination room prior to commencing the hands-on examination while preventing exposure to extraneous stimuli that can lead to stress (e.g., sudden or unfamiliar noises; see also Chapter 46).

While observing the bird from a distance, the rate, rhythm, and depth of respiration should be assessed. In a normal, calm bird, respirations should hardly be noticeable. With space-occupying masses in the coelom, the respiration will often be rapid and shallow, while obstructions in the upper respiratory tract (particularly the trachea/syrinx) will generally lead to a deeper respiration, with relatively limited increase in respiration rate. Some avian species (e.g., Pionus parrots, [*Pionus* spp.], Amazon parrots [*Amazona* spp.]) may pant when stressed. This is a normal physiologic response that should not be misinterpreted as dyspnea due to a pathological process.

Attention should be paid to potential respiratory sounds, change of voice (in psittacines), and presence of accessory respiratory movements (i.e., open-beak breathing, tail bobbing, inflation of the sinuses during the respiratory cycle, vent lip motions coindicing with the respiratory cycle) indicative of the severity of the dyspnea, as discussed earlier. Birds with dyspnea often show a characteristic tail bob with every breath, which may be accompanied by open-beak breathing in case of more severe respiratory problems. Respiratory problems associated with excess fluid production may cause gurgling sounds that are audible during inspiration and expiration. Be aware that some parrots produce noises that may be mistaken for abnormal sounds by the inexperienced owner or veterinary surgeon unfamiliar with the species. For example, grey parrots may show a characteristic growling, whereas cockatoos and Pionus parrots will hiss or produce a sniffling sound when anxious or stressed, respectively. In parrots, in particular, it is important to realize that these species are capable of mimicking human sounds (e.g., coughing, sneezing), which an owner may inadvertently interpret as respiratory disease.

The head and neck should be carefully inspected for any obvious abnormalities that can be present such as ocular or nasal discharge; occlusion; lesions or deformities of the nares, beak, and/or cere; periorbital swelling (in case of sinusitis); hyperinflation of the cervicocephalic diverticulum; and/or subcutaneous emphysema. Finally, the posture and movements of the bird are worthwhile to assess. For example, a wide-legged stance or a hunched stance with a ventrally deflected, kinked tail may be indicative of a space-occupying mass in the coelom (e.g., in budgerigars with gonadal or renal neoplasia), whereas swaying movements or stretching of the neck versus yawning or excessive rubbing or scratching of the head can indicate problems in the trachea versus nasal cavity and sinuses, respectively. In birds with respiratory distress or those suffering from hyperthermia, the wings may also be drooped and/or held away from the body.

HANDS-ON PHYSICAL EXAMINATION

If the bird is well enough to withstand the stress of being handled, a physical examination should be performed. Prior to handling, the bird can temporarily be placed in an incubator or oxygen cage to preoxygenate the bird. Additionally, the use of sedatives (e.g., midazolam) should be considered as this may help to reduce stress, hence reducing the risks of handling (see Chapter 46). Care should be taken to minimize handling times while carefully monitoring the bird throughout and (temporarily) interrupting the physical examination to allow the bird to recover in the oxygen cage, if necessary.

During the physical examination, all components of respiration should be evaluated. An initial assessment of the respiration is done from a distance and should be performed prior to handling of the bird (see Observational Assessment from a Distance). This will help to ensure that baseline values are obtained by eliminating effects from human interference as the stress from handling and restraint (especially in birds that are not used to handling) will inevitably result in significant alterations of the bird's respiration. Nevertheless, the bird's respiration should also be evaluated during and following handling, as changes in the respiration, including the time to return to baseline, will provide additional clues on the severity of the problem.

Evaluation of the respiration rate may be challenging as reference ranges are not routinely available for all species, and respiration rates may be significantly altered in a novel, unfamiliar environment. For some species, frequencies are reported (i.e., 3–5 breaths per minute [BPM] in the ostrich *[Struthio camelus]*; 13 BPM in turkeys *[Meleagris gallopavo]*; 25–30 BPM in pigeons *[Columba livia domestica]*, and 40–50 BPM in cockatiels).[1] Studies that have been performed over half a century ago came up with a formula that would allow calculation of the normal respiration rate in rest based on the weight of the bird. Within this formula [$f = 17.2\ (kg^{-0.31})$][2,3] f represents the respiration rate. When using this formula for the species listed earlier, the frequencies are pretty much in accordance with the reported frequencies (i.e., cockatiels [100 g] = 35 BPM, pigeons [500 g] = 21 BPM, and ostrich [70 kg] = 4 BPM).

Although the aforementioned formula theoretically allows normal frequencies to be calculated for all species, some

authors report that recording respiration rates has limited value as it can differ so widely.[4] However, this is not only true for birds but also for mammals. As respiration rate by itself rarely allows for accurate assessment of compromised respiratory function, rhythm, depth, and type of respiration should also be assessed. These parameters are less likely to change significantly from baseline values in birds without respiratory distress. The rhythm should always be regular; irregular or agonal breathing often indicates a life-threatening emergency and ensuing death. In birds, depth of respiration is often difficult to assess, unless it has increased significantly. Deep respirations are characterized by an increased excursion of the sternum and tail bobbing. Some authors hypothesize that increased excursion of the sternum could be considered the equivalent of "costal breathing" in mammals, while tail bobbing would be the equivalent of "abdominal breathing" in mammals.

Respiration may be uneventful at the time of presentation in the clinic, but once the bird is handled, respiratory parameters may change drastically. The bird may become so dyspneic during handling that it should immediately be released and returned in its cage. After releasing the bird, it is important to evaluate how much time it needed for the respiration to return to baseline values prior to handling. The longer it takes for these values to normalize, the more clinically significant the changes to the respiratory system are.

Once the respiration is evaluated at rest, the bird is handled to allow for a closer inspection of relevant body parts. Important parameters to assess include the bird's overall body condition (by assessing pectoral musculature and fat deposits), body weight, and hydration status (e.g. by testing skin tenting of the lower eyelid), as these provide general insight into the bird's overall health status and chronicity of the problem. Nest, the head of the bird is closely inspected. Particular attention is paid to the dorsal and cranial aspects of the head and the periorbital region, which are all carefully inspected for presence of subcutaneous masses or swellings, and rhythmic inflation of the sinuses (concurrent with each respiration). The nares and cere should be inspected for changes in size, shape, and symmetry; presence of lesions or other deformities; presence of nasal discharge, which may be visible as fluid or dried exudate in or around the nare(s), or result in staining of the surrounding feathers. Gentle pressure can be applied to the periorbital region and ceres to check whether exudate can be expelled from the nares or lacrimal ducts. The oropharynx should be inspected from up close, whereby special attention should be paid to the choanal slit and glottis. The choanal slit is evaluated for blunting of the choanal papilla (as can be observed with vitamin A deficiency, infections, and other diseases) and presence of swellings, exudate, plaques, or other lesions. The laryngeal opening or glottis is also evaluated for presence of swellings, lesions, or discharge that may block the entrance, as can be seen, for example, in case of infectious laryngotracheitis (ILT) in chickens *(Gallus gallus domesticus)* and other Galliformes. Dependent on the temperament and species, a paperclip, mouth gag, or speculum may need to be used to enhance visualization of these structures. Alternatively, tape or gauze loops can be used to open the beaks and facilitate examination. The mucous membranes should be assessed for color to determine if pallor (associated with anemia) or cyanosis (indicative of severe hypoxia) are present. In chickens and other Galliformes, anemia and cyanosis are often noticeable upon inspection of the combs or wattles. Severe forms of anemia can also lead to pale discoloration of the iris.

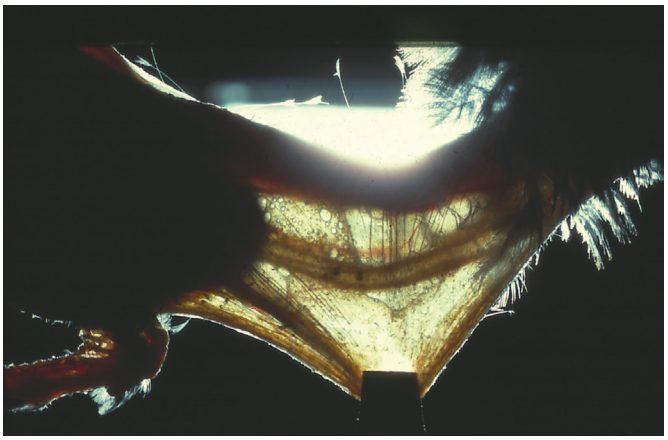

FIGURE 27.1 In small birds, transillumination using a bright light source may be useful to detect foreign bodies or tracheal mites, as can be seen in this Gouldian finch *(Chloebia gouldiae)*. (Photo courtesy Gerry Dorrestein.)

The physical examination continues with an evaluation of the neck and trachea. The neck should be closely inspected and palpated for abnormalities, such as hyperinflation of the cervicocephalic diverticulum. Palpation of the trachea may reveal anatomic alterations indicative of trauma, which are commonly accompanied by subcutaneous emphysema (see also Chapter 34). In smaller passerines and psittacines, transillumination of the trachea can be helpful to identify intraluminal abnormalities, such as tracheal mites (Figure 27.1) or foreign bodies (e.g., millet seed that got stuck in the trachea of a cockatiel

The lungs and air sacs can be auscultated over the dorsum and flanks, respectively. Ideally, a good-quality pediatric or infant stethoscope should be used. Although the lungs in birds do not change in size during respiration, auscultation may still provide valuable information as crackles may be heard in case of lung alterations and a lack of sounds may indicate a large lesion in the lung. Friction or wheezes may be heard in case of an airsacculitis. Heart auscultation, which is performed over the sternum, is warranted in patients suspected of lung edema or ascites due to cardiovascular disease. (see Current Therapy in Avian Medicine and Surgery, Vol 1, Chapter 6, Cardiology).

The respiratory examination is concluded with a palpation of the coelomic region. The distance from the sternum to the pubic bones and interpubic distance are evaluated to determine whether there is coelomic distension leading to compression of the air sacs. Ascites, eggs, or masses can often be discerned following careful exterior palpation. In larger species (e.g., macaws, chickens), a cloacal palpation can also be performed, while in smaller birds, detailed inspection of the internal organs may be possible following wetting of the feathers (e.g., using alcohol) and subsequent transillumination of the region using a bright light source.

While other aspects of the physical examination may bear relevance to the underlying condition and management of the patient (e.g. assessment of fractures in case of traumatic events), their further evaluation will depend greatly on the patient's condition and how well it coped with the examination (see also Chapter 34).

BOX 27.1 CLINICAL SIGNS ASSOCIATED WITH INVOLVEMENT OF THE SPECIFIC PARTS OF THE RESPIRATORY TRACT

Part of the Upper Respiratory Tract Involved in the Disease Process	Clinical Signs Associated With Involvement of the Specific Parts of the Respiratory Tract
Nares and nasal cavity	◆ Sneezing ◆ Nasal discharge ◆ Staining or dried discharge in the feathers surrounding the nares ◆ Nasal plugs, occlusion of the nares ◆ Abnormally shaped nares ◆ Swollen cere ◆ Scratching or rubbing of the beak (with or without concurrent feather loss) ◆ Head shaking ◆ Yawning ◆ Discharge or mucus in the choanal slit ◆ Open-beak breathing ◆ Epiphora, conjunctivitis ◆ Longitudinal groove(s) in the beak (chronic rhinitis) ◆ Often seen in combination with sinusitis
Sinuses	◆ Periorbital swelling (may be soft, firm, or fluctuating) ◆ Protrusion of the eye (exophthalmos) ◆ Sunken eyes (chronic sinusitis, particularly in macaws) ◆ Scratching or rubbing of the head ◆ Periorbital feather loss ◆ Often seen in combination with rhinitis
Trachea and/or syrinx	◆ Loss of vocalization ◆ Change of pitch or voice ◆ Abnormal breathing sounds (stridor), particularly on inspiration ◆ Head shaking ◆ Coughing ◆ Gurgling ◆ Dyspnea, breathing with an open beak and tail bobbing ◆ Breathing with an extended neck
Lungs and/or air sacs	◆ Severely altered respiration pattern or frequency, e.g., increased sternal movements ◆ Accessory respiratory movements, most notably tail bobbing ◆ Exercise intolerance; slow recovery following handling or activity ◆ Respiratory sounds including wheezes, friction, or crackles upon auscultation ◆ Weakness, collapse ◆ Often accompanied by other clinical signs indicative of general malaise such as weight loss, failure to gain weight (in raptors), fluffed up appearance, loss of appetite
Air sac compression due to space-occupying lesions in the coelomic cavities	◆ Rapid, shallow respiration pattern ◆ Widened leg stance ◆ Increased sternal-pubic and/or interpubic distance, or bulging of the coelom ◆ Palpable mass (e.g., egg) in the abdominal region ◆ Hunched posture with kinking of the tail ◆ Other clinical signs such as tenesmus, unilateral paresis/paralysis can be present

Modified from van Zeeland YRA: Upper respiratory tract disease. In Chitty J, Monks D, editors: *BSAVA Manual of avian practice: a foundation manual*, Quedgeley, UK, 2018, BSAVA British Small Animal Veterinary Association, pp. 299–316.

DIAGNOSTIC WORKUP

Dependent on history and the physical exam findings, it may already be possible to specify the anatomical location involved in the respiratory distress (Box 27.1):

- Nasal discharge, sneezing and/or staining, or dried discharge in the feathers around the nares suggest involvement of the nasal cavity.
- Periorbital swellings or sunken eyes (especially in macaws) point toward sinus involvement.
- In case of tracheal or syringeal disease, signs often include coughing, abnormal breathing sounds (stridor), and change in pitch or voice (particularly in psittacine birds).
- Frictions, crackles, or wheezes heard upon auscultation are suggestive of involvement of the lungs or air sacs in the disease process.
- A widened leg stance, increased interpubic or sternopubic distance, or palpable mass is indicative of space-occupying lesions in the coelomic cavity.

Differential diagnoses for each of the aforementioned locations can be found in Tables 27.1 to 27.4.

Dependent on the suspected location of the problem, additional workup may include one or more of the following diagnostic tests:

- Nasal or sinus flushing, including collection of samples for cytology, bacteriology, mycology, parasitology (wet mount),

TABLE 27.1

Differential Diagnosis for Nasal/Sinus Disease (Distorted Nares, Nasal Discharge, Sinus Swelling)

Differential Diagnosis	Comments
BACTERIAL INFECTIONS	
Gram-negative bacteria (e.g., *E. coli*, *Haemophilus*, *Klebsiella*, *Pasteurella*, *Pseudomonas*), gram-positive bacteria (e.g., *Mycobacterium*, *Streptococcus*, *Staphylococcus*)	Gram-negative infections most common; *Haemophilus* in chickens *(Gallus gallus domesticus)* (see Chapter 6)
Spirochetes	Spirochetes in cockatiels *(Nymphicus hollandicus)* of 3–10 weeks of age (lockjaw syndrome; see Chapters 31 and 41)
Chlamydia psittaci	All bird species susceptible; consider in all birds that have recently been in contact with other birds; often systemic illness (see Chapter 18)
Mycoplasma spp.	Common in smaller Psittaciformes (budgerigars *[Melopsittacus undulatus]*, cockatiels *[Nymphicus hollandicus]*), Passeriformes, Galliformes (see Chapter 20)
FUNGAL INFECTIONS	
Aspergillus spp., *Candida albicans*, *Cryptococcus* spp., *Mucor* spp.	Common in birds with malnutrition or stress; formation granulomas that block the trachea or syrinx; may also affect other parts of the respiratory system (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease) *Cryptococcus* infrequently causes disease in birds (see Chapter 21)
VIRAL INFECTIONS	
Avian influenza, herpesvirus, poxvirus, reovirus	Poxvirus common in Columbiformes, Galliformes, Passeriformes (canaries [Serinus canaria]), birds of prey (see Chapter 15)
PARASITIC	
Cryptosporidium spp.	Particularly in Galliformes, birds of prey (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease)
Trichomonas gallinae	Columbiformes, Passeriformes, smaller psittacines, birds of prey (see Chapter 22)
Aprocta cylindrical	Nematode, identified in European robins *(Erithacus rubecula)*, a variety of African and Asia passerines, and a parrot
Knemidocoptes (scaly mite)	Particularly in budgerigars *(Melopsittacus undulatus)*
NUTRITIONAL	
Hypovitaminosis A, resulting in squamous metaplasia and noninfectious granulomas	Particularly in Psittaciformes fed an all-seed diet and/or eating selectively
Rhinolithiasis	Often resulting from nutritional imbalances, particularly hypovitaminosis A, leading to squamous metaplasia of the epithelium (see Chapter 28)
ALLERGIC	
Inhalant allergens (e.g., smoke, perfume, feather dander)	Macaws *(Ara spp.)* may be more susceptible (see Chapter 28)
TOXIC	
Cigarette or tobacco smoke, aerosol sprays, ammonia	History, demonstrating a relationship between exposure and time of onset of clinical signs, is suggestive (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 18, Advancements in Diagnosis and Management of Toxicologic Problems)
NEOPLASTIC	
Lymphoma, fibrosarcoma, (adeno)carcinoma, melanoma, papilloma, squamous cell carcinoma, etc.	Older birds (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 3, Neoplastic Diseases in Avian Species)
ENVIRONMENTAL	
Low humidity, dust, feather dander of other birds (notably cockatoos, [Cacatuidae], grey parrots [*Psittacus erithacus*])	Birds housed under suboptimal conditions (see Chapter 28)
FOREIGN BODY	
For example, millet seed	May result in secondary rhinitis
TRAUMA	
Resulting in (subcutaneous) hemorrhage, emphysema, distortion, and/or fractures	History is suggestive (see Chapter 34)

TABLE 27.1

Differential Diagnosis for Nasal/Sinus Disease (Distorted Nares, Nasal Discharge, Sinus Swelling)—cont'd

Differential Diagnosis	Comments
COAGULOPATHY	
Bleeding disorders resulting in epistaxis (e.g., conure bleeding syndrome)	Conure bleeding syndrome (only in conures, including -but not limited to - the blue-crowned conure *[Thectocercus acuticaudatu]*, nanday conure *[Aratinga nenday]*, sun conure *[Aratinga solstitialis]*, peach-fronted conure *[Eupsittula aurea]*, orange-fronted conure *[Eupsittula canicularis]*, and Patagonian conure *[Cyanoliseus patagonus]*)
HORMONAL, ENDOCRINE	
Brown cere hypertrophy	Hormone-related, female budgerigars *(Melopsittacus undulatus)*
CONGENITAL DEFORMITIES	
Choanal atresia	Young birds (particularly grey parrots *[Psittacus erithacus]*; see Chapters 31 and 41)

Modified from van Zeeland YRA: Upper respiratory tract disease. In Chitty J, Monks D, editors: *BSAVA Manual of avian practice: a foundation manual*, Quedgeley, UK, 2018, BSAVA British Small Animal Veterinary Association, pp 299–316.

TABLE 27.2

Differential Diagnosis for Tracheal Disease (Voice Change, Stridor, Coughing)

Differential Diagnosis	Comments
BACTERIAL INFECTIONS	
Gram-negative (e.g., *Pseudomonas*)	Common in cockatoos (Cacatuidae); resulting in diphtheritic plaques and granulomas (see also Chapter 6)
Chlamydia psittaci	All bird species susceptible; consider in all birds that have recently been in contact with other birds; often systemic illness (see Chapter 18 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease)
FUNGAL INFECTIONS	
Aspergillus spp.	Common in birds with malnutrition or stress; formation granulomas that block the trachea or syrinx; may also affect other parts of the respiratory system (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease)
VIRAL INFECTIONS	
Adenovirus, avian influenza virus, cytomegalovirus, herpesvirus (e.g., Amazon tracheitis), poxvirus, polyomavirus, paramyxovirus	Species commonly affected: Cytomegalovirus: finches (Fringillidae) Herpesvirus: finches (Fringillidae), Amazon parrots *(Amazona spp.)*—rare (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease) Poxvirus: Columbiformes, Galliformes, Passeriformes (canaries *[Serinus canaria]*), birds of prey (see Chapter 15) Paramyxovirus: birds of prey, chickens (Newcastle disease) (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 15, Management and Medicine of Backyard Poultry)
PARASITIC	
Cryptosporidium spp. Gape worms: *Syngamus trachea*, *Cyathostoma* spp. Tracheal mites: *Sternostoma tracheacolum*, *Cytodites* spp. *Trichomonas gallinae, Tetratrichomonas anatis*	Species commonly affected: Cryptosporidiosis: Galliformes, birds of prey (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease) Gape worms: larger Passeriformes (e.g., crows *[Corvus spp.]*, starlings [Sturnidae]), chickens *(Gallus gallus domesticus)* Tracheal mites: smaller Passeriformes (e.g., canaries *[Serinus canaria]*, finches [Fringillidae]) Trichomoniasis: Columbiformes, Passeriformes, birds of prey, smaller Psittaciformes (see Chapter 22) Tetratrichomoniasis: Anseriformes
NUTRITIONAL	
Hypovitaminosis A, resulting in squamous metaplasia and noninfectious granulomas	Particularly in Psittaciformes fed an all-seed diet and/or eating selectively

Continued

TABLE 27.2

Differential Diagnosis for Tracheal Disease (Voice Change, Stridor, Coughing)—cont'd

Differential Diagnosis	Comments
ALLERGIC	
Inhalant allergens (e.g., smoke, perfume)	Macaws [*Ara* spp.] may be more susceptible? (see Chapter 28)
TOXIC	
Airborne toxins, e.g., cigarette or tobacco smoke, perfume, aerosol sprays	History, demonstrating a relationship between exposure and time of onset of clinical signs, is suggestive (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 18, Advancements in Diagnosis and Management of Toxicologic Problems)
ENVIRONMENTAL	
Dust, dander of other birds (particularly cockatoos, [Cacatuidae], grey parrots *[Psittacus erithacus]*)	Birds housed under suboptimal conditions (see Chapter 28)
NEOPLASTIC	
Carcinoma, adenocarcinoma, papilloma, squamous cell carcinoma, tracheal osteochondroma, etc.	Older birds (see see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 3, Neoplastic Diseases in Avian Species)
FOREIGN BODY	
For example, millet seed	Common in cockatiels *(Nymphicus hollandicus)*
TRAUMA	
Postintubation stricture, resulting in tracheitis and stenosis	History is suggestive; macaws (*Ara* spp.) may be predisposed (see Chapter 28)
IATROGENIC	
Aspiration of food, medication	May result in acute asphyxia and death
EXTRAMURAL MASSES OR COMPRESSION	
Goiter; granulomas; neoplasia	Goiter common in budgerigars *(Melopsittacus undulatus)* as a result of all-seed diet resulting in iodine deficiency (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 10, Clinical Endocrinology of the Protein Hormones)
Fractures of the coracoid bone (excessive callus formation)	

Modified from van Zeeland YRA: Upper respiratory tract disease. In Chitty J, Monks D, editors: *BSAVA Manual of avian practice: a foundation manual*, Quedgeley, UK, 2018, BSAVA British Small Animal Veterinary Association, pp 299–316.

TABLE 27.3

Differential Diagnosis for Disease Affecting the Lungs and/or Air Sacs

Differential Diagnosis	Comments
BACTERIAL INFECTIONS	
Gram-negative (e.g., *Pseudomonas, Salmonella*), gram-positive (e.g., *Nocardia*)	May occur secondary to inflammatory disease (see Chapter 6)
Chlamydia psittaci	All bird species susceptible; consider in all birds that have recently been in contact with other birds; often systemic illness (see Chapter 18 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease)
Mycoplasma spp.	Common in Galliformes, Passeriformes; often difficult to diagnose (see Chapter 20)
Mycobacterium spp.	Commonly *M. avium-M. intracellulare, M. genavense*; causes granulomatous or miliary pneumonia, systemic disease; occasionally involvement of the air sacs (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease)
FUNGAL INFECTIONS	
Aspergillus spp.	Common in birds with malnutrition or stress; granulomas in the lungs and/or air sacs (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease)
VIRAL INFECTIONS	
Avian influenza virus, infectious bronchitis, herpesvirus (e.g., Amazon tracheitis, parakeet herpesvirus), poxvirus, polyomavirus, paramyxovirus I, reovirus	Species commonly affected: Infectious bronchitis—chickens (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease and Chapter 15, Management and Medicine of Backyard Poultry) Poxvirus: Columbiformes, Galliformes, Passeriformes (canaries) *[Serinus canaria]*) (see Chapter 15) Polyomavirus: nestling psittacines (cockatoos [Cacatuidae], macaws [*Ara* spp.])

TABLE 27.3

Differential Diagnosis for Disease Affecting the Lungs and/or Air Sacs—cont'd

Differential Diagnosis	Comments
PARASITIC	
Sarcocystis spp. *Leukocytozoon* spp. *Toxoplasma gondii* *Sternostoma tracheocolum* Nematodes, e.g., *Serratospiculum, Syngamus/Cyathostoma* Trematodes (*Circumvitellatrema* spp.), Pentastomids	Species commonly affected: *Sarcocystis falcatula*: definitive host—Virginia opossum; *(Didelphis virginiana)*; cowbirds (*Molothrus* spp.) and grackles (*Quiscalus* spp.)—intermediate hosts; parrots are inadvertent hosts (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease) *Sternostoma*: finches (Fringillidae), canaries *(Serinus canaria)* *Syngamus/Cyathostoma:* seen particularly in birds (Galliformes, softbills) kept in soil- or turf-based aviaries *Serratospiculum:* common in birds of prey from the Middle East *Circumvitellatrema* spp. have been described in barbets (Capitonidae, Lybiidae, Megalaimidae, Semnornithidae), mynahs (*Acridotheres* spp.), motmots (Momotidae); trematode uses terrestrial snails as part of its life cycle
NUTRITIONAL	
Hypovitaminosis A, resulting in squamous metaplasia of the bronchi	Particularly in Psittaciformes fed an all-seed diet and/or eating selectively; predisposes to secondary bacterial and fungal infections
Pulmonary mineralization	Excess dietary calcium or severe renal disease
ALLERGIC	
Inhalant allergens (e.g., smoke, perfume) Macaw pulmonary hypersensitivity	History, demonstrating a relationship between exposure and time of onset of clinical signs, is suggestive (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 18, Advancements in Diagnosis and Management of Toxicologic Problems). Macaw pulmonary hypersensitivity likely due to exposure to dander from grey parrots *(Psittacus erithacus)* or cockatoos (Cacatuidae) (see Chapter 28)
TOXIC	
Polytetrafluoroethylene (PTFE, Teflon) Other airborne toxins, e.g., cigarette or tobacco smoke, perfume, aerosol sprays	Diagnosis based on history (cooking with new pans or other cooking utensils with nonstick coating); very common; often leads to death unless very small amounts are inhaled (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 18, Advancements in Diagnosis and Management of Toxicologic Problems).
ENVIRONMENTAL	
Pneumoconiosis, e.g., due to exposure to airborne pollutants	Birds housed under suboptimal conditions
Chronic pulmonary interstitial fibrosis	Particularly common in (older) Amazon parrots, (*Amazona* spp.), possibly associated with right-sided heart failure (see Chapter 28 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 6, Cardiology)
NEOPLASTIC	
Primary: Bronchial (adeno)carcinoma, air sac cystadenocarcinoma, fibrosarcoma, undifferentiated pulmonary tumors, etc.	Older birds
Secondary: metastases	Tumor metastases in the lungs include metastases from (adeno)carcinoma, fibrosarcoma, hemangiosarcoma, liposarcoma, lymphosarcoma, melanoma, mesothelioma, and osteosarcoma (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Neoplastic Diseases in Avian Species)
FOREIGN BODY	
Embolic pneumonia	Pulmonary emboli from fat, bone marrow, and egg yolk have been recognized.
Inhalation of foreign material	Potentially due to trauma
TRAUMA	
Air sac rupture, hemorrhage	History is suggestive (see Chapter 34)
IATROGENIC	
Aspiration of food, medication	Aspiration of hand-feeding formula, particularly in hand-fed psittacine chicks; may result in acute asphyxia and death (see Chapter 41)
CARDIOVASCULAR	
Lung edema	Due to left-sided cardiac insufficiency, pulmonary hypertension; particularly in older birds (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 6, Cardiology)
IMMUNE-MEDIATED	
Amyloidosis	In response to many chronic conditions
IDIOPATHIC	
Endogenous lipid pneumonia	Unknown cause; may represent storage disease or acquired disorder due to reduced airway clearance

Continued

TABLE 27.3

Differential Diagnosis for Disease Affecting the Lungs and/or Air Sacs—cont'd

Differential Diagnosis	Comments
Pulmonary proteinosis	Characterized by eosinophilic, amorphous, or crystalline material within the lumen of tertiary bronchi and air capillaries; cause and significance are unknown
Osseous metaplasia	Characterized by small spicules of bone in the pulmonary parenchyma, particularly in older birds; cause and significance are unknown
Melanosis	Pigment deposition in the lungs of larger birds, particularly cockatoos (Cacatuidae); should be considered normal

Modified from van Zeeland YRA: Upper respiratory tract disease. In Chitty J, Monks D, editors: *BSAVA Manual of avian practice: a foundation manual*, Quedgeley, UK, 2018, BSAVA British Small Animal Veterinary Association, pp 299–316.

TABLE 27.4

Differential Diagnosis for Extrarespiratory Disease Resulting From Coelomic Distension

Differential Diagnosis	Comments
ASCITES	
(Modified) transudate	Cardiac disease, liver cirrhosis, hypoproteinemia/hypoalbuminemia (e.g., due to renal disease, hepatopathy, protein-losing enteropathy), neoplastic (e.g., mesothelioma) (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 3, Neoplastic Diseases in Avian Species, Chapter 6, Cardiology, and Chapter 8, Pleura, Pericardium, and Peritoneum: The Coelomic Cavities of Birds and Their Relationship to the Lung–Air Sac System)
Exudate	Egg yolk coelomitis to peritonitis, e.g., due to intestinal perforation
Blood	Trauma (e.g., liver rupture), coagulopathy
ORGANOMEGALY	
Proventricular dilatation disease	Common in psittacine birds; avian ganglioneuritis, associated with bornavirus infection (see Chapter 14 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease)
Intestinal impaction, ileus	Mechanical obstruction (e.g., neoplasia, foreign body); paralytic ileus (e.g., heavy metal toxicity; see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 18, Advancements in Diagnosis and Management of Toxicologic Problems)
Hepatomegaly	
Renal	
Gonadal	Fatty liver; viral or bacterial hepatitis (e.g., *Chlamydia* spp.); aflatoxicosis; neoplastic (e.g., lymphoma) (see Chapter 18 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease, Chapter 3, Neoplastic Diseases in Avian Species, Chapter 18, Advancements in Diagnosis and Management of Toxicologic Problems)
	Neoplasia (e.g., renal carcinoma; see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 3, Neoplastic Diseases in Avian Species), cysts; hydronephrosis
	Cysts; testicular or ovarian neoplasia Cysts; testicular or ovarian neoplasia (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 3, Neoplastic Diseases in Avian Species)
FAT ACCUMULATION	
Obesity; nutritional	Birds with a sedentary lifestyle, being fed ad libitum, often seed-based diets. Particularly common in Amazon parrots (*Amazona* spp.), galahs *(Eolophus roseicapillus)*, budgerigars *(Melopsittacus undulatus)*
EGG	
Egg binding	Often related to calcium deficiency, but other options (e.g., oviductal torsion, salpingitis, neoplastic processes, geriatric birds, primiparity, obesity) also possible
TRAUMATIC	
Ventral abdominal herniation	Common in female birds, related to chronic reproductive problems (e.g., excessive egg laying; see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 12, Reproduction))

Modified from van Zeeland YRA: Upper respiratory tract disease. In Chitty J, Monks D, editors: *BSAVA Manual of avian practice: a foundation manual*, Quedgeley, 2018, BSAVA British Small Animal Veterinary Association, pp. 299–316.

and/or testing for specific pathogens (see Section 5: Updates on Infectious Diseases and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease);
- Choanal or pharyngeal swabs for further testing (as listed for nasal flushes);
- Tracheal swab or lavage for further testing (as listed for nasal flushes);
- Diagnostic endoscopy of the nasal cavity, trachea, and/or coelomic cavities, with subsequent sampling for culture and sensitivity testing, cytology, and/or histopathology (see Chapter 30);
- Hematology and biochemistry (see *Current Therapy in Avian Medicine and Surgery*, Vol 1., Chapter 13, Advances in Clinical Pathology and Diagnostic Medicine);
- Blood gas analysis;

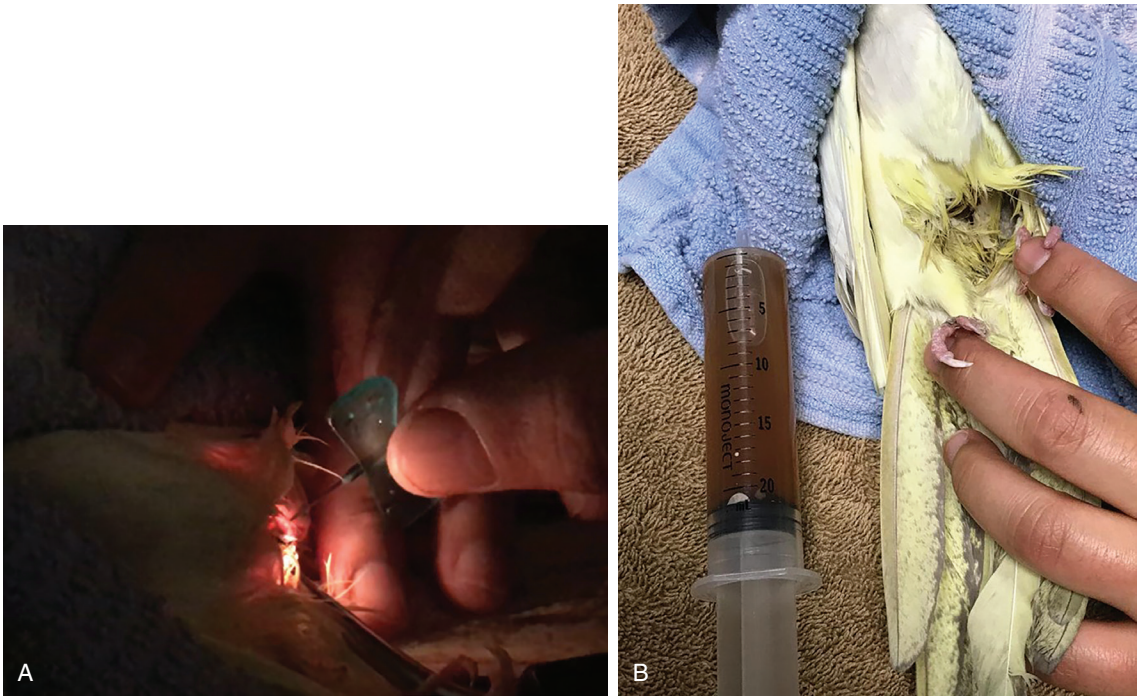

FIGURE 27.2 Coelomocentesis in a female cockatiel *(Nymphicus hollandicus)* with marked ascites. (A) There are three people involved in the procedure, which is performed in a darkened room: one person restrains the bird and provides flow-by oxygen, another transilluminates (light source is at the right lower aspect) and places the butterfly needle for aspiration, and a third aspirates fluid. (B) A total of 22 mL of transudative fluid was removed from this bird through a single puncture. Once stabilized, a primary diagnosis was able to be pursued and was confirmed to be ovarian carcinoma at surgery.(Photos courtesy Brian Speer.)

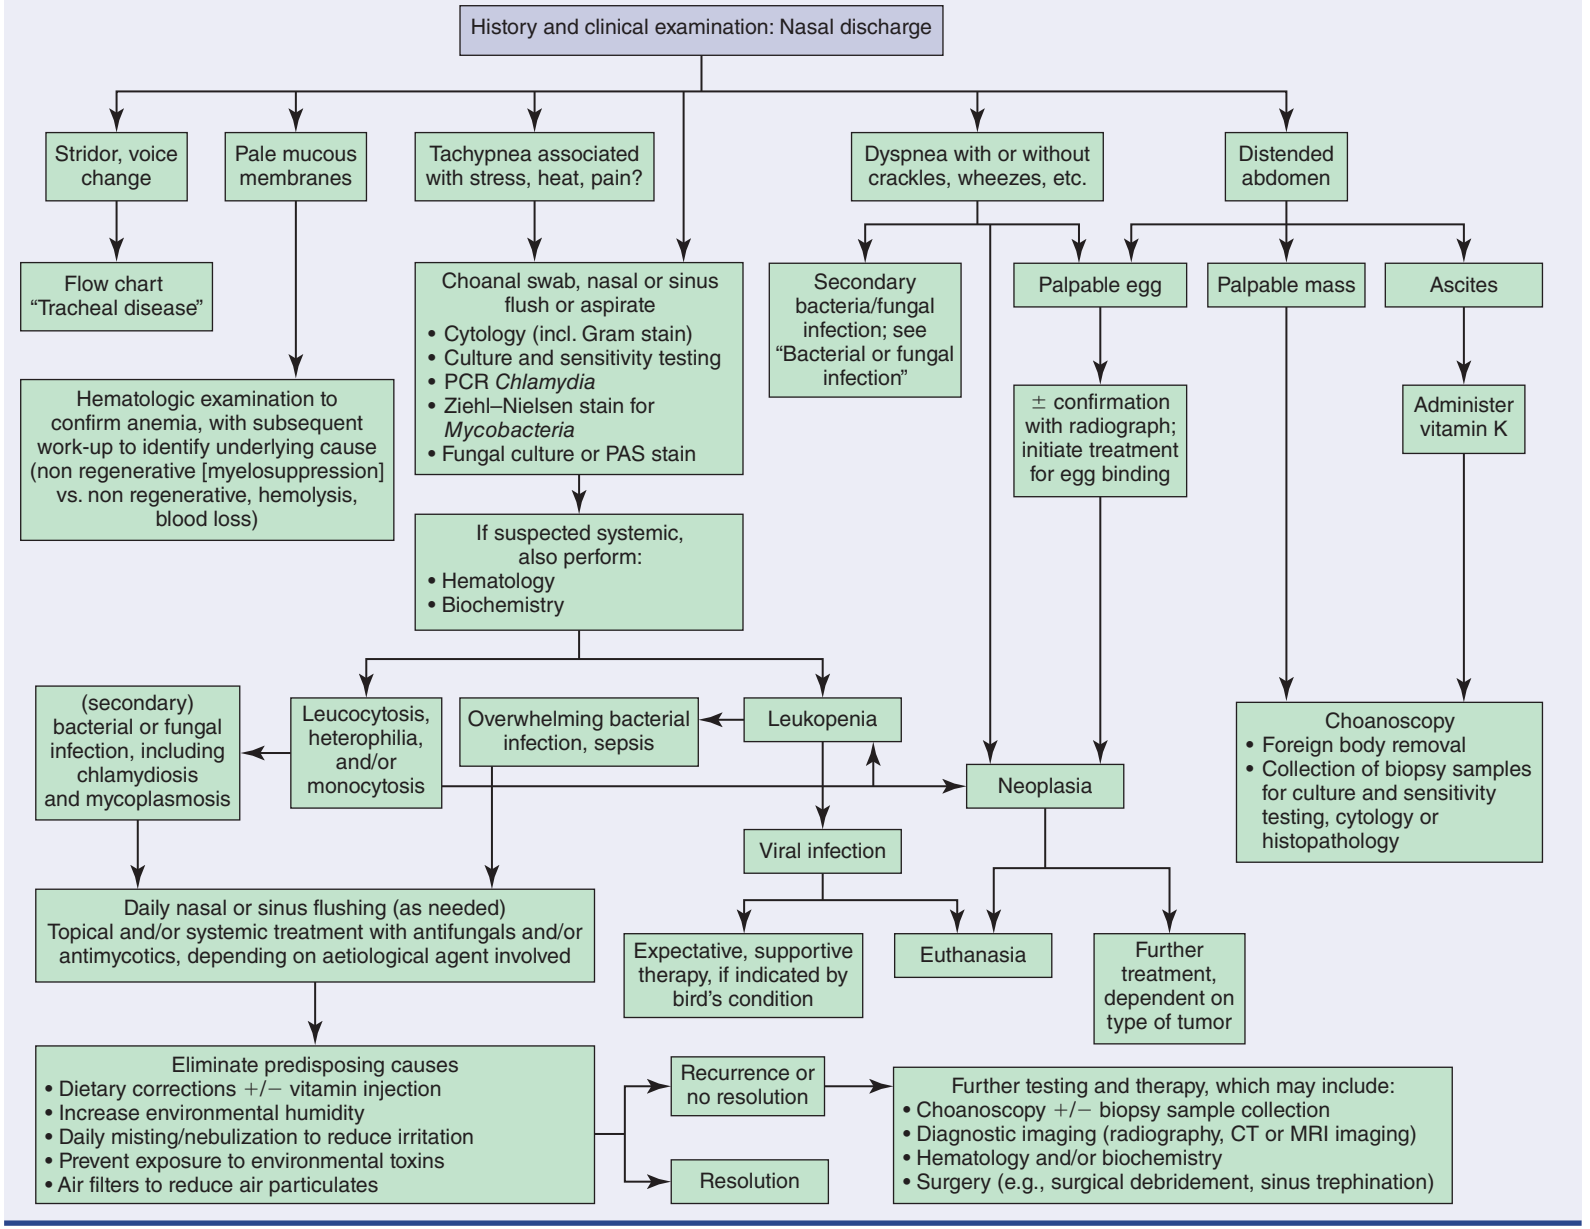
- Diagnostic imaging of the lungs and air sacs by means of radiography, standing fluoroscopy, and/or computed tomography (CT) (see Chapter 2 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 14, Advances in Diagnostic Imaging);
- Evaluation of the coelom by means of transillumination in small bird species (Figure 27.2), ultrasonography, radiography, and/or CT imaging (see Chapter 2 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 14, Advances in Diagnostic Imaging);
- Blind or ultrasound-guided coelomocentesis or fine needle aspirates for biochemical analysis, microbiology, and/or cytology (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 13, Advances in Clinical Pathology and Diagnostic Medicine);
- Fecal examination for presence of nematode eggs (*Syngamus trachea*, *Capillaria* spp.).

Boxes 27.2 to 27.4 provide flow diagrams to help guide the workup of nasal discharge, tracheal disease, and respiratory distress.

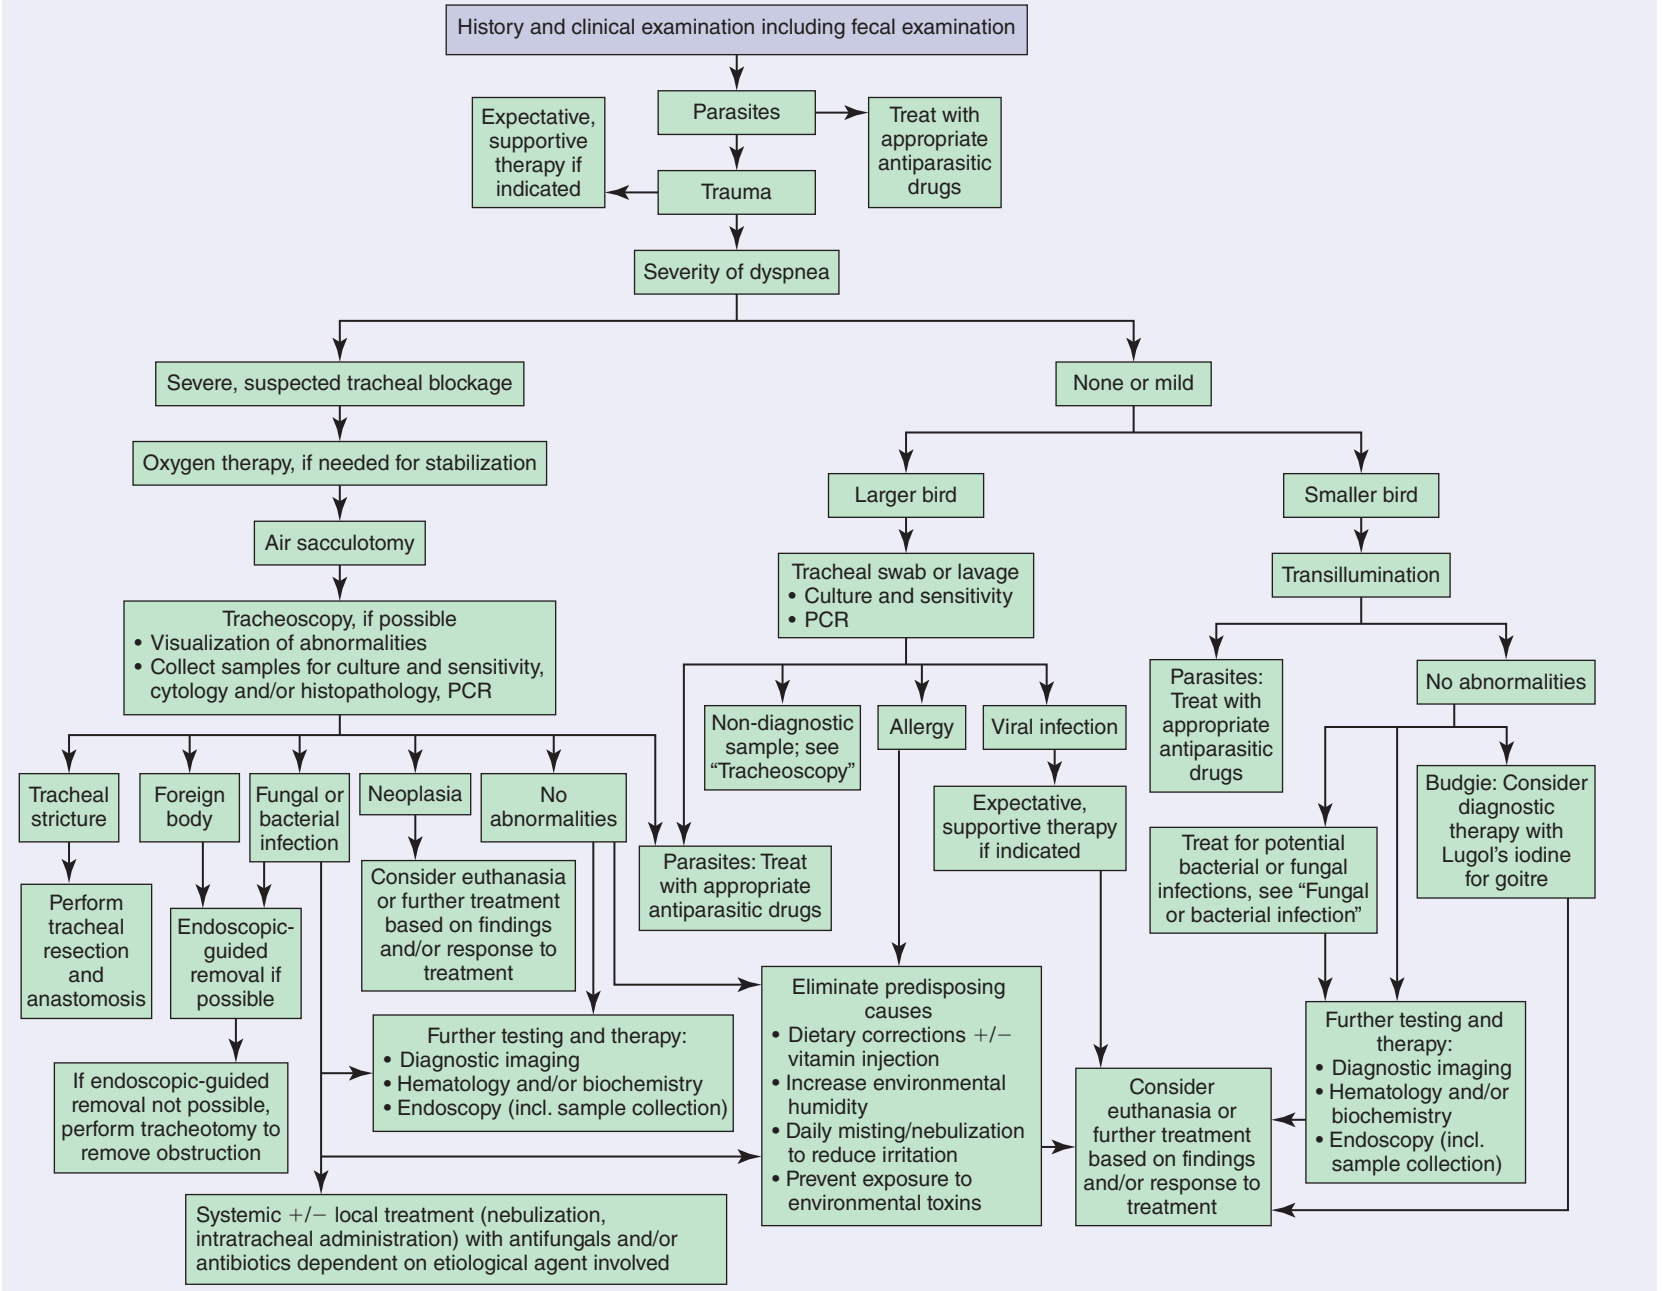
Nasal and Sinus Flushing



A nasal flush can be obtained with relative ease by placing a syringe filled with sterile, lukewarm saline in one of the nares, tilting the patient upside down, and then forcefully flushing the saline into the nasal passage while the other naris is simultaneously held closed with a finger (Figure 27.3). Commonly used volumes per naris include 3 to 5 mL for smaller birds (e.g., budgerigar, cockatiel), 6 to 12 mL for middle-sized birds (e.g., grey parrot, Amazon parrot), and 12 to 20 mL for larger-sized birds (e.g., large cockatoos, macaws). Flushing of the nares should be performed carefully while closely monitoring the patient as excessive and/or rapid flushing may cause the patient to aspirate fluids and suffocate. Following a nasal flush, the infused saline should be expelled via the choana and can be collected for, for example, cytology or microbiology.

Aside from obtaining samples, nasal flushing is also helpful from a therapeutic standpoint, helping to clear exudate from the nasal cavity and sinuses. However, the complex anatomy of the sinuses makes it difficult to successfully flush out all the material and remove the nidus of an infection, hence increasing the likelihood of relapse or reoccurrence of the infection. Infraorbital aspiration and flushing may therefore provide better results.

Collection of Swabs from the Choanal Slit



Swabs may be collected from the choanal slit to be submitted for cytology, microbiology, or testing for specific pathogens, such as *Chlamydia psittaci* (see Chapter 18 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). If fungal disease is suspected, samples may be submitted for periodic acid-Schiff staining or fungal culture; Ziehl-Nielsen staining or polymerase chain reaction (PCR) testing may be useful in case of suspected mycobacteriosis (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Results should always be interpreted with care since samples collected from the nares or nasal cavity may easily be contaminated. The normal flora of the nasal cavity in many bird species primarily consists of

FIGURE 27.3 Nasal flush in a blue-fronted Amazon parrot *(Amazona aestiva)*. For this procedure, the bird is tilted with the head and beak held low to prevent water from running into the trachea. After placing a syringe filled with sterile, lukewarm saline in one of the nares, the saline is forcefully flushed into the nasal passage, while the other naris simultaneously can be held closed with a finger. Often, material leaks out of the choanal slit, which may subsequently be collected for further workup (e.g., cytology, culture and sensitivity testing). (Photo courtesy Yvonne van Zeeland/Nico Schoemaker.)

gram-positive rods and cocci, while yeasts and/or gram-negative rods are less common as normal flora.[5–8] False-negative results may also occur, especially if *Mycoplasma* spp. are involved, which are notoriously difficult to isolate using routine testing (see Chapter 20).

Sinus Aspirate

Sinus aspirates may be collected from the ventral and rostral parts of the infraorbital sinus using a 22- to 25-gauge (G) needle and syringe (Figure 27.4; see also Chapter 29). It is preferable to sedate or anesthetize the patient for this procedure as sudden movement by the patient may lead to puncture of the eye or other vital structures.

The rostral area may be approached by inserting the needle at the commissure of the beak and directing it perpendicular to the skin below the jugal arch to a point between the eye and naris, whereas the ventral area may be approached from two directions:

- ventral to the jugal arch and just ventral to the eye, while holding the needle perpendicular to the skin;
- just caudal to the commissure of the beak while directing the needle toward the point ventral to the eye and jugal arch.

If aspiration fails to produce any material, sterile fluid may be infused into the sinus using one of the abovementioned locations. The collected fluid can be submitted for further microbial and cytological analysis. Should a surgical approach be indicated (see Chapter 29), biopsies can be collected from the sinus epithelium and submitted for histopathology or culture and sensitivity testing.

Tracheal Swabs or Lavage

In case of suspected tracheitis, tracheal swabs or lavage can be performed to collect material for cytology or microbial culture. Tracheal lavage is preferably performed under general anesthesia, using a soft, sterile tube to infuse sterile saline (0.5–10 mL/kg) into the trachea, which is subsequently aspirated using a sterile syringe that is attached to the tube. Alternatively, 18- to 22-G Teflon catheters may be transdermally inserted into the trachea.

Hematology and Biochemistry

In patients with respiratory distress, a complete blood count (CBC) and protein electrophoresis can be helpful to determine whether an infection is present. Although results rarely point toward a specific disease, a leukocytosis, heterophilia, or monocytosis may indicate presence of a (bacterial or fungal) infection or inflammation, whereas leukopenia is highly suggestive of presence of an overwhelming viral or bacterial infection. The hematocrit or packed cell volume (PCV) can be helpful to evaluate the presence of anemia (which may result

in tachypnea) or polycythemia, which can develop in response to chronic hypoxia, for example, due to lung fibrosis.

Blood Gas Analysis

Blood gas analysis of arterial blood samples provides superior information on the efficacy of gas exchange compared to venous blood samples.[9] However, obtaining arterial blood samples from dyspneic birds generally poses a greater risk for the patient as the handling is profoundly longer, and the risk of complications (e.g., hematoma formation, infection, and thrombosis) is high. Venous blood samples, on the other hand, can be obtained relatively quick, safe, and easy, with minimal stress for the bird. In mammals, venous blood samples are also used in case of acute exacerbation of chronic pulmonary disease. Blood gas analysis of these samples has been shown to correlate well with blood gas analysis of arterial samples and can therefore be used to reliably predict the arterial blood gas values.[10]

In recent years, multiple studies have been performed on healthy individuals from different bird species. Except for Amazon parrots, in which results were obtained from arterial samples, venous blood samples were used. Table 27.5 summarizes the data on blood gas analysis in the various bird species.

Aside from the type of blood sample collected, circumstances under which the samples are obtained also influence the results. When blood is collected using sedation or anesthesia, results are commonly influenced, for example, as a result of supplemental oxygen being provided during, for example, isoflurane anesthesia, or as a result from hypoventilation that can occur as a result of the drugs used for sedation/anesthesia (Table 27.6).[22]

Despite the increasing number of studies in healthy birds, data on blood gases in birds with respiratory diseases are still limited[21] and warrant further studies to enable evaluation of their true merit.

Conventional Radiography versus Computed Tomography

In the first volume of *Current Therapy in Avian Medicine and Surgery*, an extensive chapter (Chapter 14) was devoted to Advances in Diagnostic Imaging.[23] With the ongoing advancements and increased availability of CT imaging, this modality seems to be gaining popularity in clinical practice. It has been demonstrated many years ago that CT is superior to conventional radiography for evaluation of the respiratory tract (Figure 27.5).[24] Preliminary results from a more

The arrow in ventrodorsal radiograph (A) indicates the location that is suggestive for the lesion that is clearly seen on the CT image (C). On the lateral view of the radiograph (B), however, no such lesion can be clearly distinguished. *CT,* Computed tomography.

recent study comparing the interpretation of plane radiographs and CT images with postmortem results also showed that avian and radiology specialists who were asked to evaluate both the radiographs and CT could identify all lesions that were present on postmortem examination through CT while missing 50% of the pathologies on radiography, particularly those situated in the lungs. Additionally, 50% of the lesions that were identified upon radiography turned out to be absent on pathology, hence indicating that conventional radiography poses a high risk for misdiagnoses, including both false-negative and false-positive results (M. Huynh, personal communication).

CHAPTER 28

Diseases of the Respiratory Tract

Hugues Beaufrère

Visit eBooks.Health.Elsevier.com for a complete set of references.

NASAL AND SINUS DISEASES

Rhinitis and sinusitis are common diseases in birds. They frequently extend to the periorbital region, and have the potential to also spread to other structures of the head owing to the extensive pneumatization of the head. Sinus exudates do not drain well in birds because of the dorsal location of the sinus opening into the nasal cavity (see Chapter 26) and the thick nature of many inflammatory exudates.

Infectious rhinitis and sinusitis may be caused by a variety of agents and frequently manifest as nasal discharge, periorbital swellings, redness, and facial feather loss (Figure 28.1). Gram-negative bacteria, *Chlamydia psittaci*, and *Mycoplasma* spp. are frequently cited as common etiologic agents in various species of birds. Uncomplicated chlamydiosis in cockatiels *(Nymphicus hollandicus)* and pigeons *(Columba livia domesticus)* frequently presents solely as mild rhinitis and conjunctivitis. Poultry suffer from a high rate of sinusitis for which *Mycoplasma gallisepticum*, *Avibacterium paragallinarum* (infectious coryza of chickens, formerly *Haemophilus*), and *Bordetella avium* (turkey coryza) are common etiologic agents.[1] *Mycoplasma gallisepticum* is also a significant pathogen causing significant morbidity in house finches *(Haemorhous mexicanus)* in North America and typically presents as conjunctivitis and sinusitis.[2] Mycoplasma infection is also associated with upper respiratory disease in psittacine birds.[3] In Falconiformes and Accipitriformes, *Mycoplasma* spp. appear to be commensal organisms.[4,5] *Mycobacterium tuberculosis* and *M. marinum* have been associated with upper respiratory granulomas in psittacine birds.[6–10] Spiral bacteria (spirochetes) have been implicated in upper respiratory disease, pruritus, and infection of the choanal slit and oral cavity in (juvenile) cockatiels (see also "lockjaw syndrome" in Chapter 31 and 41).[11] Chronic sinusitis in macaws may lead to the so-called sunken-eye syndrome.[7,12] Diagnosis is typically achieved through computed tomography (CT) scan of the head, endoscopy of the nares, choana, and/or culture of choanal swabs or sinus samples. Projection radiographs are not sensitive for these disorders except in severe cases and in larger species of birds (see Chapter 27).

Medical treatment for rhinitis and sinusitis depends on the isolated bacterial or fungal pathogen and the amount of necrotic and caseous debris present in the upper airways. Aerosol therapy may help humidify the nasal passage and facilitate local delivery of antimicrobials. Flushing the nasal cavity with saline with or without antimicrobials and/or mucolytics may help dislodge nasal debris. The head is typically held down to prevent aspiration of instilled liquid. Nasal flushing may be performed once to twice daily for several days/weeks. A nasal flush formula has been described combining amphotericin B, trypsin, and neomycin.[13] More drastic debridement is usually needed in case of rhinoliths (see later). In terms of general management and prevention, increasing the environmental humidity is frequently beneficial in psittacine species considering their natural tropical range. Improving air quality with high-efficiency particulate air (HEPA) filter may also help decrease potential airborne toxins and allergens.

Chronic granulomatous rhinitis (or rhinolith) is frequently encountered in psittacine birds on a seed-only diet and is particularly common in cockatiels, grey parrots *(Psittacus erithacus)*, and Amazon parrots (*Amazona* spp.). It seems to be promoted by nutritional deficiencies, most notably those in vitamin A. Concretions of desquamated epithelium, debris, necrotic, and inflammatory materials occupy the nasal cavity and induce progressive tissue destruction, which can be extensive. Opportunistic organisms frequently involved in the disease process include a variety of gram-negative bacteria (*Escherichia coli*, *Enterobacter* spp., *Pseudomonas* aeruginosa, *Klebsiella* spp.) and fungi (*Aspergillus* spp., *Candida* spp., *Cryptococcus* sp., Zygomycetes).[7,12] Nasal plugs consecutive to chronic rhinitis also occur in falcons.[14] It is recommended to use surgical loupes with a light source to facilitate thorough debridement of the nasal cavities and preserve the nasal operculum (only in parrots). Debridement should be done with caution as the nasal structures are fragile and are prone to bleeding. A small dental curette or an equivalent instrument with a narrow extremity should be used to remove the concretion starting at the edges to detach it from the nasal wall. The granuloma is either removed *in toto* or in fragments. Once the bulk of the granuloma is removed (Figure 28.2), the nasal cavity is thoroughly debrided with a mixture of curettage and flushing with physiological saline. (Note: The bird should be intubated to prevent aspiration during nasal irrigation; see also Chapter 29.) The nasal deficit left by the granuloma is often extensive and permanent. Granulomatous materials should be submitted for bacterial and fungal culture, and topical treatment should be pursued. Since the integrity and function of the nasal structures are compromised, this procedure would unfortunately have to be repeated periodically to clean nasal debris that constantly accumulates. A rigid endoscope may be used to explore the nasal cavities after debridement.

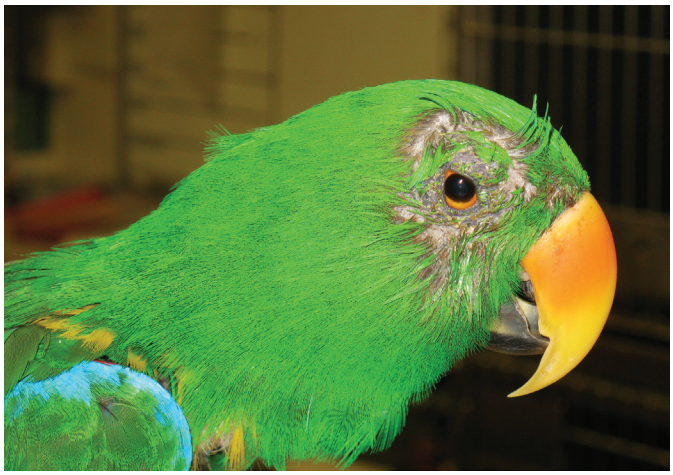

FIGURE 28.1 Periocular feather loss in an Eclectus parrot *(Eclectus roratus)* diagnosed with infraorbital sinusitis.

FIGURE 28.2 Rhinoliths removed from the nasal cavities of a grey parrot *(Psittacus erithacus)*.

For chronic sinusitis or granulomatous sinusitis, a sinusotomy or sinus trephination may be attempted. The infraorbital sinus is generally easily approached from just below the eye and jugal arch (Figure 28.3).[15] Sinus trephination is rarely performed but may allow access to hard-to-reach sinus diverticula such as in the maxillary or frontal bone (see also Chapter 29). An example of such indication can be found in a case report of a Swainson's toucan *(Ramphastos ambiguus swainsonii)* with rhinosinusitis.[16]

Viruses with specific nasal and sinus tropism are uncommon, but turkey rhinotracheitis is caused by a pneumovirus. Poxvirus infection may cause localized skin diseases around the nostrils (see Chapter 15). *Cryptococcus neoformans* was identified as the cause of a chronic rhinosinusitis in a Major Mitchell's cockatoo *(Cacatua leadbeateri)* (see Chapter 21).[17] Parasitic diseases of the nasal and sinus system are less common. Knemidocoptic mites may cause hyperkeratosis of the cere with subsequent obstruction of the nares in budgerigars *(Melopsittacus undulatus)* (Figure 28.4). Trichomoniasis may extend to the choanal area and sinus in raptors and pigeons (see Chapter 22). *Cryptosporidium baileyi* was the cause of upper respiratory infections in falcons (*Falco* spp.) and scops owls *(Otus scops)* (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).[18–20] Cryptosporidia can be diagnosed through polymerase chain reaction (PCR) or conjunctival cytology. Treatment of respiratory cryptosporidiosis may be attempted using paromomycin or azithromycin, but response appears variable (see Chapter 9).[18,19,21] Various helminth parasites may be found in the nasal and sinus tissues in wild water birds, in particular Anseriformes, including trematodes of the Cyclocoelidae family, *Trichobilharzia* spp. schistosomes, and *Theromyzon* spp. nasal leeches.[22–24]

Plant or seed foreign bodies can be lodged in the nasal cavity or the choanal opening, and chicks may aspirate formula through their choanae. Respiratory irritants may also promote nasal inflammation and sneezing. Choanal atresia has been reported in grey parrots and an umbrella cockatoo *(Cacatua alba)* and is characterized by the incomplete development of communication from the nasal passageways to the choanal slit; however, the detailed anatomic nature of the

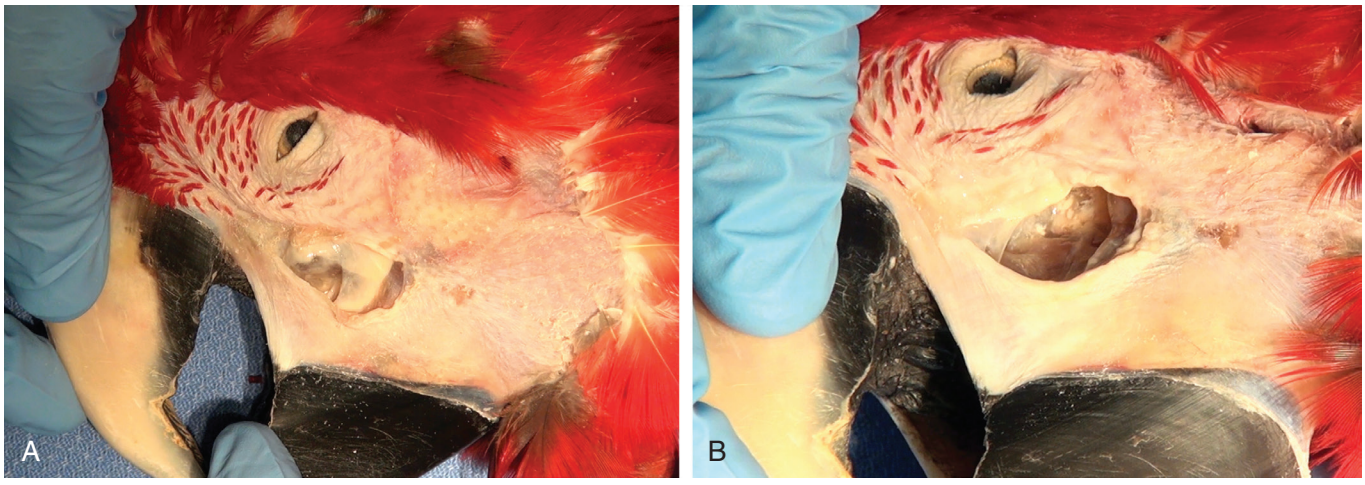

FIGURE 28.3 Sinusotomy in a scarlet macaw cadaver (*Ara macao*). A) The upper beak is flexed (protraction) and the lower beak is extended, which opens the infraorbital space and optimizes exposure as is seen in close up image B. (Courtesy Brian Speer.)

FIGURE 28.4 Budgerigar *(Melopsittacus undulatus)* with periocular knemidocoptosis that has progressed to the ceres and is starting to partially block the nares.

problem has yet to be clarified (see Section 9: Embryology, Neonatology, and Pediatrics).[7,25] It is typically repaired surgically by creating an artificial choanal opening (see Chapter 29). A pin is used to perforate a communication through each nostril to the choanae. The pin is inserted perpendicularly to the frontal bone into the nostril. A fenestrated (e.g., red rubber catheter) tube is passed through one nostril to the choanae and passed through the contralateral nostril. The tube ends are then tied on the back of the head and the tube is left in place for 4 to 6 weeks until tissue heals around it, which creates permanent communication. Significant bleeding should be expected with this surgery.

Hyperinflation/rupture of the cervicocephalic diverticulum of the infraorbital sinus is a relatively common occurrence and manifests by one or multiple large subcutaneous air pockets. This condition has been described in multiple avian species.[7,26–28] In severe cases, it may significantly restrict neck motions (Figure 28.5) as well as compromise the welfare of the bird. The pathophysiology is poorly understood, and the location of air leakage in case of a rupture has not always been properly documented. This condition may be caused by different diseases of the cervicocephalic diverticulum such as trauma, infection, congenital abnormality, and disruption of normal connection with the infraorbital sinus. The condition can either be treated through repeated aspiration of air from the cervicocephalic diverticulum, creating a stoma by marsupialization to the skin, or the placement of a stent. Another approach consists of connecting the inflated area with other parts of the head-neck and cervicocephalic diverticulum to the interclavicular air sac, deep between the clavicles to shunt air into the lower respiratory system (see Chapter 29). Finally, a technique of "pleurodesis" or "ablation" of the diverticulum may be attempted by injecting a sclerosing agent in the inflated tissue (such as doxycycline[28] or tetradecyl sodium sulfate). The neck is massaged to distribute the solution in the entire area, and a light bandage is placed to maintain pressure between the walls of the diverticulum.

Choanal and sinus squamous cell carcinoma have been reported at least in a black-footed penguin *(Spheniscus demersus)* and an Eclectus parrot *(Eclectus roratus)*, but many other cases have likely been diagnosed by veterinarians without being formally published (Figure 28.6).[29,30] Other nasal and sinus neoplasms reported in psittacine birds include lymphosarcoma, carcinoma, fibrosarcoma, and melanoma.[12]

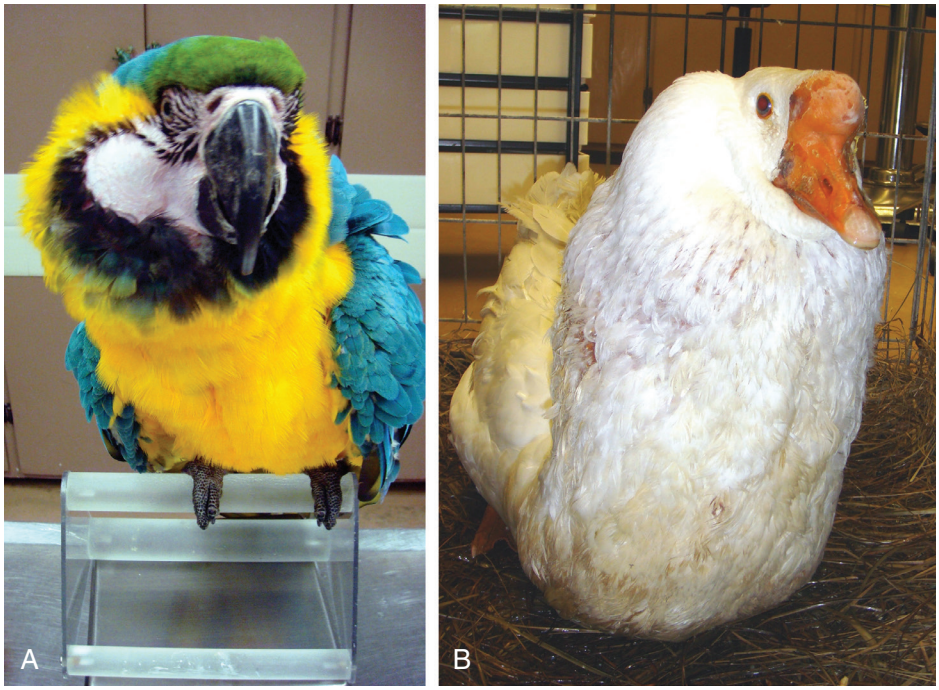

FIGURE 28.5 Cervicocephalic diverticulum rupture in a blue-and-gold macaw (*Ara ararauna*; A) and a domestic goose (*Anser anser domesticus*; B).

FIGURE 28.6 Squamous cell carcinoma in a blue-fronted Amazon parrot *(Amazona aestiva)* almost completely blocking the glottis.

TRACHEAL DISEASES

Diseases of the larynx are uncommon. Reported diseases include glottal internal papillomatosis (mainly in green-winged macaws [*Ara chloropterus*]) and laryngeal trauma from intubation (damage to the *crista ventralis*).[31–33] However, other causes (e.g., neoplasia and bacterial, mycotic and parasitic infections) should be considered in the differential diagnosis as well. (see also Chapter 27).

Postintubation tracheal stenosis usually occurs approximately 1–2 weeks after an intubation event and has been reported in parrots, raptors, and many other species.[34–38] Tracheal stenosis secondary to severe tracheitis or tracheal trauma has also been reported.[39–41] The diagnosis is readily made by tracheoscopy (Figure 28.7) but may also be made at CT imaging or even radiography in some cases. These cases are typically treated with a partial tracheal resection and anastomosis (see Chapter 29). Generallym, between five to ten tracheal rings are removed, but up to 12 to 15 rings have been removed in extreme cases.[35–38,40–42] It is essential to remove all of the tracheal tissue affected by fibroproliferation as this may inevitably lead to recurrence. Even when minimally reactive sutures are used (e.g., polydioxanone), granulomas and exudates around the sutures are not uncommon, and it is recommended to monitor the trachea periodically by tracheoscopy during the following months/years. Voice changes may also be encountered due to neurologic and muscular trauma of syringeal muscles and modification of tracheal airflow. Stenting of the trachea has been described using a custom-made nitinol stent, which was deployed in the trachea of an Eclectus parrot using tracheoscopy and fluoroscopy (see Chapter 29).[43]

Tracheal foreign bodies are more common in small psittacine birds, and particularly in cockatiels inhaled millet seed is a common cause for obstructions.[26,44–46] A tracheotomy may be necessary to remove the foreign body (see Chapter 29). Prior to the removal of a tracheal foreign body, a tracheoscopy or—in smaller species—transillumination of the trachea may be required to precisely locate the foreign body, mark the area, and insert a needle into the trachea distal to the obstruction to prevent distal migration (see Chapter 27). In small birds for which tracheotomy is challenging, an alternative technique has been proposed whereby a needle is introduced just distal to the seed with the bevel up and a large quantity of air is forced up the trachea to dislodge the seed.

When tracheal obstruction is suspected, an air sac tube may be placed either in the caudal thoracic or the abdominal air sac (see Chapter 29). The tubes frequently get obstructed, so it is advisable to fenestrate its extremity and monitor patency of the tube at least daily. During the placement of the

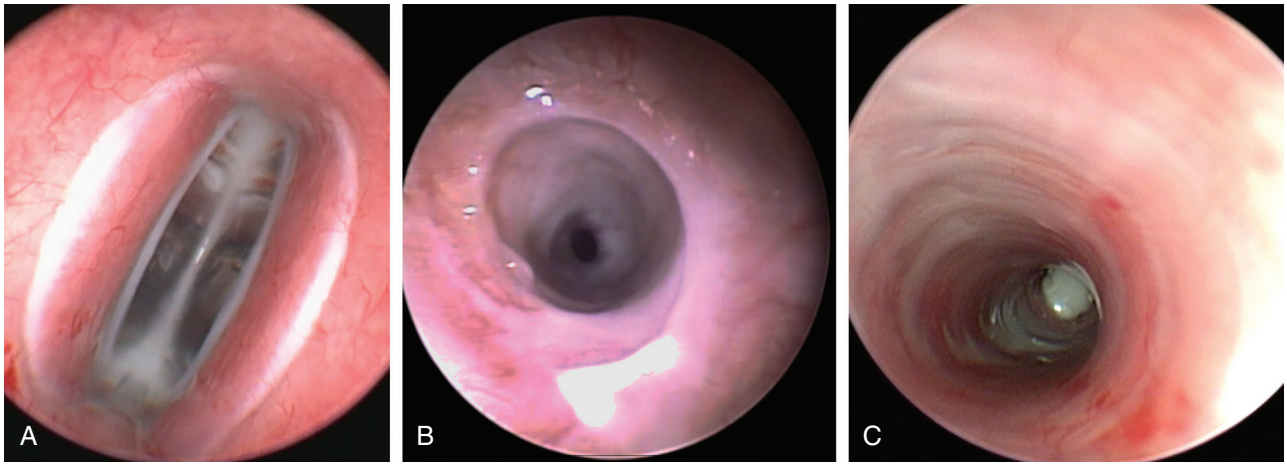

FIGURE 28.7 Tracheoscopy in birds showing the normal syrinx in an Eclectus parrot (*Eclectus roratus*; A), a fibrogranulomatous lesion associated with tracheal stenosis in a blue-and-gold macaw (*Ara ararauna*; B), and a syringeal aspergilloma in an Eclectus parrot (C).

air sac tube, it is best to perform a brief endoscopic examination through the tube to both ensure correct placement regarding the caudal ostia and perform an examination of the air sac, lung, and coelomic organs. The tube is sutured to the skin using a retention disk (Figure 28.8), tape, or directly onto the tube using a Chinese finger trap suture. A filtering system should be placed on the tip of the tube to avoid inhalation of dust and feather debris. Several materials may be used for this purpose such as found in surgical or facial masks. The tube is commonly kept for a maximum of 5 to 7 days, following which occlusion frequently occurs, and the tube should be replaced. A new tube should be placed in the contralateral air sac, if needed. When the air sac tube is removed, it is recommended to culture its tip and to perform a brief endoscopic examination of the area. Air sac tubes induce considerable inflammatory reaction, and it is not uncommon to diagnose focal aspergillosis. If such lesions are observed, a topical instillation of amphotericin B (1 mg/kg) is recommended. The stoma should be left patent until it heals by secondary intention. Topical ointment may be used to prevent or treat local infections of the site.

Various bacterial agents have been implicated in tracheitis, which may lead to tracheal stenosis either by fibrous tissue or by granuloma formation. The trachea was the principal replication site for experimental *C. psittaci* infection in the turkey (Meleagris gallopavo domesticus).[47] *Bordetella avium* primary infects the trachea in turkeys.[1] *Mycoplasma* spp. are routinely recovered from the trachea of normal birds of prey.[4,5] *Enterococcus faecalis* is associated with chronic tracheitis in canaries *(Serinus canaria)*.[48,49] A granulomatous tracheitis caused by *Mycobacterium genavense* was diagnosed in an Amazon parrot.[50]

Viral diseases of the trachea cause diphtheritic lesions and include mainly herpesvirus infections such as the infectious laryngotracheitis virus in recently imported chickens (and also pheasants and guinea fowl), the Amazon tracheitis virus in recently imported Amazon parrots and a few other psittacine species, cytomegalovirus in Australian finches, psittacid herpesvirus 3 infection in Eclectus parrots and Bourke's parakeets (*Neopsephotus bourkii*; see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease), and poxviruses which cause typical diphtheric lesions (wet form of poxviruses) that are typically encountered in passerine birds, various parakeets, lovebirds, and mynahs (see Chapter 15).[1,7,12,31,51–54] Vaccination with chicken attenuated infectious laryngotracheitis virus may cause disease in other galliform species.

Fungal infections of the trachea are seen notably with tracheal and syringeal aspergillosis (Figure 28.7; see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Species more commonly diagnosed with a tracheal location of aspergillosis include Amazon parrots, grey parrots, macaws, and falcons. Hypovitaminosis A is frequently cited as a predisposing factor for the formation of tracheal and syringeal aspergilloma.

Several parasites are known to infest the trachea and include nematodes such as *Syngamus* spp. (mainly *S. trachea*) and *Cyathostoma* spp. (mainly *C. bronchialis*) and acarids such as *Sternostoma tracheacolum*.[1,7,55] Tracheal worms infest a wide range of species, but clinical diseases are most frequently encountered in captive birds of prey, poultry, and gamebirds. The life cycle of *S. trachea* is direct, and earthworms may act as paratenic hosts, which facilitates reexposure in a closed environment with access to the ground (larvae may remain viable for up to 3 years in earthworms). *C. bronchialis* infests mainly Anseriformes and birds of prey and requires earthworms as intermediate hosts.[56] *S. tracheacolum* (tracheal, air sac mites) infests primarily canaries and Gouldian finches *(Chloebia gouldiae)*. The mite has a direct life cycle and is passed from parents to chicks.[12,56] It is usually treated with oral or percutaneous ivermectin (see Chapter 9).

Inhaled toxins and smoke inhalation injuries may cause severe necrotizing tracheitis (see Chapter 26). Hypovitaminosis A not only predisposes to respiratory diseases by altering mucosal defenses but may also promote epithelial changes, notably in the syrinx. Tracheal neoplasia is uncommon, but tracheal osteochondroma has been reported in parrots.[12] Extra-respiratory diseases resulting in tracheal compression are also numerous and are dealt with in the corresponding section.

LUNG/AIR SAC SYSTEM

Infectious Diseases

Bacteria

Lower respiratory diseases are common in birds, and infectious causes tend to predominate. Bacterial pneumonia and airsacculitis have been reported with a variety of agents, but gram-negative bacteria seem to predominate. Bacteria commonly reported to cause lower respiratory infections in birds include *Pasteurella multocida*, *Ornithobacterium rhinotracheale* (mainly chickens), *E. coli*, *Klebsiella* spp., *Salmonella* spp., *C. psittaci*, *Riemerella anatipestifer* (mainly waterfowl), *Pseudomonas aeruginosa*, *Staphylococcus* spp., *Streptococcus* spp., *Mycoplasma* spp., and *Mycobacterium* spp.[1,7,14] The importance and pathogenicity of bacterial isolates also depend on the species of bird involved. *C. psittaci* often causes diffuse airsacculitis, whereas *Mycobacterium* spp. generally results in large granulomatous lesions.[1,57–59]

Chlamydiosis is an important disease of birds in general and of Psittaciformes in particular due to its zoonotic potential.

Clinical signs are variable but commonly involve the respiratory system and mild to severe airsacculitis is a frequent necropsy finding. Diagnosis is typically confirmed by PCR from a conjunctivo-choano-cloacal swab or tissue biopsies (see Chapter 27). A strong inflammatory leukogram and hyperglobulinemia are frequently seen on the complete blood count (CBC) and protein electrophoresis, and liver parameters may be elevated as well. The treatment of chlamydiosis relies on using antibiotics with intracellular distribution such as tetracyclines and macrolides.

For further information on chlamydiosis, the reader is referred to Chapter 18 and to *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease.

Viruses

Viral diseases of the lungs are less common than other infectious causes but include orthoavulavirus 1 (formerly paramyxovirus I), avian influenza, infectious bronchitis (chickens), avian polyomavirus (in nestling cockatoos), and canarypox.[1,12,31]

Fungi

Aspergillosis is the predominant respiratory fungal infection in birds. Avian species reported to be more susceptible to respiratory aspergillosis include northern raptorial species (snowy owls, gyrfalcons *[Falco rusticolus]* and hybrids, rough-legged hawks *[Buteo lagopus]*), juvenile red-tailed hawks *(Buteo jamaicensis)*, golden eagles *(Aquila chrysaetos)*, Eurasian goshawks *(Astur gentilis)*, penguins, flamingos, seabirds (e.g., pelicans, auks, gannets, gulls, petrels, loons, etc.), certain parrot species, waterfowl, storks, and mynahs. Large epizootics in wild birds have been reported when gregarious species are exposed simultaneously to a large amount of spores.[60] Wild bird chicks of susceptible species may have a high mortality rate that seems to be associated with nest materials and dynamics.[60] *Aspergillus fumigatus* is the main species isolated, but other *Aspergillus* species can be cultured (e.g., *flavus*, *niger*, *nidulans*, etc.; see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Aspergillosis is not zoonotic and is not contagious, but is an opportunistic environmental pathogen. Any environmental strain may be potentially pathogenic. The pathogenesis seems to rather involve either exposure to a high spore load resulting in acute pulmonary aspergillosis or some degree of immunosuppression leading to chronic pulmonary—air sac aspergillosis. Tracheal and syringeal aspergillosis constitutes a third form of the disease (Figure 28.7). Risk factors that have been associated with an increased susceptibility include lead toxicosis (waterfowls, raptors), smoke inhalation injury, captivity (especially seabirds), stress, steroids, tetracyclines (likely due to immunomodulatory effect of long-term use), neoplasia, circovirus infection, hypovitaminosis A, and others.[60–64] In the authors' experience, an air sac cannula kept for several days frequently leads to focal aspergillosis lesions. Since the air sac system pneumatizes most of the body, aspergillosis lesions may extend to any internal organ by local invasion or distantly by hematogenous dissemination as *Aspergillus* spp. demonstrate angiotropism in tissues. In addition, *Aspergillus* spp. produce a wide variety of mycotoxins, some with immunosuppressive effects such as the gliotoxin, which may participate in the disease progression and pathogenesis.[65] Various experimental avian models have been developed to further elucidate the pathogenesis and progression of the disease.[66–70]

Aspergillosis can be suspected on diagnostic imaging such as radiographs (Figure 28.9 and Figure 27.5) or CT scan (much more sensitive) (Figure 27.5). A strong inflammatory leukogram and globulinemia are also frequently, but not

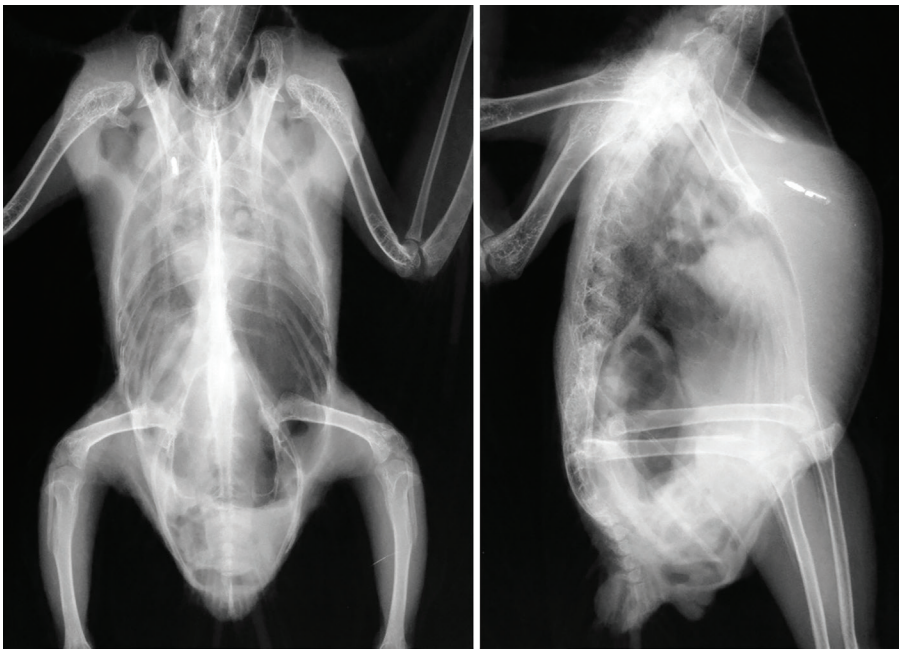

FIGURE 28.9 Whole body radiographs of a grey parrot *(Psittacus erithacus)* with respiratory aspergillosis. On the ventrodorsal view *(left)*, the right part of the air sac system presents some soft tissue opacities, and on the lateral view *(right)*, the air sacs are considerably thickened by aspergillosis lesions, which form characteristic "caverns."

FIGURE 28.10 Close-up view of a focal lesion of aspergillosis on an air sac membrane in a snowy owl *(Bubo scandiacus)*. The air sac is displaying mild thickening and hypervascularization and the small fungal plaque is supplied by a small vessel.

always, present on the CBC and protein electrophoresis. Host systemic response may be significantly influenced not only by the severity of infection but by the location of Aspergillus infection as well. The diagnosis can be confirmed by histopathology, cytology, and/or fungal culture from endoscopic biopsies of lesions (Figure 28.10).[71] Galactomannan assay and protein electrophoresis are not particularly useful in the diagnosis of aspergillosis in the individual bird owing to their low diagnostic accuracy.[72,73] *Aspergillus* serology is also of limited usefulness.[71] Culture or PCR on swabs and lesions without demonstrable histologic lesions may be difficult to interpret due to the ubiquity of the fungus in the environment.[71] Newer fungal biomarkers have also been proposed, but data on diagnostic accuracy on clinical cases are lacking for most of these tests, and they are also mainly restricted to the research laboratory.[71]

The treatment of aspergillosis is complicated, long, and multifaceted. Usually a combination of nebulized, local, and systemic antifungals is used, but antifungal monotherapy has resulted in good outcomes in some cases (see Chapter 8 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).[74] The prognosis should be determined based on radiographic, CT, and/or endoscopic evaluation. The treatment is lengthy with typically 3 to 8 months of oral antifungal medications required. Ideally, the treatment should be based on fungal culture and sensitivity as resistance to azoles such as itraconazole, clotrimazole, and voriconazole has been described,[76–79] but laboratories offering fungal sensitivity are few and minimum inhibitory concentrations of antifungals for fungal isolates may not be readily available.

Available antifungals include the polyenes (e.g., amphotericin B, nystatin, not absorbed orally), which bind ergosterol (fungal wall constituent) and permeabilize fungal cell membrane; the azoles (e.g., ketoconazole, fluconazole, itraconazole, voriconazole, clotrimazole), which inhibit a P450-dependent enzyme of lanosterol 14-α demethylation thereby decreasing ergosterol synthesis; the allylamines (e.g., terbinafine), which inhibit squalene epoxidase, another enzyme involved in ergosterol synthesis; and echinocandins (e.g., caspofungin), which interfere with glucan synthesis (see Chapter 8).[80,81] Pharmacokinetic and pharmacodynamics studies have been performed on a few species for itraconazole, fluconazole, voriconazole, and terbinafine.[74,81–91] Polyenes are not absorbed orally. Using a combination of antifungals with different mechanisms of action, and different routes of delivery, somewhat dictated by disease location can be beneficial (see Chapter 8). Drug treatment choices may have a synergistic effect and may reduce fungal resistance. Voriconazole is the newest antifungal used in birds and seems particularly effective. It has been shown to be effective in treating experimental aspergillosis in pigeons and spontaneous aspergillosis in falcons and parrots.[75,82,85] For more information on antifungals, the reader is invited to consult Chapter 8 as well as *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease.

The author typically favors an aggressive approach in moderate to advanced cases using a combination of antifungals with potential synergistic effects consisting of 1 to 3 days of intravenous (IV) amphotericin B or voriconazole, combined with nebulized amphotericin B and oral voriconazole, occasionally combined with terbinafine. Endosurgical debridement has also been employed for larger granulomas in birds,[93] followed by endoscopic-guided local instillation across fungal plaques or intragranuloma injections of antifungals, depending on clinical details and location of lesion(s). Intratracheal administration of (IV solutions of) amphotericin B or voriconazole may also be performed. The use of multiple routes and methods of delivery, as well as the use of antifungals with different mechanisms of action, may enhance effectiveness and is relatively well tolerated by most patients. Also, the slow onset of some triazoles may make early combination therapy advisable. Various results have been obtained in humans where concentration-dependent synergism or antagonism was observed between antifungals.[94] Synergistic action between triazoles and amphotericin B or triazoles and terbinafine has been observed on human *Aspergillus* isolates in vitro.[95] However, no in vivo research has been done on antifungal synergisms and antagonism in birds, so combination therapy is largely empirical.

Parasites

Several lower respiratory parasitic diseases are of significance in birds. *Sarcocystis falcatula* is a sporozoan parasite, which has an indirect life cycle with the Virginia opossum as the final host and cockroaches as potential mechanical vectors (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). It is associated with an acute pulmonary form in Old World species such as cockatoos rather than the classic muscular form.[96,97] Pulmonary lesions are also common with disseminated visceral coccidiosis due to *Eimeria* spp. in cranes.[98] *Toxoplasma gondii* is a protozoan parasite

whose final host is the cat, which can affect a wide range of avian species. In birds, pulmonary lesions are common with toxoplasmosis.

Atoxoplasmosis is caused by the coccidian parasite *Isospora serini* and affects diverse passerine birds from various families (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Canaries and finches are commonly reported to have the disease. Pulmonary lesions are reported, but hepatic and splenic lesions predominate. The treatment of atoxoplasmosis can be challenging, and treatment response is usually highly variable. Drugs that have been used to treat systemic coccidiosis in passerines include mainly toltrazuril and sulfachloropyridazine (see Chapter 9 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).[99,100]

The air sac mites, *S. tracheacolum*, live in the air sacs and lungs but are most often pathogenic in the upper airways (see earlier). Various filarioid nematodes have been identified in the lower respiratory system of birds including the genera *Paronchocerca*, *Splendidofilaria*, *Chandlerella*, *Serratospiculum*, and *Diplotriaena*.[101,102] Most infections do not lead to clinical disease. *Serratospiculum seurati* is a common parasite of air sacs in saker *(Falco cherrug)* and other falcons in the Middle East. Beetle species are the intermediate hosts. Other species of *Serratospiculum* have been reported in birds of prey from various geographical locations. *Serratospiculum* and *Diplotriaena* do not produce microfilariae but rather eggs that develop in insect hosts. These parasites may produce airsacculitis and promote lower respiratory infections. Several genera of air sac flukes (trematodes) have been reported to parasitize wild and captive zoo birds and are associated with mollusks intermediate hosts.[24,103] Treatment of respiratory parasites mainly consists of administering parenteral antiparasitic medications (see Chapter 9). Intramuscular ivermectin is most commonly used for helminthiasis (e.g., falcon serratospiculosis, tracheal worms).[21] Fenbendazole is also effective against tracheal worms. Endoscopic removal of tracheal worms may be indicated if tracheal obstruction is an issue. Endoscopic removal of nematodes from air sacs may also be performed but is rarely necessary if an appropriate ivermectin dose is used. Praziquantel has been used with variable results in treating air sac flukes.[103] Preventative measures should also be implemented by reducing access to intermediate host such as limiting access to the ground and having appropriate aviary design.[21]

Noninfectious Diseases

Birds are very sensitive to smoke inhalation toxicosis and airborne toxins because of their large and efficient pulmonary exchange surface (see Chapter 26). Toxic fumes frequently include PTFE (polytetrafluoroethylene [Teflon], Fluon, Hostaflon, and Polyflon) from overheated cookware, cigarette smoke, household aerosols (house perfumes, candles, disinfectants), carbon monoxide, and ammonia (chickens). Signs are most often acute, especially in PTFE inhalation and other toxic fumes, and severe pulmonary hemorrhage and congestion typically ensue (Figure 28.11). Respiratory signs may develop as long as 3 days after toxin exposure. Oxygen therapy is the mainstay of treatment, and many of these patients may benefit from preemptive treatment with antibiotics and antifungals.

Several other noninfectious diseases of clinical significance have been reported in captive birds. Aspiration pneumonia may be encountered in baby birds (chronic poor doer) and hospitalized birds being gavage fed. The "conure bleeding syndrome" frequently manifests as bleeding in the respiratory tract and hemoptysis. Hemoptysis and pulmonary hemorrhage also occur in birds of prey with secondary rodenticide poisoning.[104] Advanced atherosclerosis and cardiac diseases may cause respiratory signs. Chronic pulmonary interstitial fibrosis has been reported in Amazon parrots, is frequently seen in the Netherlands, and has been associated with right heart failure in some birds.[105,106]

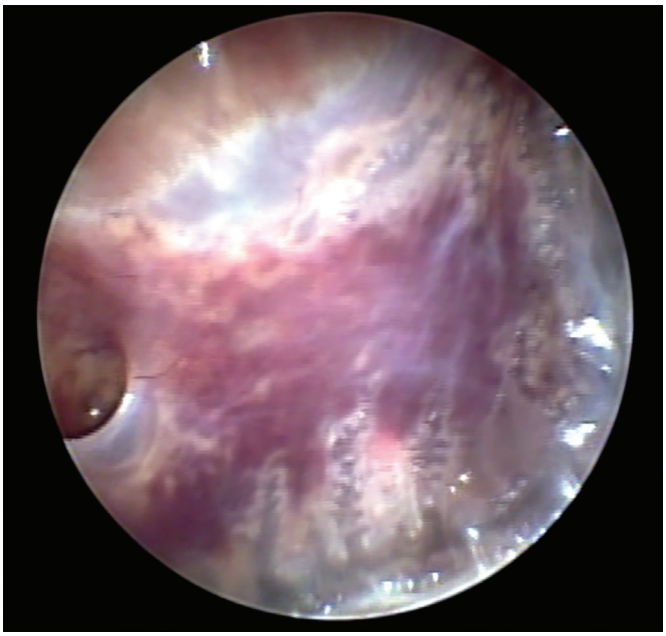

FIGURE 28.11 Pulmonary congestion diagnosed in a grey parrot *(Psittacus erithacus)* with smoke inhalation injury. The tip of the endoscope is in the left caudal thoracic air sac.

A chronic obstructive respiratory disease is also seen in blue-and-gold macaws (*Ara ararauna*) (and in several green-winged macaws by the author) housed with feather powder–producing species such as cockatoos, cockatiels, and grey parrots.[12,107] This syndrome is characterized by polycythemia, pulmonary congestion, atrial smooth muscle hypertrophy, and atrial loss. Severe, intermittent inspiratory dyspnea with open-mouth breathing is often seen. Lung biopsies can be obtained endoscopically from the thoracic air sacs or through a surgical intercostal approach (if lesions are not amenable to endoscopic biopsies) to confirm the diagnosis and assess its severity (see Chapter 29). The condition is typically treated with short- or long-term bronchodilators, nonsteroidal antiinflammatory drugs, and strict environmental management to reduce further antigenic exposures (see General Therapeutic Principles). The author has frequently used nebulized terbutaline or albuterol for acute treatment in combination with oxygen therapy and oral theophylline/salbutamol for chronic treatment. Increasing the relative humidity of ambient air seems to be beneficial for tropical bird species. Short-term low-dose corticosteroids may also help to decrease pulmonary inflammation initially (prednisone 0.1–0.2 mg/kg PO q12–24h), though caution is warranted when using these drugs due to their immunosuppressive effects. It seems that advanced disease, when chronic

histopathologic changes in the lung parenchyma are too severe, does not continue to respond to bronchodilators. Consequently, and preventatively, macaws should not be kept in an area with dander-producing parrot species.

Pneumoconiosis (synonyms: anthracosis, silicosis) results from the accumulation of foreign materials (dust) and dust-laden macrophages in the lungs and has been reported in various species.[22] Pulmonary fat embolism has been reported in an osprey *(Pandion haliaetus)* and yolk embolism in pet psittacine birds.[22,108] Air sac cannulation for several days often causes moderate to marked air sac inflammatory reaction. Subcutaneous emphysema around the body may be caused by an air sac trauma such as resulting from a surgical procedure (e.g., coeliotomy, air sacculotomy), endoscopy, abdominal wall herniation, or fracture of a pneumatized bone.

Neoplasms described in the lower respiratory tract include pulmonary adenocarcinoma, air sac adenocarcinoma, and metastasis of malignant tumors. Pulmonary/bronchogenic carcinomas have been reported in multiple bird species and often manifest as pelvic limb ataxia/paresis due to local invasion of the tumor into the spine.[109–113] These tumors frequently invade the humeral air sac diverticulum. Air sac cystadenocarcinoma has mainly been reported in cockatoos, but a case in a grey parrot has also been documented. These tumors usually arise from the proximal humeral and axillary air sac diverticulum[114–117] Undifferentiated neoplasms of the lungs and air sacs have been recognized in cockatiels and seem to be most often diagnosed in the thoracic inlet occasionally compressing the trachea (Figure 28.12).[22,31] Marek disease may cause pulmonary tumors in chickens.[1] Treatment is limited for respiratory neoplasia, but surgery, chemotherapy, and/or radiation therapy may be attempted if diagnosed early on (see Chapter 29 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 3, Neoplastic Diseases in Avian Species).

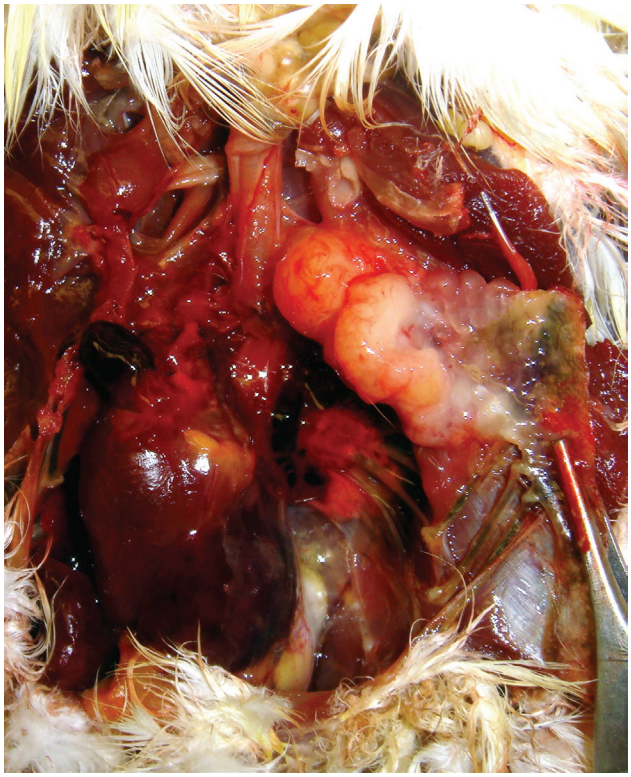

FIGURE 28.12 Soft tissue sarcoma in the interclavicular air sac of a cockatiel *(Nymphicus hollandicus)* that presented with open-mouth breathing and regurgitation.

EXTRA-RESPIRATORY DISEASES: AIRFLOW OCCLUSION AND AIR SAC COMPRESSION

Due to the extensive nature of the air sac system in birds in their abdominal and thoracic regions, any extra-respiratory disease resulting in reduction of air sac volume or occlusion of major airways may result in respiratory clinical signs.

In the thoracic inlet, masses of nonrespiratory origin may occlude the trachea, syrinx, and interclavicular air sac leading to inspiratory dyspnea, aphonia, or voice changes. These masses include thyroid masses (goiter, especially in budgerigars, thyroid neoplasia), bony callus from a coracoid fracture, aneurysms, large granulomas, and neoplasia such as undifferentiated sarcoma, hemangiosarcoma, thymoma, and other tumors.[118–121] Cardiomegaly does not typically induce coughing in birds as it does in mammals.

A significant reduction in air sac space may occur with fluid accumulation in the hepatic and intestinal peritoneal cavities of birds such as ascites resulting from cardiac, hepatic, or neoplastic diseases and egg yolk peritonitis. Severe respiratory complications may arise if the fluid/yolk gains access to the inside of the respiratory system. Coelomic fluid should be drained by centesis until dyspnea has improved. Additionally, diuretics can be used to promote forced diuresis (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 6, Cardiology).

Space-occupying masses are also associated with impairment of abdominal ventilation and are encountered with large tumors (e.g., in budgerigars), granulomas, eggs, and organomegaly. Obstruction of air sac ostia is rare but may interfere with ventilation. An ostrich *(Struthio camelus)* was reported with intestinal entrapment in a right pulmonary ostium.[122] Finally, obesity with intraperitoneal fat accumulation may impair normal ventilation and induce dyspnea, especially after exercise.

GENERAL THERAPEUTIC PRINCIPLES

Principles of Oxygen Therapy

The goal of oxygen supplementation is to increase the oxygen concentration of inspired air (fraction of inspired oxygen [FiO_2]), to improve blood oxygenation, and to increase tissue delivery of oxygen. General hypoxia may be due to anoxic hypoxia (low FiO_2, hypoventilation, diffusion impairment, ventilation/perfusion mismatching), anemic hypoxia (anemia, methemoglobinemia, carbon monoxide toxicosis), stagnant hypoxia (low blood flow due to cardiac failure or hemorrhage), and histiocytic hypoxia (cyanide poisoning).[123] Common indications of oxygen therapy include severe anemia, hemodynamic compromise, and hypoxemia (decreased blood oxygen concentration) due to pulmonary and obstructive airway diseases.[124]

Oxygen therapy is typically implemented using an oxygen cage in birds because of its low stress and noninvasiveness.

The authors strongly encourage veterinarians to measure the FiO_2 that can be achieved in their oxygen cages using an oxygen sensor to verify their performance. Some incubators have doors within doors, which allow manipulation of the animal without massive loss of oxygen from the cage. An FiO_2 of 25% to 45% may be reached using flow-by oxygen and 35% to 60% using facemasks.[123,124] It is ideal to monitor the SpO_2 or PaO_2 during oxygen supplementation, but this is rarely practical in birds.

Response to therapy should also be used for monitoring and titrating the oxygen flow. The response to oxygen therapy may be poor depending on the disease process(es) present. For instance, a poor to fair response may be seen in diseases producing a low ventilation/perfusion mismatch (perfusion predominates with decreased supply of oxygen to the exchange surface) such as pulmonary edema, pneumonia, asthma, pulmonary neoplasia, pulmonary fibrosis, and atelectasis. In extreme cases of these diseases (severe pneumonia), oxygen therapy may not be efficacious because blood essentially makes no contact with ventilated lungs. Response is more commonly good in diseases with a high ventilation/perfusion mismatch (low perfusion in normally ventilated lungs) such as pulmonary thromboembolism.[123] Improving cardiac function and fluid resuscitation are best to correct stagnant hypoxemia. While the degree of response to oxygen therapy may be variable, regardless of the underlying conditions, any patient with acute respiratory distress and signs of hypoxia (cyanosis, dyspnea, tachypnea, open-mouth breathing) may benefit from supplemental oxygen. Oxygen therapy seems extremely beneficial to birds, which have higher metabolic demand for oxygen and may benefit more from increased FiO_2 due to their more efficient gas exchange surface. Sedation with midazolam in dyspneic birds may also reduce anxiety thereby resulting in better ventilation.

The most common complication associated with oxygen therapy is oxygen toxicosis because oxygen is a potent oxidizing agent. The degree of toxicity is related to the level of oxygen and duration of exposure. The lung is the most vulnerable organ to oxygen radicals. General guidelines recommend not to supplement oxygen at 60% to 100% for more than 24 to 48 hours in mammals.[123,124] Depletion of endogenous antioxidant levels may also promote oxygen toxicosis at lower oxygen percentages. Oxygen toxicosis has been described in birds. A study demonstrated oxygen toxicity in canaries and budgerigars at 68% to 100% after 3 to 8 days.[125] In another experiment, budgerigars were found to have pulmonary lesions 3 hours after exposure to 100% oxygen.[126]

Principles of Aerosol Therapy

The goals of aerosol therapy are to deliver airborne therapeutics directly to diseased respiratory tissues and to moisten airways in order to increase clearance of exudates and necrotic debris.[7] Local therapeutic delivery may be indicated when vascularization is decreased in diseased tissues (e.g., inflammatory and infected exudates in airways) or in low-perfused respiratory areas such as the air sacs (see Chapter 5). Nebulization allows one to reach high local concentration of therapeutics, maximizing its efficacy while minimizing systemic absorption, reducing potential for toxicosis, and reducing drug biotransformation. Humidification of the mucociliary escalator may also improve its efficiency.

Depending on particle sizes and airway diameters, aerosolized therapeutics may only reach the upper respiratory system, the larger airways, or lungs and air sacs. Birds' airways have extremely small diameters with parabronchi diameters ranging from 0.5 mm (e.g., hummingbirds) to 2 mm (e.g., chicken, penguins) and air capillaries ranging from 3 μm (e.g., passerines) to 10 μm (e.g., swans, coots; see also Chapter 26).[127] In comparison, mammalian alveoli have an approximate diameter of 30 to 150 μm (the smallest is in mice).[128] Consequently, birds' airways require smaller nebulized particle sizes and particle diameters of 0.5 to 3 μm are generally recommended.[7,129] During endoscopy, the author has seen amphotericin coating caudal air sacs of birds that have been nebulized, suggesting that nebulized drugs reach the caudal thoracic and abdominal air sacs also in diseased birds.

Aerosol therapy includes humidification, vaporization, and nebulization. The first two methods produce particles that are too large to reach the lower respiratory system but may be adequate for upper respiratory or tracheal diseases. The latter produces particles small enough to be deposited in smaller pulmonary airways. Nebulization can be achieved with a variety of devices using different technology such as air-jet nebulizers and ultrasonic nebulizers (including vibrating mesh technology).[130] Air-jet nebulizers are noisier and heavier but are less expensive and have a greater ability to nebulize viscous liquid than ultrasonic nebulizers (Figure 28.13). Pressurized metered-dose inhaler aerosols such as classically available for albuterol are a type of air-jet nebulizer and deliver 1- to 2-μm particles.[131] Drugs used for nebulization should ideally be hydrosoluble, of low viscosity, and display adequate nebulization characteristics. Drugs that are commonly nebulized include 0.9% saline, antibacterials, antifungals (when from a hydrosoluble formulation), antiparasitics, bronchodilators, and mucolytic agents (Table 28.1). Nebulized drugs may induce bronchospasm and patients should be assessed before and after administration (e.g., *N*-acetylcysteine [NAC]).

Nebulization typically lasts 15 to 30 minutes and is performed once to twice daily. However, a study on nebulized

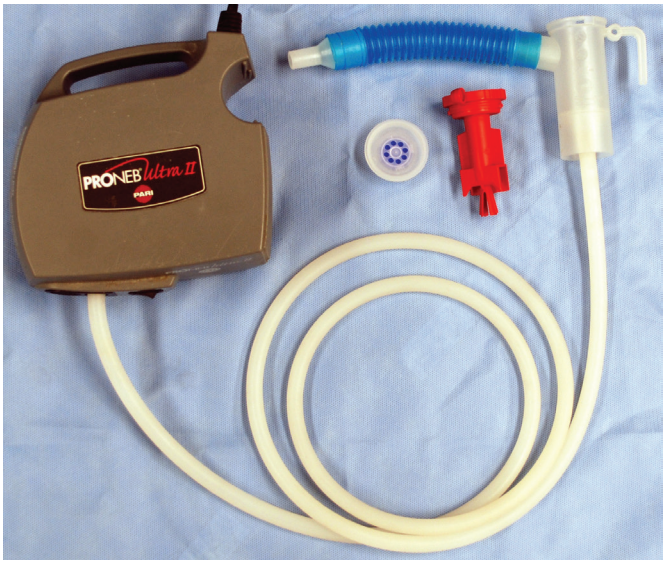

FIGURE 28.13 Air-jet nebulizer commonly used in avian medicine.

TABLE 28.1

Drugs Commonly Used for Nebulization in Birds

Drug	Dose
ANTIBACTERIALS	
Amikacin	5–6 mg/mL sterile water/saline
Gentamicin	3–6 mg/mL sterile water/saline
Cefotaxime	10 mg/mL saline
Doxycycline	13 mg/mL saline
Tobramycin	1 mg/mL saline
Enrofloxacin	10 mg/mL saline
Piperacillin	10 mg/mL saline
ANTIFUNGALS	
Amphotericin B	0.1–5 mg/mL sterile water
Enilconazole	10 mg/mL sterile water/saline
Clotrimazole	10 mg/mL in propylene glycol
Terbinafine	1 mg/mL sterile water
Voriconazole	10 mg/mL saline
BRONCHODILATORS	
Aminophylline	3 mg/mL sterile water/saline
Terbutaline	0.01 mg/kg in 5–10 mL saline
MUCOLYTIC	
N-acetylcysteine	22 mg/mL sterile water

fluorescein-labeled propylene glycol and saline in pigeons found that only mild staining of the air sacs was observed at 30 minutes, with much higher intensities achieved at 4 hours.[132] These findings suggest that nebulization may have to be performed for longer than previously thought. In birds, the respiratory surface and functional efficiency of their lungs may lead to greater systemic absorption of the nebulized drugs than in other species. This may be advantageous in certain circumstances to obtain drug plasma therapeutic levels without having to restrain the bird. For instance, the pharmacokinetics of the following nebulized drugs have been performed in birds: terbinafine, voriconazole, oxytetracycline, and ceftriaxone.[81,133–136] However, plasma concentrations achieved are usually low and of short duration.

Principles of Respiratory Pharmacology

Other than antimicrobials and antiinflammatories, the pharmacologic options for treatment of respiratory tract pathologies include expectorants, mucolytics, decongestants, bronchodilators, cough suppressors, and respiratory stimulants.[137,138] Most of these drugs have been studied in mammals, and their effects may be variable in birds due to different pharmacokinetic properties, different mechanisms of respiratory diseases, and different physiology.

The main mucolytic used in veterinary medicine is NAC. It breaks the disulfide bonds within mucus molecules, which decreases the viscosity. NAC is mainly used for upper respiratory and tracheal diseases. Another mucolytic drug is bromhexine. Expectorants include potassium iodide and guaifenesin. They increase mucus production, which aids in airway secretion clearance. The use and efficacy of expectorants and mucolytics is debatable. Moreover, NAC is well known to induce bronchospasm and is recommended to be combined with a bronchodilator, if used.[137]

Decongestants include sympathomimetic drugs such as ephedrine and phenylephrine, which constrict dilated blood vessels within the nasal cavity, thereby reducing swelling and congestion of the upper respiratory mucus membranes and allowing air to pass more freely. H1-antihistamines such as diphenhydramine or hydroxyzine, which have a synergistic effect and can help to relieve symptoms that occur in response to allergens, such as sneezing and nasal discharge, may also be considered in birds with sinusitis and rhinitis.

Birds have bronchial and parabronchial smooth muscles, so bronchodilators may be beneficial in decreasing resistance to airflow. However, bronchodilators should be used appropriately as they can increase the ventilation-perfusion mismatch in some diseases, which results in worsening of hypoxia. Different classes of bronchodilators with different mechanisms of action are available. Parasympatholytic drugs such as atropine and glycopyrrolate induce bronchodilation by competition with acetylcholine on muscarinic receptors in the airways. Beta-2-sympathomimetic (=beta adrenergic) drugs such as albuterol (=salbutamol) and terbutaline are the most effective bronchodilators and induce bronchodilation by agonist effects on beta-2 adrenergic receptors in the airways. Side effects are related to residual beta-1 effects on the cardiovascular system potentially leading to tachycardia and arrhythmias. Methylxanthines such as aminophylline and theophylline are phosphodiesterase inhibitors that induce bronchodilation and have local antiinflammatory effects. Adverse effects seen with methylxanthines include nausea, cardiac arrhythmias, and neurological signs.

Doxapram is a centrally acting respiratory stimulant, but its use is questionable in most respiratory diseases.

Antibacterials, antiparasitics, and antifungals are used when such microbial infection is diagnosed at doses like other systems. For more detailed information, the reader is referred to Section 3: Therapeutic Intervention and Appendix 1.

CHAPTER 29

Surgery of the Respiratory Tract

David Sanchez-Migallon Guzman • Brian L. Speer • M. Scott Echols

Visit eBooks.Health.Elsevier.com for a complete set of references.

SURGICAL PRINCIPLES, INSTRUMENTATION, AND MATERIALS

Magnification, focused light, and microsurgical instrumentation are important components of many surgical procedures of the respiratory system, including sinusotomy and tracheal procedures. Magnification makes hand tremors more apparent to the surgeon and necessitates slow, deliberate motions. It can result in a slower surgical pace, requiring appropriate anesthesia protocols and patient monitoring for the duration of the procedure.[1] Focused light is sometimes essential to seeing anatomic details in dark recesses common within body cavities. The basic microsurgical pack should contain a long jeweler's forceps that has a fine delicate tip but flat handles, round handled microsurgical forceps, Castroviejo needle holder that is at least 5.25 inches (13.3 cm) with fine jaws and rounded handles, and microsurgical scissors that are spring loaded and at least 7 inches (17.8 cm) or similar size and have rounded handles.[1] Sterile cotton-tipped applicators should be available for focal tissue manipulation and point hemostasis.[1] Hemostatic clips are also very useful and come in a variety of sizes. Right-angled appliers are available for special applications in deep cavities.[1] Heiss blunt retractors, Alm retractors, or ring retractors are suitable for use in varied species and procedures (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 21, Surgery).

Halsted's principles of surgery should be followed when performing surgery in any species or anatomic location. These principles include (1) gentle handling of tissue, (2) meticulous hemostasis, (3) preservation of blood supply, (4) strict aseptic technique, (5) minimum tension on tissues, (6) accurate tissue apposition, and (7) obliteration of dead space (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 21, Surgery).

PATIENT PREPARATION

Birds have a very thin epidermis that is diffusely supplied by capillaries in the dermis, unlike what is seen in mammals. There is little subcutaneous tissue, and the dermis is generally firmly attached to the underlying muscle fascia, although there is more free space and relative mobility in the neck of most birds as opposed to other areas of the body.[1] Most blood vessels are comparatively less protected by surrounding tissues, leaving more potential for hemorrhage as compared to mammals.[1] This concern is particularly of merit when performing surgery in the cervical regions of the upper respiratory tract, where blood loss can lead to associated complications into the distensible spaces beneath cervical skin or even to blood clot occlusions of the trachea. Body contour feathers are easily plucked in the direction of their growth, once the patient is anesthetized.[1] Some bird species may have particularly thin skin, predisposing them to iatrogenic tears while feathers are being plucked, including many dove species. The skin is prepared with routine cleansing with chlorhexidine alternating with sterile saline, or similar disinfection protocols. Draping the patient quickly with the use of clear, transparent plastic drapes helps to retain heat better than using cloth drapes and also allows respiration to be monitored during the procedure.[2] Supplemental heat (e.g., warm water bottles, circulating warm water blankets, heat lamps, and forced warm air) should be provided to the patient to maintain normothermia and prevent heat loss.[2]

SURGERY OF THE UPPER RESPIRATORY SYSTEM

Rhinotomy and Rhinolith Removal

Indications

Removal or biopsy of masses present in the nares, due to the presence of rhinolithiasis, foreign bodies, infections, or neoplasms. Malnutrition (e.g., hypovitaminosis A) can lead to progressive development of rhinoliths, and secondary infections can often occur.

Surgical technique

Rhinoliths may often be gently removed using saline to soak and soften them beforehand, if needed. Topical local anesthetics can be applied, following which a stainless steel aural curette can be used to gently remove the material.[3,4] Some rhinoliths can be very firm, dry, and somewhat impenetrable to topical softening attempts (Figure 29.1). Some larger rhinoliths may need to be sectioned or otherwise reduced in situ to facilitate removal. Significant distortion of the naris and the operculum can occur, and computed tomography (CT) may be indicated for some patients prior to the contemplated procedure (see Chapter 2 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 14, Advances in Diagnostic Imaging). Fistulas into the maxillary and adjacent diverticulae of the infraorbital

FIGURE 29.1 (A) Large rhinolith in the left nare of a grey parrot *(Psittacus erithacus)*. The size and firmness of this rhinolith presented mechanical challenges for the application of topical moistening agents to offer much immediate benefit. The patient has been sedated with midazolam and butorphanol, in preparation for removal using a stainless steel aural curette. (B) The left nare of the same grey parrot, following complete removal of the rhinolith. Focal areas of bleeding are noted where a local block with lidocaine was injected through the caudal aspect of the nare, prior to its removal. Mild bleeding is present, which was easily controlled with topical pressure using cotton-tipped applicators. Aerobic bacterial cultures from deep in this cavity produced a pure isolation of *Pseudomonas aeruginosa*. (C) The rhinolith removed. The keratinaceous material on the right was the most superficial portion initially removed, and the material on the left was the remaining portion removed. (D) A different grey parrot that had a similar sized rhinolith removed from its right nares 6 months earlier. The nasal opening remains distorted but has reduced by approximately 50% of its original distorted diameter. Some degree of permanent disfigurement is common following the removal of large rhinoliths as demonstrated in these figures.

sinuses can occur, as well as osteomyelitis. General anesthesia may be required for more involved procedures. In some cases, an incision may be required to increase access to the nasal cavity, in which case radiosurgery or laser should be available to achieve adequate hemostasis. Samples should be collected for cytology and culture to guide the treatment plan (see Chapter 27). Postoperative treatment might require nasal flushing, topical and/or systemic antimicrobial treatment, as well as pain management (see Chapter 28).

Potential complications

Hemorrhage, fistula into the infraorbital sinus, and permanent distortion of the nares.

Choanal Atresia Repair

Indications

Confirmed choanal atresia or obstruction between the nasal cavities and the nasopharynx. Choanal atresia typically is a congenital problem and has been described in the grey parrot (Figure 29.2)[7] and umbrella cockatoo *(Cacatua alba)*.[5] The detailed anatomic deformities associated with atresia are incompletely described in birds but may represent either or both bony and soft tissue developmental abnormalities.[6]

Surgical technique

A technique for surgical correction has been described in the grey parrot (Figure 29.2).[7] By hand drilling a 7/64-1/8 Steinmann pin from each naris, through the nasal conchae and into the rostral choana, a functional communicating channel is created. Following this, a tomcat urinary catheter is placed, into which a single 8-French red rubber catheter is nested to enable passage of the softer urinary catheter through the nares and out the choana. The procedure is replicated on the opposite side, with the cut end of the urinary catheter similarly inserted and pulled through, ultimately leaving the central loop of the catheter bridging the cere. The ends of the urinary catheter are then tied behind the head. The catheter is left in place for 4 to 6 weeks to allow the formation of permanent communication between the nasal cavity and rostral choanal slit (see Chapter 41). During this period, the catheter may be replaced with larger sized tubing to help increase the size of the hole gradually. Nasal flushing should be performed for 7 to 10 days after catheter removal to prevent the buildup of mucus and development of occlusion of the newly created communicating pathway.

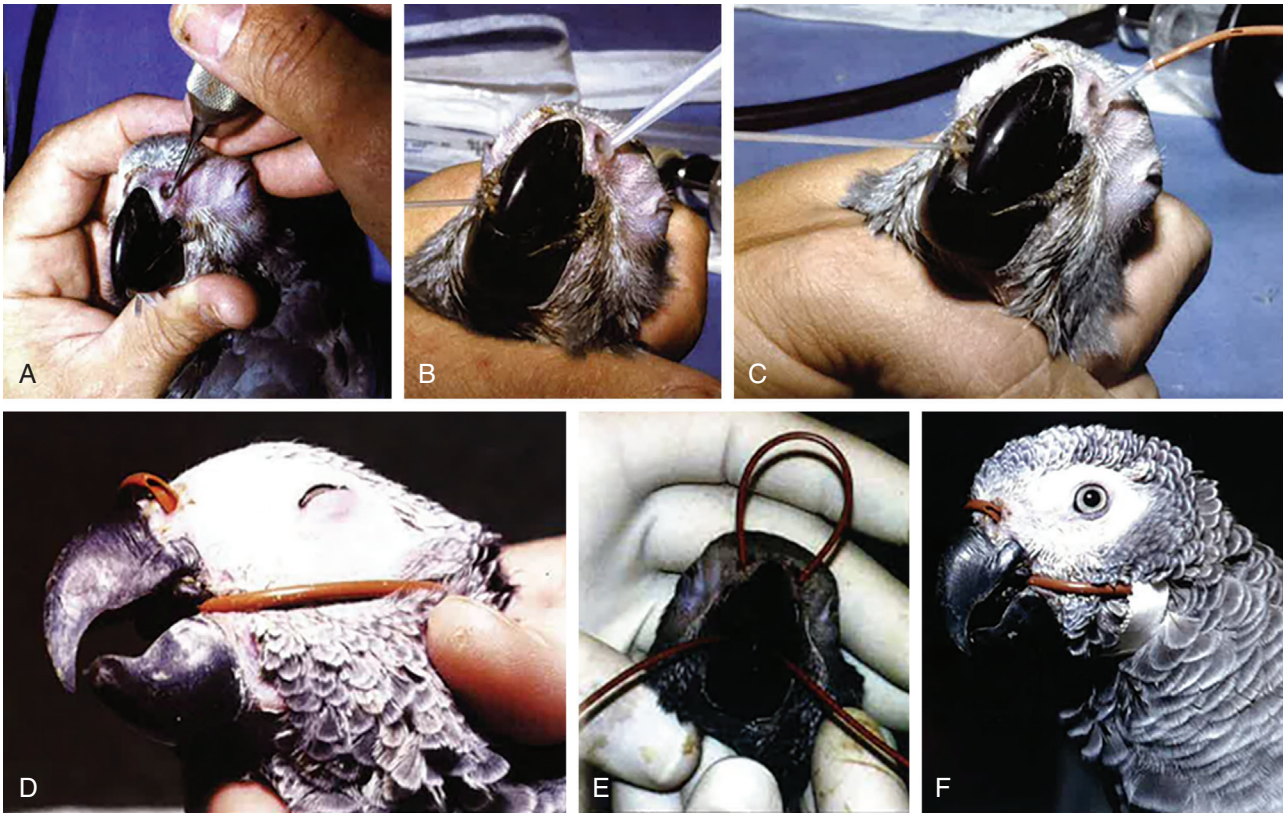

FIGURE 29.2 (A) Placement of Steinman pin through the nares and out of the choana in a grey parrot *(Psittacus erithacus)*. (B) A tomcat urinary catheter, which is firmer than the rubber urinary catheter, is then inserted through the opening created with the Steinman pin. (C) The red rubber urinary catheter is nested into the end of the tomcat catheter, and the entire structure is pulled out of the choana, functionally leaving the red rubber catheter in the newly created passageway. (D) The same procedure is duplicated on the opposite side, allowing the red rubber catheter to be looped over the cere, with both ends equally exiting the choana. To prevent further mucus accumulation in the nares and conchae, note the fenestrated opening that has been cut into the exiting tube from both nares. (E) A rostral to caudal view of the urinary catheter placement, showing the looped placement over the cere. (F) The ends of the catheter are tied behind the head and left in place for 4 to 6 weeks. Following catheter removal, nasal flushes should be regularly performed to minimize the further accumulation of mucus and debris and occlusion of the newly created pathway. (Photos courtesy Don J Harris.)

Potential complications

Damage to the palatine bone, hemorrhage, reocclusion of the drainage pathway, and (secondary) infection.

Sinusotomy

Indications

Known or suspected infectious or neoplastic disorders in the infraorbital sinus or associated regions.[8] This sinus has been referred to as the "infraorbital sinus," "subocular sac," "orbital sinus," "maxillary sinus," and several other terms. As the infraorbital sinus is located in the antorbital fossa, the term "antorbital sinus" has also been proposed.[9] For the purposes of uniformity, this sinus is referred to as the infraorbital sinus in this document. In addition to their identification, surgical access can enable complete or partial excision of lesions within the sinus and in the regions adjacent to the sinus. Infraorbital sinusotomy can also provide access to the maxillary process of the palatine, jugal, pterygoid, and quadrate bones.[5] In some instances, an infraorbital sinusotomy may be used to facilitate access to the palatine bone when attempting to reduce palatine luxation (see Chapter 31).

Surgical technique

To approach the body of the infraorbital sinus, in most psittacine species, retract the maxillary beak (closing) while the mandible is extended (opening or lowered; Figure 29.3). This functionally enlarges the sinus space and enables greater access within. In the grey parrot, due to the larger relative size of the ethmomandibularis muscle, the upper beak should be elevated (protracted) to facilitate best exposure to the infraorbital sinus. Incise into the infraorbital sinus space ventral to the jugal arch. The infraorbital sinus space can be visually inspected, and magnification loupes with a focal light source, operating microscopy or endoscopy can be used in selected cases for deeper visualization, if indicated. The jugal arch may be incised and reflected to improve exposure, if needed. Reanastomosis of the jugal arch can be accomplished using a monofilament suture placed through predrilled holes in the bone. Every attempt to preserve the encountered muscles should be made. Closure of the surgical site is accomplished in two separate layers: the lateral wall of the infraorbital sinus and the overlying skin.

Different surgical methods have been described in nonpsittacine species to address sinus-associated problems (Figure 29.4). Infection, extending from the nasal passageways and resulting in mucus accumulation and necrosis of the ventral air pouch, was described in a marabou stork *(Leptoptilos crumenifer)*.[10] Surgical removal of the necrotic lower portions of the pouch, placement of a Penrose drain to facilitate further drainage, and targeted antibacterial treatments for the

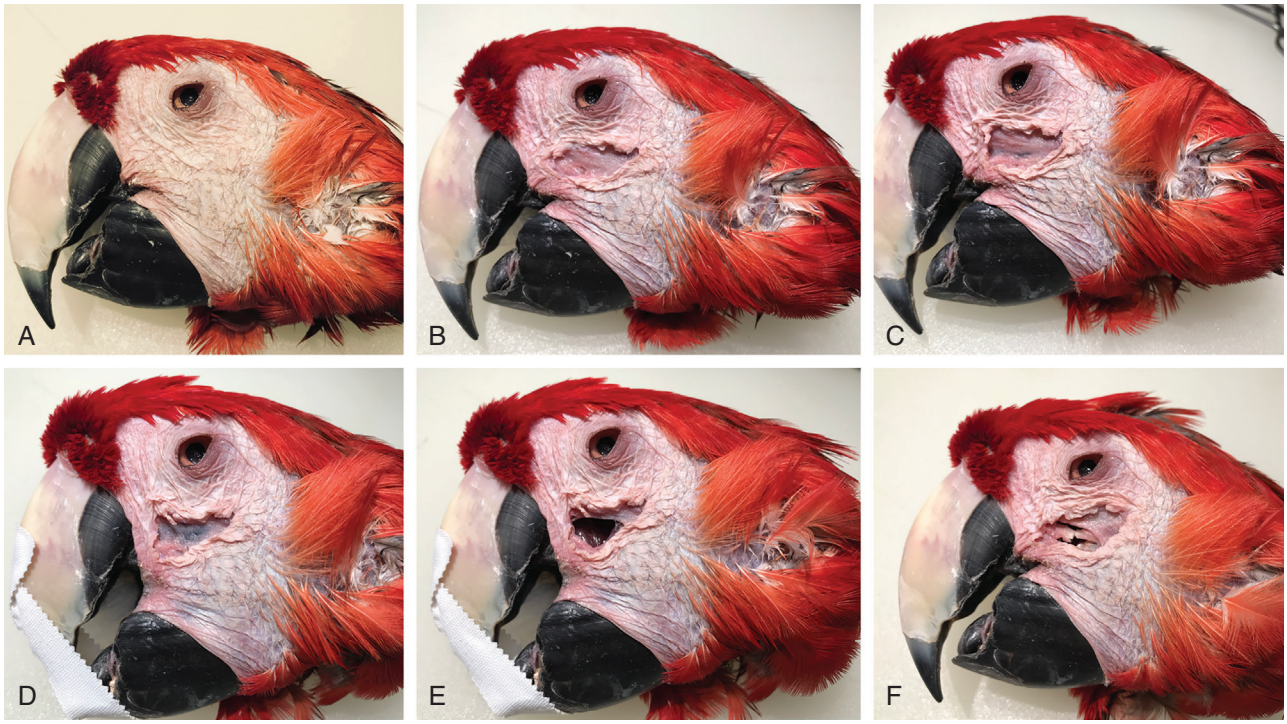

FIGURE 29.3 (A) Cadaveric head of a scarlet macaw *(Ara macao)*. Prior to making a skin incision, the jugal arch is palpated, and the incision may be made longitudinally to the jugal, ventral to the bone, or on some occasions, dorsally. (B) Skin incision has been made, and the immediate subcutaneous space is exposed. (C) Using magnified sharp-sharp dissection, the semitransparent outer wall of the infraorbital sinus is exposed. (D) By retracting the maxillary beak and placing its rostral tip inside the mandibular beak, the functional access into the infraorbital sinus is greatly increased ventral to the jugal. (E) Sinusotomy into the infraorbital sinus space, exposing the ethmomandibularis in the rostral portion of the sinus space. (F) Transection of the jugal arch, which can then be reflected or retracted to facilitate increased exposure, particularly for access to the dorsal and deep sinus spaces.

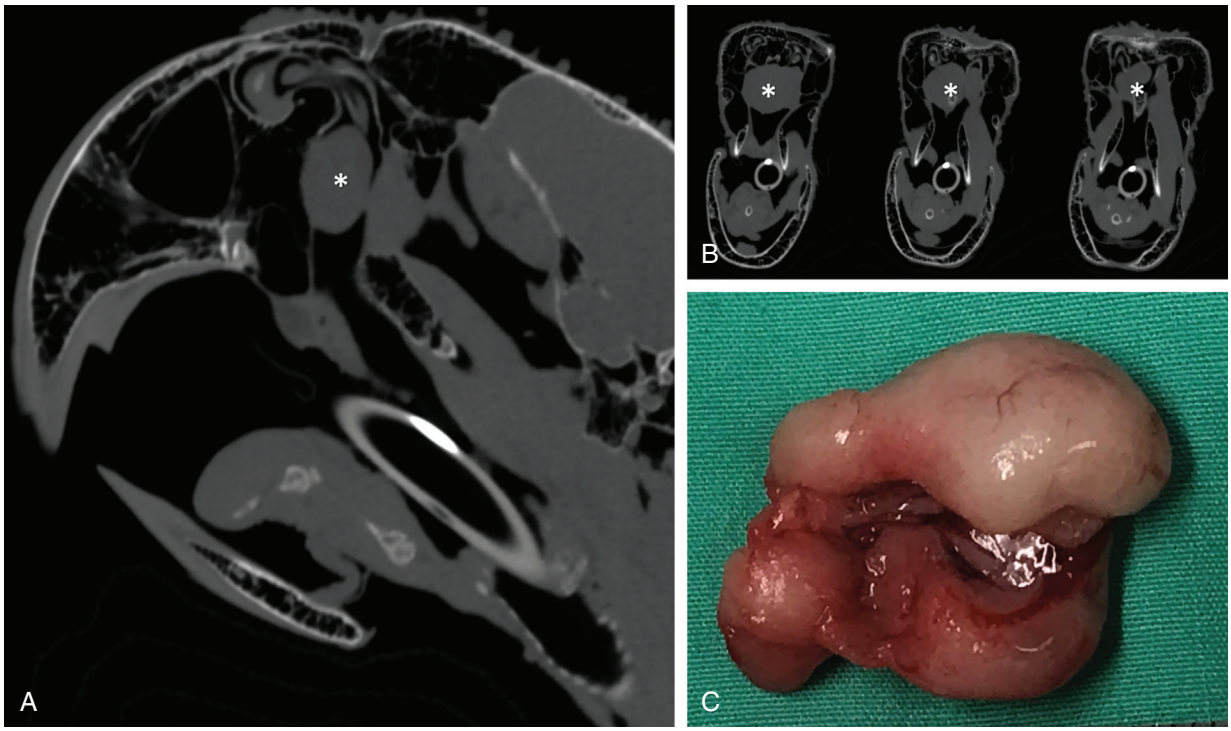

FIGURE 29.4 (A) Sagittal computed tomographic view of the adult blue-and-gold macaw *(Ara ararauna)* with a large, well-defined mass in the central and caudal nasal passageways bilaterally at their communication with the rostral choanal region, medial to the infraorbital sinus. Choanal endoscopic evaluation of this area confirmed the presence of this mass-effect; however, diagnostic full-thickness endo biopsies were unable to be obtained *(asterisk)*. (B) Transverse views of the same computed tomographic study at the level of the mass *(asterisks)*. (C) The right jugal was transected and reflected to facilitate entrance to this region medial to the infraorbital sinus via sinusotomy, and the fibromatous polyp, measuring 2.5 × 2 cm in size, was successfully removed.

Aeromonas and *Proteus* isolates lead to successful resolution of the problem 2 months postoperatively.

Potential complications

Subcutaneous air leakage from the sinus incision or jugal bone, (secondary) infection, nerve damage, hemorrhage.

Sinus Trephination

Indications

Known or suspected presence of neoplasms, granulomas, or specific infections localized in the sinus cavities beneath the cortical bone of the skull.[8] The more common areas where trephination may be performed include the dorsal-rostral aspect of the frontal bone, the area caudal to the nasal-frontal hinge, and the maxillary bone (Figure 29.5).[11]

Surgical technique

Approach to the sinus beneath the frontal bone cortex. After making a skin incision, holes are drilled into the frontal bone using Michele trephine or pneumatic bone burrs, at about one-half to two-fifths the distance from the rostral most plane of the eye to the naris.[3,11] Cortical bone is removed until the cancellous bone above the supraorbital sinus is visualized. Drilling continues into the sinus while widening the hole to an appropriate diameter. Cancellous bone is removed as needed to facilitate exposure and access to the

FIGURE 29.5 Lateral radiographic image of the skull of an anesthetized blue-and-gold macaw *(Ara ararauna)*. The location of the frontal bone site for trephination is depicted (^) and the rostral (nasal or maxillary) diverticulum of the infraorbital sinus is visualized and its location for trephination *(asterisk)*. (Courtesy Brian Speer.)

desired location. When trephining into the frontal bone, care should be taken to avoid injury to the eyes or their sockets. Following the collection of samples for diagnostic investigation and the remainder of the surgical procedure, the sinus may be irrigated.

Approach to the rostral (nasal) diverticulum of the infraorbital sinus. Trephination of the maxillary bone allows surgical access to the nasal (rostral) diverticulum of the infraorbital sinus. Using an appropriate diameter trephine or dental drill, a hole is made into the lateral maxillary beak, rostral to the nares, at approximately half the distance ventrally from the culmen. The specific location of where to drill is best determined by imaging and careful determination of surgical landmarks.[12] Once the sinus cavity is penetrated with the trephine, the core of bone is removed. This may be moistened with sterile isotonic fluids, saved and replaced at closure, submitted for histologic or other diagnostic evaluations, or discarded. As with the infraorbital sinusotomy, the exposed sinus space can be visually inspected, and magnification loupes with a focal light source, operating microscopy or endoscopy can be used in selected cases for deeper visualization, if indicated (Figure 29.6). Following collection of diagnostic samples, the open trephination often is covered with light nonporous tape, although in some circumstances, it may be closed with acrylics or resins, with or without the removed bony core being replaced. In parrot species, the speed of closure and healing of these trephination sites occur within a few weeks, while in toucan species full closure may take longer.

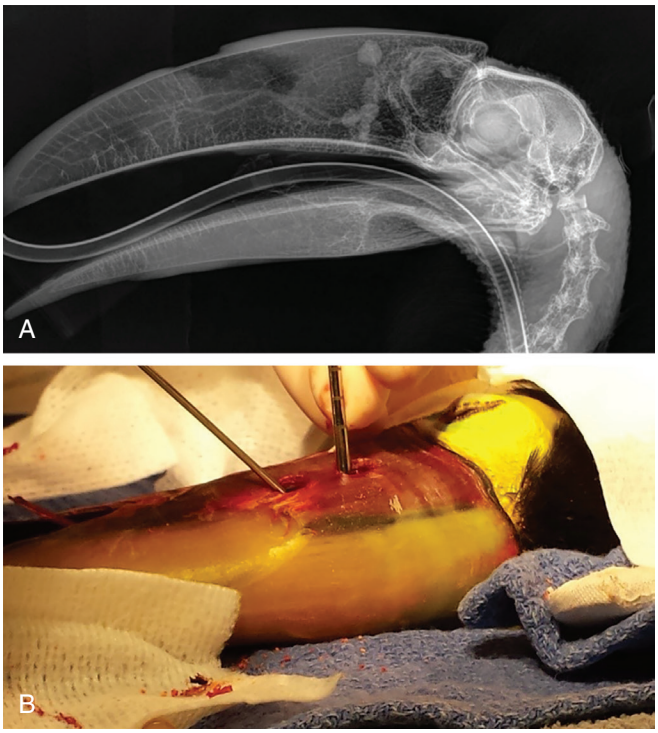

FIGURE 29.6 (A) Lateral radiographic image of a Swainson's toucan *(Ramphastos swainsonii)* with granulomas present within the rostral (nasal, or maxillary) diverticulum of the infraorbital sinus within the maxillary beak. (B) Use of two trephination sites into the sinus for inspection and removal of granulomas identified by projection radiographic and CT imaging studies. The rigid endoscope is being inserted in the more proximal site, and biopsy/grasping forceps are being introduced into the second more rostral site.

Potential complications

Iatrogenic trauma (including hemorrhage) during the trephination process, and (secondary) infection of the surgical sites.

Cervicocephalic Airsacculotomy

Indications

Traumatic injuries to the neck including the air sac system, infectious and neoplastic disease conditions (see Chapter 28).[13,14]

Surgical technique

A skin and air sac incision is made in the non-feathered (apteria) regions, parallel with the longitudinal axis of the neck. The exposed air sac space can be visually inspected, and magnification loupes with a focal light source, operating microscopy or endoscopy can be used in selected cases for deeper visualization, if indicated (Figure 29.7). Following collection of diagnostic samples, and/or debridement and flushing, the air sac incision is apposed with appropriate size monofilament suture (5-0 to 7-0 in many companion bird species). Skin is closed routinely in a second layer.

Complications

Hemorrhage into the air sac or open spaces,[13] epistaxis and subcutaneous emphysema,[15,16] and iatrogenic trauma to adjacent structures (nerves, trachea, esophagus).

Cervicocephalic-Clavicular Air Sac Shunt

Indications

Chronic hyperinflation of the cervicocephalic air sacs in psittacine species that is resulting in appreciable compromise to the patient welfare.[17]

Surgical technique

On the affected side, a superficial longitudinal incision is made laterally in the region of the thoracic inlet. Where the cervical portion is intact, a purse-string suture is made in the air sac. If the air sac is ruptured, a nonabsorbable purse-string suture can be placed between the inner lining medially and the lateral subcutaneous tissue. A shunt is prepared by modifying a small (1.0–3.0 mm) tracheal or other sterilized tube by removing the cuff and placing the side-port openings near one end. Through a stab incision, the tube is placed into the air sac about halfway up the neck. The purse-string is tied and then sutured around the tube. The crop is gently dissected ventrolaterally from its fascia attachment to the coracoid and clavicle until the clavicular air sac lumen is entered. The tracheal tube is then shortened, and side-ports added distally before it is inserted into the clavicular air sac. After anchoring the suture to the clavicle, the crop and muscular fascia is closed around the tube in a purse-string fashion. Sutures to the coli longus muscle further anchor the tube in place. The skin is closed routinely, and a small stab incision is made laterally to allow some postoperative air leakage until the clavicular air sac completely seals around the shunt.

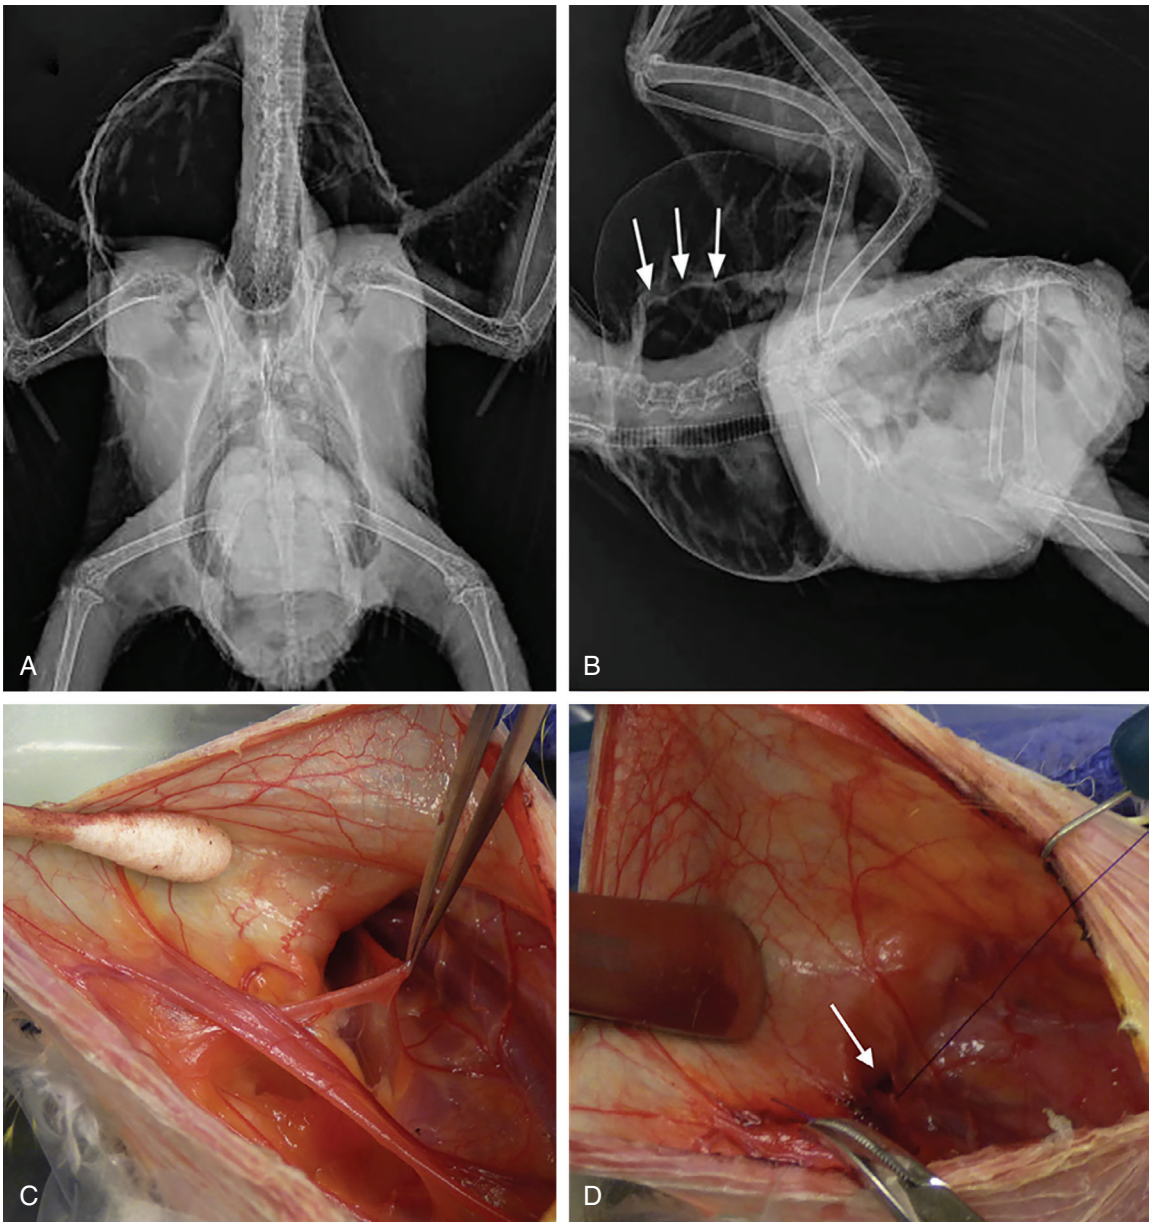

FIGURE 29.7 Closure of a large cervicocephalic air sac rupture in a double yellow-headed Amazon parrot *(Amazona ochrocephala oratrix)*. The airsac deficit was identified with a combination of projection radiographic (A and B) and CT imaging studies. Note the linear radiopaque structure that was most consistent with a thickened air sac rupture site *(arrows)*. A monofilament absorbable suture was used to close the air sac membrane (C and D) (remaining area to be closed identified by *white arrow*, D), and skin was closed separately. (Courtesy David Eshar.)

Potential complications

Occlusion of the tube, shunt failure, and infection.

Air Sac Cannulation

Indications

Placement of an alternative airway to facilitate ventilation includes the presence of obstructive tracheal disease or the need to have free access to the upper airways of the bird surgically. Common indications for air sac cannulas include obstructive tracheal granulomas (*Aspergillus* spp.), tracheal foreign bodies, and tracheal injuries that require surgical repair. Less commonly, intratracheal hemorrhage, neoplasms, redundant tracheal membranes or strictures, or even mucus tracheal plugs may be seen, necessitating placement of this manner of an alternative airway.[18,19]

Surgical technique

Preoxygenation may help facilitate the procedure, and midazolam often can have great value as an anxiolytic and conscious sedative. Combined, these may reduce the time required for induction and hence the ability to safely place the air sac cannula. General anesthesia often is required, and

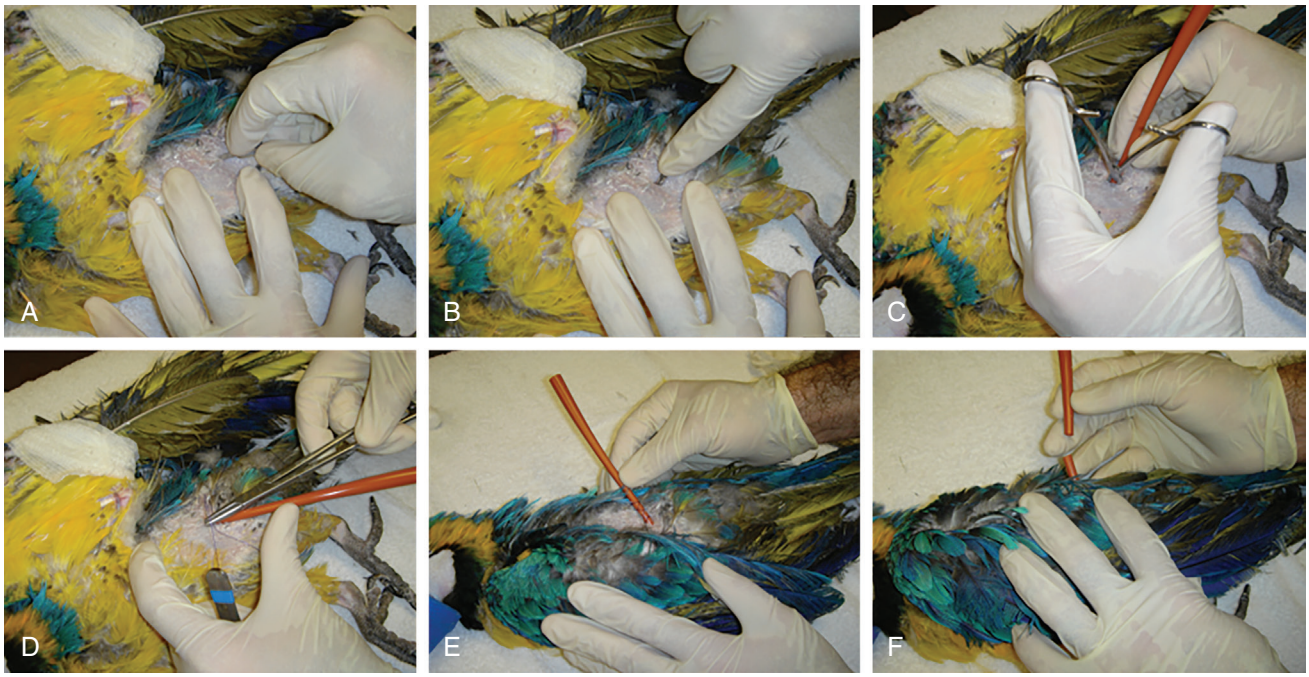

FIGURE 29.8 For air sac tube placement, the bird is positioned in right lateral recumbency. The tube is placed in the left lateral flank. The skin is prepared with a surgical scrub and a small incision is made caudal to the last rib or between the last two ribs (A). Mosquito forceps are used to bluntly penetrate the muscle wall and enter the air sac (B). The end of the fenestrated tube is inserted into the air sac between the opened jaws of the mosquito forceps (C). A finger-trap suture is used to and suture to the skin and abdominal muscles (D). Finally, the tube is cut at the appropriate length (E and F). (Courtesy David Sanchez-Migallon Guzman.)

speed is important, especially in patients with (obstructive) tracheal disease. The caudal thoracic and abdominal air sacs are the most common sites for tube placement. To perform the procedure, the patient should be positioned in lateral recumbency (Figure 29.8). Landmarks for access to the caudal thoracic air sac include the caudal margin of the last (eighth) rib, the cranial thigh musculature, and the dorsal trunk musculature. The caudal thoracic and the abdominal air sacs can both be accessed with the leg extended cranially, whereby the caudal thigh muscles define the cranial margin, and the pubic bones and the dorsal trunk musculature define the caudal and dorsal margins, respectively. Alternatively, with the leg extended caudally, the tube can be placed into the caudal thoracic air sac in the left flank area between the last two ribs or caudal to the last rib. The end of an endotracheal tube can be used as an air sac cannula; alternately, a red rubber tube can be cut to an appropriate diameter; or commercially manufactured air sac tubes can be used. The inner diameter of the tube placed should be equal to or exceed the (estimated) inner diameter of the trachea of the patient. After making a small incision in the skin, bluntly dissect through the muscle of the lateral body wall to the air sac. Apply gentle pressure to "pop" hemostats through the air sac membrane into the air sac. Use caution and keep the index finger close to the tip of the instrument to avoid penetrating viscera. Insert the air sac tube craniomedially through the open hemostats, but not too deeply. Test for air flow with cotton strands, cottonwool, down feather, or a microscope slide. Suture the tube in place using a tape tab placed at the tube at its skin interface, or a finger-trap suture. Test again for patency and stability of the tube once the sutures are in place. It is uncommon to require cervical restraint collars or Elizabethan collars to block the bird from accessing the tube. Oxygen or anesthetic systems can be attached directly to the air sac tube as long as these attachments do not add weight and discomfort for the bird. These alternative airways are left in place typically for periods up to 5 days. Patency needs to be regularly checked. To determine if the trachea is functional, the air sac breathing tube may be sealed with a piece of (paper) tape or clamped off with a hemostat while observing the patient's breathing character. If no change in respiration occurs, and the patient breathes normally, then the air sac tube can be removed. The entry site of the cannula may be closed with suture or be allowed to heal by second intention.

Potential complications

Obstruction of the tube, discomfort due to placement location of the tube, visceral organ trauma, hemorrhage or perforation, and infection.

Tracheotomy

Indications

Foreign bodies or masses in the trachea might require tracheotomy.[20,21] Tracheotomies are performed when less invasive approaches, like endoscopy or suction,[22,23] have failed to resolve the problem. Tracheal surgery requires prior air sac intubation to maintain anesthesia.

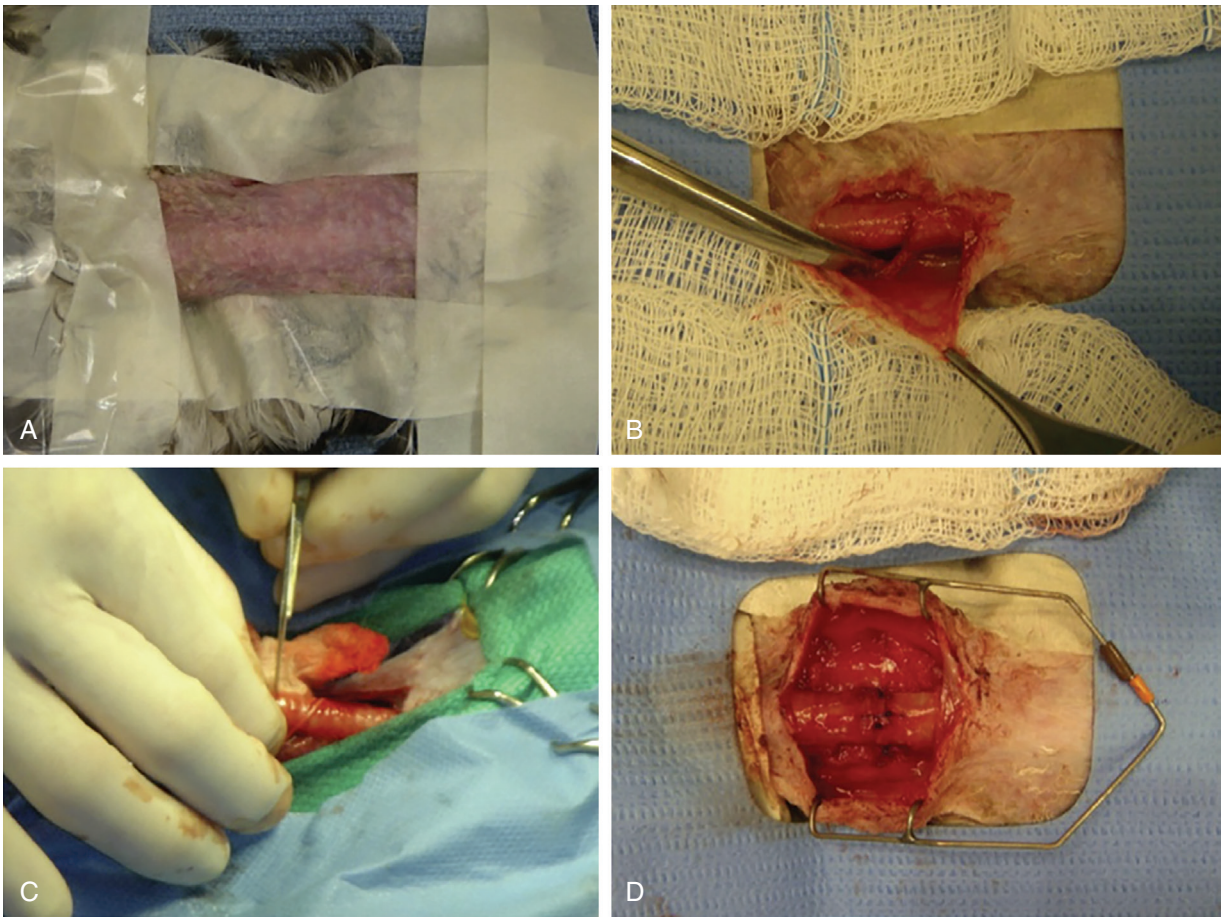

FIGURE 29.9 Tracheotomy in a red-tailed hawk *(Buteo jamaicensis)*. (A) The feathers have been removed over the skin in the ventral cervical region with the bird positioned in dorsal recumbency. (B) The subcutaneous tissues are dissected to reveal the paired sternothyroideus muscles. The recurrent nerves are identified and avoided. (C) A transverse incision over the ventral aspect of the trachea is performed in a different bird with a No. 11 blade. (D) Simple interrupted sutures are placed incorporating one tracheal ring on each end of the incision using an absorbable monofilament suture. (Courtesy David Sanchez-Migallon Guzman.)

Surgical technique

The bird is positioned in dorsal recumbency (Figure 29.9). The skin is incised along the ventral midline of the neck or just lateral to the crop. The subcutaneous tissues are dissected to reveal the paired tracheal muscles that are associated with the trachea in birds (i.e., *Mm. sternohyoideus*, *tracheolateralis*, *sternotrachealis*, and *cleidotrachealis*). Note that the location of these muscles is variable depending on the species. The recurrent nerves are identified along the ventral lateral to lateral (depending on species) aspects of the trachea and care should be taken to avoid these through the use of careful dissection techniques, if possible. If the location of the lesion cannot be determined externally, a red rubber catheter can be passed through the trachea to a point of resistance in the case of stenosis, or a rigid endoscope can be inserted to identify the affected area. Transillumination or measurements taken from projection radiography or CT imaging may also help localize the lesion prior to surgical incision (see Chapters 2 and 27 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 14, Advances in Diagnostic Imaging). A transverse incision with a No. 11 scalpel blade or beaver miniblade over the surgical site of approximately 50% of the tracheal circumference is performed on the ventral tracheal surface. Next, stay sutures are placed around the tracheal rings adjacent to the tracheotomy site to manipulate the trachea. Foreign material may be grasped and removed, gently debrided, suctioned, or pushed cranially to exit through the glottis. A hypodermic needle may be placed transversely caudal to the obstruction to help prevent it from being inadvertently moved caudally during extraction efforts. A rigid endoscope may facilitate visualization and confirmation of complete removal of the target material or resection of the affected area. Simple interrupted sutures are preplaced to incorporate one to two tracheal rings on each end of the incision using small, 4-0 to 8-0 monofilament absorbable (e.g., polydioxanone) suture. The subcutaneous and skin closure is routine.[4]

Postoperative care

Antibiotics, antifungals, opioids, and antiinflammatories are administered as needed. Removal of the air sac cannula after

temporary occlusion and careful observation for respiratory distress following air sac cannula removal are recommended. Cage rest can be considered to prevent trauma of the surgical site.

Complications

Intraluminal granuloma formation at the suture site has been described as common.[4] Hemorrhage early after surgery and stenosis late after surgery have been reported in a blue crane *(Grus paradisea)* that underwent tracheotomy to remove a rock.[20] Other possible complications include infection of the surgical site, aspiration, and pneumonia.

Prognosis

For uncomplicated procedures, the prognosis is good. If further damage to the trachea occurs or diseased tissue is not removed, tracheal stenosis may develop, and resection and anastomosis might be required.

Tracheal Resection and Anastomosis

Indications

Trauma, infection, inflammation, or neoplasia may result in tracheal stenosis requiring resection of the affected segment of the trachea. There are several case reports in the literature involving a wide range of species.[20,24–34] In most cases, the trachea is of sufficient length that several tracheal rings can be removed without the creation of undue tension when anastomosed.

Surgical technique

The patient is positioned typically in dorsal recumbency, and the surgical site is approached as described earlier for the tracheotomy (Figure 29.10). Ideally, the recurrent nerves and their associated vascular bundle are carefully dissected off the trachea and not severed. Suture can be used to retract these nerves and vessels away from the surgical site during the remainder of the procedure. Cranial and caudal to the affected segment,

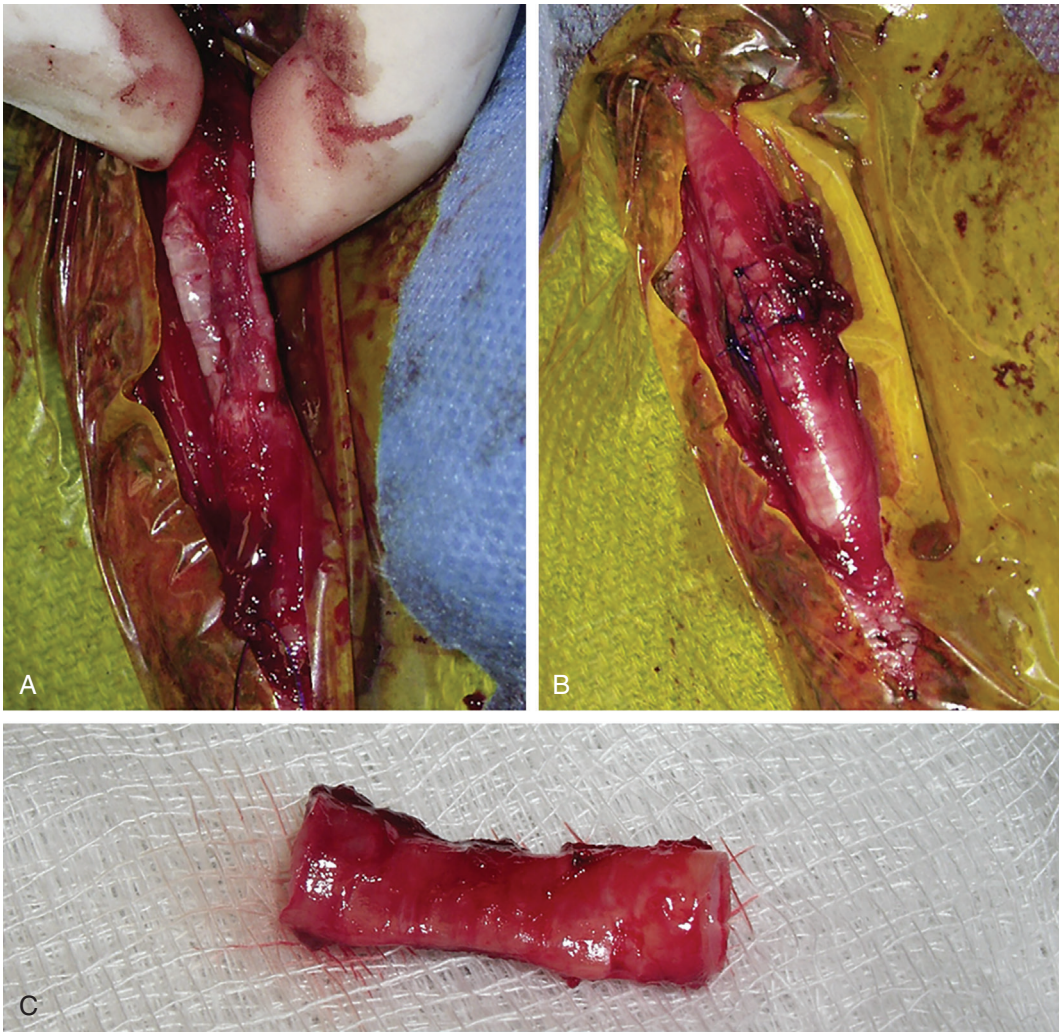

FIGURE 29.10 Tracheal resection and anastomosis in a mallard duck *(Anas platyrhynchos)*. (A) The collapsed tracheal segment is exposed following incision of the skin and muscles over the ventral aspect of the trachea with the bird positioned in dorsal recumbency. (B) The collapsed segment has been resected and the ends of the trachea anastomosed with simple interrupted and tension relief sutures. (C) Segment of the trachea resected. (Courtesy David Sanchez-Migallon Guzman.)

a tracheal ring is bisected circumferentially with a No. 11 or beaver scalpel blade. Alternatively, the intratracheal ring tissue is cut one tracheal ring cranial and caudal to the affected segment. The tracheal ends are approximated by preplacing simple interrupted sutures of 4-0 to 8-0 monofilament absorbable (e.g., polydioxanone) on a tapered needle. Typically, a minimum of four sutures are used for the anastomosis. The sutures are tightened individually with extraluminal knots to oppose the tracheal ends. If there is a need to remove a larger portion of the trachea, it may be noted that the distal end is smaller than the proximal portion with some species, and it is impossible to oppose the tissues. In these circumstances, the proximal end is usually placed such that the distal end fits into it. The subcutaneous and skin closure is routine.

Postoperative care

Antibiotics, antifungals, opioids, and antiinflammatories as needed. Removal of the air sac cannulation after temporary occlusion, careful observation for respiratory distress following air sac cannula removal, and cage rest are commonly recommended. Endoscopic examination of the trachea may aid for confirmation of effective healing and an absence of stricture or granuloma formation.

Complications

Injury to the recurrent nerves resulting from surgical manipulation or radical resection. The recurrent nerve does not innervate the larynx in birds but instead innervates the esophagus, crop, tracheal, and syringeal muscles; thus damage to the recurrent nerves will not cause laryngeal paralysis but might instead cause a change in voice. The larynx in birds is innervated by the glossopharyngeal nerve. Postsurgical tracheal stenosis might develop if there is no good apposition of the anastomosis site, if reactive suture material or traumatic suture technique is used, and/or if high tension is applied to the anastomosed site. A mismatch of the diameter of the tracheal ends is more likely to occur in some species (e.g., macaws, cockatoos) when a large segment is resected in the most cranial third of the trachea, since there is a significant decrease in diameter from cranial to caudal in this area.

Prognosis

The prognosis for complete resolution in uncomplicated cases is good. In some cases, problems may reoccur. Reassessment of birds undergoing tracheal anastomosis for tracheal stenosis by endoscopy and radiography at 1, 2, and 6 months after surgery has been suggested.[28]

Tracheostomy

Indications

Glottal and periglottal lesions can result in upper airway obstruction requiring a tracheostomy.

Surgical technique

The patient preparation and surgical approach are as described for the tracheotomy. The surgical site is 1 to 2 cm ventral to the mandible, which helps to ensure that the stoma is not obstructed when the bird flexes the neck (Figure 29.11). A transverse incision between the tracheal rings of approximately one-third the circumference of the trachea is made with a No. 11 or beaver blade. A second parallel incision is made in the trachea so that final stoma length would be approximately three times the width. The parallel incisions are connected incising the tracheal rings, resulting in a rectangular-shaped stoma. The placement of a (custom-made) stainless steel stent in the stoma may help prevent it from closing prematurely, although this has not yet been described. The skin is sutured to the stoma with 5-0 to 7-0 monofilament absorbable suture material with cutting or reverse cutting needle in a simple continuous pattern.[35]

FIGURE 29.11 Postoperative tracheostomy in a blue-and-gold macaw *(Ara ararauna)*. Subglottal obstruction, which was nonresponsive to medical and surgical treatments, leads to the decision to create a more permanent stoma. Complications included progressive mucus accumulation and the formation of granulation tissue at the stoma site. (Courtesy Angela Lennox.)

Postoperative care

Antibiotics, antifungals, opioids, and antiinflammatories as needed. Daily cleaning of the surgical site with saline to remove secretions.

Complications

Dehiscence of the surgical site, subcutaneous emphysema, (secondary) infections, granuloma formation around the stoma with reduction in diameter, and mucus accumulation in the lower airway tract.[35,36]

Prognosis

Poor long-term prognosis. Of the three cases reported in the literature, survival times were 5 weeks in a hooded vulture *(Necrosyrtes monachus)* versus 3 and 4 months in two psittacine birds, respectively.[35,36] Euthanasia or spontaneous death has

occurred largely due to a loss of effective airflow through the stoma and recurrence of obstructive airway–associated clinical signs.

Tracheal Stenting

Indications

In extensive tracheal stenosis, when other approaches like balloon dilation or tracheal resection fail or are not considered possible because of the length of the affected trachea.[37]

Surgical technique

Endoscopic examination and/or CT imaging is performed to confirm the cranial and caudal extent of the tracheal narrowing and stricture. The stent is introduced through the glottis and advanced under fluoroscopic guidance. In the case of the eclectus parrot *(Eclectus roratus)* described in the literature, a custom-made nitinol wire stent measuring 4 × 36 mm (Vet Stent; Infiniti Medical, Menlo Park, CA, USA) was used.[37] The undeployed stent is positioned expanding cranially and caudally over the affected area, and then the stent is deployed and expanded (Figure 29.12).

Postoperative care

Antibiotics, antifungals, opioids, and antiinflammatories as needed. Nebulization with a combination of saline, acetylcysteine, and dexamethasone was needed in the eclectus parrot described in the literature. Multiple attempts to wean the patient off nebulization therapy and to switch to a corticosteroid-free combination were unsuccessful.[37]

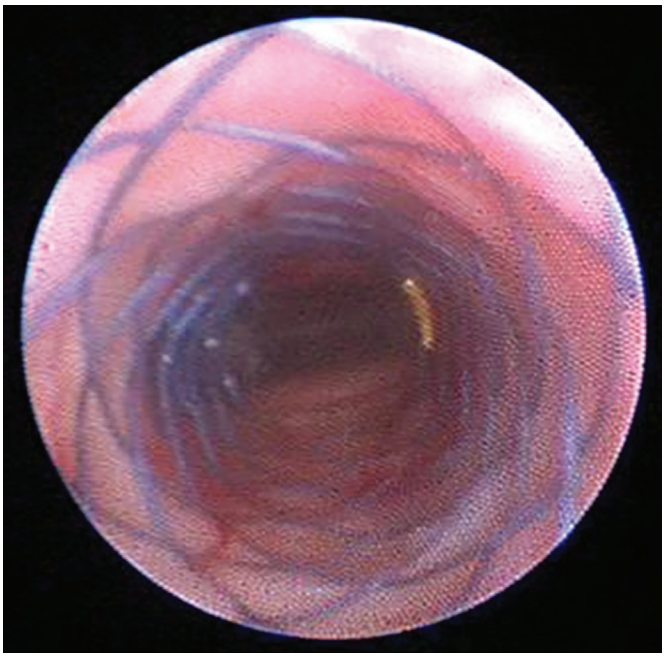

FIGURE 29.12 Endoscopic view following deployment of a nitinol wire stent in an eclectus parrot *(Eclectus roratus)* with tracheal stenosis. The undeployed stent was positioned over the region of stenosis and then expanded. The syringeal membranes are visible centrally, distal to the deployed stent. (Courtesy of Stephen Divers, University of Georgia)

Complications

In the eclectus parrot, tracheitis and tracheomalacia were reported as complications resulting in euthanasia almost 2 years after the procedure.[37] Other potential complications of stent placement are obstructive granulation tissue, stenosis at the ends of the stent (epithelium growing over stent wires), migration of the stent, mucous plugging, infection, and stent fracture.

Prognosis

In the single case reported with an internal tracheal stent, the bird survived almost 2 years following surgery. After stent placement, intermittent episodes of mild to moderate dyspnea continued, which responded to medical management. Given the possible complications, short- and long-term reassessments of birds undergoing stent placement for tracheal stenosis by endoscopy and/or radiography are recommended.

Tracheal Prosthesis

Indications

Tracheal collapse.[38]

Surgical technique

In the literature, the procedure has been described in an ostrich *(Struthio camelus)*. In this bird,[38] six tracheal rings had been transected by a previous laceration, leaving a 1.5-cm section of the trachea devoid of medial/lateral support, resulting in tracheal collapse on inspiration. Following a standard midline approach to the trachea, a 2.5-cm diameter, 0.75-cm-wide polypropylene ring devised from a 12-mL syringe case was sutured to the tracheal cartilages and submucosa as a splint-ring prosthesis, without perforating the tracheal lumen, with 2-0 polydioxanone or other appropriate monofilament suture. The subcutaneous tissues and skin were closed routinely.

Postoperative care

Antibiotics, antifungals, opioids, and antiinflammatories as needed.

Complications

Short-term complications described in the ostrich included swelling of the surgical site 3 days after the surgery.[38] No long-term complications were reported up to 6 months after surgery. Other complications that have been described in dogs include laryngeal paralysis and recurrence of laryngeal collapse. However, these are less likely to occur in birds due to their anatomy and the likelihood of a traumatic event underlying the tracheal pathology necessitating such approach.

Prognosis

In the single case reported with an external tracheal prosthesis, the bird survived for at least 6 months.

Syringotomy

Indications

Localized infections (e.g., bacterial, fungal), foreign bodies, when noninvasive methods like endoscopic removal or suction are not possible.

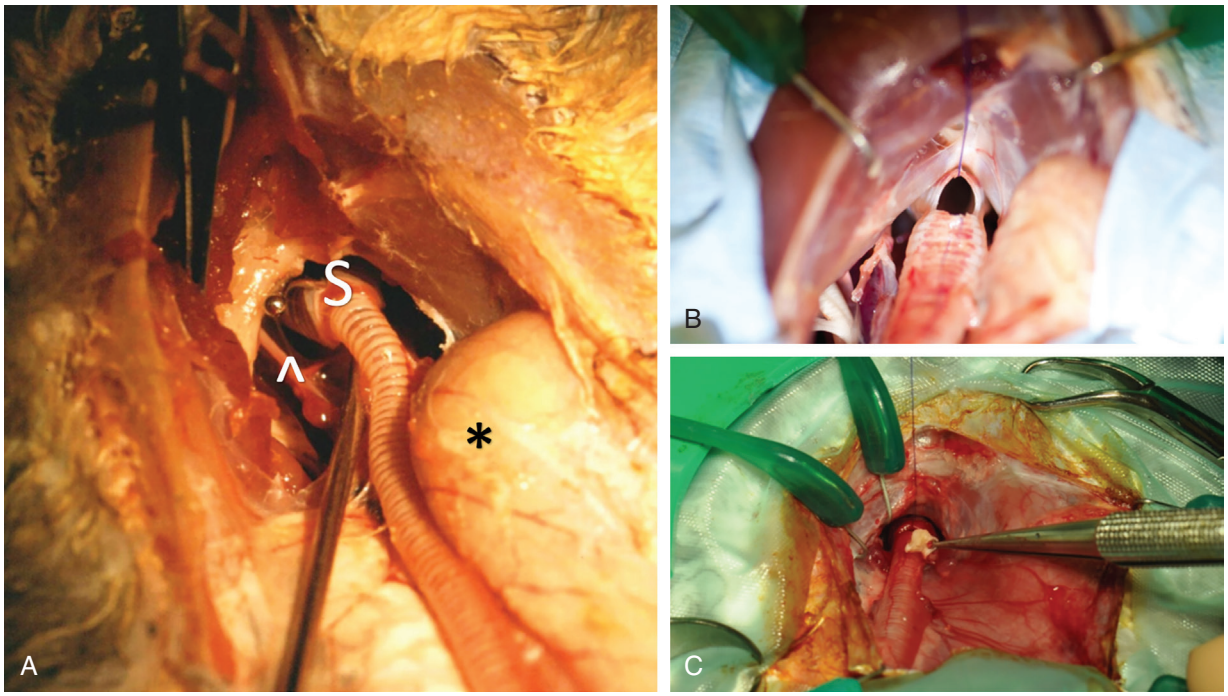

FIGURE 29.13 Ventral approach to the proximal trachea and syrinx. (A) The ingluvies *(asterisk)* is visible and has been reflected to the right. The paired sternotrachealis muscles have been transected, and the left internal carotid artery is visible (^) with its associated thyroid gland. The syrinx *(S)* has been elevated, exposing the trachea and its attachments to it. (B) The syrinx has been elevated with a stay suture, and a 180-degree incision three to five tracheal rings distal to the syrinx has been made, exposing the inner aspects of the syrinx. (C) Syringotomy being used for excision of a single mycotic plug at the syrinx in an Amazon parrot (*Amazona* spp.). (A, C, Courtesy Neil Forbes.)

Surgical technique

The patient is positioned in dorsal recumbency. Incise the skin along the ventral midline of the thoracic inlet and elevate the skin from the crop to the level of the clavicle (Figure 29.13). The crop is dissected free from its clavicular attachments and reflected to the left side. Fat that may be present must be removed using careful blunt tissue dissection. The clavicular air sac is incised, and the trachea is exposed as it enters the region of the thoracic inlet. If additional access is required, the superficial pectoral muscles are elevated, which will allow an osteotomy of the clavicle to be performed on one side of its symphysis. The paired sternotrachealis muscles are visualized traversing obliquely along the trachea and attaching caudolaterally. Before transecting the muscles bilaterally, which will allow cranial retraction of the syrinx, the large vessel between these muscles should be coagulated. To manipulate the trachea and syrinx atraumatically, a blunt hook can be placed around the syrinx. Alternatively, stay sutures can be placed around tracheal rings craniad to the obstruction. In most species, it is impossible to completely exteriorize the syrinx. A syringotomy is performed three to five rings cranial to the bifurcation on the ventral surface of the tracheal syringeal cartilages using the method as described for the tracheotomy. The tracheal incision is closed as described earlier for the tracheotomy, using 2-0 polydioxanone or other appropriate monofilament suture. If a clavicular osteotomy is performed, the two ends of the clavicle are opposed at closure. The skin is closed routinely.

A lateral approach to the syrinx, which includes performing a thoracotomy, has also been described when other options are not available but is rarely performed.[4] For this procedure, the bird is placed in right lateral recumbency with the wings elevated in an upward position. A skin incision is made over the second and third ribs at the dorsolateral margin of the pectoral muscles, reflecting ventrally the pectoral muscles. A portion of each of the second and third ribs is transected and removed, exposing the cranial portion of the lung. This portion of the lung is gently dissected and reflected from its attachments using a moistened cotton-tipped applicator. The syrinx is visualized dissecting between the major vasculature (jugular vein, pulmonary artery, and branches of the subclavian artery) and incised using microsurgical scissors at its junction with the left primary bronchus. The foreign material is removed. The syringeal incision is allowed to heal by secondary intention, and following placing the lung back in its normal position, the pectoral muscle is pulled over the defect in the rib cage, to then close the skin in a routine manner.

Complications

For the ventral approach to the syrinx, unintentional tears of the trachea that are too large for repair, tracheal stricture. Hemorrhage.

Prognosis

In localized lesions, without the abovementioned intraoperative and immediate postoperative complications, the access to the syrinx through the trachea has the potential to be curative and carry good long-term prognosis. No information is

available on cases in which a lateral approach of the syrinx via thoracotomy has been performed.

SURGERY OF THE LOWER RESPIRATORY TRACT

Pneumonotomy/Bronchiotomy

Indications

Surgical access to bronchi with obstructive lesions, localized infections, and neoplastic processes of the lung for collection of diagnostic samples.[3,39,40]

Surgical technique

A direct approach to the lesion is best planned though advanced imaging (Figure 29.14; see also Chapter 2 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 14, Advances in Diagnostic Imaging). In most cases, the bird is placed in lateral recumbency with the wings extended upward. An intercostal approach is made by reflecting skin and incising through the intercostal musculature. If needed, a rib may be transected or even portions of the rib can be removed. If a biopsy is needed, a sample is collected with biopsy forceps. If approach to a bronchus is needed, the bronchi are exposed and incised using microsurgical scissors. Using a small curette or catheter, the mucopurulent to granulomatous material can be removed from the bronchus to successfully restore airflow (Figure 29.14). Hemorrhage can be controlled with pressure, moistened cotton-tipped applicators, or hemostatic clips as needed. Vascular clips are placed on the lung, as needed, to minimize air leakage and hemorrhage. Placement of oxidized regenerated cellulose (Surgical; Johnson & Johnson Medical, Arlington, TX) may be utilized to help reduce continued bleeding.

Complications

Air leakage with subcutaneous emphysema, hemorrhage, bronchial tears.[40]

Prognosis

Pneumonotomy and bronchiotomy patients appear to function normally postoperatively.[3,39,40]

Pneumonectomy

Indications

Infection or neoplasia may require partial pneumonectomy.

Surgical technique

The lungs may be approached through the caudal thoracic air sac or the dorsal intercostal spaces following retraction or

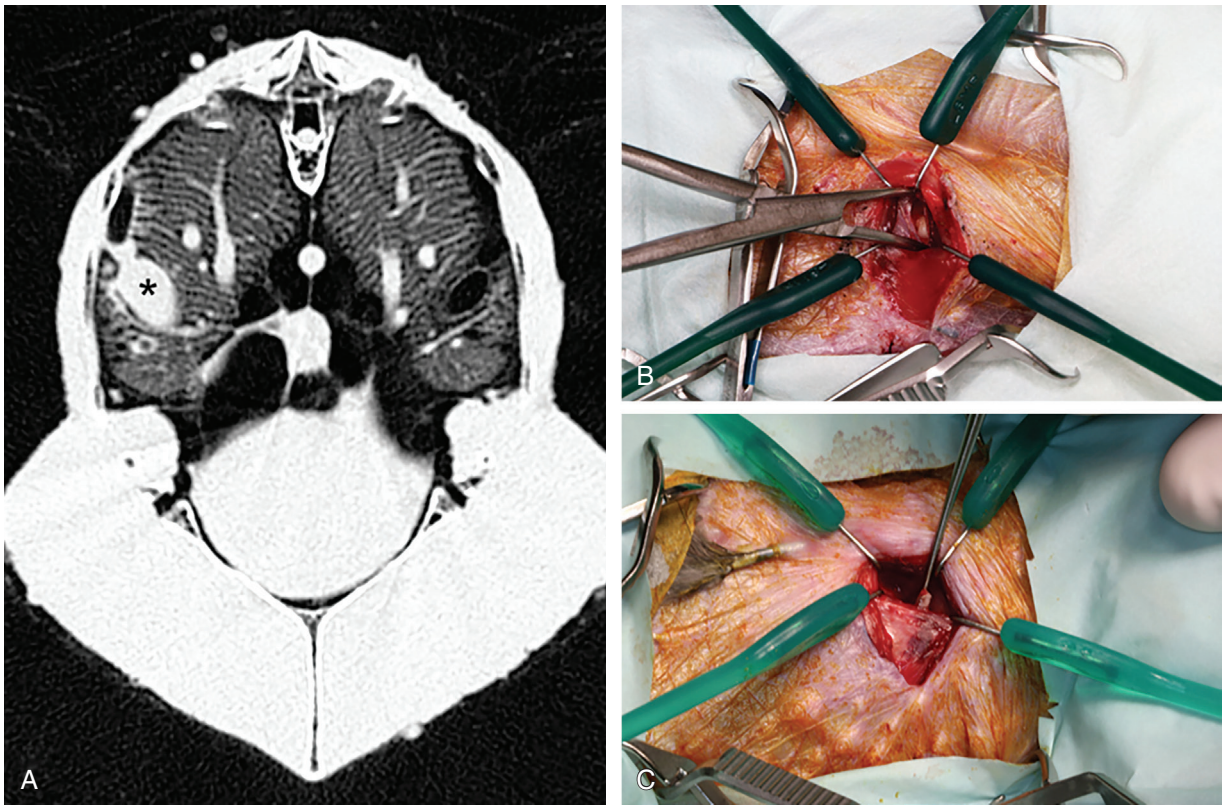

FIGURE 29.14 (A) Transverse plane of a computed tomography study in a parrot showing an obstructed primary bronchus *(asterisk)*. (B) Direct lateral approach to the lung and bronchus, ventral to the *top* and cranial to the *right* of the image. The skin has been incised over the previously localized lesion, and intercostal musculature incised and retracted. Hemostats are used to retract the pleural membrane, exposing the caseous lesion within the bronchus. (C) Removal of the bronchial plug with a curette, following surgical exposure via lateral approach to the lung. (Courtesy Nico Schoemaker/Yvonne van Zeeland.)

removal of the ribs. The lung is elevated from the ribs and other structures using a spatula or moistened cotton-tipped applicator. Hemostatic clips are placed on the lung tissue to isolate the portion to be removed. The portion distal to the clips is then removed. The skin is closed routinely.[41]

Complications

Air leakage with subcutaneous emphysema, hemorrhage.

Prognosis

No information is available on pneumonectomy reported cases, and the procedure is rarely performed.

CHAPTER 30

Diagnostic Endoscopy, Endoscope-Assisted Therapy, and Endosurgery of the Avian Respiratory System

Stephen J. Divers

INTRODUCTION

There are around 10,000 species of birds that vary tremendously in their anatomic, physiologic, and ecologic adaptations, and it is impossible to cover all species and possible situations. Consequently, focus has been concentrated on describing endoscopic principles of diagnosis and therapy with multiple-taxa examples, while prioritizing those species most encountered in clinical practice.

Endoscopy offers several advantages over other diagnostic modalities. Unlike serologic testing for aspergillosis, which takes several days to obtain results, endoscopic diagnosis is immediate, and the collection of biopsies for culture and sensitivity testing provides greater confidence in appropriate drug selection and permits minimum inhibitory concentration (MIC)-calculated drug doses. Indeed, general reliance on broad-spectrum antimicrobials implies a low level of skill and ability on the part of the clinician. Unlike cross-sectional imaging, including computed tomography (CT), endoscopic examination also facilitates biopsy for a definitive (histologic and microbiologic) diagnosis and topical or intralesional therapy to be administered. It is for these reasons why endoscopic evaluation of the respiratory system is the accepted standard of care for domesticated mammals and humans, and birds are no exception. Indeed, by the time a bird at rest shows clinical evidence of respiratory disease, severe compromise has often occurred, and the case should be considered emergent. Diagnostic investigations should proceed quickly following stabilization.

Endoscopy is a surgical procedure and requires general anesthesia. Therefore, although a brief tracheoscopic examination may only require 30 seconds of gas anesthesia, any contraindication for anesthesia is generally a contraindication for endoscopy. That said, birds, even with pronounced respiratory compromise, are often more stable when anesthetized with 100% oxygen than when handled in room air.

ENDOSCOPY EQUIPMENT

A full list of equipment can be found in Table 30.1.

Light Sources

The telescope is connected via a fiber-optic light guide cable to a light source. While halogen light sources are inexpensive but still effective for birds under 2 kg, xenon and LED light sources provide better-quality light and an intensity that can illuminate the body cavities of larger species. The LED light source of the mobile Karl Storz Tele Pack Vet X LED (Karl Storz Veterinary Endoscopy [KSVEA], Goleta, CA, USA) has an extended life expectancy of up to 30,000 hours.

Cameras

An endovideo camera connected to the eyepiece of the telescope is an integral part of the endoscopy system and greatly facilitates the surgeon's performance (Figure 30.1). Cameras, available in both European PAL and American NTSC formats, can vary dramatically in cost from budget single-chip cameras to three-chip digital high-definition (HD) and 4K models. The traditional video system provided a resolution of 720 × 480 and therefore inevitably led to some cropping of the image for display on a traditional 4:3 aspect monitor. The advent of HD systems has increased the video size to 1920 × 1080 pixels. In addition, the new 16:9 aspect ratio provides a 33% wider field of view while progressive (as opposed to interlaced) scan produces improved resolution, color clarity, and refresh rates. Additional camera advances including 4k high resolution (3840 × 2160 pixels), three-dimensional (3D), light filters, fluorescence imaging, and chromoendoscopy are already available, although such equipment may currently be cost-prohibitive for anyone outside of a large academic or referral hospital. The fact remains that *any* camera will greatly improve performance compared to using the eyepiece directly and will also facilitate photodocumentation. Operating room setup is important, and the monitor should be positioned directly in front of the endoscopist, with instruments within easy reach.

Photodocumentation

The ability to record still images and video of procedures is becoming increasingly important for maintaining accurate medical records, as well as for generating pictures for brochures, presentations, or scientific publications. Most camera systems generate S-Video or digital outputs that can be connected to a myriad of nonprofessional, commercial recording devices (e.g., laptops) that can ultimately save material in various formats to digital media. Professional-grade devices, although more expensive, provide dedicated functions that are important in medicine. For example, most professional endoscopy recording devices will support still images (tiff, bmp, jpeg) and video (MPEG2) with audio voice-over (WAV). Modern systems can also provide network and web-based

TABLE 30.1

Diagnostic and Endosurgical Endoscopy Equipment

Equipment Description	Primary Indications
VISUALIZATION AND DOCUMENTATION	
Endovideo camera and monitor Light source and light guide cable Digital capture device	Required for all endoscopy procedures
RIGID TELESCOPES AND ENDOSCOPES	
1-mm × 20-cm semirigid miniscope, 0 degrees	Stomatoscopy, rhinoscopy, tracheoscopy
1.9-mm × 18.5-cm telescope, 30 degrees oblique, with integrated 3.2-mm operating sheath	Stomatoscopy, rhinoscopy, tracheoscopy, and coelioscopy (<300 g)
2.7-mm × 18-cm telescope, 30 degrees oblique, with separate 3.5-mm protection and 14.5 Fr operating sheaths or 2.7-mm × 18-cm telescope, 30 degrees oblique, with integrated operating sheath (11.5 Fr)	Stomatoscopy, rhinoscopy, tracheoscopy, and coelioscopy (100 g–1 kg)
5-mm × 29-cm telescope, 0 degrees, with 6-mm × 6.5-cm Ternamian EndoTIP cannula	Coelioscopy (over 15 kg)
5-mm × 29-cm telescope, 30 degrees oblique, with 6-mm × 6.5-cm Ternamian EndoTIP cannula	Coelioscopy (over 15 kg)
5-mm × 8.5-cm otoendoscope, 0 degrees, with integrated operating sheath	Stomatoscopy (>1 kg)
FLEXIBLE INSTRUMENTS FOR USE WITH RIGID TELESCOPES AND OPERATING SHEATHS	
3 Fr biopsy forceps 3 Fr grasping forceps	For use with 1.9-mm telescope and integrated sheath
5 Fr biopsy forceps 5 Fr single-action scissors 1.5 mm remote injection needle 5 Fr grasping/retrieval forceps 5 Fr wire basket retrieval 5 Fr polypectomy snare	For use with 2.7-mm telescope and 4.8-mm operating sheath or the 11.5 Fr telescope with integrated sheath
FLEXIBLE ENDOSCOPES	
Fiberscope, 2.5-mm × 100-cm working length, 1.2-mm instrument channel, two-way tip deflection	Transglottal respiratory evaluations (>500 g)
Video bronchoscope, 5.9-mm × 61-cm working length, 2.2-mm instrument channel, four-way tip deflection, suction, and irrigation	Transglottal respiratory evaluations (>5 kg)
INSTRUMENTS FOR USE WITH FLEXIBLE ENDOSCOPES	
Grasping forceps, 3 Fr × 120 cm Biopsy forceps, 3 Fr × 120 cm	For 2.5-mm fiberscope
Biopsy forceps, round cupped jaws, diameter 5 Fr, working length 120 cm Grasping forceps, alligator jaws, 5 Fr × 120 cm	For 5.9-mm video bronchoscope
ENDOSURGICAL INSTRUMENT HANDLES	
Two plastic handles without rachets One plastic handle with Mahnes-style rachet One plastic handle with hemostat-style rachet	These ClickLine handles are interchangeable and can be used with most instruments
CANNULAE, TROCARS, AND ENDOSURGICAL INSTRUMENTS	
3.9-mm graphite and plastic cannula and trocar, with silicone leaflet valve, and luer-lock insufflation port	Accommodates 2.7-mm telescope and 3.5-mm protection sheath
2.5-mm × 4-cm, graphite and plastic threaded cannula and trocar, with silicone leaflet valve, and luer-lock insufflation port (for 2-mm instruments, typically two required) 2-mm Reddick-Olsen dissecting forceps 2-mm Metzenbaum scissors 2-mm Babcock forceps	For endosurgery (<300 g) Instruments are all 20 cm in length
3.5-mm graphite and plastic threaded cannula and trocar, with silicone leaflet valve, and luer-lock insufflation port (for 3-mm instruments, typically two required) 3-mm fenestrated grasping forceps 3-mm Reddick-Olsen dissecting and grasping forceps	For endosurgery (>200 g) Instruments are all 20 cm in length

Continued

TABLE 30.1

Diagnostic and Endosurgical Endoscopy Equipment—cont'd

Equipment Description	Primary Indications
3-mm short curved Kelly dissecting and grasping forceps	
3-mm atraumatic dissecting and grasping forceps	
3-mm Babcock forceps	
3-mm Blakesley dissecting and biopsy forceps	
3-mm scissors with serrated curved double-action jaws	
3-mm microhook scissors, single-action jaws	
3-mm Mahnes bipolar coagulation forceps	
3-mm irrigation and suction cannula	
3-mm palpation probe with centimeter markings	
3-mm distendable palpation probe	
3-mm ultramicro needle holder	
3-mm knot tier for extracorporeal suturing	
6-mm × 5.5-mm Ternamian EndoTIP cannula, with silicone leaflet valve and insufflation stopcock (for 5-mm instruments, typically two required)	For endosurgery (15–150 kg) Instruments can be 36 cm or 43 cm in length
5-mm biopsy forceps	
5-mm Blakesley dissecting forceps	
5-mm curved Kelly dissecting and grasping forceps	
5-mm Babcock grasping forceps	
5-mm curved Metzenbaum scissors	
5-mm suction and irrigation cannula	
5-mm needle holders	
5-mm hook scissors	
5-mm bipolar forceps	
HEMOSTASIS EQUIPMENT	
Autocon III Vet electrosurgery and vessel sealing (or similar)	Enables many endoscopic instruments to be used as monopolar devices and facilitates bipolar coagulation using bipolar forceps. A wide variety of 2-, 3-, and 5-mm instruments are available.
Monopolar lead to connect to plastic instrument handles	
Bipolar lead to connect to 3-mm Mahnes bipolar coagulation forceps	
LigaSure Force-Triad energy platform with foot pedal	
5-mm × 37-cm LigaSure laparoscopic instrument	Only available in 5- or 10-mm instrument sizes but a useful instrument that combines sealing and cutting. The instruments are disposable human items but most veterinarians clean and reuse.

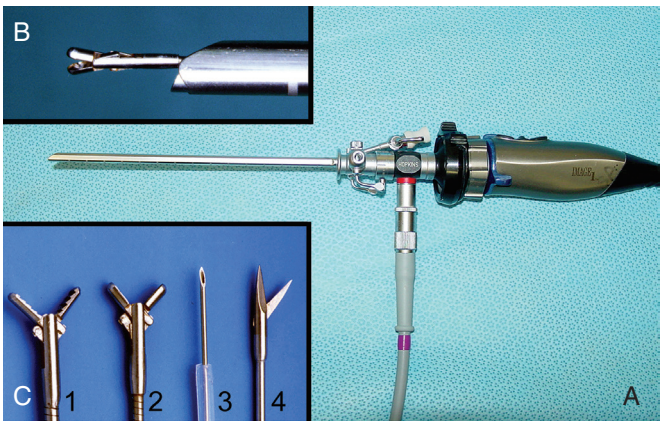

FIGURE 30.1 A 2.7-mm telescope system. (A) A 2.7-mm telescope housed within a 4.8-mm operating sheath, connected to a light cable and an endovideo camera. The newer 11.5 Fr telescope with integrated sheath has the same 2.7 mm optics. (B) A 5 Fr biopsy forceps inserted down the instrument channel, emerging directly in front of the telescope. (C) A variety of 5 Fr instruments can be used through the operating channel, including retrieval forceps *(1)*, biopsy forceps *(2)*, a remote injection/aspiration needle *(3)*, and single-action scissors *(4)*. (Courtesy Dr. Stephen Divers, University of Georgia)

storage and file sharing, including industry-standard DICOM (Digital Imaging and Communications in Medicine) support.

Mobile Units

The Tele Pack Vet X LED system combines an LED light source, endovideo camera, 38 cm (15″) color LED, with digital image and video capture onto SD memory cards or USB drives into a portable unit that is as well suited for field work, as in the hospital environment (Figure 30.2). This unit has also become popular in practice as it supports both rigid and flexible endoscopy systems, and a newer HD version of the Tele Pak has recently become available. An even more mobile option is the endogo HD camera (Cook Medical, Bloomington, IN, USA) and battery-powered light, which provides real pocket mobility albeit with reductions in light intensity and quality.

Flexible Endoscopy

There are two main classifications of flexible endoscope: the fiberscope (which transmits the image via a bundle of fiber-optic fibers) and the video endoscope (which transmits the image electronically from a charge-coupled device [CCD] stationed at the distal tip). Fiberscopes are less expensive but suffer from pixelation and poorer image quality compared to video endoscopes. Video endoscopes are considerably more

FIGURE 30.2 Tele Pack Vet X LED. This small, portable unit includes a camera, light source, 15″ monitor, and insufflation pump, is capable of recording still images and video, and is compatible with both rigid and flexible endoscopes. (Courtesy Dr. Stephen Divers, University of Georgia)

expensive but offer superior image quality. Furthermore, until relatively recently, flexible and rigid endoscopy light sources and cameras were generally incompatible, which necessitated separate rigid and flexible tower systems. This undoubtedly forced practitioners to make a choice for one or the other. Fortunately, the advent of modern cameras and light sources now enables practitioners to invest in just one endoscopy unit that can be used with both rigid and flexible endoscopes. Consequently, the ability to offer both flexible and rigid services has substantially increased in practice.

Flexible endoscopes vary from 14 mm to less than 1 mm in diameter, and those greater than 2 mm often offer tip deflection and possess a working instrument channel. Current commercial video endoscopes are limited to around 2.5 mm with a 1.2-mm instrument channel (although technology now exists to produce a <1-mm video camera). Therefore, smaller fiberscopes (0.5–2.5 mm and considerably cheaper) still have a role in avian bronchoscopy, although they often have just one- or two-way tip deflection and smaller working channels.

Telescopes and Sheaths

The 2.7-mm telescope system, first championed by Taylor for use in avian species, still remains the workhorse in avian practice because of its versatility and ability to be expanded as caseloads dictate.[1] The 2.7-mm Hopkins telescope can be used with a 3.5-mm protection sheath or with a 4.8-mm operating sheath that possesses ports and an operating channel for the introduction of 1.7-mm (5 Fr) instruments (Figure 30.1). More recently, the same 2.7 mm telescope became available with an integrated sheath resulting in an overall reduction in diameter to 11.5 Fr, while maintaining the same 5 Fr instrument channel. A smaller 9.5 Fr telescope with an integrated sheath can accommodate the introduction of 3 Fr instruments. A 1.0-mm semirigid (fiber-optic) miniature straight endoscope can be useful for smaller species (Figure 30.3), while 4-, 5-, and even 10-mm telescopes can be used with large to giant species.

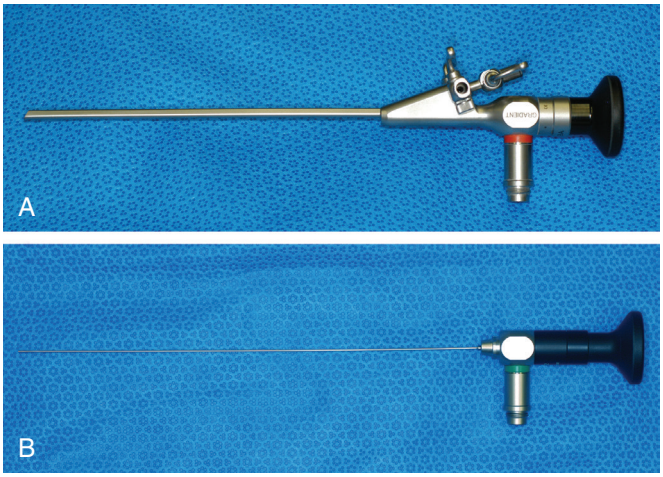

FIGURE 30.3 (A) A 9.5 Fr telescope with an integrated operating sheath. (B) A 1.0-mm semirigid miniature straight endoscope. (Courtesy Dr. Stephen Divers, University of Georgia)

Flexible Instrumentation

Flexible instruments can be used through the instrument channel of the 2.7-mm/11.5Fr and 1.9-mm/9.5 Fr systems in a single-entry endoscopic procedure. The most frequently used instruments include biopsy forceps, retrieval forceps, scissors, and remote injection/aspiration needle (Figure 30.1C). The 3 and 5 Fr (1.0- and 1.7-mm) grasping forceps are useful for manipulating tissues, debridement, and retrieving foreign objects or parasites. The fine aspiration/injection needle can be used for the aspiration of fluid from cystic structures where biopsy may be contraindicated due to risks of leakage. The needle can also be used for irrigation and endoscopic drug administration. The flexible biopsy forceps are used to harvest tissue samples for histopathology and microbiology in patients as small as 30 g. The small sample size usually permits the collection of several biopsies for multiple laboratory tests and serial biopsies to monitor disease progression over time to assess response to treatment. To take a sample, the biopsy forceps are inserted down the operating channel and into the field of view (Figure 30.4). It is much easier to advance and manipulate the telescope-instrument as a single device than to try and keep the telescope still and independently move the biopsy forceps back and forth. With the biopsy forceps held open, the telescope-instrument is advanced to the tissue of interest and when tissue enters the biopsy cup, the handle is released. Little pressure on the handle is required to close the jaws. Excessive clamping force will damage the forceps and does nothing to improve hemostasis. Some structures may be protected by a more fibrous membrane or capsule, while chronic airsacculitis can result in grossly thickened air sac walls. The fixed blade of the scissors is inserted at a shallow angle through such membranes, and the sheath-telescope-scissors are advanced as a single unit, cutting the membrane as they proceed. The scissors can then be replaced by the biopsy forceps to take a sample through the capsular incision or of the air sac wall. Other instruments that can be invaluable in specific situations include flexible suction catheters (e.g., 3 or 5 Fr red rubber catheters), radiosurgical needle electrodes (for pinpoint ablation or coagulation), and a dedicated CO_2 laser guide fits the 5 Fr instrument channel.

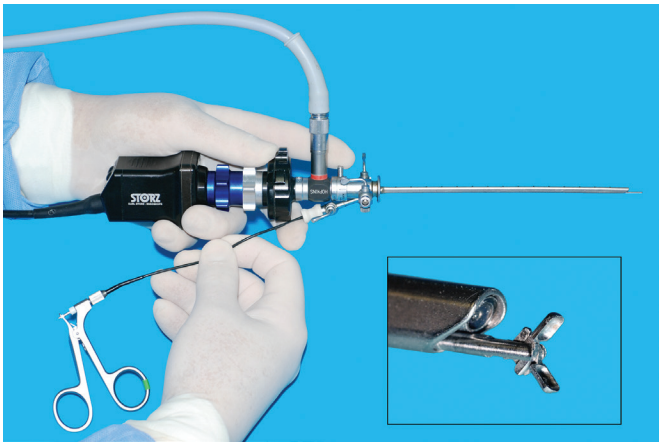

FIGURE 30.4 A 2.7-mm telescope within a 4.8-mm operating sheath, with an endovideo camera and light guide cable attached. Biopsy forceps (1.7 mm) passed through the working channel emerging in front of the terminal lens *(insert)*. (Courtesy Educational Resources, University of Georgia)

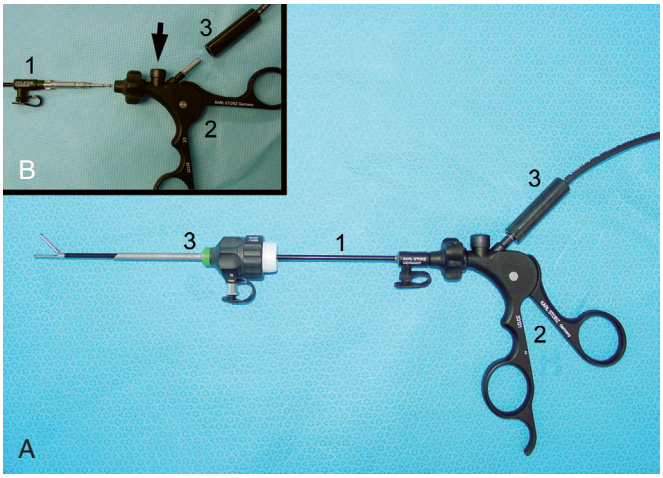

FIGURE 30.5 A 3-mm laparoscopy equipment. (A) A 3-mm instrument *(1)* attached to a standard ClickLine handle *(2)*. The instrument, attached to a radiosurgery unit via a connector on the handle *(3)*, has been inserted through a 3.5-mm graphite/plastic cannula *(4)*. (B) Instrument *(1)* and handle *(2)* can be quickly exchanged by pressing the release button (*arrow*). The radiosurgical connection is also shown *(3)*. (Courtesy Dr. Stephen Divers, University of Georgia)

Multiple-Entry Endosurgery

Rigid instruments, triangulated with, but physically separate from, the telescope are used to perform more complex endosurgical procedures within coelomic cavities and lower respiratory tract. In order to operate within the coelomic cavities, in addition to the telescope, it is necessary to introduce additional, independent instruments (Figure 30.5).[2] In order to maintain CO_2 insufflation during endosurgery in mammals and reptiles, it is necessary to use cannulae. These cannulae possess valves to prevent CO_2 leakage when instruments and telescopes are inserted or removed from the animal. CO_2 insufflation is not required (and contraindicated within the respiratory tract) in birds, as the air sacs remain inflated during anesthesia (especially if positive pressure ventilation is used). Nevertheless, cannulae are still valuable for facilitating faster transfer of instruments in and out of the coelomic cavities and preventing anesthesia compromise through the surgical site(s). As the air sac system does not collapse, it is also practical to insert telescope and rigid instruments through the same incision without cannulae, although triangulation becomes more challenging and active scavenging of anesthetic gas from the surgical site is required.

These instruments, and the cannulae through which they pass, are grouped into various size classes that are often color coded. For example, 2-mm instruments are used in conjunction with 2.5-mm cannulae, 3-mm instruments with 3.5-mm cannulae, and 5-mm instruments with 6-mm cannulae. The 2.7-mm telescope housed within a 3.5-mm protection sheath will pass through a 3.9-mm cannula, while the unsheathed 2.7-mm, integrated 1.9-mm, or 3 mm telescopes will pass through a 3.5-mm cannula.[2]

Cannulae

Cannulae are made of surgical steel or graphite/plastic construction and have internal leaflet valves (and optional insufflation stopcocks for gas delivery) (Figure 30.6). The metal cannulae (3.9 mm and greater) are more robust and heavier and therefore are reserved for large birds over 10 kg. The plastic-graphite models are lightweight and ideally suited to most smaller birds (i.e., 2.5- and 3.5-mm cannulae for 2- and 3-mm instruments, respectively). The threaded cannula (e.g., Ternamian EndoTIP) has an external screw thread to enable gradual advancement by rotation.[3] These threaded cannulae are available in 3.5, 3.9, and 6 mm sizes and do not require a trocar or much in the way of axial penetrative force for insertion.

Rigid instruments and handles

At least one, often two, and rarely three instruments are inserted through cannulae, and into the endoscopic field of view. Instruments must be triangulated to bring the instrument tips together (convergence) to enable surgery within the coelomic cavities. There is a huge assortment of 5-mm instruments available, initially developed for humans but equally applicable for animals over 10 kg. However, it was not until the development of human pediatric laparoscopy that smaller 2- and 3-mm instruments became available, and multiple-entry endosurgery became feasible in most birds.[4]

Currently, 2-mm instruments are limited to Babcock forceps, Reddick-Olsen forceps, and scissors. A greater selection of 3-mm instruments is available including a variety of dissection forceps, grasping forceps, scissors, biopsy forceps, palpation, and irrigation probes (Figure 30.7). All these instruments have a standard attachment that enables them to be used interchangeably with a selection of ClickLine handles (Figure 30.8). Handles are of plastic or metal construction and can possess a radiosurgical connection that enables scissors or forceps to be used as monopolar devices. An optional hemostat or Mahnes (disengageable) rachet mechanism is available to maintain a firm hold of tissue even if the endoscopist releases their grip on the handle.

Surgical devices and hemostasis

To effectively and safely perform endosurgery, accurate hemostasis becomes increasingly critical as the mere act of clamping

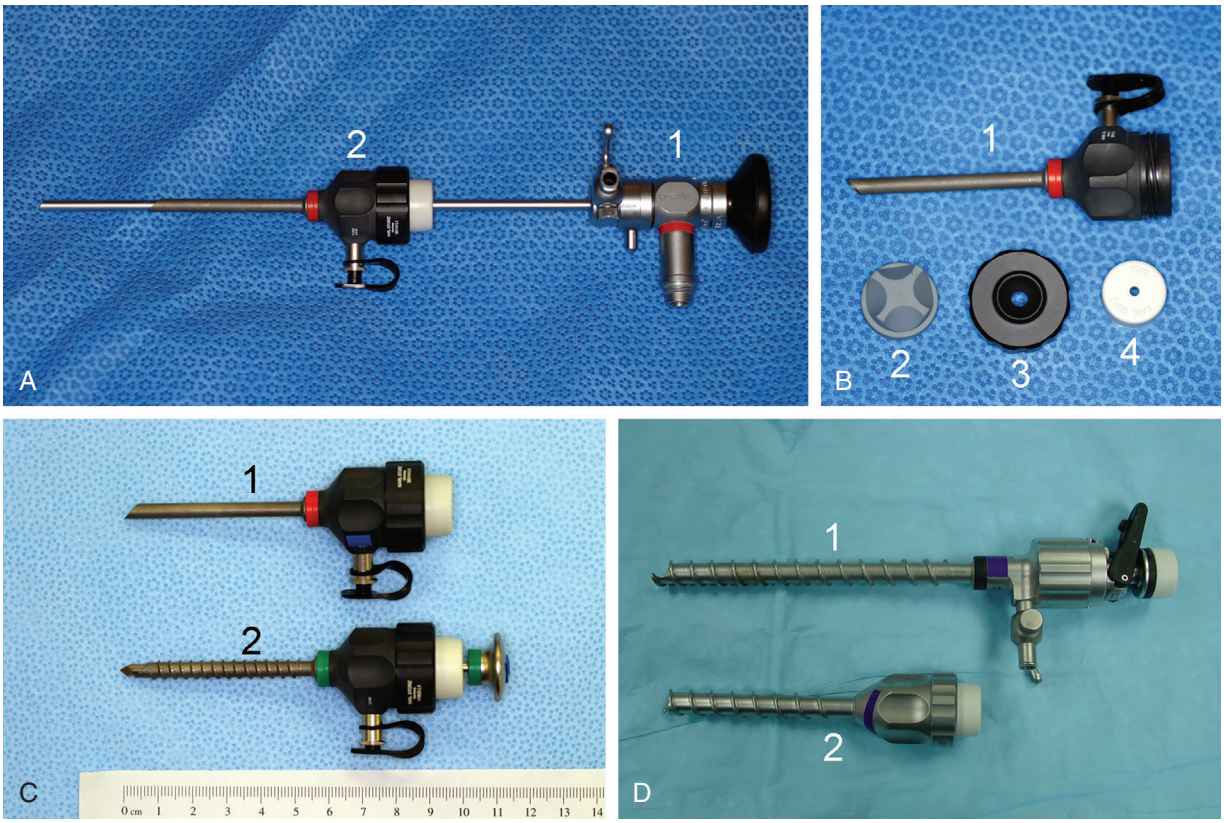

FIGURE 30.6 Cannulae and trocars. (A) A 2.7-mm telescope within a 3.5-mm protection sheath *(1)* inserted through a 3.9-mm × 10-cm graphite/plastic cannula with an insufflation side port *(2)*. (B) A 3.9-mm × 10-cm graphite/plastic cannula disassembled to illustrate the graphite cannula *(1)*, leaflet valve *(2)*, screw cap *(3)*, and instrument seal *(4)*. (C) A 3.9-mm × 10-cm graphite/plastic cannula with an insufflation side port *(1)*, and a 3.5-mm × 10-cm threaded cannula with an insufflation side port and a trocar inserted *(2)*. The 3.9-mm cannula can accommodate the 2.7-mm telescope housed in a 3.5-mm protection sheath while the 3.5-mm cannula can accommodate 3-mm instruments, and thanks to the threaded design, it resists dislodgement in small exotic species. (D) Ternamian EndoTIP cannulae; a 6-mm × 15-cm with an insufflation side port and a multifunctional valve *(1)*, and a 6-mm × 10.5-cm cannula with a silicone leaflet valve *(2)*. These metal cannulae are far heavier and best restricted to animals over 10 kg. (Courtesy Dr. Stephen Divers, University of Georgia)

a bleeding vessel or dabbing with gauze may be impossible. Surgical devices including electrocautery, radiosurgery and laser have become available and facilitated the ability to incise and debride internally while controlling hemorrhage. It is important to appreciate that such devices represent an ignition risk within the high-oxygen environment of the air sac system, and considerable care is required to ensure that nothing flammable is present (e.g., alcohol associated with surgical site preparation).

Diode lasers (e.g., AccuVet Lumenis Inc., Norwood, MA, USA) are by design able to pass through flexible fiber-optic probes that can be inserted through instrument channels or cannulae.[5,6] A variety of diode laser probes are available; however, 400 to 600 μm conical or flat tips at 2 to 10 W are generally most useful (SurgiMedics Inc., The Woodlands, TX, USA). Until recently CO_2 lasers (AccuVet Lumenis Inc.) could not be used via endoscopic instrument channels because of the inflexible nature of the ceramic delivery probes. The development of a long semirigid probe (AccuVet Lumenis Inc.), however, has enabled the use of the CO_2 laser via the 1.7-mm instrument channel of the 4.8-mm operating sheath, but, although functional, it is rather cumbersome. Probably the most versatile, especially when using ≤3-mm instrumentation systems, is electrocautery/radiosurgery because a wide variety of tools are available for use with foot pedal–activated units (e.g., Autocon III 400, Karl Storz Veterinary Endoscopy America Inc.). The most useful of these include various needle electrodes, bipolar forceps, and retractable polypectomy snares. The degree of power required during endosurgery varies with operating conditions and the instrument being used, but due to the microsurgical nature of most endosurgical procedures, lower settings are generally required compared to open surgery. Considerable growth in endoscopic electrocautery/radiosurgery has led to the availability of many monopolar and bipolar devices. One particularly favored device among human and veterinary endosurgeons is the Ligasure Force-Triad (Covidien, Boulder, CO, USA). This system detects the thickness (by measuring electrical impedance) of tissue to be coagulated and automatically

defines the amount of energy required and the delivery time. An acoustic signal informs the surgeon when vessel obliteration is complete, and transection is possible. Unfortunately, endoscopic handpieces below 5 mm are not available, limiting its usefulness to 5-mm systems and the largest of birds.

Another useful item from human and domestic animal laparoscopy is the endoscopic vascular clip applicator. These devices contain a cartridge of clips that can be rapidly employed without having to remove from the patient and reload. Again, the smallest available size is 5 mm, which restricts their use to large birds.

DIAGNOSTIC ENDOSCOPY PROCEDURES

Diagnostic endoscopy focuses on the appreciation of normal and abnormal structures within the respiratory tract using magnification and focused light. Furthermore, when abnormalities are identified, specific samples can be collected under direct visual control for laboratory analyses, which typically provide a definitive diagnosis. General anesthesia is required, and close monitoring is essential as these are often critical patients.

One of the greatest benefits of endoscopy is that when an abnormal structure or pathologic lesion is observed, biopsy specimens can be taken under direct visual control. Biopsy specimens can be harvested from virtually any soft structure, taking care to avoid perforating cardiovascular, intestinal, or fluid-containing structures. It is important to try and examine as much of the target structure as possible to determine whether pathology is focal, multifocal, or diffuse. In cases of diffuse lung or air sac disease, biopsy specimens taken from the most convenient sites are preferred. In cases of focal or multifocal disease, single or multiple discrete lesions may be visible and biopsy specimens should ideally be harvested from the edge of the lesion (to acquire both normal and abnormal tissue in the same biopsy sample) or, size permitting, multiple biopsies should be collected for both microbiologic and histologic analysis. Focal disease deep within an organ showing no surface changes, although rare, may be missed on endoscopic examination. The advent of endoscopes with terminal ultrasonography probes is already available in human

medicine. It is important to correlate histopathologic and microbiologic biopsy results with clinicopathologic data when organ disease is present. It is often surprising how biopsy results provide a definitive diagnosis even in the face of unremarkable or conflicting imaging and clinicopathologic data.[7]

When a potentially cystic lesion or abscess is present, it is safer to first attempt fine-needle aspiration rather than risk leakage into the air sacs or coelomic cavities. When confronted by a thickly encapsulated lesion, incising the capsule before inserting the biopsy forceps is often more rewarding. Postsampling hemorrhage tends to be minor and inconsequential, thanks to the extrinsic coagulation pathway of birds.

Rhinoscopy and Sinuscopy

Following insertion of the telescope through the external naris, careful negotiation around the operculum (if present) allows advancement into the nasal cavities. The medial nasal concha are visible dorsad and the caudal nasal concha are more caudal. Pigmentation is variable. It is often possible to visualize the opening to the choanae but not always possible to advance the rigid endoscope down to their level. However, it is not possible to navigate from the nasal conchae into the infraorbital sinus because of the acute turns required to enter the different diverticula of the sinus. However, a focal surgical approach to an infraorbital sinus does permit entry of the telescope and provides far greater visualization than would be possible externally. The endoscope can also be introduced into the oral cavity and the 30-degree deflection aids in examining the dorsal choanae. Again, it is often practical to enter the choanae and direct the endoscope craniodorsad to examine the nasal meatus and conchae from this caudoventral perspective. Biopsies are readily collected for histopathology and microbiology and common pathologies include choanal atresia/dysplasia, rhinitis, and sinusitis (Figure 30.9).

Laryngotracheoscopy

A brief examination (<30 seconds) of the larynx and trachea is possible following mask induction and is useful for a rapid assessment of possible obstruction. However, where more prolonged surgery time is anticipated, placement of a caudal thoracic or—less preferable—abdominal air sac tube to maintain anesthesia is

FIGURE 30.9 Endoscopic views of (A) choanal atresia in a grey parrot *(Psittacus erithacus)*. (B) Nasal meatus and concha as seen from an intraoral view through the choana in an Amazon parrot (*Amazona* spp.). (C) Caseous laryngitis in a green-cheeked conure *(Pyrrhura molinae)*. (Courtesy Dr. Stephen Divers, University of Georgia)

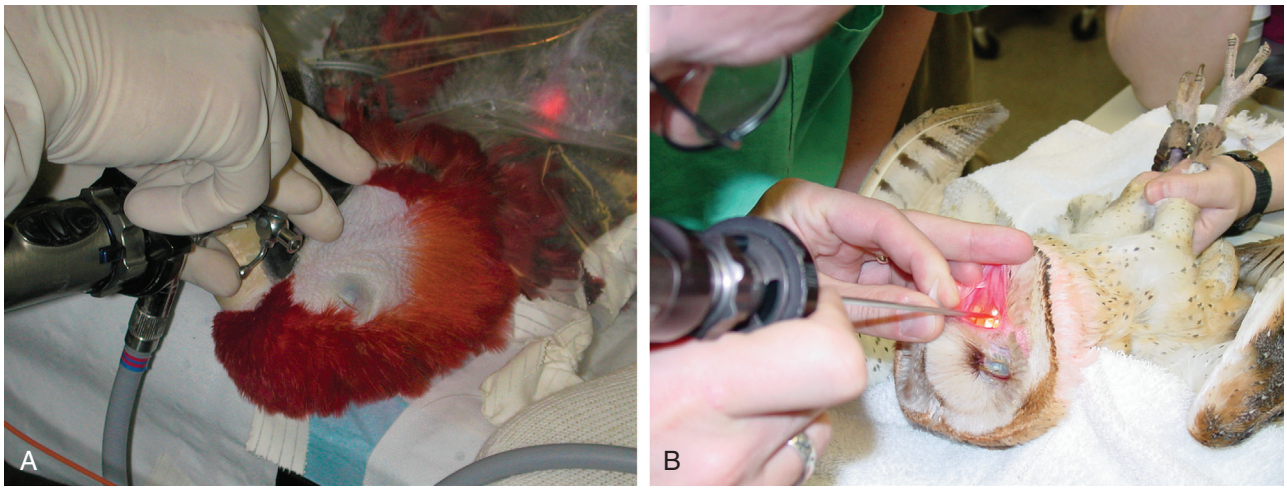

FIGURE 30.10 Tracheoscopy in large birds, such as this scarlet macaw (*Ara macao*) can be performed using the 2.7-mm telescope within the operating sheath (A). However, in smaller birds, such as this barn owl (*Tyto alba*), the naked 2.7-mm or smaller endoscopes must be used (B). (Courtesy Dr. Stephen Divers, University of Georgia)

essential (see Chapter 29). The bird can be positioned in dorsal or ventral recumbency. Examination of the larynx is typically straightforward, and entry through the glottis should be performed with care to avoid damaging the laryngeal cartilages and their associated mucus membranes. Additional caution is required when performing a biopsy of caseous laryngitis (Figure 30.9).

To avoid damage to the tracheal mucosa, the 30-degree telescope should be advanced with the lumen in the lower third of the monitor image while keeping the neck as straight as possible. This is often achieved by the endoscopist holding the head and maintaining mild tension (against an assistant holding the pelvic limbs) to keep the head and neck maximally extended (Figure 30.10). In most birds under 1 kg, it is possible to advance the 2.7-mm telescope down to the tracheal bifurcation and, if present at that location, the syrinx (Figure 30.11). By rotating the telescope around its longitudinal axis, the 30-degree deflection often permits examination of each primary bronchus. In larger birds, small flexible endoscopes can navigate the primary bronchi, pass the parabronchi, and even enter the abdominal air sacs. This is particularly useful in Sphenisciformes and Anseriformes where the relatively reduced volume of the air sacs can make surgical access more challenging. Tracheal modifications of note include anterior bifurcation (e.g., penguins); short loop or coiling (e.g., male magpie geese, both sexes of guinea fowl); long loops and extensive coiling (whistling and whooping swans, cranes); sac-like diverticula (female emus and male ruddy ducks); and bulbous expansions (many male ducks).[8]

As the telescope is advanced, the integrity of the mucosa and any exudates or abnormal membranes or foreign bodies can be appreciated. In large psittacines and raptors, the 2.7-mm telescope can be used with an operating sheath to facilitate instrument entry, whereas in smaller birds it is often necessary to advance instruments alongside the unsheathed telescope (or use a smaller 11.5 Fr or 9.5 Fr integrated endoscope). Foreign body material can be removed with grasping forceps or suctioned, while abnormal tissues or granulomas can be biopsied and submitted for histopathology and microbiology. Samples should also be submitted for immediate cytology, which may direct intraoperative drug therapy.

Pulmonoscopy (Lung and Air Sacs)

There are three possible approaches to the lower respiratory system: left, right, and interclavicular. Physical examination and diagnostic imaging (radiography, CT) should be conducted to identify the most appropriate approach. Cross-sectional imaging is particularly valuable when considering entry into the lower respiratory system of a less familiar species or those with relatively smaller air sacs (Sphenisciformes and Anseriformes). Significant ascites represents a contraindication for either lateral approach, as the procedure creates a connection between the hepatic/intestinal peritoneal cavities and the caudal air sacs.

Left and right caudal thoracic air sac approaches

The most common endoscopic approach by convention is the left approach to the air sac system, and therefore unless imaging indicates a predominantly right-sided problem, this preference can prevail. The following description pertains to psittacines, passerines, and raptors, while modifications of this approach are used for aquatic birds. The bird is positioned in right lateral recumbency with wings secured dorsad over the bird's back with the use of self-adhesive tape. In large birds (e.g., macaws) it is advisable to place a towel or foam separator between the wings to reduce ventilatory compromise. The left pelvic limb is pulled craniad and secured to the neck, again with the use of a self-adhesive bandage, to expose the left flank (Figure 30.12). The entry site is located immediately behind the last rib and just ventral to the flexor cruris medialis muscle as it courses from the caudal stifle to the ischium. Few feathers typically need to be plucked before aseptic preparation of the area. Following a 2- to 4-mm skin incision, straight hemostats, directed in a slight craniodorsal direction, are used to bluntly dissect between the thin subcutaneous tissues and enter the caudal thoracic air sac. The hemostats are withdrawn and replaced by the telescope, and the correct position within the caudal thoracic air sac is confirmed by the identification of left lung (straight ahead), left cranial thoracic air sac (left), left abdominal air sac (right), caudal edge of left liver lobe and proventriculus (ventral), and ribs and intercostal muscles (dorsal) (Figure 30.13). The primary ostium of the caudal thoracic air sac has a craniodorsal location, and it is often possible to advance the telescope to examine the lung and parabronchi.

Lung tissue is most accessible from within the caudal thoracic air sacs (Figure 30.13). The air sac and pleural membranes must first be incised with scissors. It is generally easier to rotate the scissors within the instrument channel, such that the fixed blade is dorsal. The scissors-telescope unit is advanced to the target site, and the point of the fixed blade is inserted shallowly through the pleural membranes by advancing the scissors-telescope unit in a ventromedial direction. This creates an opening through the pleura through which biopsy forceps can be inserted to collect lung tissue. While there is typically more hemorrhage from lung biopsies, the pleural membrane acts as a barrier and facilitates clot formation. Common pathologies include hemorrhage, exudates, allergic pneumonitis, and aspergillosis (Figure 30.14).

Exploration of adjacent air sacs is accomplished by pressing the leading edge of the telescope against the air sac membranes and advancing the telescope in a sweeping motion until the air sac membranes are breached. Normal membranes are transparent, and tissues seen through the adjacent air sac can be visualized and avoided. Great care is required when breaking

(Courtesy Dr. Stephen Divers, University of Georgia)

through thickened opaque air sacs because vision is impaired, and trauma can occur if the telescope is blindly advanced. In such cases it is safer to incise the air sac or collect full-thickness air sac biopsies before advancing the telescope into the adjacent air sac. Common pathologies include airsacculitis, hemorrhage, exudates, and granulomas (Figure 30.15).

There is no need to repair the small air sac or pleural perforations because they typically heal within 10 days. However, large rents in the air sac will result in permanent connections, which, although insignificant for captive birds, would potentially harm the athletic performance of falconry or free-ranging individuals. Postoperative subcutaneous emphysema may be seen in some birds when only skin closure is performed. Therefore, either a single absorbable (poliglecaprone 25) suture that incorporates both muscle and skin or a two-layer closure is recommended.

The same approach described earlier is used for the placement of an air sac tube. Instead of a protection sheath, a sterile endotracheal tube is placed over the telescope before being advanced into the left caudal thoracic air sac. Once the correct position is confirmed, the endotracheal tube is slid off the telescope into the air sac and secured with suture.

Most right-handed surgeons find the right approach more challenging, but it is primarily indicated if imaging identifies pathology within the right lung or air sacs. The right approach is essentially the same as previously described.

Clavicular air sac approach

The clavicular approach is seldom indicated, except for cases involving the extramural syrinx, clavicular air sac, great vessels, and craniodorsal surface of the heart. This approach requires considerable care due to the proximity of the carotid/brachiocephalic/subclavian arteries, jugular veins, and major nerves. The bird is positioned in dorsal recumbency, and a small towel or gauze is placed under the midscapular region to allow the neck to be placed dorsal to the coelomic inlet. A 2-cm dorsoventral skin incision is made in the coelomic inlet (Figure 30.16). Careful dissection and lateral displacement of the crop (if present) provide access to the coelomic inlet. The clavicular air sac is identified and perforated by grasping and retracting on of the air sac membrane. Perforation by pushing is not recommended due to the likelihood of damaging vital structures. The telescope is advanced, and the distal trachea and external surface of the syrinx are usually obvious. Careful navigation around the syrinx provides visualization of the brachiocephalic and subclavian arteries. Given the proximity to the heart, there are usually rapid movements of all structures in time with cardiac activity. If abnormal structures are identified, then biopsy forceps may be used with caution. Great care is required but this technique has been used to definitively diagnose neoplastic lesions within the cranial coelom (Figure 30.17).

THERAPEUTIC ENDOSCOPY AND ENDOSURGERY

During the last 10 to 15 years, there has been significant development in the evolution of endoscopy from solely diagnostic to include more therapeutic and endosurgical options.[4,9,10] Single-entry endosurgery (e.g., syringeal granuloma removal) is relatively straightforward, but progression to multiple-port endosurgery and the additional demands of triangulation certainly represents a significant increase in procedural complexity and difficulty (Figure 30.18). However, the ability to access remote areas of the coelom and perform procedures that would otherwise be markedly more invasive or simply impossible are major advantages. Advanced training is typically required and regularly offered within the United States and elsewhere.

Tracheal Stenosis and Strictures

Tracheal stenosis and strictures are not uncommon and can be easily identified endoscopically, although determining their etiology is more difficult (Figure 30.19). Endoscopic biopsy from these stenotic lesions typically reveals fibrosis. Despite the relative ease by which these strictures can be debrided (using scissors, retrieval, and biopsy forceps) and airway patency restored, although clinical signs improve dramatically, recurrence can be frustratingly common. In those cases where the lesion(s) extend over just a few tracheal rings, tracheal resection and anastomosis offer the

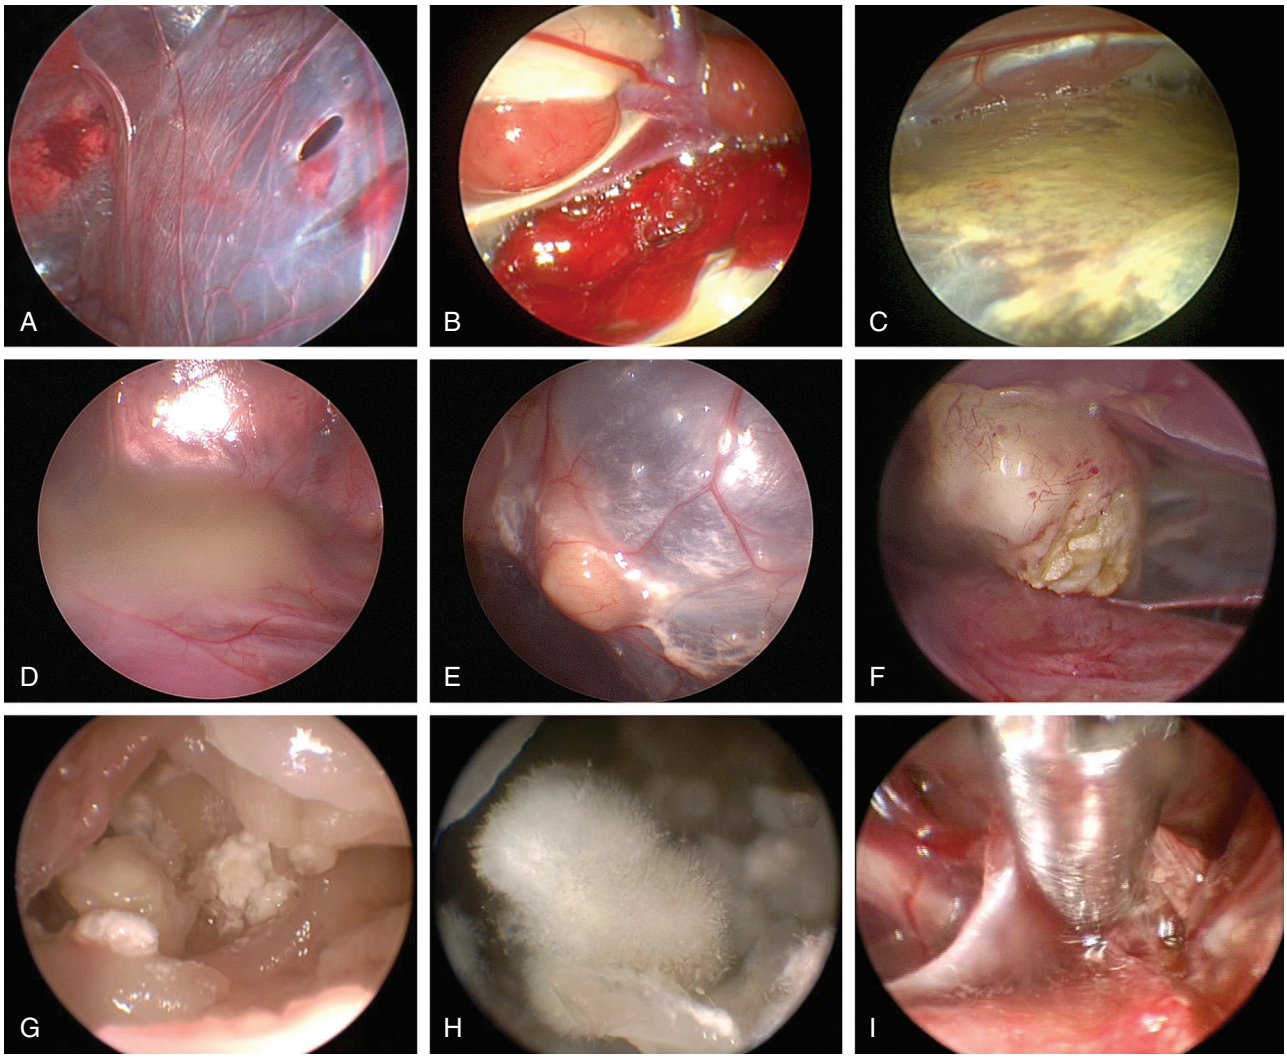

FIGURE 30.15 Endoscopic views of air sac pathology. (A) Inflamed air sacs often appear thickened (less transparent) with more obvious blood vessels. greatest chances of success (see Chapter 29). For more extensive cases, the fluoroscopic deployment of a tracheal stent and endoscopic evaluation have proven effective in a parrot for nearly 2 years (Figure 30.20).[11]

Aspirated Foreign Bodies and Syringeal Granulomas

Aspirated foreign bodies often become lodged at the level of the syrinx, which is also the most common site for *Aspergillus* granulomas. Typically, endosurgical debridement using biopsy forceps continues at the time of initial endoscopic diagnosis and biopsy (Figure 30.21). On rare occasions, the entire granuloma may come away with the first biopsy attempt, but more typically, repeated biopsy attempts are required to achieve patency. However, large pieces should not be pulled through the instrument channel or past the endoscope; instead, the telescope should be removed at the same time to prevent breaking up large pieces. Any sign of bleeding indicates the need for greater caution, particularly to avoid damage to the syringeal cartilages and membranes. If the foreign body or granuloma cannot be removed, then pushing the structure into the primary bronchus and into the abdominal air sac for subsequent (endo)surgical removal is preferable to continued blockage of the upper airway (see Chapter 29).

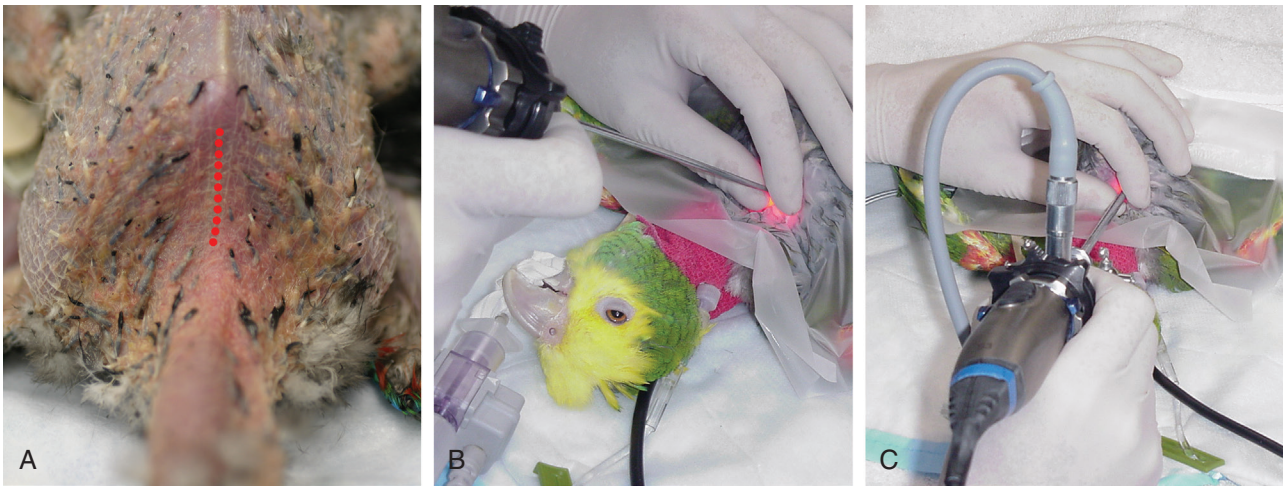

FIGURE 30.16 (A) In preparation for clavicular air sac endoscopy, this feather-picking eclectus parrot (*Eclectus roratus*) has been positioned in dorsal recumbency, with the proposed skin incision indicated. (B) and (C) Following the entry into the clavicular air sac, the unsheathed 2.7-mm telescope is used to carefully navigate in this yellow-headed Amazon parrot *(Amazona oratrix)*. FIGURE 30.19 (A) Endoscopic view of tracheal stenosis in a grey parrot *(Psittacus erithacus)*. (B) Endoscopic debridement using biopsy forceps. (C) Postoperative view. In this case, stenosis did not recur, but recurrence is not uncommon. (Courtesy Dr. Stephen Divers, University of Georgia)

Withdrawing infected material up the trachea has not resulted in multifocal disease spread.

Following debridement of a granuloma, the area is sprayed with either aminoglycoside (bacterial abscess) or an intravenous formulation of an antifungal (mycotic granuloma) delivered via the remote injection needle. It is often beneficial to dilute these drugs to create a large enough volume, often 1 to 3 mL, to flood the area. Neither amphotericin B nor aminoglycosides are well absorbed across the respiratory epithelium and therefore double the recommended systemic dose appears well tolerated within the respiratory tract.

The air sac tube must be maintained postoperatively as there is often pronounced tracheal swelling; however, it is helpful to place a filter over the tube to reduce contamination of the air sacs. Even so, it is important to remove these air sac tubes within 2 to 3 days, and to that end repeat tracheoscopy should be performed 24 to 48 hours after initial surgery. If there is adequate patency then the air sac tube should be removed; if not, further debridement is undertaken. Tracheoscopy is again repeated in 10 to 14 days to determine recovery and whether therapy can be discontinued. Syringeal granulomas that are endosurgically debrided can be completely resolved within 7 to 14 days, thereby avoiding protracted antifungals for weeks or even months.

Lung and Air Sac Aspergillosis, Masses, and Granulomas

Air sac granulomas have been successfully removed in several parrots using a combination of endoscopic debridement and diode laser ablation.[5] Because of the avascular nature of granulomas, debridement with a 5 Fr biopsy forceps is possible without additional hemostasis (Figure 30.22). Lasers and radiosurgery have been used to ablate and sterilize infected areas. When dealing with small masses and granulomas,

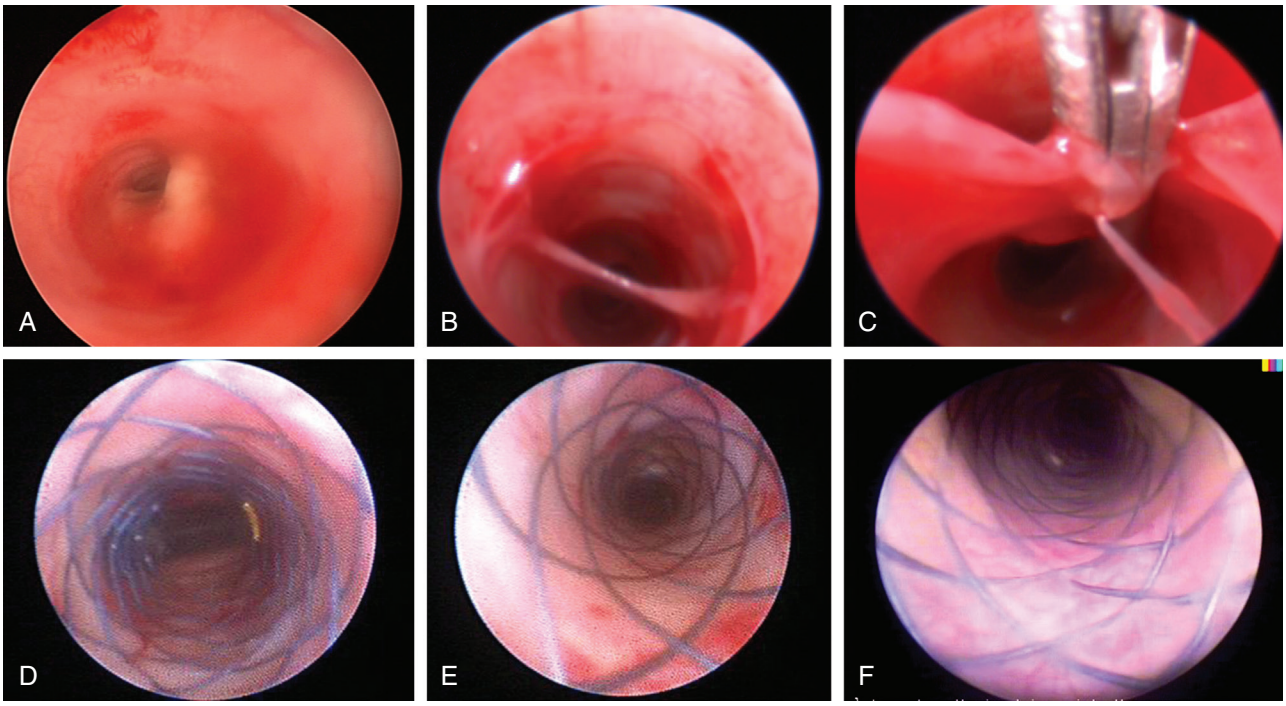

FIGURE 30.20 (A) and (B) Extensive tracheal stenosis and strictures in an eclectus parrot *(Eclectus roratus)*. (C) Debridement using biopsy and retrieval forceps resolved the dyspnea temporarily but the membranes recurred. (D–F) Endoscopic evaluations of a fluoroscopically delivered custom-made wire stent that resolved clinical signs for 2 years. Note how the mucosa has grown over the wire. (Courtesy Dr. Stephen Divers, University of Georgia)

resection is often best accomplished with the biopsy forceps and the telescope, and hemostasis is rarely a concern. However, it is often more practical to remove forceps and the telescope together than to risk fracturing material by attempting to pull it through the instrument channel of the sheath.

When dealing with more widespread air sac mycosis, debridement should continue until most of the material has been removed; however, surgery may have to be prematurely curtailed due to patient risks and anesthesia-related concerns. Diligence is required to avoid contaminating adjacent air sacs or the coelomic surgical access with infected material. Before closure, the area is sprayed with an intravenous formulation of an antimicrobial medication as described earlier in Laryngotracheoscopy. In the case of drugs like amphotericin B, which are poorly absorbed across the respiratory epithelium, up to double the daily systemic dose can often be used, but the volume should be diluted (often 1–4 mL) to allow dispersal throughout the infected air sac. Following 1 to 2 weeks of parenteral antifungal therapy, repeat endoscopy will usually demonstrate consolidation of the active vegetative lesions into a more organized granuloma. Intralesional injections of antifungal medication into these granulomas can result in further size reduction but are seldom curative, ultimately necessitating endosurgical removal.

Double- and triple-entry techniques have been used to endoscopically sample, debulk, and remove coelomic cavity neoplasms, abscesses, and granulomas from the respiratory tract (Figure 30.23). The use of 3-mm biopsy and debriding forceps facilitates faster tissue removal when compared to using 5 Fr biopsy forceps. A combination of instruments is often beneficial for incision, blunt dissection, and removal of solid material. Suction probes are useful when fluids are encountered after opening a granuloma. Generally, a surgical assistant holds the telescope so that the primary surgeon can focus on endosurgery, and this becomes essential when two instruments are being used simultaneously (Figure 30.24). Care is required to remove as much gross material as possible, including from around the surgical site. While systems exist in human and domesticated laparoscopy to resect and remove large masses without causing contamination, this is far more difficult in the confines of the coelomic cavities of birds. Therefore, the endoscopist must take precautions to remove as much material as possible and be diligent in trying not to seed infection along the instrument tracts. In cases of bacterial or fungal granulomas, it is often beneficial to treat locally (by intralesional injections/spray) following endosurgical debridement.

CONCLUSIONS

Endoscopy, endoscope-assisted therapy, and endosurgery offer significant advances over other diagnostic and treatment options. No other techniques can provide the same visual acuity, ability to collect biopsies, and minimally invasive approach to therapeutic and surgical interventions. The value of endoscopy is entrenched within human and domesticated animal pneumonology and is well-documented in avian respiratory medicine.

ACKNOWLEDGEMENTS

The author is grateful to Karl Storz Veterinary Endoscopy for their continued support in both endoscopic research and avian procedural development.

CHAPTER 31

The Beak: Form, Function, and Problems

Brian L. Speer • Roberto S. Fecchio • Casey M. Holliday

Visit eBooks.Health.Elsevier.com for a complete set of references.

The anatomy and function of the heads and beaks of birds are complex, but there are some shared common features on top of many unique adaptations and niche functions specific to species groups. The beak of birds serves multiple functions related to eating and procuring food, deglutition, grooming, killing prey, fighting, courtship, thermoregulation, locomotion, nest construction, and the feeding of young. Several disease conditions can result in direct or secondary damage to the bony and soft tissue structures of the beak. These injuries can lead to secondary problems such as beak deviation, abnormal keratin growth and wear, and opportunistic infections. A sound understanding of the species-specific anatomy, accuracy of the diagnosis established, and clarity of the medical and surgical options that may be employed are essential when contemplating treatment.[1–6]

ANATOMY AND FUNCTION OF THE BEAK

Topographical Anatomical Terminology

The bill, or beak, of birds, is known anatomically as the rostrum. It includes the bones of the maxillary and mandibular beak, dermal and other soft tissues, and horny sheaths. The upper component of the bill is the maxillary rostrum *(rostrum maxillare)* and the lower component is the mandibular rostrum *(rostrum mandibulare)*.[7,8] The rostral parts of the upper and lower beaks of birds are covered by a hard, epidermal structure derived from keratin. Synonyms for this keratin covering are the horny bill and rhamphotheca. Synonyms for the upper and lower horny sheaths are the maxillary rhamphotheca (or rhinotheca) and the mandibular rhamphotheca (or gnathotheca), respectively.[8] The mid-dorsal profile of the maxillary rhamphotheca is the culmen. The maxillary rhamphotheca has a cutting edge or tomium on the left and right side (the maxillary tomia), which matches the opposing mandibular tomium. The rostral tomia of the maxillary and mandibular rhamphotheca do not line up in all birds depending on their diet and feeding behaviors. There is an inner occlusal rhinothecal ledge that facilitates force delivery from the rostral gnathothecal tomium against food items, particularly prominent in most Psittaciformes.[8] The midventral profile of the whole length of the mandibular rhamphotheca is termed the gonys. The rhamphotheca is a constantly growing and dynamic structure. The inter-ramal region, or inter-ramal space, is the zone of soft tissue that begins at the caudal end of the gonys and extends caudally between the mandibular rami as far as the end of the mandible. The caudal portion of the inter-ramal space is the gular region, which forms the floor of the caudal part of the oropharynx.[8] The entire opening of the mouth is called the oral opening or gape. The rictus is the caudal part of the oral opening, beginning at the caudal end of the tomia and ending caudally at the angle of the mouth.[8] These terms and their synonyms are displayed in Table 31.1 and Figure 31.1.

Osteology and Joints

The bony upper beak is formed by paired and fused premaxillary and nasal bones. In most birds, the upper beak functions as a rigid triangular block, which can be elevated or depressed.[7,9] The upper beak hinges in many bird species at the flexible junction of the upper beak with the neurocranium at the craniofacial hinge, or nasofrontal hinge. In parrots, this joint is in part a synovial joint, yet with a bridge of chondroid bone near the midline and is also known as the ginglymus. Movement of the upper beak requires accompanying movement of four pairs of bones: the jugal arch, the pterygoid, the palatine, and the quadrate bones. Movement of the bony upper beak is also made possible by the presence of flexible elastic zones in the facial bones known as streptognathism. In prokinetic birds, a short elastic zone called the craniofacial elastic zone occurs at the junction between the braincase and

TABLE 31.1

Terms and Common Synonyms Used to Describe Beak Topographical Anatomy, Function, and Types of Prosthetics

Anatomic Term	Synonyms
Rostrum	Bill or beak
Maxillary rostrum	Upper bill or beak
Mandibular rostrum	Lower bill or beak
Rhamphotheca	Keratin sheath of the beaks, horny bill
Rhinotheca	Maxillary rhamphotheca Keratin sheath of the upper bill
Gnathotheca	Mandibular rhamphotheca Keratin sheath of the lower bill
Tomium (singular), tomia (plural)	Rostral and lateral cutting edges of the rhamphotheca
Maxillary tomium, tomia	Rostral and lateral cutting edges of the maxillary rhamphotheca
Mandibular tomium, tomia	Rostral and lateral cutting edges of the mandibular rhamphotheca
MIDLINE BEAK PROFILE TERMS	
Culmen	Mid-dorsal profile of the maxillary rhamphotheca
Gonys	Midventral profile of the mandibular rhamphotheca
OTHER TOPOGRAPHIC TERMS	
Gape	The entire opening of the mouth
Rictus	Caudal part of the oral opening, beginning at the caudal end of the tomia and ending caudally at the angle of the mouth
Inter-ramal region or space	Zone of soft tissue beginning at the caudal end of the gonys, extending between the mandibular rami as far as the caudal end of the mandible
Gular region	Caudal portion of the inter-ramal space
Naris (singular), nares (plural)	Nostril, nostrils
FUNCTIONAL TERMS	
Protraction of the maxillary beak	Elevation of the maxillary rostrum
Retraction of the maxillary beak	Lowering of the maxillary rostrum
Protraction of the mandible	Movement of the mandible rostrally
Retraction of the mandible	Movement of the mandible caudally
Cranial kinesis	The relative movement between the upper beak, bones of the palate, and the braincase
Prokinesis	The upper beak is elevated about a clear craniofacial hinge joint, usually through movements of the palate powered by jaw muscles
Rhynchokinesis	The upper or lower beaks can flex, either through deformation about craniofacial joints or within the bones themselves (i.e., streptognathism)
Amphikinesis	The upper beak elevates or depresses through a series of internal rhynchokinetic movements of the craniofacial bones
Coupled kinesis	Movements of the upper and lower beaks are somewhat dependent on one another, often through the powering activities of jaw musculature and the linkage system imparted by the palatal bones
PROSTHETIC TERMS	
Autologous	Tissue derived from the same individual
Homologous, allogenic	Tissue originating from another individual of the same species
Heterologous, xenogenic	Tissue originating from an individual of a different species
Synthetic	Made with inorganic materials
Endoprosthesis	Prosthesis is fully implanted and surrounded by body tissue
Exoprosthesis	Prosthesis is worn outside of the body

the nasal and premaxillary bones. This joint varies in its degree of flexibility among avian taxa and can be sutured, synovial, or bridged by chondroid bone.[7,9–11] The palate is formed by a combination of the palatal processes of the premaxillae and maxillae, the palatine bones, the vomers, the jugal arches, and the pterygoid and quadrate bones.[7,9,10] Unlike the palate of mammals, the palate of birds does not form a complete shelf between the nasal and oral cavities. The internal nares lie between the vomers and the palatine bones, rostrally. The pterygoid articulates rostrally with the rostral portion of the palatine bone and caudally with the quadrate bone in a synovial hinge joint.[7,9] The jugal arch articulates rostrally with the maxilla and caudally, it forms a ball-and-socket joint with the quadrate bone.[7,9] The joint formed between the quadrate and the braincase is a double articulation. Rotation of the quadrate bones rostrally pushes on the pterygoid and jugal arches rostrally, resulting in an upward push being applied to the palatine bone and the palatovomeral complex. This in turn causes it to slide rostrally about the palatobasal joint formed with the central bony ridge of the ventral braincase (os

mesethmoidale; parasphenoid) and forcing the maxillary rostrum to swing upward at the craniofacial hinge (protraction). This articulation is a diarthrosis with fibrous tissue. Rotation of the quadrate bones caudally causes the maxillary rostrum to swing downwards (retraction). These bony structures are displayed in Figure 31.2.

The jugal arch consists of three bones fused together; from rostral to caudal, they are the jugal process of the maxillary bone, the jugal bone, and the quadratojugal bone.[7,9] There is no true zygomatic arch or bone in birds. The quadrate bones are immensely mobile and function as the key elements in most of the movement of the upper and lower beaks in the prokinetic beak: articulating with the mandibles, the braincase, the jugal arch, and the pterygoid bone.[7,9] The quadrate bone forms the primary link between the mandibles and the neurocranium.[7,9,10] All of these bony elements are coupled mechanically; hence, force applied at any point in the system, either internally by muscle contraction or via external factors, will be transmitted throughout the system and cause deflection of the system in one or the other direction.[7,9] Convention is to consider the quadrate bone as the starting point and to describe all movements as initiated from it.[7] Articular and linkage ligaments unify the function of the mandibles with the braincase, the palate, and the maxillary rostrum.[7,9] Linkage ligaments function to join the upper and lower beaks together mechanically, resulting in coupled kinesis, in which the movements of the upper and lower beaks are somewhat dependent on one another, but not entirely so. The two rami of the mandible are joined in the rostral midline at the rostrum (symphysis) mandibulae.[7] Some birds have intramandibular mobility (e.g., nightjars, pelicans).[12] Intraramal synovial joints and streptognathy in pelicans enable the swallowing of large prey. A similar joint has been described in loons, grebes, albatrosses, penguins, herons, storks, New World vultures, great frigate birds *(Fregata minor)*, and the brown booby *(Sula leucogaster)*.[13] All bones of the skull are pneumatized by air diverticula coming from the tympanic cavity (braincase) or the infraorbital sinus (all other bones), although some species of aquatic birds including penguins, grebes, cormorants, mergansers, and alcids have reduced or absent pneumatization.[14]

Osteology of the juvenile psittacine skull

Juvenile macaw skull osteology can be distinguished from adults by specific unique characteristics. In the juvenile skull, suture lines can be found in the premaxilla, maxilla, nares, prefrontal, frontal, temporal, and parietal regions, as well as along the jugal arch. These bones are in a very active phase of growth and remodeling and, as such, can be guided in their direction of growth easier than in their adult counterparts. Their softer, partially ossified nature also can directly influence the choices of surgical repairs needed for injuries and deformities in these immature birds. The bony upper beak consists of several bones including the premaxilla, maxilla, and nasal bone, which eventually fuse together. The orbital ring is incomplete in all macaws when they hatch. In *Ara* species, the preorbital process continues to grow and joins the postorbital process by the time the bird is 11 months old. This does not occur in the genera *Anodorhynchus* or *Cyanopsitta*.[15] In certain species, such as the blue-and-gold macaw *(Ara ararauna)*, the cranial bones mature more rapidly than in other macaw species. The opening of the nares is quickly reduced to the adult size, and the maxilla retains a midline suture for several months. Other species, such as the green-winged macaw *(Ara chloroptera)*, have clearly visible suture lines for several months and have a significantly larger naris at the same age.[15] The skulls of an adult and juvenile macaw are displayed in Figure 31.3.

The Prokinetic Muscles of the Beaks

In most birds, seven pairs of muscles act on the upper and lower beaks. Parrots have two unique pairs of muscles and lack one of the original seven pairs.[7,10] These muscles are displayed in Figures 31.4 and 31.5; their origins, insertions, and actions are displayed in Table 31.2. Parrots have neither a *m. pseudotemporalis profundus* nor its attachment, the orbital process of the quadrate, while these are present in other bird lineages. Two muscles open the beaks: *m. protractor pterygoidei et quadrati* by raising the upper beak through the linkage system of the palate, and *m. depressor mandibulae* by lowering the lower beak. Two muscles simultaneously close both the upper and lower beaks, i.e., *m. pterygoideus* and *m. pseudotemporalis profundus*. The pterygoideus muscles in parrots also function in the movement of the lower mandible forward (protraction) and in lowering the upper beak during chewing. Three muscles raise or elevate the mandibles: *m. adductor mandibulae externus*, *m. pseudotemporalis superficialis*, and *m. adductor mandibulae caudalis* (*m. adductor mandibulae posterior* in reptiles).[7,16] The two unique pairs of muscles that are present in parrots are *m. ethmomandibularis*, a derived belly of *m. pterygoideus*, and *m. pseudomasseter*, a derived belly of *m. adductor mandibulae externus* (Figure 31.4).[17] *M. ethmomandibularis* closes and protracts the lower beak, and the *m. pseudomasseter* raises the mandible. These muscles can act without eliciting a prokinetic behavior and exist in species without prokinesis. Rostral rotation of the quadrate bone at its articulation functions to raise the upper beak, and this action is accomplished by the contraction of *mm. protractor pterygoidei et quadrati*, *pseudotemporalis superficialis*, *adductor mandibulae caudalis*, and *adductor mandibulae externus*. Extension of the jaw (quadrate-mandibular) joint (depressing the lower beak) is accomplished by contraction of *m. depressor mandibulae*. Closing of the jaw joint (elevating the lower beak) is accomplished by contraction of *mm. pseudotemporalis profundus*, *adductor mandibulae externus*, *ethmomandibularis*, and *pterygoideus*. The superficial prokinetic muscles of the Grey parrot (*Psittacus erithacus*) are displayed in Figure 31.5. The occlusal force applied by these four muscles is greater on objects caudally near the base of the beak and decreases gradually as objects are prehended and manipulated more rostrally, closer to the tip of the beak.

Innervation

In birds, generally the nerve endings of the upper bill are innervated by the maxillary and ophthalmic divisions of the trigeminal nerve (5th cranial nerve; CNV) and those of the lower bill by the mandibular division.[20] The ophthalmic nerve supplies the palate, the edge of the upper beak, and the bill tip organ.[20] The maxillary nerve is purely afferent and supplies receptor endings in the lateral tomia of the upper bill. The mandibular nerve is both somatic afferent and efferent and passes the length of the mandibular canal, providing branches to the skin associated with the lower beak, including the mandibular bill tip organ.[20] The mandibular division of the trigeminal nerve provides the primary motor innervations for the jaw muscles, except for the *m. depressor mandibulae*, which is supplied by the facial nerve (CNVII).[7]

Vascular Anatomy

The common carotid artery is the primary source of blood to the structures of the beak and oral cavity in birds. This artery divides into internal carotid and vertebral arteries, which ascend the neck and form numerous anastomoses. Areas supplied by the common carotid artery include the lower beak and its muscles, the palate, oropharynx, upper beak, larynx, nasal cavity, and orbit.[21] The vascular anatomy of the head of a domestic duck (*Anas platyrhynchos*) is shown in Figure 31.6.

Integumentary Anatomy of the Bill

Keratin is produced by the underlying dermis of the beak with varying contributions from the cere. Both keratin surfaces are made up of a covering type (very thin) and a pressure-bearing type (very thick) of keratin. These surfaces are worn continuously through use and mechanical abrasion. The degree of wear may vary due to foraging styles and differences between individuals, seasonal variations in food types, and within populations.[22,23] Figure 31.7 shows the variation of keratin type and thickness in three selected species (hawk-headed parrot *[Deroptyus accipitrinus]*, Harris' hawk *[Parabuteo unicinctus]*, and hyacinth macaw *[Anodorhynchus hyacinthinus]*). The base of the culmen in some birds is enlarged to form ornamental excrescences.[23] Examples of these are seen in coots (*Fulica* spp.) and hornbills (Bucerotidae). Puffins (*Fratercula* spp.) molt their decorative rhinotheca after completion of the breeding season.

The horny bill resembles skin, consisting of epidermis, dermis, and bone. The dermis is closely attached to the periosteum. The epidermis is modified in two ways: the stratum corneum is very thick, and the cells of the stratum corneum contain free calcium phosphate and orientated crystals of hydroxyapatite. These two modifications are in addition to the abundant keratin and keratin-bound phospholipids and calcium, which characterize the cells of the stratum corneum of ordinary skin. The combination of these modifications provides the horny bill with its typical hardness.[24] Keratin arises from the Malpighian cells of the bird's epidermis, growing from plates at the base of each mandible. There is a vascular layer between the rhamphotheca and the deeper layers of the dermis, which is attached directly to the periosteum of the bones of the beak. Covering-type keratin is located on the outer and lateral surfaces of the upper and lower beak. As implied, covering-type keratin is quite thin. Pressure-bearing-type keratin is much thicker and denser, located on the undersurface of the upper beak (occlusal ledge of the rhinotheca), the piercing/shearing point of the upper beak (rostral rhinothecal tomium), the chisel edge of the lower beak (rostral mandibular tomium), and at the lateral tomia of the rhamphothecae (Figure 31.7). In the monk parakeet *(Myiopsitta monachus)*, a keratin monomer of approximately 15,500 daltons (Da) molecular weight is typical for the harder, pressure-bearing surfaces, and a larger monomer of 25,000 Da is more common with the softer, covering-type keratin structures.[22] Comparatively, solubilized keratinized epithelium in the monk parakeet had a molecular weight of 46,000 to 66,000 Da.

Keratin normally migrates rostrally along the surface of the beak and laterally from its vascular bed. The keratin replacement time of the rhamphotheca is closely linked to the natural use of the beak. In large parrots, complete replacement of the rhinotheca occurs in approximately 6 months, whereas in Ramphastidae there is a growth rate of approximately 0.25 cm per year.[2,4] Normally the gnathotheca is replaced two to three times faster than the rhinotheca.[2] The

beaks of birds are usually short and thick or long and thin. The beak of the toucans is an exception: it is both long and thick. Its length is about one-third of the total length of the animal, but its weight represents approximately 5% of the total live weight.[4,25] The toucan beak possesses extraordinary biomechanical resistance, aided by its layers of keratin and a trabecular fibrous network of bone and calcium-rich proteins. The thickness of the keratin layer in toucans ranges from 0.5 to 0.75 mm and is arranged in the form of hexagonal plate overlays. Its density is approximately 0.1 g/cm^3, which allows the toucan to fly by keeping the center of mass in the plane of the wings.[25,26]

In waterfowl, the bill is hard only at the tip of both the upper and lower bill. These specific adaptations form the maxillary and mandibular nails, respectively.[24] The nail and its associated dermis form a complex sensory organ. The whole complex is known as the bill tip organ and plays an important role in the sensory discrimination between food and other particles. The horn of the nail is perforated by canals that open through minute pores on the occlusal surface of the nail. Each of these canals is filled by a dermal core, corresponding to a highly specialized dermal papilla containing a profuse array of mechanoreceptor nerve endings. These dermal papillae project slightly through the pores on the occlusal surface of the nail, their projecting tips being capped by a thin covering of keratinized epithelium. Since the tips of the dermal papillae reach the occlusal surface of the nail, they are directly accessible to tactile stimuli during feeding. A bill tip organ has been described in the Senegal parrot *(Poicephalus senegalus)*, and likely exists in many other parrot species.[27] In the Senegal parrot, seven pairs of pits within the rhamphotheca can be seen along the tomial edges of the rhinotheca, with a single pit at the bill tip. These pits, as described in waterfowl, probably contain clusters of mechanoreceptors. Irregular grooves are present in the maxillary or mandibular bones of the Senegal parrot, leading down toward the bill tip, suggesting the course of the blood vessels or nerve fibers supplying mechanoreceptors embedded in the keratin sheath. These tactile pits are visible in Figure 31.8. Papillae have been identified three-dimensionally (3D) and two-dimensionally (2D) within these pits recently, demonstrating the clear presence of neurosensory structures within them.[28]

FIGURE 31.7 Sagittal sections of the beak/head of three birds: (A) hawk-headed parrot *(Deroptyus accipitrinus)*; (B) Harris' hawk *(Parabuteo unicinctus)*; (C) hyacinth macaw *(Anodorhynchus hyacinthinus)*. Note the variations in the thickness of keratin over the culmen and the occlusal regions and tomia of the rhinotheca. (Photos A and B courtesy Nigel Harcourt-Brown; photo C courtesy Brian Speer.)

Many parrots also have grooves in the hard keratin (occlusal ledge) of the oral aspect of the rhinotheca, which likely aid in grip, grinding, and cracking of food items (Figure 31.7).[24,27,28] A similar arrangement of tactile pits in the maxilla is found in the mandible of the Senegal parrot, but in smaller numbers.[27]

Mechanoreceptors and innervation of the beak

The principal type of mechanoreceptor in the bill tip organ is the Herbst corpuscle.[24] These corpuscles have an onion-like structure with a central axonal ending surrounded by numerous slender concentric cellular lamellae. These corpuscles are highly sensitive to vibration and are capable of following very fast frequencies up to 1000 Hz. The number and location of Herbst corpuscles that are present in the bill are related to the way the bill is used as a tactile exploratory organ during feeding.[24,27,29]

In grain-eating birds, including many parrot species, which cut or crack open seeds, the tip and lateral ridges of the bill are also well supplied with Herbst corpuscles. These corpuscles are the most widely distributed mechanoreceptors in the avian body, occurring wherever there is a mechanical disturbance that may require tactile detection. These can be found at the base of feather follicles, along the bones of the wing and pelvic limb, in muscles, tendons and joint capsules, near large blood vessels, and even in association with the alimentary canal and especially the cloaca. Grandry corpuscles are distributed in the dermis of the bill that is associated with the soft horn in waterfowl, particularly near the sides and tip.[30] These corpuscles consist of one or two granular cells associated with

FIGURE 31.8 The white tactile pits for mechanoreceptors are visible in this young blue-and-gold macaw *(Ara ararauna)* through the surface of the rostral gnathotheca *(A)*.

numerous axonal endings and closely resemble mammalian Merkel cells. These are rapidly adapting, velocity-sensitive mechanoreceptors. Grandry corpuscles are present in the dermis of the bill of grain-eating passerine species as well. Merkel cell receptors share a similarity with the intraepidermal Merkel cell receptors of mammals, but these are in the dermis of birds rather than the epidermis.[30] Merkel cells have been found predominantly in the beak and tongue of various nonaquatic birds. It is speculated that Merkel cells function as secondary sensory cells like hair cells in the inner ear. Merkel cells may occur as single cells as well as in groups and may even be organized as corpuscles with stacked arrangement like Grandry corpuscles of aquatic birds.[30]

Biomechanics of the Beak

The occlusal biomechanics and force delivery of the beak of many bird species have been explored in different ways.[14,26,31,32] In the order Psittaciformes, biomechanics have been detailed in the monk parakeet,[22] the Grey parrot,[33] and Pesquet's parrot *(Psittrichas fulgidus)*.[34] During feeding or locomotion, when the beaks are occluded, three forces act on the beak. The first, applied by *m. pterygoideus*, is transferred in the caudorostral direction of the maxillary beak. A second force is applied perpendicular to the longitudinal axis of the beak during occlusion. This force has been described in toucans and reaches values close to 270 N (~27 kg) in beaks weighing about 20 g. The third force is angular to the nasofrontal hinge joint. The combination of these three forces maintains the structural stability of the maxillary beak. The occlusal force applied by *m. pterygoideus* is greater to objects at the base of the beak and decreases gradually as the objects are pressed more rostrally close to the tip of the beak.[31]

Biomechanics and Function of the Beak

Cranial kinesis

Cranial kinesis of the beak is the term used to describe significant movement of skull bones relative to each other in addition to movement at the joints between the upper and lower beaks. Generally, cranial kinesis refers to relative movement between the upper beak and the braincase (neurocranium). There are three basic forms of cranial kinesis in birds: prokinesis, rhynchokinesis, and amphikinesis (Figure 31.9). The more widespread form is prokinesis, where the upper beak itself is inflexible and moves at the point where it articulates with the braincase at the craniofacial hinge joint, which is particularly evident in the order Psittaciformes, though it is found to some degree in several taxonomic orders. Rhynchokinesis describes the ability possessed by some birds to flex their upper beak. Unlike prokinetic birds, rhynchokinetic birds do not have a single craniofacial bending zone that includes the nasal bones and the nasal processes of the premaxillae. Instead, they have one bending axis passing through the dorsal ends of the lateral bars, and one or more others further rostral on the dorsal bar.[9,35] Flexion of the upper beak some way along its length is seen, either upward, in which case the upper beak and lower beak diverge, resembling a yawn, or downward, in which case the tips of the beaks remain together while a gap opens up between them at their midpoint. There are five distinctly described forms of rhynchokinesis: proximal, central, distal, double, and extensive.[35] Rhynchokinesis is known in Struthioniformes, Rheiformes, Apterygiformes, Ciconiiformes, Gruiformes, Charadriiformes, Columbiformes, Apodiformes, and Passeriformes. In amphikinesis, the entire upper beak is raised, and the tip of the beak is bent up in addition during protraction, and in retraction the tip bends down with respect to the rest of the upper beak. Amphikinesis is seen in Rallidae.[35]

Thermoregulation

Thermal regulation of excess body heat from the oropharyngeal cavity in some avian species such as pelicans (*Pelecanus* spp.) is accomplished through evaporative heat loss by thermal tachypnea and gular flutter. Thermal tachypnea involves open-mouth breathing or thermal panting, which is associated with an increased respiratory rate, resulting in an increased rate of evaporative cooling effect. The gular flutter is characterized by a rapid flutter of the gular region caused by flexure and relaxation of the hyoid apparatus.[36] In addition to evaporative cooling mechanisms for heat exchange, toucans and hornbills are capable of heat exchange from their bill, using it as a controllable vascular radiator.[3]

DEFORMITIES AND DISORDERS OF THE BEAK AND SKULL

Beak deformities in birds are either congenital or acquired. Comparatively, there are few congenital deformities described (present at or before the time of hatch), and the vast majority of problems are acquired, and manifest with progressive developmental changes as continued keratin growth occurs and force vector delivery is altered. Acquired beak deformities can result from primary mechanical injuries to bone, dermis, innervation, or the prokinetic musculature itself. Abnormal keratin growth can also result from disease conditions. Traumatic

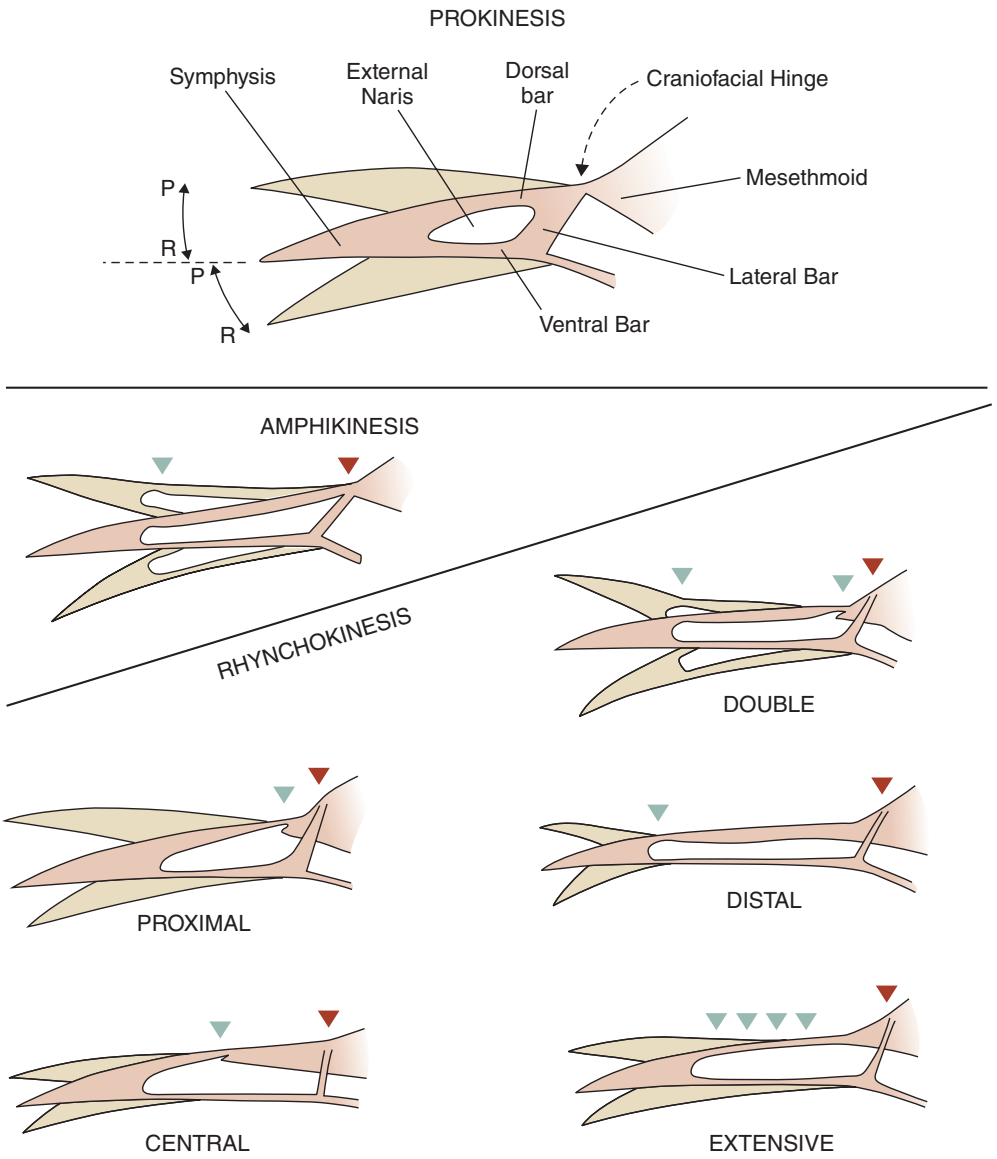

FIGURE 31.9 The forms of avian kinesis: prokinesis (A), amphikinesis (B), and rhynchokinesis (C), of which five subforms (proximal, distal, central, double and extensive rhynchokinesis) can be distinguished. *Stippled* figures show upper jaw in closed position. *P,* Protraction; *R,* retraction; *solid pointer* indicates craniofacial hinge; *open pointers* indicate additional bending axes on dorsal bar.

injuries, infectious organisms (parasitic, mycotic, viral, bacterial), nutritional, metabolic, and neoplastic causes are all well represented in the literature. These etiologies may have primary or secondary roles in beak deformities seen in birds, with secondary rhamphothecal overgrowth. Beak malalignment often results in abnormal keratin wear, requiring periodic corrective rhamphothecal reshaping procedures. More severe cases of congenital or acquired beak deformities may result in difficulty prehending food, and thus impaired welfare and quality of life. As such, it is appropriate to describe the deformities carefully and hypothesize or diagnose their causality with an understanding that the primary cause may be elusive at times. Diagnosis should be sought to the level of understanding required to facilitate therapeutic intervention and strategize the most anatomically sound way to trim and shape rhamphothecal surfaces.

Nutritional Disease

Nutritional deficiencies and imbalances can result in pathology of the beak and skull. Malnutrition may result in softening and flaking of the rhamphotheca. Nutritional metabolic bone disease can cause abnormal bone growth in juvenile birds and can potentially result in developmental beak deformities when the bones of the skull are involved. These types of deformities may also be acquired secondary to metabolic bone disease at later ages (Figure 31.10). Secondary (opportunistic) bacterial and mycotic infections are common and can set the stage for the development of beak deformities.[5,37]

FIGURE 31.10 Chronic rhamphothecal deformities in a 23-year-old Grey parrot *(Psittacus erithacus)*, with right lateral rhinothecal overgrowth and left lateral rostral gnathothecal tomial overgrowth. Not visible, but also present is considerable overgrowth of the rhinothecal occlusal ledge, where the rostral gnathothecal tomium should normally occlude. Note the lingual and inward folding of the left mandible and gnathotheca, likely the cause of the abnormal mandibular angulation and resulting malocclusion and tomial overgrowth. Metabolic bone disease and weaker mandibular structural integrity and/or trauma were hypothesized as underlying causes of this deformity when the bird was younger, and the rhamphothecal overgrowth was first noted at 6 years of age. (Photo courtesy Brian Speer.)

FIGURE 31.11 Squamous cell carcinoma in a 35-year-old yellow-fronted Amazon parrot *(Amazona ocrocephala)* of unknown gender, resulting in a crusting, wart-like growth of the rictus on the right side of the beak. Squamous cell carcinomas are well known to invade the adjacent tissues, as can be observed in this bird as well, where oral inspection revealed the neoplasia to have invaded the hard palate. (Photo courtesy Yvonne van Zeeland and Nico Schoemaker.)

FIGURE 31.12 Squamous cell carcinoma involving the mandibular beak in a budgerigar *(Melopsittacus undulatus)*. Note loss of the rostral gnathothecal tomium, erosion of the keratin of the gonys, and overgrowth of the rostral rhinothecal tomium. (Photo courtesy Lauren Powers DVM, DABVP (Avian Practice); with permission.)

Neoplasia

Many neoplasms form visible masses of the beak or oral cavity (Figure 31.11), while others are not directly visible. Such neoplasms may eventually become clinically apparent by the distortion of rhamphothecal growth,[37] presence of tissue necrosis or hemorrhage,[37] dysphagia and/or difficulty prehending food, or dyspnea.[5,37] Definitive diagnosis generally requires cytology or histopathology.[37]

Squamous cell carcinoma

Squamous cell carcinoma has been described in a number of avian species, including a timneh parrot *(Psittacus timneh)*,[38] a Buffon's macaw *(Ara ambigua)*,[39] great hornbill *(Buceros bicornis)*,[40,41] a common stork *(Ciconia ciconia)*,[42] and an African penguin *(Spheniscus demersus)*.[43] Squamous cell carcinoma is often locally invasive, with a high rate of local recurrence but a low potential for distant metastasis (Figure 31.12).[37] Secondary bacterial and mycotic infections are common.[37] Aggressive surgical resection,[39–41] chemotherapy (intralesional cisplatin),[40] radiation therapy (cobalt 60),[39] photodynamic therapy,[40] and topical and oral antiangiogenic therapy[41] have been described with mixed success in birds. Therapeutic options for squamous cell carcinoma are reviewed in *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 3, Neoplastic Diseases in Avian Species. In some of these cases, particularly those where amputation or aggressive resection is a part of the treatment, the use of surgical beak repair and/or prosthetics may have value in improving quality of life (see also Chapter 56).[41]

Melanoma

Melanoma is generally considered a malignant neoplasm in birds.[37,44] Malignant melanoma of the beak or surrounding tissues has been described in the Grey parrot,[45] thick-billed

parrot *(Rhynchopsitta pachyrhyncha)*,[46] pigeon *(Columba livia)*,[47] mandarin duck *(Aix galericulata)*,[48] and macaroni penguin *(Eudyptes chrysolophus)*.[44] Not all melanocytic tumors in birds are grossly pigmented, and therefore all suspicious masses should be closely evaluated and sampled for diagnostic testing.[44,48] Reported treatments include surgical excision,[45,47] radiation therapy,[44,46] and oral antiangiogenic therapy.[46] Distant metastasis to the lungs, liver, kidney, spleen, bone marrow, and other organs is common.[37,44–48] As with squamous cell carcinoma, the use of surgical beak repair and/or prosthetics may have particular value in improving quality of life, when amputation or aggressive resection is required.

Fibroma and fibrosarcoma

Fibrosarcoma is generally considered to be the most common primary beak tumor in birds, although fibromas may also occur (Figure 31.13).[37,49] Fibrosarcoma is most common in budgerigars *(Melopsittacus undulatus)* and cockatiels *(Nymphicus hollandicus)*,[37] although it has also been reported to be associated with a pathologic fracture and distal avulsion of the maxillary beak in a Grey parrot.[49] Fibrosarcomas tend to be locally aggressive with a low risk of distant metastasis, although metastasis has been documented and local recurrence is common after surgical resection.[37] Local invasion into the nares, nasal turbinates, and bone can result in deformation of the beak. Histopathology is generally considered diagnostic.[37,49] Chemotherapy (intralesional cisplatin) and radiation therapy were used in the treatment of a facial fibrosarcoma in a blue-and-gold macaw.[50]

Infectious Diseases

Viral diseases

Several viral diseases are associated with damage to the structures of the beak and oral cavity. Psittacine beak and feather disease (PBFD) is caused by a nonenveloped virus in the genus *Circovirus*, family *Circoviridae*. In the chronic form, beak lesions and feather loss are often observed (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Diseases). Reported beak and oral lesions include rhamphothecal elongation, transverse or longitudinal beak fractures, oral ulceration, and palatine necrosis.[37,51] The rhinotheca may separate from the underlying dermis, potentially resulting in exposure of bone (Figure 31.14). Diagnosis can be made through the use of serology, polymerase chain reaction (PCR), and histopathology and demonstration of basophilic intranuclear and intracytoplasmic inclusion bodies.[37,51] Although birds can survive with supportive care for long periods after developing lesions, immunosuppression, and life-threatening opportunistic infections are common.[37,51]

Avian pox is caused by viruses of the genus *Avipoxvirus* in the family *Poxviridae*. Poxvirus infections are common in avian species but are only occasionally diagnosed in psittacine birds.[36] There are two major forms of clinical disease—a dry (cutaneous) or a wet (diphtheroid) form, although a septicemic form can also occur (see Chapter 15).[37] In the dry form, papules, pustules, nodules, crust, and eschar form on nonfeathered areas of the skin, frequently around the eyes, beak commissures, and cere.[37] Beak and keratin deformities can on occasion result from some of these lesions. In the wet form, plaque and diphtheritic membranes form over oral mucus membranes and respiratory mucosa. Diagnosis is generally made through biopsy and histopathology, with demonstration of intracytoplasmic eosinophilic inclusion bodies (Bollinger bodies; see Figure 15.5), although PCR can also be used to demonstrate the presence of virus.[36] Mortality rates are higher with the wet forms of the disease.[37] Cutaneous lesions will usually spontaneously resolve, and treatment is primarily supportive.

FIGURE 31.13 Budgerigar *(Melopsittacus undulatus)* with a slow-growing soft tissue mass at the base of the beak. The bird initially presented with a scaly, eroding beak, which the primary care veterinarian suspected to be related to a scaly mite infestation. Following treatment with ivermectin and a beak trim, growth of the flesh-colored mass was noted, resulting in significant distortion and lateral deviation of the beak. Biopsy revealed the mass to be a fibroma. (Photo courtesy Yvonne van Zeeland and Nico Schoemaker.)

FIGURE 31.14 Rhamphothecal overgrowth and deformity in a sulfur-crested cockatoo *(Cacatua galerita)*, secondary to degeneration and necrosis of the dermal layers of the maxillary beak. Note the scissors deformity and marked overgrowth of the rostral gnathothecal tomium. Secondary and opportunistic bacterial and fungal infections of these exposed tissues are not uncommon. (Photo courtesy Bob Doneley.)

Avian polyomavirus (genus *Polyomavirus*, family *Polyomaviridae*) is often fatal in finches. However, some surviving birds, particularly Lady Gouldian finches *(Erythrura gouldiae)*, may develop elongation to tubular deformation of the rostral beak tips and inflammation and necrosis of the beak germinal epithelium.[37] A novel picornavirus and poecivirus are associated with rhamphothecal deformities in birds of prey and passerine species in northwest North America, respectively.[52,53,54]

Viral diseases that are largely representative of systemic processes with manifestations including rhamphothecal deformities carry overall a poor prognosis. However, poxviral infections may be ultimately self-limiting, and restorative or corrective beak procedures may offer value for some affected individuals where the biomechanics of beak function is impaired.

Bacterial diseases

Primary bacterial infections of the beak are unusual in birds, whereas secondary bacterial infections are somewhat more common.[37,55] Secondary bacterial infections often involve opportunistic Gram-negative bacteria as well as Gram-positive organisms. The diagnosis of bacterial infection is generally made through culture, although additional diagnostics such as Gram stain and acid-fast stain cytology can be used to further characterize observed bacteria.[37] Isolation of bacteria from fragmented slabs of keratin of the beak alone does not necessarily confirm infection. Treatment of bacterial infections should be based on results of culture and sensitivity testing, may include both topical and systemic modalities, and should also include treatment of predisposing and underlying diseases as well as supportive care as indicated.

Infection with *Bordetella avium* in juvenile cockatiels can result in a severe sinusitis and rhinitis with involvement of surrounding jaw musculature and bone.[56,57] Some affected birds have reduced ability to open their beaks. Isolated strains of *B. avium* from cockatiels have been found to possess a dermatonecrotic toxin gene (DNT)[57–59] and to produce osteotoxin.[56,59,60] Diagnosis of *B. avium* infection and resultant lockjaw may be made with clinical signs, physical examination findings, aerobic isolation of the organism, or PCR identification of the same. While *B. avium* appears susceptible to most antimicrobial agents,[52] antibacterial treatment should be based on the results of culture and sensitivity testing. Once muscular stiffness sets in, the prognosis for recovery is guarded to poor, although treatment can still be attempted and should include nonsteroidal antiinflammatory drugs (NSAIDs), pain management, and physical therapy in addition to targeted antibacterial treatments. Successful treatments where these approaches have been used in combination are reported.[61]

Mycotic diseases

Primary mycotic infections of the beak are uncommon in birds, but secondary or opportunistic infections have been reported and are likely more frequently encountered.[37,62] Sinusitis caused by *Cryptococcus neoformans* var. *gattii* in a 7-year-old male Major Mitchell's cockatoo *(Cacatua leadbeateri)* was associated with destruction of the rhinotheca.[62] Infection with *Penicillium cyclopium* resulted in rhinothecal necrosis and destruction in a blue-and-gold macaw.[63] Topical itraconazole had been ineffective prior to the diagnosis.[63] *Aspergillus* sp. was cultured from an adult yellow-naped Amazon parrot *(Amazona auropalliata)* with sinusitis, radiographic osteolysis of facial bones, and distorted growth of the distal rhinotheca.[64] Fungal mats were observed by histopathology on debrided beak tissues. The bird was treated with itraconazole administered *per os*.[64] During and following treatment of these infections, strategic rhamphothecal shaping procedures often will be required to augment and normalize force vector delivery and return normal keratin wear.

Parasitic diseases

Several ectoparasites can result in damage to the beak and surrounding tissues. Infection with *Knemidocoptes pilae* (scaly face mite; scaly leg mite) is somewhat common in small passerine birds and psittacine birds such as budgerigars, kākārikis *(Cyanoramphus novaezelandiae)*, and *Neophema* and *Polytelis* genera parrots.[37] The entire life cycle of the mite is spent on the host.[37] Mites are often found along the beak margins but can be found elsewhere on the body, such as the legs, wing tips, and vent.[37] The skin and rhamphotheca can develop a hyperkeratotic and pitted or honeycombed appearance (Figure 31.15).[37,65,66] Advanced lesions can result in severe distortion of the rhamphotheca.[37,67] Diagnosis is made through direct visualization and microscopic examination of skin or deep rhamphothecal scrapings (Figure 31.16).[37,66,67]

Avermectins such as ivermectin and moxidectin are commonly used to treat infections and are often administered at 7- to 10-day intervals until clinical resolution. Ivermectin can be administered orally or applied topically to lesions.[65,67] Weekly topical application of 0.05 mL of a 1 mg/mL solution was effective in eradicating mites within 2 weeks in budgerigars.[67] Systemic treatment is recommended for birds with severe or generalized infections.[67] As mentioned with mycotic infections, during and following treatment of infections, strategic rhamphothecal shaping procedures often will be required to augment and normalize force vector delivery and return normal keratin wear.

FIGURE 31.15 Knemidocoptic mange in an adult female Pacific parrotlet *(Forpus coelestis)*, resulting in rhamphothecal deformity and overgrowth, particularly of the rhinotheca. (Photo courtesy Lauren Powers DVM, DABVP (Avian Practice); with permission.)

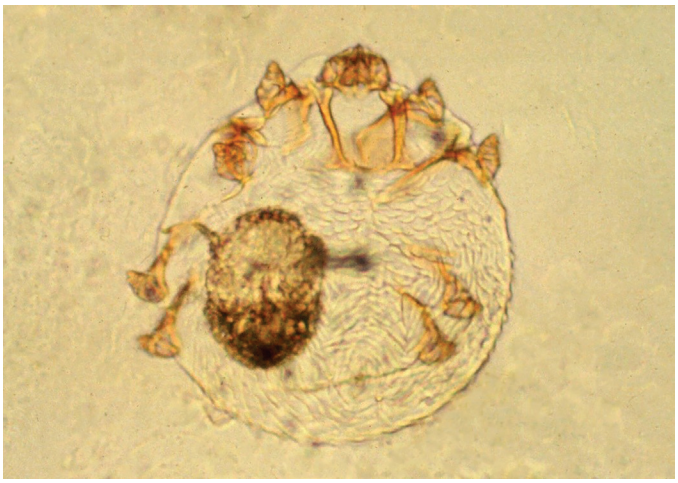

FIGURE 31.16 *Knemidocoptes pilae* (female), potassium hydroxide stain, 4×. *Knemidocoptes* are small, round burrowing sarcoptiform mites that can be found in various avian species. Mites usually invade the lightly or nonfeathered portions of the legs and skin, causing feather loss, scaliness, hyperkeratosis, and distortion of the beak, legs, and claws. Larvae undergo two nymphal stages before reaching maturity, which will take between 14 and 21 days to complete. Diagnosis can be made through deep skin scrapings. (Photo courtesy Yvonne van Zeeland and Nico Schoemaker.)

FIGURE 31.17 Marked gnathothecal overgrowth, resulting in actual penetration of the right lateral gnathothecal rostral tomium into the cere of an adult cockatiel *(Nymphicus hollandicus)*. There also is a paired overgrowth of the rhinothecal rostral and left lateral tomia. By keeping serial digital photos of a patient such as this, the strategy for, and assessment of effectiveness of a rhamphothecal shaping procedure toward the longer-term goal of functional correction can be made. (Photo courtesy Brian Speer.)

Trauma

Beak trauma is very common in companion and aviary birds as well as in wild birds and includes bite wounds from other birds, predators, crushing, and impact injuries.[37] Most wildlife cases are related to window collisions, gunshot wounds, bite wounds, and vehicular trauma.[6] Birds should be stabilized and fully evaluated for the extent of the injuries. An overall assessment of the patient's stability and systemic health status is essential prior to focusing specifically on the beak and musculoskeletal injuries of these patients (see Section 8, The Trauma Patient). Trauma involving the bony structures of the beak is common, and poorly healed fractures can result in beak deviations and uneven rhamphothecal wear.[68] Patients should receive appropriate supportive care and analgesic therapy.[5,6,68] The clinical assessment of the beak and skull includes a visual evaluation of the external beak, external palpation of the mandible and jugal arches, and range of motion assessment of the maxillary and mandibular beaks. Diagnostic imaging procedures are often, but not always, indicated.[5,6] Specific traumatic injuries and corrective surgical procedures are discussed in the following.

RELEVANT DIAGNOSTIC IMAGING OPTIONS

Photographic Imaging

Imaging is a useful and important diagnostic modality for evaluating disorders of the beak and oral cavity. It is particularly useful to document lesions with a high-quality digital camera, ideally one with excellent macro and lighting features. Standardization of patient position while obtaining these images will help improve methods of comparison when they are evaluated serially. These types of digitally recorded images can facilitate direct comparison of patient status and progression over time, allow quantitative measurements of lesions or deformities, and provide photodocumentation of current patient status as is described in medical records. With the growing use of digital medical record–keeping systems in veterinary health care, these images are easily embedded in most medical records, allowing rapid access and easier sharing with specialists for further consultation if indicated.[5] An example of a specific deformity where practical application of this means of serial photographic imaging could have value is shown in Figure 31.17.

Projection Radiographic Imaging

Radiographic imaging is a standard and key aspect of the practice of avian medicine by allowing for noninvasive visualization of anatomic features in both health and disease states.[5,69] Due to the often relatively small body size of many companion bird species, variations in technique and image quality obtained, and the significant overlap of the multiple structures of the head, diagnostic acuity may be more limited as compared to what can be obtained with other imaging studies or plain images of other anatomic regions (Figure 31.18). Regardless, in the correct clinical situation, these plain radiographic images can offer a significant benefit as a component of a diagnostic investigation.[5,69] Particular problems and diagnostic challenges, which may be aided with plain radiographic imagery, may include

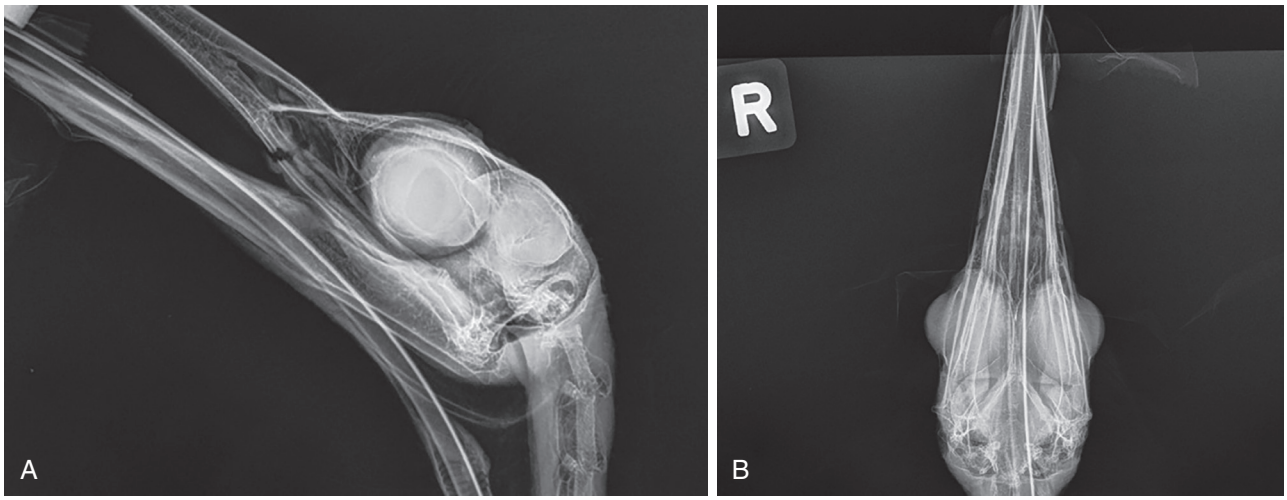

FIGURE 31.18 Projection radiographic images of a black-crowned night heron *(Nycticorax nycticorax)* that was found injured in its enclosure. Although fractures to the jugal and palatine bones can be identified in these lateral (A) and ventrodorsal (B) images, superimposition makes detailed evaluation of other bony structures more challenging without the use of CT imaging. (Photos courtesy Brian Speer.)

malocclusions with keratin overgrowth, certain skull fractures, and some sinus problems.[5,69]

Computed Tomography

Computed tomography (CT) has become an increasingly valuable tool in avian species, with applications that are useful for planning, guiding, and monitoring therapy (see Chapter 2, and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 14, Advances in Diagnostic Imaging).[69–71] The main advantage of CT imaging compared with standard projection digital radiography is that there is no interference from superimposition. Two-dimensional and 3D renderings obtained through CT imaging enable better visualization of various tissues and structures, including those that would otherwise have remained undetected with conventional radiographs (see Chapter 2). In general, high-definition, high-resolution CT imaging has greater diagnostic acuity than projection digital radiography. In areas with significant bone superimposition, CT imaging has been found especially useful. An example of some of the merits of CT imaging is provided in Figure 31.19. CT has a large range of relevant and practical applications, particularly for the head, and is considered superior to radiographs for evaluating the nasal cavity, conchae, and sinuses, allowing detailed studies of the various anatomic structures.[69] Contrast media may be used to increase the radiodensity of tissues, organs, and/or vascular systems, which helps depict lesions or abnormalities. Soft tissue structures with abnormal vascularization caused by disease (e.g., neoplasia, inflammation) will show increased uptake of contrast medium, differentiating it from normal tissue.[71]

Other Imaging Modalities

Other imaging techniques may be useful in specific conditions of the beak and head, such as magnetic resonance imaging (MRI), nuclear imaging (including positron emission tomography [PET]), and scintigraphy (see Chapter 2, and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 14, Advances in Diagnostic Imaging). Because of its characteristics, MRI is primarily used to image and diagnose soft tissue structures. The primary disadvantages associated with MRI may include prolonged imaging procedure times for some studies and special spatial resolution challenges. With the increased availability of higher resolution systems, the use and practical implication of MRI in avian medicine is likely to become more prevalent in veterinary practice overall and avian practice.[71]

RHAMPHOTHECAL TRIMMING AND SHAPING STRATEGIES

Normal and Abnormal Keratin Wear

Despite its hardness, the horny tissue of the bill is normally lost by wear and is continuously being replaced.[8] In birds that are maintained in companion or captive settings and the diets being fed as well as their means of acquisition are not consistent with those of their wild counterparts' behavior, the bill is sometimes not subjected to its ethologically normal intended use and resulting wear. This may be the result of the consumption of different food items, a lack of the normal enrichments that would provide such wear or other factors. A frequent consequence of the lack of normal wear is the perceived or potential need for trimming of these beaks, which is often focused on the flaky layers of covering-type keratin as a cosmetic procedure.[5] Many of these grooming procedures are unnecessary, and strategic enrichment of the birds' environment and self-maintenance behaviors may be most appropriate (see Chapter 47). An example of normal keratin accumulation in the absence of malocclusion that suggests a lack of normal beak use and rhamphothecal surface wear is provided in Figure 31.20. Where there is appreciable malocclusion or rhamphothecal overgrowth present, a keratin-shaping strategy may be indicated, based on functional diagnosis of its cause. In addition to a lack of normal use and keratin wear, overgrowth can often be seen secondary to uneven rhamphothecal wear resulting from other disease processes.[5,52,68,72]

FIGURE 31.19 Selected 3D-constructed CT images of a griffon vulture *(Gyps fulvus)* with multiple skull deformities. (A) Photo of the bird. (B) Left lateral 3D reconstruction. (C) Right lateral 3D reconstruction. Interpretive findings from the CT imaging study: the mandible is skewed to the right, and maxillary beak to the left; there is a left jugal fracture, with the nasal-most component missing and no apparent articulation with the left premaxilla; the palatine bone has an incomplete fracture at the symphysis, with depression of the left side apparent. The vomer appears intact, and the left and right pterygoids appear intact. The left lacrimal bone is ventrally displaced and appears to be pressing on the scleral ossicles of the left eye, causing ventral displacement of the globe. Most significantly, however, are the changes to the left temporal bone. There is a displaced fracture of the temporal bone's postorbital process over the articular region for the quadrate and including the articular points for the quadrate. The dorsal aspect of the quadrate appears to be fractured as well. These fragments are displaced rostrally, leading to what appears to be rostral extension of the quadrate, whereas it is merely due to the displacement of that ventral quadrate fragment. (Photos courtesy Louisville Zoological Gardens.)

In principle, any disease process that causes uneven growth or abrasion (wear) of the rhamphotheca can result in deformation and overgrowth of the beak keratin. Chronic liver disease appears to be associated with excessive rhinothecal growth and elongation in some psittacine species, but the explanation for this association is unknown.[5]

The Beak Trim

Chickens

Beak trimming (amputation of the distal aspect of the upper bill) has been used in the poultry industry to provide a mechanical prevention of feather pecking and cannibalism, and while several countries have banned the use of this technique,

FIGURE 31.20 Covering-type keratin buildup in a red-lored Amazon parrot *(Amazona autumnalis)*. Although a keratin-grinding procedure may help remove these exfoliating layers, longer-term maintenance would be most effectively accomplished with strategic enrichment of more normal beak use and wear. (Photo courtesy Laura Wade.)

FIGURE 31.21 This leghorn shows a healed maxillary beak following a beak trimming procedure that was performed 8 days earlier. (Photo courtesy Pat Wakenell.)

its practice still continues in many countries today.[73–75] The practice of beak trimming in poultry is typically done very early in life and, although still intrusive, is less so than when performed in adults.[73] When carried out correctly, the upper beak, and in some methods, the lower beak, is trimmed or amputated not more than one-third of the distance from the tip to the entrance to the nostrils (Figure 31.21).

Trimming the maxillary beak, specifically using the hot blade method, results in altered prehension between the upper and lower bills, which mechanically prohibits these undesired behaviors. Normal food prehension, feather care, and normal occlusion and keratin wear are also altered,[76] as well as the mechanoreceptors and magnetoreceptors of the beak.[77]

Feeding efficiency (number of pecks per gram of pellets ingested) is also reduced by beak trimming (hot blade method). In adult poultry, this type of beak trimming has been observed to result in a temporary fall in the intake of food and a reduction in body weight that lasts at least 6 weeks. These effects are greater if half of the beak is removed rather than one-third. Humanely and ethically, the profuse sensory innervation of the beak and the loss of capability of normal behaviors to be performed should be considered before advocating this procedure, particularly in adults.[78] The only time beak trimming is used after 1 day of age in layer hens is for prevention of severe behavioral persecution/pecking injuries leading to death, and it has been done with a hot blade. As opposed to the traditional hot blade method for beak trimming, the more current use of infrared technology done at 1 day of age has become a preferred method. Infrared beak treatment methods have shown better weight gains in chicks and other species of poultry. It is not as painful as the hot blade method, and birds will perform their normal behaviors and will remain active after having their beaks treated. The beak will fall off around 2 weeks of age, and the birds exhibit normal eating, drinking, and eating behaviors after it falls off as well.[74,76]

Birds of prey

Coping is a medieval term used to describe the trimming and reshaping of talons and beaks. Overgrown beak keratin is often encountered in captive raptors (Figure 31.22), due to insufficient keratin wear associated with the use of soft, inadequate perching surfaces and lack of a natural diet. Injuries to rhamphothecal surfaces may also require reshaping and alignment of tomial edges. In some cases, rhamphothecal overgrowth may be seen because of malnutrition or other medical conditions.[79]

Psittacine species

Abnormal keratin buildup is frequently removed from captive parrots and the procedure(s) are often also referred to as beak trim procedures, although they do not imply the removal of bone as occurs in poultry. Beak trimming is often performed on parrots by veterinarians in private practice for cosmetic purposes, to remove excessive keratin that could lead to abnormal force vector delivery, or to shape overgrown keratin that is clearly associated with malocclusion. With the latter and more chronic example, jaw muscle tension, form, and function can become altered, as can the shape of the bones of the upper and lower beaks themselves. Keratin-trimming procedures aimed at blunting the beaks to prevent feather-damaging behaviors or biting behaviors are largely viewed as unethical and should be discouraged. The joints and linkage ligaments associated with prokinesis can also become secondarily strained or altered as a result. These deviations in force vector delivery in turn lead to continued development of malocclusion and continued abnormal keratin growth as a result. As keratin grows abnormally, force vector delivery of the bills becomes progressively altered, leading to augmented malocclusion. Beak-trimming procedures for many chronic rhamphothecal overgrowths should best reflect a working level of diagnosis and strategy, rather than merely be accepted as a routine procedure. As such, when trimming the beaks of these birds, it is logical and prudent to describe the deformities carefully, hypothesize the causality of the deformities with

FIGURE 31.22 This captive-bred, juvenile (6–8 months old) female gyrfalcon *(Falco rusticolus)* shows a vertical splitting crack on the caudal edge of the left lateral rhinothecal tomium. This type of injury is often due to a lack of normal abrasion and wear, caused by the absence of hard surfaces (e.g., rocks) where food is offered and consumed. Normally, falcons tend to brush the beak repeatedly after eating on the edge of these hard substrates to clean it after eating, providing the abrasive wear needed to file the beak and maintain its shape. If these are not corrected on time it could cause a more severe fracture. A coping procedure to remove this keratin and balance the overall tomial occlusion is appropriate. Since the rhamphothecal surfaces are comparatively soft, coping may be accomplished with the use of a straight-edged human nail cutter as opposed to a concave edge, to cut the tomial tooth into shape and reduce the crack or split reduced by using a modified nail file. These types of cracks cannot be corrected in one session. Repeat procedures, weekly, are recommended until the crack is resolved. (Photo courtesy Jaime Samour.)

an understanding that the primary cause may be at times elusive, and strategize the most anatomically sound way to trim. In addition, once keratin overgrowth has been shaped more correctly, a targeted enrichment strategy may help to reduce the frequency of necessary trimming procedures, if not ultimately eliminate them through a careful restoration of normal form and function.[5,80]

Procedural concepts

Low-stress handling and restraint methods are an essential component of these procedures, regardless of the species (see Chapter 46). The potential for escalating escape and avoidance behaviors, learned fear, increased aggression, generalized fear, or even apathy is very real. These undesired consequences may not only adversely affect the outcome of the procedure itself directly but also the longer-term health and welfare of the bird, as well as the continued strength of the doctor-client relationship. Where appropriate, skilled handling, strategic shaping of the restraint experience, conscious sedation, or even general anesthesia may be indicated (see Chapter 46 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 19, Anesthesia). Effectiveness at reducing the degree of learned fear is best judged by assessment of the behavior of the bird during future visits and procedures and comparing with what was observed and recorded previously in past assessments in the medical record.[80]

The use of a hobby drill tool (e.g., Dremel) or other grinding tools is popular and effective for many keratin-trimming procedures. These tools offer procedural speed and access to the multiple keratin surfaces that may require attention. The optimal use of this tool requires the selection of the proper size and shaped bits, manual skills in handling and using the tool, and appreciation of the potential for heat that can be generated with excessive pressure or contact time. Not all keratin deformities require the use of a grinding tool, and a variety of other hand-held trimming tools can be used, depending on the patient species, size, behavior, and the specifics and complexity of the deformities being addressed.

Keratin structures that should be evaluated and shaped in concert with each other include the rostral and lateral rhinothecal tomia, the rostral and lateral gnathothecal tomia, the culmen, and the inner occlusal ledge of the rhinotheca, which functions as the occlusal site for the rostral gnathothecal tomium. An example of the description of specific rhamphothecal deformities in a macaw is provided in Figure 31.23. With careful assessment, a more focused and effective reshaping procedure can be developed for an individual bird's set of deformities. Where dermal or bony involvement is planned or is known to have occurred, pain management should be incorporated into the procedural plan. In some select cases, preprocedural radiography (Figure 31.24) can help delineate the extent of trimming that may be most appropriate, and general anesthesia can be helpful for some more involved beak corrective trimming procedures.

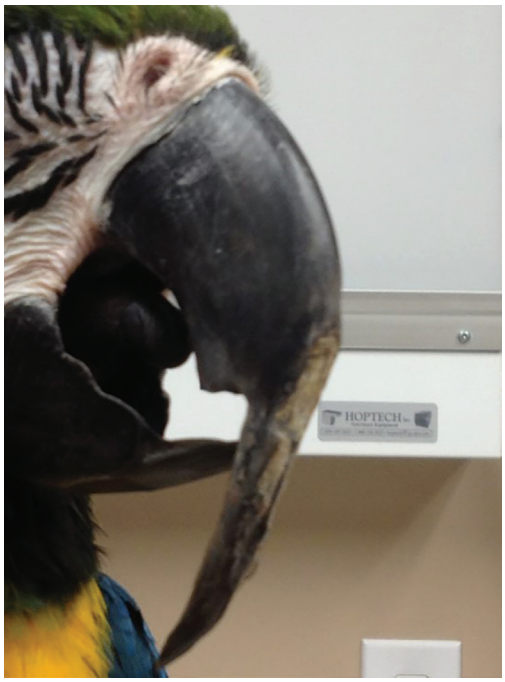

FIGURE 31.23 Rhamphothecal overgrowth in a chronically obese 1754-g blue-and-gold macaw *(Ara ararauna)*. There is overgrowth of the rostral rhinothecal tomium with abnormally soft and malodorous keratin at the distal culmen, rostral overgrowth and distortion, and overgrowth of the rhinothecal occlusal ledge, overgrowth of both the left and right lateral rhinothecal tomia, and overgrowth of the rostral gnathothecal tomium. (Photo courtesy Brian Speer.)

FIGURE 31.24 (A) Marked chronic rhamphothecal overgrowth in a green-winged macaw (*Ara chloroptera*). Note the scissoring deformity of the gnathothecal rostral and lateral tomia on the bird's left and rhinothecal rostral and lateral tomia on the bird's right. This deformity had been present for more than 15 years, and the apical aspects of the rhinothecal overgrowth had been periodically trimmed. The overgrowth of the occlusal ledge of rhinotheca is not visible in this first image. (B) Lateral projection survey skull radiograph of the bird depicted in (A). Measurements of the upper and lower bill allow for strategic calculation of what keratin overgrowth should be trimmed to optimize occlusion and force vector delivery under general anesthesia. (C) Following removal of the right lateral and rostral tomial overgrowth, the tomial surfaces are ground down to produce a symmetrical base for occlusion. (D) Preparation for cutting and shaping the gnathotheca. Note the black indelible ink marker at the point where the mandibular diaphysis was measured to be located. Overgrowth and distortion of the rhinothecal occlusal ledge are also visible from this angle. This was also ground and shaped appropriately.

FIGURE 31.24, cont'd (E) The same patient immediately following the procedure. Note the apparent improved kinetic function and ability to chew hard foods. Longer-term follow-up still is indicated, with a balanced and enriched behavior change strategy focused on increased chewing activities. (Photos courtesy Brian Speer, DVM, DABVP (Avian Practice), DECZM (Avian), Oakley CA; with permission.)

Following completion of the procedure, a targeted enrichment strategy to result in the functional increased use of these structures in more normal alignment should be contemplated and incorporated as a part of the whole procedure and its follow-up with a goal to reduce the need for and frequency of future procedures, if not eliminate their need completely (see Chapter 47).

ORTHOGNATHIC CORRECTION PRINCIPLES

Orthognathic procedures are those designed to correct deformities of the jaw and associated malocclusion in mammals. Applied to deformities of birds, these principles are applicable to both the upper and lower bills. The principle for correction of beak deviations is similar to that used in mammals and is based on the use of forces of small but constant intensity, applied in the opposite direction of the deviation. The repetitive compression force on the same side during normal kinesis causes the orientation of the cells of the dermal keratin-producing layers to migrate to the opposing side that is undergoing stress, correcting some of the malocclusions being addressed. As a result of these changes, the prokinetic musculature is utilized in more of a balanced manner and the resultant return of effective force delivery across keratin tomial contact points, more normal beak occlusion, and balanced prokinetic muscle usage in principle set the stage for effective resolution of many, but not all, problems. Most orthognathic procedures are used in young birds with deformities including lateral beak deviations (scissors beak) and mandibular prognathism, as there is more rapid growth and a greater potential for rapid remodeling. Those species with higher rates of rhamphothecal growth rates, such as birds of prey and psittacine birds, are also better orthognathic candidates.[4,80,81] Dental acrylics and resin-based composites can be used for orthognathic procedures and beak repair. Chemically activated monomeric compounds are efficient adhesive systems for use on the rhamphothecal surfaces of birds. This efficiency is attributed to the micromechanical retentivity obtained, due to the low-molecular-weight adhesives and their ability to penetrate between the layers of keratin and then polymerize afterward, producing a stronger and more efficient seal. Combinations of different primers, acrylics, and resins can be utilized for added strength and versatility. Table 31.3 displays some of the common adhesive systems that may be used, examples of common brand names, and their applications in beak repair and rhamphorthotics. Because some of these products, particularly the methyl methacrylates, produce an exothermic reaction during the polymerization process that may be damaging to living tissues, the specific physiochemical properties of the product should be understood prior to its use. Resin-based composites generally reach lower temperatures than acrylics during polymerization.[5,6,82]

Light-curing composites are composed of light-sensitive synthetic materials that can be molded and used to fill large defects or create beak orthoses or prosthetics. The use of a curing light may speed composite polymerization but, depending on the product, may not be mandatory as some are self-curing. Methyl methacrylate can be used as a light but strong binding adhesive material in the construction of external fixators (see Box 31.1 for a summary of the procedure).

TABLE 31.3

Materials Available for Beak Repair, Orthotics, or Prosthetics[82–89]

Material Class	Material Subdivision (When Applicable)	Applications	Trade Names (Not Comprehensive)	Notes for Use
Cyanoacrylics—soft tissue medical adhesives		Beak repair, soft tissue repair	Tissue-glue, Vetbond, Dermabond	
Methacrylate resins—also known as acrylic or acrylic resins	Methyl methacrylates	Beak prosthesis/orthosis	Ortho-Jet, Technovit, Vipi Flash	Very exothermic, strong fumes; come as a powder and liquid, which must be mixed
	Ethyl methacrylates		Kooliner	Less exothermic; comes as a powder and liquid, which must be mixed
	Other methacrylates		Tuff-Temp Plus	Dual cure; comes in a dual-syringe system with a mixing tip
Proprietary material	Urethane dimethacrylate	Prosthesis/orthosis	Triad TranSheet	Light cure, comes as a formable sheet; must be used with a bonding agent or cement
Provisional composite resins and restoratives	Bis-acrylic composite; BIS-GMA	Prosthesis/orthosis	Protemp Plus, 3M ESPE, Maxi-Temp, TempSpan, Build-It	Self-curing or dual curing; typically come in a dual-syringe system with a mixing tip; much less exothermic
	Flowable composite	Prosthesis/orthosis in conjunction with other materials	Silkflow, Natural Elegance Flowable	Light cure
	Packable composite	Prosthesis/orthosis in conjunction with other materials	Filtek P60, Filtek Z250, Filtek Z350	Light cure
Stainless steel orthopedic wire		Prosthesis/orthosis in conjunction with other materials	Many brands	Used for additional stabilization in association with other techniques
Fiberglass		Prosthesis/orthosis	Many brands	Used for additional stabilization in association with other techniques
Resin cements		Prosthesis/orthosis in conjunction with other materials	3M RelyX, Enforce, Panvia	Dual- and light cure; come as two syringes, which are mixed
Bonding adhesives		Prosthesis/orthosis in conjunction with other materials	Prime + Bond 2.1, Optibond, Scotchbond, Enforce	May need to be used with an etch, or may be self-etching; light cure

BOX 31.1 STEPS FOR APPLYING ADHESIVES TO BEAK KERATIN

1. Clean and remove debris from the surfaces.
2. Remove organic tissues and oils from the surface of the beak, exposing the spaces between the layers of keratin for polymer application. 70% Ether and alcohol are helpful. Take caution to prevent contact of these solutions or their fumes with the eyes or upper respiratory epithelium.
3. Prepare the surface to be restored with chemically activated monomeric adhesives, providing for optimal mechanical microretention.
4. Final construction is accomplished with polymeric material capable of polymerizing on the monomer adhesive previously used.

Once polymerization is complete, both resin-based composites and acrylics can be reshaped and/or polished with a drill or Dremel tool, although some can be extremely hard and difficult to reshape. A review of bone cements and their potential use in mandibular endoprosthesis in humans concluded that plain polymethyl methacrylate (PMMA) is the default choice for the initial development phase of this procedure. Modified PMMA cements, composite resin cements, osteoinductive calcium phosphate compounds, and cementless fixation are options that offer some advantages over PMMA cements, and, therefore, further research should be conducted to study their suitability and use in birds.[90]

SPECIFIC PROBLEMS AND PROCEDURES

Lateral Beak Deviation (Scissors Beak)

Lateral beak deformity is most often seen in macaws[1,68,91] but can also be seen in other psittacine species as well as doves, raptors, and domestic chickens, among others.[1] The causes of many pediatric developmental beak abnormalities are incompletely understood but are likely complex, variable, and multifactorial.[1,5,84] Lateral beak deformity is characterized by a lateral bowing of the maxillary beak, including the rhinotheca and often including the underlying maxillary beak bony

structures,[1,27,81,92] which generally occurs when there is a disrupted or altered growth of the bony structures of the maxillary beak such as the rictus or the premaxilla, nasal, and frontal bones.[1] Proposed underlying causes of lateral beak deviations include genetic abnormalities, incorrect egg incubation techniques, malnutrition, mycotoxicosis, improper hand-feeding techniques, and trauma.[5] As force vectors are repeatedly applied during regular beak use and with the normal rates of continued rhamphothecal growth, this deformity often will become progressively worse, ultimately generating a "scissors effect".[66,78] Uneven and imbalanced abrasion results in lateral rhinothecal and gnathothecal tomial elongation or shortening, leading to more pronounced abnormal occlusion.[5,80,91] Severe deformity may ultimately result in difficulty prehending food.

The details of treatment vary with the severity of the problem and the age of the bird.[5] In young birds with mild and early deviations, application of digital pressure regularly to the appropriate side of the beak for several minutes (two to three times daily) may lead to effective realignment. Progressive beak malalignment and abnormal rhamphothecal wear often require periodic corrective keratin-reshaping procedures in adult birds.[67,79] In some circumstances, this may be an effective management strategy, if the frequency of these procedures and stress sustained by the bird are not excessive or noted to carry adverse behavioral consequences. Corrective surgical procedures may be indicated for more severely affected cases or for those noted in young birds to reduce or eliminate the need for a lifetime of corrective rhamphothecal shaping procedures and optimize the welfare of the bird.[1,5,80,91]

Surgical corrective techniques for lateral beak deviation

Surgical correction is most successful in young birds when the beak tissues are more fully ossified, but still developing and more pliable than in adult birds.[1,5,80] There are two main types of orthognathic repair procedures. The first involves building a ramp orthotic device along the lateral wall of the beak to redirect bite forces to a more normal plane. This technique is employed more often in immature birds. The second involves applying lateral redirectional forces to the maxillary beak through transfrontal pinning and the use of tension wires or bands.[1,80]

For the beak ramp orthosis, an extension (inclined plane) of the lateral mandibular beak wall is created using structural adhesive resins such as liquid acrylic, epoxy putty, or light-cured dental resin composites.[80,81,84,85] The device is applied to the mandibular beak on the same side to which the maxillary beak is deviating and redirects bite forces to a more natural plane (Figure 31.25). Although ramp orthoses are most commonly applied to the mandibular beak, a maxillary beak ramp orthosis was successful in correcting a lateral beak deformity in a 2-year-old striped owl *(Rhinoptynx clamator)*.[81] The height of the orthosis must be tall enough to prevent the opposite beak from extending over it.[80] Stainless steel mesh, nylon mesh, cerclage wire, or a combination of materials can be used to support, build, and reinforce the orthosis.[1,81] Anesthesia may not be necessary if rapidly setting materials are used, such as dental composites, and if construction of the device does not involve perforation of deeper tissues such as bone, and if the patient is amenable to being held still during application.[1] Lightly notching the rhamphotheca can improve adhesion of the ramp construct to the beak keratin. Extending the orthosis to wrap around the beak to the opposite side can also strengthen the device.[80] The orthotic device should be designed to functionally create a deflecting lateral pressure from it that is relayed to the lateral maxillary beak. The amount of resin or orthotic material applied should be sufficient to cause occlusion of the key rhamphothecal tomial normal position, without preventing the bird from feeding. Normal beak movements and feeding, in this light, facilitate the effectiveness of the orthotic device. If the lateral rhamphothecal tomia are elongated due to uneven wear, the keratin should be reshaped to a more normal appearance to permit improved apposition. Potential complications include malalignment at the mandible-quadrate interface and fracture of the mandible, particularly in immature birds. Some orthotic devices may loosen and fall off, necessitating repeat application.[4,79] Correction using a ramp orthotic typically requires 1 to 3 weeks.

FIGURE 31.25 Ramp orthosis applied to a young scarlet macaw *(Ara macao)* to correct a left lateral maxillary beak deviation. The height of the ramp must be sufficient to prevent the bird from elevating the maxillary beak up and over the point of the orthosis. The device is removed when the alignment appears to have been corrected, or the ramp no longer contacts the lateral rhinothecal wall. (With permission from Abramson J, Speer BL, Thomsen JB, editors: *The large macaws*, Fort Bragg, CA, 1995, Raintree Publications.)

Tension band techniques are considered by some to be more effective for severe beak deviations in adult birds but can be effective also in subadult birds.[1,4,91] In the first technique, a transfrontal pin is utilized to facilitate lateral tension delivery to the distal maxillary beak (Figure 31.26). An intramedullary (IM) pin or Kirschner wire is carefully drilled transversely through the frontal bone caudal to the nasofrontal hinge and caudoventral to the nares.[1] Threaded pins are preferable to nonthreaded pins. The exposed end of the pin on the side of the beak opposite the direction of the deviation is left long and used to construct a connecting rod for tension band placement. The pin can either be left straight and short or bent at a 90-degree angle and extended rostrally parallel to the maxillary beak with the end in close apposition to the tip

FIGURE 31.26 (A) Right lateral beak deformity in a young blue-and-gold macaw *(Ara ararauna)*. Note that the maxillary beak is mildly skewed to the bird's right, exposing the left lateral aspect of the gnathothecal tomium, which in turn will lead to more progressive rhamphothecal overgrowth and deformity. (B) Ventral view of the rhinothecal surfaces of the same bird. Note the distortion of the rhinothecal occlusal ledge as the result of imbalanced occlusion of the rostral gnathothecal tomium. (C) A transfrontal pin has been placed with the threaded end of the pin seated in the right frontal bone and a 90-degree angle employed to facilitate direct lateral force being applied by a rubber band to the distal tip of the maxillary beak. Note that malocclusion appears to have been corrected. Prior to anesthetic recovery, the deformity of the rhinothecal occlusal ledge was reshaped. (D) A different blue-and-gold macaw 3 days after a similar procedure. The tension band has been loosened, and occlusion appears to have been corrected. Note that the transfrontal pin procedure was slightly different, in that the pin was completely driven through the right frontal bone and then curled, as opposed to the threaded pin used in (C). One potential disadvantage of this latter method is that the pin can shift laterally, resulting in variability in the degree of tension delivered to the distal maxillary beak. This pin was left in place for another 24 hours to verify that functional occlusion had been corrected, prior to cutting the pin where it exits on the left frontal side and removing it. (Photos courtesy Brian Speer.)

of the maxillary beak.[1,4,80] An elastic band is then looped around the tip of the maxillary beak at one end and through a loop created in the distal end of the pin at the other, applying gentle lateral tension to the beak tip. There are no biomechanical studies that have determined the amount of force to be applied in this procedure, but the use of small forces for long periods is generally preferred. The exit points of the pins or screws implanted in the frontal bone should be cleaned daily with chlorhexidine solution (0.12%). Effective correction can often be accomplished in a matter of a few days to 2 weeks in most birds.[1,4,80] Potential complications from this procedure include infection and iatrogenic damage to the frontal bone and sinus, nasofrontal hinge, and maxillary beak structures, particularly in young birds.[80,92]

In another tension band technique, an orthopedic screw (wire or pin may on occasion be used alternatively) is placed transversely into the frontal bone caudal to the nasofrontal hinge and caudoventral to the nares, opposite to the direction of the deviation, similarly to the placement of the transfrontal pin described earlier (Figure 31.27). Another screw (or wire/pin) is then placed into the rostral portion of the beak, seated in the distal maxillary or premaxillary bone. In some cases, the screw can be placed laterally into the rhinothecal occlusal keratin ledge, and not be directly seated into bone itself.[93] An orthodontic elastic (rubber or band) is then added, extending from the frontal bone pin/screw and stretched to the rostral pin, providing tensile force that is delivered throughout the lateral side and length of the beak.[1,4,26] There are no biomechanical studies that have determined the amount of force to be applied in this procedure, but the use of small forces for long periods is generally preferred, as with the transfrontal tension band procedure described earlier. The exit points of the pins or screws implanted in the frontal bone should be cleaned daily with chlorhexidine gluconate solution (0.12%). Complete correction of the lateral beak deformity may take up to 10 months.[1] Similar to the transfrontal technique, potential complications from this procedure include infection and iatrogenic damage to the frontal bone and sinus, nasofrontal hinge, and distal maxillary beak structures, particularly in young birds.[1,4]

FIGURE 31.27 In this golden conure *(Guaruba guaruba)*, orthopedic screws are being used to provide the anchor for elastics in the correction of a right lateral maxillary beak deviation. (Photo courtesy Roberto Fecchio.)

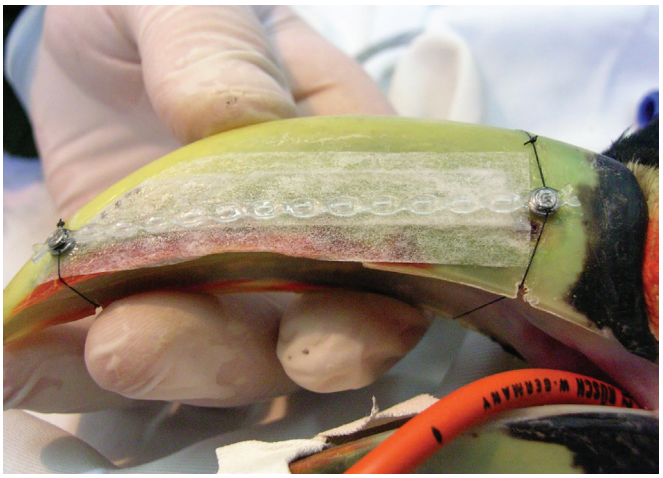

FIGURE 31.28 Application of orthodontic buttons for elastic fixation and correction of right lateral maxillary beak deviation in green-billed toucan *(Ramphastos dicolorus)*. The buttons provide functional anchors for the elastics applied, which then can allow for a much greater timeline for pressure to be applied to achieve the desired correction. The different techniques for correction of lateral maxillary beak deformities should be expected to vary depending on species and patient-specific details. In a longer-billed species such as this toucan, this approach may be a more viable option over a transfrontal pin or ramp orthosis. (Photo courtesy Roberto Fecchio.)

In bird species with slower beak keratin growth rates such as toucans, variations of these techniques should be used in a minimally invasive manner with less deep attachments to bone so that the corrective device can be maintained for years. This also can allow less secondary damage to the underlying structures and easier replacement of the device in the future. In many cases, the use of orthodontic buttons (or brackets) attached helps to anchor elastics, as in the case of toucans (Figure 31.28).[4]

Mandibular Prognathism

In brachygnathism, the maxillary beak is longer than the mandible (overshot). In prognathism, the mandible is longer than the maxilla (undershot).[94] The appearance of these two general deformities can be the result of true anatomic deformity in the actual length of the bills, or as the result of hyper-retraction of the maxillary beak in the circumstance of mandibular prognathism. Mandibular prognathism is most often seen in cockatoos but can occur in other avian species (Figure 31.29).[91] The distal maxillary beak rests caudal to the rostral margin of the mandibular beak, within the oral cavity ("underbite").[91] Mandibular prognathism can be a result of excessive contraction of the muscles that lower the maxillary beak (retraction), an abnormally curved or otherwise malformed maxillary beak, or excessively elongated mandibular beak structures.

FIGURE 31.29 Mandibular prognathism in a young hand-feeding cockatiel *(Nymphicus hollandicus)*. This deformity was successfully corrected by regular manipulation of the upper beak during each handfeeding, without the need for the application of orthotics. (Photo courtesy Brian Speer.)

Surgical corrective techniques for mandibular prognathism

As with lateral beak deviation, repair is most successful in young birds when the bony structures are still growing and pliable. Manipulation of the beaks can have early corrective merit in early cases or particularly younger birds. There are two main methods of repair; one that employs the construction of an extension along the tip of the maxillary beak and another that involves applying rostral redirection forces to the maxillary beak through tension wires or bands. Both methods apply tension to the *mm. pterygoideus* and *pseudotemporalis profundus*, which are often contracted in affected birds, resulting in continued abnormal lowering (retraction) of the upper beak.[1,6,26,92,93] The treatment choice varies with the severity of the condition and the age of the bird. In young, hand-feeding chicks, regular manipulation and extension of the maxillary beak may help mild cases be returned to normalcy. There are two general types of surgical repair for mandibular prognathism: application of an orthotic device and utilization of tension band techniques.

Surgical procedure. A variety of acrylic or dental composite products can be used for this procedure. A functional cap, extending from the cere distally, and encompassing the pressure-bearing keratin at the occlusal ledge of the upper mandible, is progressively constructed. The prosthesis is structured to duplicate and exaggerate the relative dimensions of a normal upper mandible so that the bird can function normally when it is applied. The lower bill must not be able to extend out and beyond this prosthesis, and the tomium of the gnathotheca should be capable of applying normal force at the area of the occlusal ledge of the rhinotheca (Figure 31.30).

Careful placement of a small sterile pin dorsally to ventrally directed through the tip of the premaxilla[5] or a small pin/screw into the lateral aspect of the rhinothecal occlusal ledge may help to stabilize the device.[94] This process functionally extends the upper beak, preventing placement of the maxillary beak into the lower beak, enabling normal occlusion and a normalization of the range of motion of the hyperflexed and hyperextended prokinetic joints. Pins placed through the bone of growing birds may result in trauma to the softer, pliable tissues and caution is warranted with their use. A method using dental composites has been described, which does not utilize anesthesia and may offer advantages in some cases.[95] A surgical procedure, utilizing a modification of the transfrontal pinning procedure for lateral beak deformity, has also been described in adult cockatoos with chronic mandibular prognathism.[96]

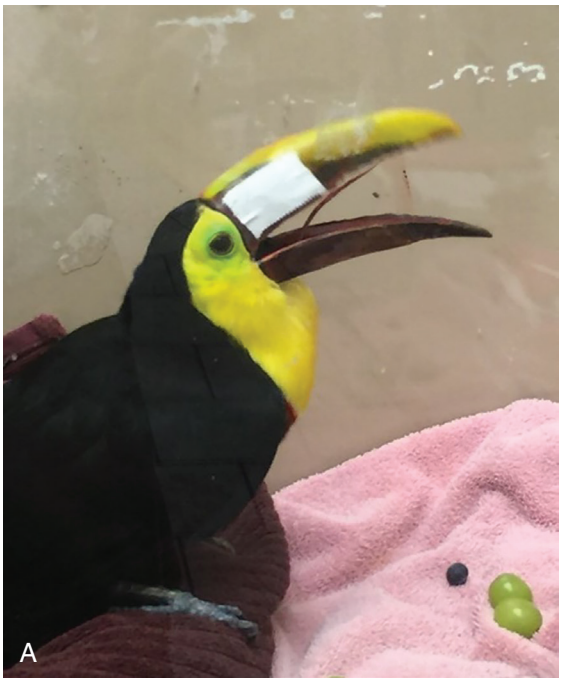
For the tension band technique, transverse placement of a pin through the frontal bone is similar to that described earlier for correction of lateral beak deviation. A second small pin or small threaded screw is placed in the bone of the maxillary beak along the midculmen at the point where inward rotation of the maxillary beak is most severe.[1] Structural adhesive resins can then be applied to support the second pin.[1] An elastic band is placed from either exposed end of the frontal bone pin to the premaxilla pin. The band can be removed after normal alignment is restored, and the pins removed once this correction is assured.[1] Potential complications with this procedure are related to the risks of trauma to bony and vascular tissues.

Beak Fractures

Fractures of the beak are often the result of trauma, although pathological fractures are also noted.[4–6,97,98] Initial treatment for these injuries consists of controlling local hemorrhage, pain management, and general patient stabilization.[5,6] Once the patient is stable, the wound should be debrided in order to remove dirt and cellular debris, and it should be kept clean until the specific treatment of the injuries is performed.[4,6,97,98] Those individual birds that have compromised ability to prehend and eat food items should be supported as indicated to maintain their caloric balance. Although some traumatic fractures and avulsions significantly alter the bird's appearance, many psittacine birds with functional amputations of their upper and (on occasion) lower beaks can learn to eat on their own, with time.[99] Thus, despite the belief of some, euthanasia is often not an absolute indication. Moreover, for those birds that learn to feed adequately on their own, and that do not have substantial malocclusion, further efforts at developing prostheses are not indicated.[26,99]

Imaging procedures including projection radiography and CT of the skull can be particularly helpful in planning a surgical repair. When there is outright loss of bone or vascular compromise, the prognosis for return to normal form and function is guarded. An attack by a cat resulted in slight lateral deviation of the mandibular beak and reluctance to open the mouth in an adult double yellow–headed Amazon parrot *(Amazona oratrix)*.[100] A mandibular fracture and disruption to the joint space between the mandible and quadrate bone were identified by CT. An esophagostomy tube was placed and the injury was allowed to heal without surgical intervention, although the ability to open the beaks remained

FIGURE 31.30 (A) Mandibular prognathism in a juvenile Moluccan cockatoo *(Cacatua moluccensis)*. This condition was successfully corrected using a maxillary beak orthosis. (B) Ducorps' cockatoo *(Cacatua ducorpsii)* approximately 10 days following application of a maxillary beak acrylic orthosis. Note the exposed proximal rhinothecal keratin, which was originally covered by the orthotic device because of the relatively rapid keratin growth rate. (C) The same Ducorps' cockatoo at day 20, when the orthosis loosened and fell off, and prior to removal of accumulated laterally exfoliating keratin. In this case, dental pins or screws were not employed to aid in stabilization of the orthosis. (Photos courtesy Brian Speer.)



compromised.[100] A 22-year-old hybrid macaw with a rigid nasofrontal hinge and laterally deviated jugal bone from a dog bite was diagnosed by CT and was successfully treated with surgical removal of the nasal-frontal-braincase and jugal-orbital arch.[70] Alternatively, surgical procedures using orthopedic or dental techniques and devices such as stainless steel plates,[101] IM pins,[102] osteogenic distractors,[103,104] dental resin composites,[105] and elastic bands,[1,4] among others, have been described and used to surgically repair beak fractures in avian patients.

Rhamphothecal cracks, fissures, and puncture wounds

Rhamphothecal cracks and fissures are most often the result of mild trauma, although there can be metabolic, nutritional, behavioral, or other factors that can contribute to their development. Treatment typically includes corrective rhamphothecal grinding to remove the crack and restore normal occlusion and alignment or local antisepsis and recoating with resins to avoid opportunistic infections. Cracks in the rostral gnathothecal

tomium, where there is no dermal or bony involvement, may be effectively addressed by grinding the surfaces to eliminate or shorten them. This often is done serially, with quantitative measurements of the length of the crack before and after each procedure. Afterward, many birds can benefit from strategic training aimed at altering their chewing/force delivery behaviors and resultant tomial wear.

Fissures and puncture wounds that penetrate through dermis and into bone structures of the beak can be covered with cellulose-based adhesive and cyanoacrylate-based adhesives (Figure 31.31), but the latter have irritative volatile substances that should not come in contact with the ocular and nasal mucous membranes. As indicated, pain management should be considered. When secondary bacterial infection is present,

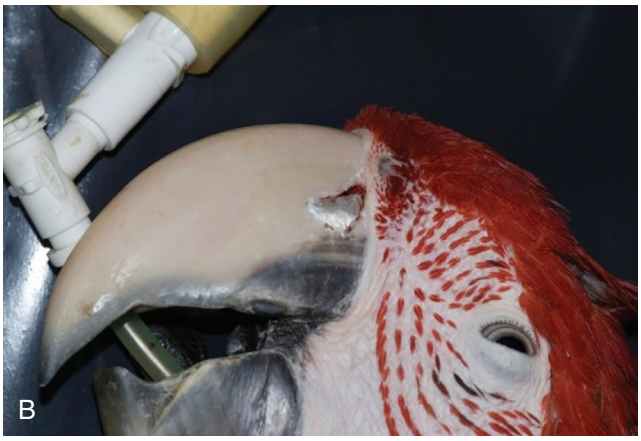


FIGURE 31.31 (A) This Swainson's toucan *(Ramphastos ambiguus swainsonii)* is recovering from sinus trephination and sinoscopy to remove granulomas that were within the nasal diverticulum of the infraorbital sinus of the maxillary beak. Both surgical and traumatic perforations through the rhamphotheca and into the bony structures and airspaces beneath them can be managed as open wounds, patched as in this case with adhesive bandaging material, or a variety of acrylic and dental composite materials. (B) Penetrating injury to the left proximal maxillary beak of a green-winged macaw *(Ara chloroptera)*. An injury like this must be investigated, as there will be variable degrees of bone, dermal, and keratin injury. With the bird anesthetized, the wound can be aseptically cleaned, and general wound care principles include replacement of compressed bony substructure, repositioning germinal layer, providing support for these tissues, maintaining a moist environment, removing fibrin clots, and preventing infection. (C) Following careful cleaning and replacement of the depressed tissues, this wound was covered with dental composites to protect and stabilize while healing. (A, Photo courtesy Brian Speer. B, C, photos courtesy Nigel Harcourt-Brown.)

systemic antibacterials and/or antifungals should be administered.[91] Some puncture wounds can effectively be treated topically without the need for covering them, or with light covering with adhesive bandages.

Mandibular symphyseal diastasis and fracture

Separation (diastasis) and/or fracture of the mandibular symphysis is a common injury in companion birds and is most often a result of an impact injury to the beak. The two mandibles are joined in the rostral midline at the *rostrum (symphysis) mandibulae* but this connection can easily become separated with trauma. Separation of this joint would be properly termed a diastasis, although fractures of the adjacent mandibular bone can also be seen, producing a similar net result (Figure 31.32). These injuries often have a guarded to poor prognosis for successful repair due in part to the thin nature of the vascular dermis and bone in this region.[72,106] If a repair is to be successful, it must be attempted soon after the injury occurs.

Successful repair techniques have been described in a Grey parrot, and have been performed in smaller psittacines (Figure 31.33), and, by the author, in chickens, and a mallard duck. In the Grey parrot case report in an acute injury scenario, interfragmentary wiring was placed through predrilled pilot holes, a 22-gauge wire was placed to provide fragmentary alignment, and the twisted ends of the wire were incorporated into a self-curing, provisional bis-acryl composite splint. Particular care was taken to minimize the amount of composite contacting the gnathothecal surfaces of the injury and the exposed dermal tissues beneath.[100] In smaller birds, a bridging construct created from structural adhesive resin may be adequate (Figure 31.33).[67] In larger birds, reinforcement with transmandibular placement of stainless steel cerclage wire or pins is often necessary (Figure 31.32).[72] The pins can be externally secured to each other using elastic bands,[1] or with loops of polypropylene or stainless steel suture or wire.[5] Pins and wire can then be covered with adhesive resin for added support and protection, with care taken to avoid direct contact with the resins to the rhamphothecal surfaces of the injury.

General beak fracture surgical repair

Significant fractures that may result in compromised healing and beak function should be stabilized and repaired. Basic

FIGURE 31.32 (A) Mandibular symphyseal diastasis fracture in an adult 8-year-old Grey parrot *(Psittacus erithacus)*. (B) Interfragmentary wire placement through predrilled holes, allowing intraoral wire passage and circumferential interfragmentary compression across both mandibles. (C) Following application of dental composite, which incorporates the wire twists but has minimal composite directly contacting the beak surface. (D) 18 Days postoperative photograph of the patient. The interfragmentary wires were removed at day 47 postoperatively, and at 21 months postoperatively, functional healing and normal rhamphothecal growth and wear were affirmed. (Photos courtesy Christoph Mans.)

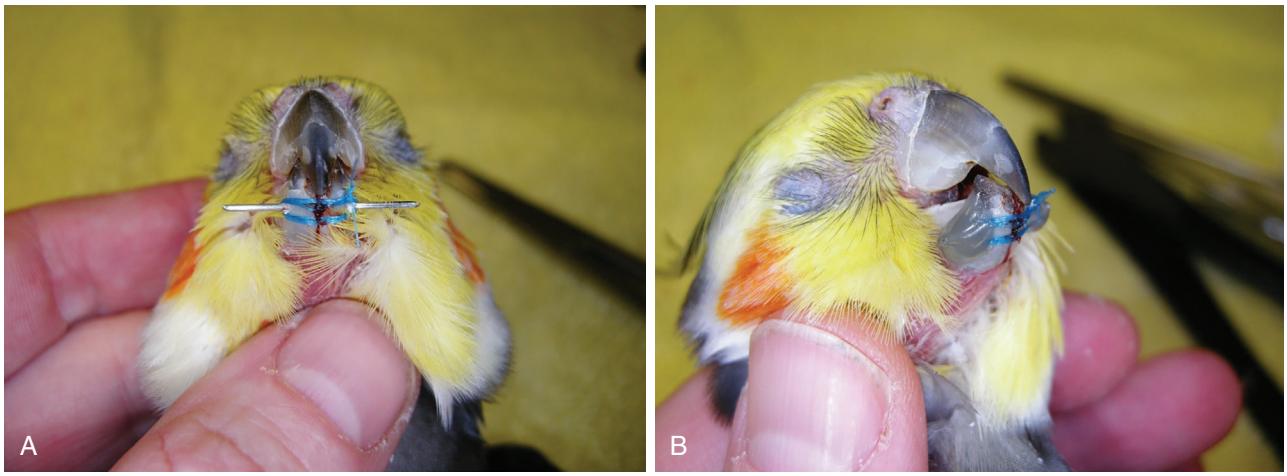

FIGURE 31.33 Repair of a mandibular symphyseal diastasis/fracture in an adult male cockatiel *(Nymphicus hollandicus)*. A successful repair was accomplished with the use of a single transmandibular pin (25 G hypodermic needle), around which polypropylene suture was looped (A), and then covered with liquid acrylic (Technovit Liquid; Jorgensen Laboratories, Loveland, CO, USA) (B). Note that the acrylic was not applied to the fracture line. (Photo courtesy Lauren Powers DVM, DABVP (Avian Practice); with permission.)

immediate functional goals with repair methods are to restore the repaired beak to immediate capability of function while healing occurs.[2] Fracture repair details are dependent on the location and extent of the injury. Fractures closer to the neurocranial articulations may be more complicated due to the biomechanical forces that will be present during the postoperative period.[4] Fractures with loss of bone fragments tend to present greater difficulty of repair and, consequently, reserved prognosis. In young birds, the chances of bone growth and remodeling in the fracture site are higher. To initially stabilize the fracture fragments, it is necessary to apply cerclage with atraumatic material (fine wire, nylon) that functions to prevent excessive torque and mobility of the fragments (similar to surgical correction of symphysis fracture or luxation). High-speed dental drills may be utilized to assist the perforation of the beak and its bony structures for the passage of the cerclage wires or nylon (Figure 31.34). The perforations should be made perpendicularly to the fracture lines when the fragments are lightly reopposed. Historically, bone plates and screws have not been utilized because the bone of the beak is so thin and has virtually no soft tissue coverage, although there are case reports of successful procedures.[101] Additionally, there are plates specifically designed for maxillofacial surgical procedures that may be more amenable to use in birds than the traditionally adapted ones used in the past. Plates may be used in large birds with fractures of the caudal mandibular beak where the bone is thicker and covered by muscle and normal skin. The thin bone of particularly the maxillary beak in most birds does not provide adequate screw purchase and bony integration. Another potential application for the use of plates is by placement over the rhamphothecal surface of some fractures. Used in this manner, the plate acts more like an external fixator because the device is outside the body tissues while the screws placed in the bone maintain effective reduction of the fracture and provide stability. Necrosis of the tissues (dermis) underneath the plate is possible, but if the fracture quickly heals these collaterally damaged tissues may still be capable of healing.[107] IM pins and orthopedic wires are also difficult to apply to the avian beak because there is no distinct medullary cavity within the flat bones of the beak, and the paucity of soft tissue over the bone would result in wires being exposed. Mandibular

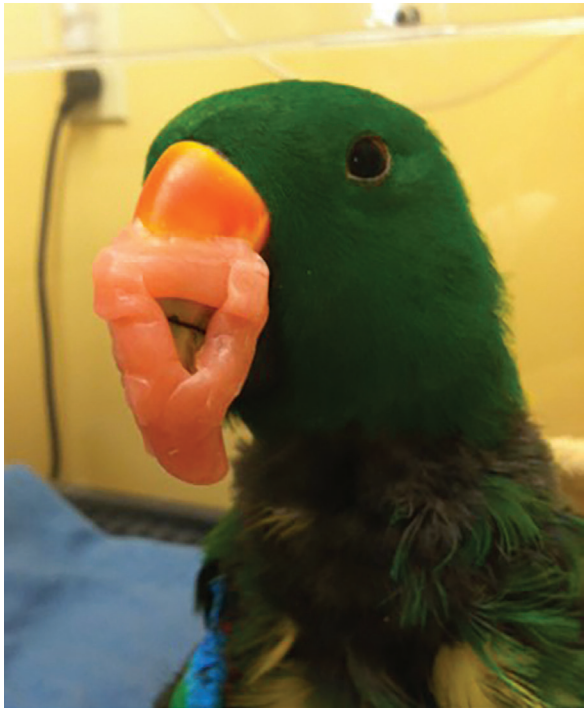

FIGURE 31.34 A transverse, distal third fracture of the maxillary beak in an adult male Eclectus parrot *(Eclectus roratus)*. Stabilization and protection of the fracture site in this case was accomplished with the use of a framework of light-cured acrylics while keeping direct contact with the fracture line minimized. (Photo courtesy Laura Wade.)

fractures, however, may facilitate the use of intermedullary pin placement and even the use of IM tie-in fixation strategies (Figure 31.35).

Interfragmentary wires or silk alone are inadequate to counter the forces acting on the fracture; however, they will hold fragments in apposition.[107] After this initial aspect of fixation, the strength of the interfragmentary wires or silk should be augmented to facilitate a rapid return of functional use of the injured beak. Such augmentation to the interfragmentary stabilization is obtained with the aid of adhesive materials and resins. Small dental pins or posts can be utilized to improve attachment of resins to the nonfractured sites of the rhamphotheca. It is essential that the surface of the beak is clean and dry prior to the placement of adhesive and resin material. As with the method described for mandibular symphyseal diastasis and fracture repair, particular care should be

FIGURE 31.35 Bilateral mandibular fracture repair in a Mallard duck *(Anas platyrynchos)*. (A) Bilateral distal third fractures of both mandibular rami are evident in this 4-week-old injury. (B) Necrotic debris was cleaned and removed, providing fresh edges of the distal and proximal mandibular fragments, and the wound was then flushed and aseptically prepared. (C) Small intermedullary pins were placed normograde into the distal fragments and out of the rostral aspect of the mandibles, then retrograded to ultimately be seated at the angle of the mandible, providing linear stability to the fractures. The ventrally bent rostral end of the pin is evident *(a)*, the location of a small threaded pin that was placed into the distal angle of the ramus is pointed out *(b)*, intravenous tubing filled with methyl methacrylate is placed over the ends of the distal intramedullary pin and the proximal threaded pin *(c)*, and a small transverse bar of methacrylate filled tubing is placed laterally between the two rami for additional stability.

FIGURE 31.35, cont'd (D) and (E) Four weeks postoperatively following removal of the fixator at 3.5 weeks, there is good functional healing of both rami.

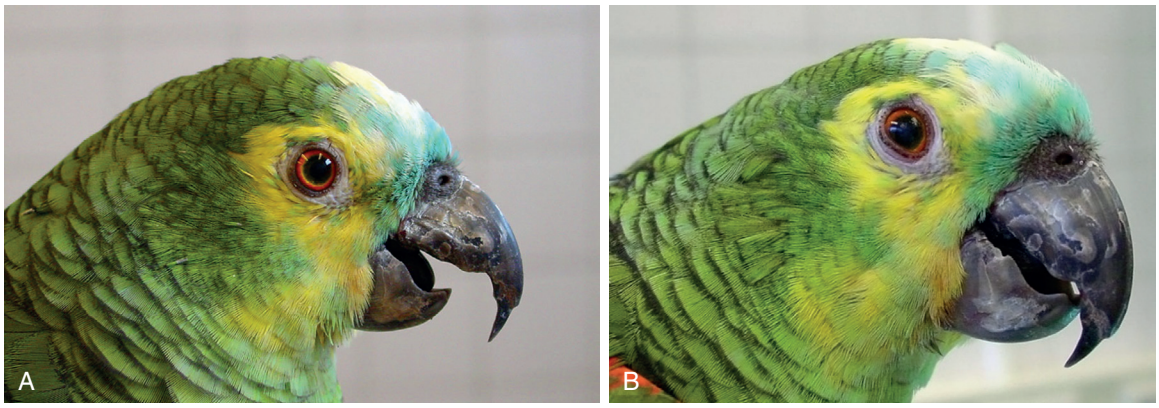

FIGURE 31.36 Palatine luxation in a blue fronted Amazon (*Amazona aestiva*). Note the hyperextension (protraction) of the maxillary beak (A). There was a complete inability to retract the beak as a result. To reduce the luxation, an intramedullary pin or Kirschner wire is driven transversely through the preorbital diverticulum of the infraorbital sinus dorsal to the jugal arch (or similar access is accomplished by a surgical infraorbital sinusotomy. Downward pressure is applied on the palatine bone while gently protracting (elevating) the maxillary beak. This enables the palatine to slide back over the mesethmoidal ridge, allowing the maxillary beak to return to its normal position (B). taken to minimize the amount of composite contacting the rhamphothecal surfaces of the injury.[2,4,87] Several resins can be used for fracture repair, but methacrylate-based resins must be cooled (irrigated or aerated) during their polymerization, as they have an exothermic phase and can cause burns and necrosis of the beak. In addition, volatile gases from acrylic resin can irritate the eyes and respiratory tracts of birds as well as the operators.[94]

Palatine bone luxation

Traumatic luxation of the palatine bone has been described in several psittacine birds, most commonly macaws.[1,80,108–110] Luxation occurs when the palatine bone is moved rostrally and then slips dorsally beyond its normal end-point on the mesethmoidal bony ridge at the ventral base of the neurocranium.[5,80] Luxation results in pathologic hyperextension and inability to close the maxillary beak (Figures 31.36 and

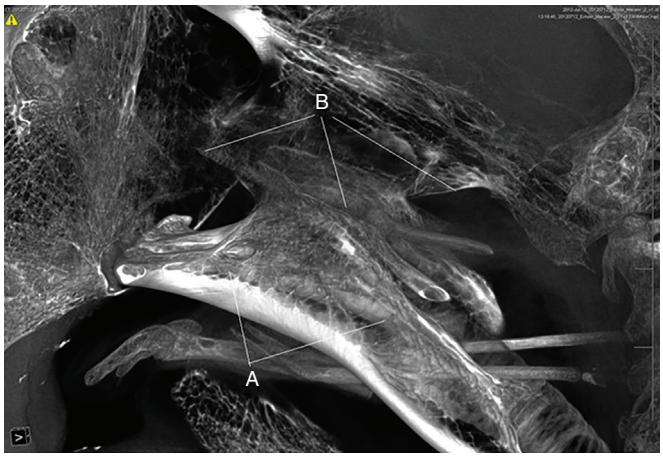

FIGURE 31.37 Micro-computed tomography (micro-CT) image of normal anatomy in a green-winged macaw *(Ara chloropterus)*. Rostral is to the left, and caudal is to the right. The mesethmoidal ridge at the base of the neurocranium (B) is visible, where it allows the central articulation with the palatine (A). When the palatine is moved too far cranially by hyperextension (protraction) of the maxillary beak, its caudal edge can catch at the cranial aspect of the mesethmoidal ridge *(far left line)*, enabling a functional lock, unless it is pulled slightly more craniad, then pushed downwards, allowing it to be replaced on the mesethmoidal ridge. (Image courtesy Scott Echols.)

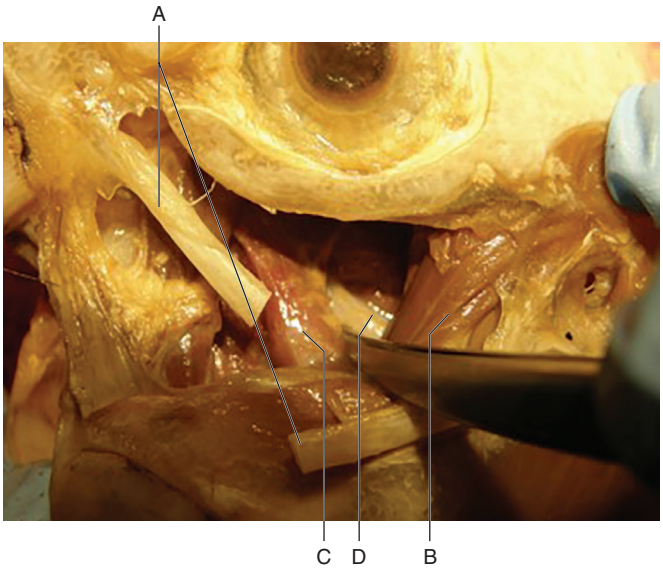

FIGURE 31.38 Cadaver dissection showing surgical access to the right jugal and pterygoid bones in a blue-and-gold macaw *(Ara aurana)*. Rostral is to the right. The infraorbital sinus has been accessed, and the jugal (A) has been cut with its rostral segment ventrally retracted. *M. adductor mandibulae externus ventralis* (B) is being cranioventrally retracted, and *M. ethmomandibularis* (C) is exposed at the tip of the scissors. The diaphysis of the pterygoid is exposed and visible deep to these two prokinetic muscles (D).

31.37).[5,80] The diagnosis is made based on history, examination findings, and radiographic findings.[1,80,108–110]

Birds may be able to spontaneously reduce the luxation on their own.[100] If the luxation does not quickly self-correct, surgical intervention is warranted.[1,80,108–110] To reduce the luxation, an IM pin or Kirschner wire is driven transversely through the preorbital diverticulum of the infraorbital sinus dorsal to the jugal arch. Care should be taken to not damage the ethmomandibularis muscle, which originates high on the rostral part of the interorbital septum and inserts onto the dorsomedial aspect of the mandible, serving to elevate (protract) the mandible (see Figures 31.4 and 31.5 and Table 31.2). Downward pressure is applied to the pin and the dorsal margins of the palatine bone, or directly should an infraorbital sinusotomy be utilized, while simultaneously extending the maxillary beak, enabling the palatine bone to slide back over the mesethmoidal ridge and allowing the maxillary beak to return to its normal position.[1,80,109,110] The pin is then removed from the sinus. Alternatively, a sinusotomy can be performed, and direct placement of pressure on the palatine bone with a variety of blunt instrument options can be accomplished in this open manner.[80] Additional stabilization can be provided by passing a suture around the suborbital arch (in those species that possess one) and jugal arch through a lateral approach (see Chapter 29).[1,80,110]

Fractures of the jugal, pterygoid bones

These specific injuries may be identified when evaluating injuries to the head and skull. When indicated, surgical repair is possible. The surgical approach to these bones can be made through the infraorbital sinus. The body of the infraorbital sinus is a large and spacious triangular cavity under the skin in the lateral region of the maxillary beak, and rostroventral to the eye.[111] The margins of the largest aspects of the infraorbital sinus are largely defined by the jaw muscles.

Surgical procedure (Anodorhynchus and Ara species). The skin ventral to the jugal arch is incised, exposing the lateral wall of the sinus. Retract the maxillary beak (closing), while extending the lower beak (opening). This functionally enlarges the sinus space and enables greater access within. Incise into the infraorbital sinus space ventral to the jugal arch (see Chapter 29). The jugal can be cut and reflected to increase deeper exposure into the infraorbital sinus (Figure 31.38). Fractures of the jugal arch can be identified and repaired with the use of hexalite shuttle pins and bone cement, or transcortical suture or wire. The infraorbital sinus space can be visually inspected, and magnification loupes with a focal light source, operating microscopy, or endoscopy can be used in selected cases for deeper visualization if indicated. Identify and caudoventrally retract *m. pseudomasseter* and other bellies of *m. adductor mandibulae externus*, *m. pseudotemporalis superficialis*, and rostrally retract the *m. ethmomandibularis*. The diaphysis of the pterygoid will be visualized deep and caudally. The pterygoids are pneumatized, enabling the potential for fracture repair methods using transcortical suture, wire, or hexalite shuttle pins and bone cement.[14] Closure of the surgical site is accomplished in two layers: the lateral wall of the infraorbital sinus and the skin.[80]

Beak avulsion

Traumatic beak avulsion is somewhat common in psittacine birds, toucans, and waterfowl. In psittacine birds, the injury is often a result of a bite from another psittacine bird. Avulsion injuries may be seen in the maxillary or the mandibular beaks

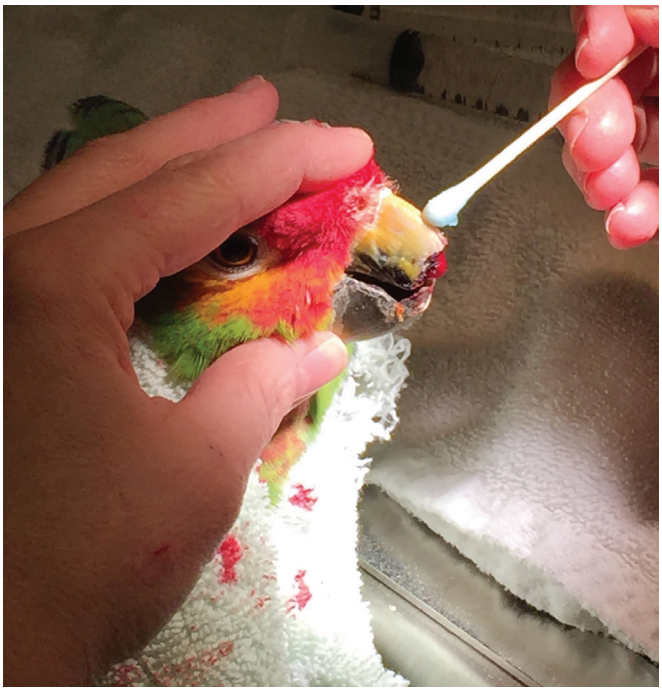

FIGURE 31.39 Traumatic avulsion of the distal maxillary beak in a red-lored Amazon parrot *(Amazona autumnalis)*. The fracture is at the level of the occlusal ledge of the rhinotheca, lending potential risk for permanent malocclusion. Rhinothecal keratin, dermis, and premaxillary bone are all missing. If the amputated portion of the beak is still available, it could be used as a part of an autologous prosthesis, to facilitate enough proximal beak growth to allow occlusion of the rostral gnathothecal tomium with an occlusal ledge and effective ability to chew and crack food items. Regardless, many parrot species can learn to eat on their own with these types of deformities. (Photo courtesy Laura Wade.)

(Figure 31.39). Surgical amputation of beak tissues may be indicated for aggressive local diseases such as neoplasia and some localized infections.[41] Ducks and geese are occasionally subjected to bites to the beak from snapping turtles or other predators. Most parrots can adapt and survive traumatic beak avulsion with appropriate wound care, supportive care, and analgesic therapy and do not require surgical intervention.[38,39,68,107] Some birds may require assisted feeding or placement of an esophagostomy tube during the initial recovery period. In one case series, 9 out of 10 psittacine birds with amputation of the beak survived, and all surviving birds were able to self-feed within 20 days, some much sooner.[99] Psittacine birds that lose most or all of the maxillary beak often lose the ability to crack seeds and nuts and other hard food items, and must be fed an altered, soft diet. Overgrowth of the rostral gnathothecal tomium occurs with amputation of the maxillary beak, typically when the injury is proximal to the occlusal ledge of the rhinotheca. Affected birds may require periodic gnathothecal restorative procedures due to inadequate keratin wear from the opposing beak.

Beak prosthetics

Avulsion of the maxillary beak in waterfowl can result in difficulty prehending food and exposure of the tongue to further desiccation and injury. These injuries of the maxillary beak can also result in difficulty with self-feeding as in other species. Loss of portions of the mandibular beak can also result in difficulty self-feeding and the performance of other maintenance behaviors.[26,97,99,101,112,113] These birds may benefit from surgical placement of a beak prosthesis. Unlike an orthosis, which functions to extend or add to an anatomic part to correct alignment or provide support, a prosthesis is an artificial replacement of a part of the body (Figure 31.40). An exoprosthesis is worn outside of the body, and endoprostheses are fully implanted and surrounded by body tissue. With most beak restorative prosthetics, the bulk of the prosthetic material is worn outside of the body, but there are often implants required to secure these in place and maintain stability. The cosmetic appearance of the bird should never be the only factor in deciding whether or not to place a beak prosthesis, particularly in psittacine birds with maxillary beak avulsion, where there is a high percentage that are capable of learning how to eat on their own in time.[92] Moreover, the strength of the jaw musculature of most psittacine birds, combined with their varied coupled kinetic directional forces applied, can more easily lead to failure of maxillary beak prosthetics. There are several descriptions of prosthetic beak placement in birds.[5,6,97] All prostheses implanted into bone will eventually fail due to cycling, resulting in bone resorption and/or implant failure. All prostheses applied to the rhamphothecal surfaces of the beak will eventually be lost due to the natural turnover of the keratin surface. If there is bone resorption, subsequent attempts to apply a prosthesis will generally fail more quickly because there is less bone stock. At the present time, there is no known permanent beak prosthesis applicable to birds.[107] Regardless, for a variable degree of time, prosthetic beak applications can return form and function to many birds and may have relevant application in specific cases.

Autologous prostheses are those that are derived from the same individual when there has been recovery of the severed beak remnant (Figure 31.41). Homologous or allogeneic prostheses originate from another individual of the same species (cadaver). Heterologous or xenogenic prostheses are derived from the cadaver of an individual of a different species. Synthetic prostheses are made with inorganic material of a variety of types (Table 31.3). 3D computer-generated prosthetics may be designed, constructed, and utilized. These can then be secured with the use of IM pins, screws, Kirschner wires, or cerclage wire secured to the trabecular bony structures of the remaining beak. For many years it was considered that the ideal beak prosthetic is one that remains fixed to its abutment for the entire remaining life of the bird. More current thought has changed, with the realization that a goal of creating a permanent, life-long prosthetic is not practical or feasible. Instead, efforts to preserve the potential for periodic maintenance and reattachment of the prostheses are more prudent. There are no studies on the long-term growth of beaks with prostheses, including studies of the rate of exchange of keratin layers. Temporary prostheses may be used if needed until effective wound healing occurs with some injuries.[42] The best results for temporary, shorter-duration prosthesis are achieved using devices applied to the surface keratin, as they do not affect the remaining tissues and allow for easier replacement and maintenance.[26,112,113] Prosthetic beaks must be monitored closely for complications such as failure and infection, and repaired and managed accordingly (Figure 31.42).[112,113]

For the use of autogenous, homologous, and heterologous prostheses (Figure 31.43), the severed beak segment should

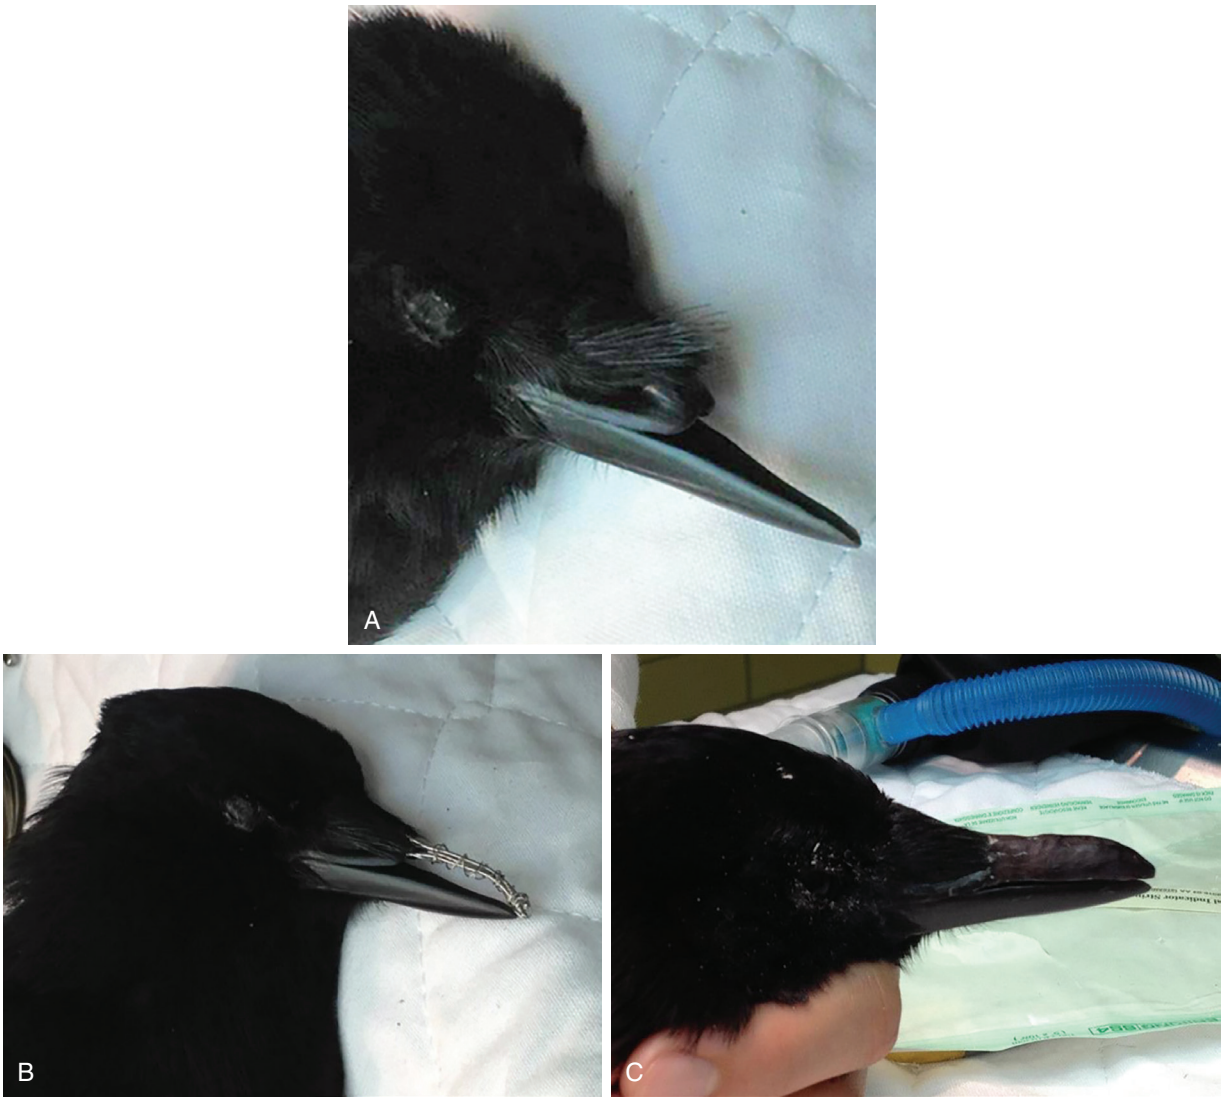

FIGURE 31.40 Construction of a synthetic prosthetic maxillary beak in an American crow *(Corvus brachyrhynchos).* (A) The maxillary beak has been amputated distal to the nares bilaterally. (B) Threaded pins are placed in the nasal, lateral, and maxillary processes of the premaxilla and maxilla, and fine wire is used to stabilize the structure. be collected and stored aseptically. Potential significant infectious agents should be ruled out.[112] An aseptic medium capable of maintaining the biological properties of the beak should be used until the date of the surgical implantation procedure. Ninety-eight percent glycerin is a more common and economically accessible method for storage at room temperature; however, beak fragments may also be sterilized using gas sterilization or autoclave techniques. Glycerin-stored tissues should be kept submerged for at least 30 days before use and must be hydrated with a physiological solution prior to use. It is feasible to maintain a bank of stored glycerin-preserved beaks, for potential future use.[112]

An impression of the beak fragment to be used for construction of a synthetic prosthetic can be made in alginate or silicone, and a model can then be generated using gypsum or resin. Similar impressions may be obtained from the avulsed stump of the severed beak in the patient, particularly when synthetic prostheses are to be employed. These models then can be manipulated and tested for optimal fit and function prior to the actual surgical procedure.[4,26] The overall procedural processes for utilizing impression-generated models are the same as those used for making metal dental crowns in mammals (Figure 31.44). The models generated can be used for fabrication of acrylic, resin, or metallic prosthetics. The use of metal prostheses may be indicated in species that can support their relatively greater weights. Waterfowl and psittacine species are common candidates in this regard for potential metallic prosthetic use. Metal alloys utilized are the same metal alloys used in mammalian dental crowns: nickel-chromium, chromium-cobalt, or copper-aluminum.

The use of 3D computer technology to produce prosthetic beaks involves four processes: (1) obtaining the 3D digital data file; (2) digital modeling of the prosthesis; (3) 3D prosthesis printing; and (4) surgical planning and fixation of the prosthetic. The ability to produce patient-specific parts directly from scan data is an obvious and cost-effective benefit,

FIGURE 31.41 Photo of a severed beak tip, including keratin as well as bony structures, which could be aseptically prepared, stored, and utilized as an autologous, homologous, or heterologous prosthesis. (Photo courtesy Laura Wade.)

as compared with more traditional conventional manufacturing techniques. These tailored parts are made possible through software that converts the scan data, utilizing CT, MRI, laser scanning, and photogrammetry. CT is considered the imaging method of choice for bone imaging for most beak prosthetic construction. MRI uses an analog method to obtain a 3D digital dataset as well. Laser scanning surveys the surface of an object and captures data represented as a collection of points (a point cloud), which is then used to generate a 3D surface. This enables parts that would be very difficult to precisely measure and 3D models to be digitized and accurately reproduced. Photogrammetry is the science of making measurements from photographs, using digital cameras or smartphones. Several photographs are required around the bird at a 360-degree angle to obtain an accurate digital model. The conversion of the photographs into a 3D digital surface is obtained through free or paid software. Unlike CT or MRI scanning, laser scanning and photogrammetry do not show the internal features of the object being scanned. After obtaining the digital 3D model, it is possible to perform the virtual surgical planning. Many software programs allow the virtual construction of real-life scale portions or the entire missing beak for the purpose of making a prosthesis. There are currently low-cost 3D printers for home use, which can be utilized for this purpose. Also, the market offers low-cost polymers for 3D printing. The most commonly used materials are polylactic acid (PLA) and acrylonitrile butadiene styrene (ABS), but the medical industry also has the ability to employ 3D printing in titanium. Based on CT or MRI data, surgeons can devise a custom surgical guide for the surgical procedure (Figure 31.45). This surgical guide is then 3D printed and used for reference before and during the surgical procedure. A fitted surgical guide can be used to indicate where the surgeon should drill or cut, and then it can be removed when the actual prosthesis is to be applied.

Surgical fixation of the prostheses in a manner that will last as long as possible can be a challenge. There is no ideal model for fixation of all prosthetics to beaks, and the details of fixation are ideally specifically chosen for the patient at hand. A functional understanding of the biomechanics of the skull and the forces that act during feeding and mastication is essential for the preparation and positioning of prostheses. Several factors contribute to the common problems encountered, namely the prosthetic loosening or falling off in a comparatively short duration of time. These include the innate characteristics of the bony structures involved (thin and porous), the absence of specific biomechanical studies of force transfer in most beaks, the lack of bone orthopedic materials that are specifically applicable to beaks, a lack of biocompatibility of the surgical materials with the bone and keratin surface, and the experience and skill set of the surgeon. Attachment of the prosthesis is accomplished using orthopedic techniques, with intradentin pins, cerclage wire/silk, and screws covered with an adhesive system (resins or composites). Fixators that transversely cross the beak and are secured laterally may be preferable. In some birds, the use of intravenous catheters can allow placement of nylon as an aid in fixation. Prostheses secured with implants such as screws or threaded pins will generally last longer. Orthopedic pins or screws can be used to help form a base structure for fixation of the prosthesis. These implants (screws, threaded pins) may be predisposed to infection and will in time result in bone reabsorption and loosen at their attachments.[4,107] The potential for growth of microorganisms at the prosthesis and beak interface is not known. As a result, periodic evaluations are rational. The maintenance time recommended for evaluation of the prosthesis can vary from every 6 months to more than a year. Since a detailed evaluation of the prosthesis and its abutments often necessitates general anesthesia and removal of the prosthesis for inspection, the interval between these inspections should be kept as far apart as possible.

CHAPTER 32

Feathers and Conditions of the Plumage

Robert J. T. Doneley • Nigel H. Harcourt-Brown • Yvonne R. A. van Zeeland

Visit eBooks.Health.Elsevier.com for a complete set of references.

ANATOMY

The outer surface of a bird is covered with feathers that form a lightweight, durable, and flexible protective barrier against mechanical impact, solar and terrestrial radiation, and water. This is important because avian skin is generally less substantial and therefore lighter but less protective than mammalian skin. Feathers are responsible for the aerodynamic shape of the bird's body as well as forming the aerofoiled shape of the wings and tail of flying birds. Feathers are colored to provide crypsis, and their form and color are a key feature of the bird's breeding strategies. Because of associated nerve supply, feathers are important tactile organs. There are two books that cover the anatomy of feathers and skin in a comprehensive and useful manner; neither are still in print but are extremely important texts.[1,2] Two in-print books describe feather anatomy[3,4] and feather color and molt.[4]

The feather is a complicated epidermal structure: it is a tough, keratinized, cellular derivative of the epidermis and is formed in a follicle that penetrates deep into the dermis. Once formed, the feather is full of airspaces as well as pigment granules and oils. The keratin of feathers is mostly β-keratin, which is only found in birds and reptiles.[5,6] Birds and reptiles also have α-keratin, but this is a softer protein structure. Feather keratins contain large amounts of the amino acids, but despite the differences in feathers between species, their compositions are very similar.[7,8] In reptiles and birds, hard-cornified β-keratins form filamentous structures made of polypeptide chains folded into β-sheets. Two β-sheets are stacked on top of each other, forming a dimer, which twists to form a helical structure.[9] The filamentous structure of reptilian and avian hard keratins is quite different from that of mammals. The β-keratin dimers are formed into sheets that are held together with a carbohydrate matrix, making a very strong but flexible structure that does not require any other supporting structure compared to, for example, horns in mammals, which are composed of a softer α-keratin laid down over bone.

FEATHER TYPES

While there are many types of feathers, they all have some similar key features (Figure 32.1). Contour feathers form most of the external plumage. The various groups of contour feathers are of great importance to ornithologists. These groups of feathers and their colors are used to describe differences in species, subspecies, and hybrids, as well as the bird's sex and age. Because of their importance, the feather groups are all named. It is often possible to predict hunting strategies (and make taxonomic judgments) from feather shape in the absence of the live bird.

Contour feathers can be divided into three main groups: primary, secondary, and—in some birds—tertiary remiges (wing feather—*remex*, Latin "rower"; Figure 32.2); rectrices (tail feather—*rectrix*, Latin "one who directs"); and body feathers. Contour feathers that cover the base of the remiges and rectrices are called tectrices or coverts (covert—*tectrix*, Latin "cover"). Contour feathers have relatively flat, close-knit (pennaceous) vanes, although the basal part of the vanes can be variably plumaceous (Figure 32.3). Each feather has a long central stalk *(scapus)*. The initial part of the stalk, seated in a tightly fitting follicle, is the calamus. The tip of the calamus is embedded in the follicle and has an opening, the proximal umbilicus that is attached to the follicle's dermal papilla. Feather follicles have sensory nerve endings that appear to be stimulated by movement of the rachis, which is the remainder part of the stalk that is more prominent on the ventral aspect of the feather. On the ventral aspect of the rachis a groove runs the whole length from the (distal) tip of the feather to the junction between the calamus and the rachis, where there is a small hole, the distal umbilicus that leads inside the calamus. The umbilici and associated groove were formed around the blood supply to the pulp core of the growing feather. The area around the distal umbilicus may have a small tuft of barbs or even a complete plumaceous feather-like structure, the afterfeather (*hypopenna*; Figure 32.4). The rachis forms the support for a series of parallel stiff branches arranged at about 45 degrees to the rachis; these are the barbs (Figure 32.5). Contour feather barbs consist of a ramus that has further branches or barbules on either side called proximal and distal barbules. The rami are spaced along the rachis to allow distal barbules from one ramus to hold onto the adjacent proximal barbules with hamuli or hooklets. In a clean, normal, healthy feather, this system forms a strong interlocked sheet, the vane (Figure 32.6). The vanes of the wing feathers are asymmetric, the leading edge being narrower. This helps to produce an aerodynamic shape (Figure 32.7).

Remiges (wing feathers) are grouped into primary and secondary feathers. The carpus is the point of division: carpus to tip of the hand is occupied by the primaries, carpus to the elbow are

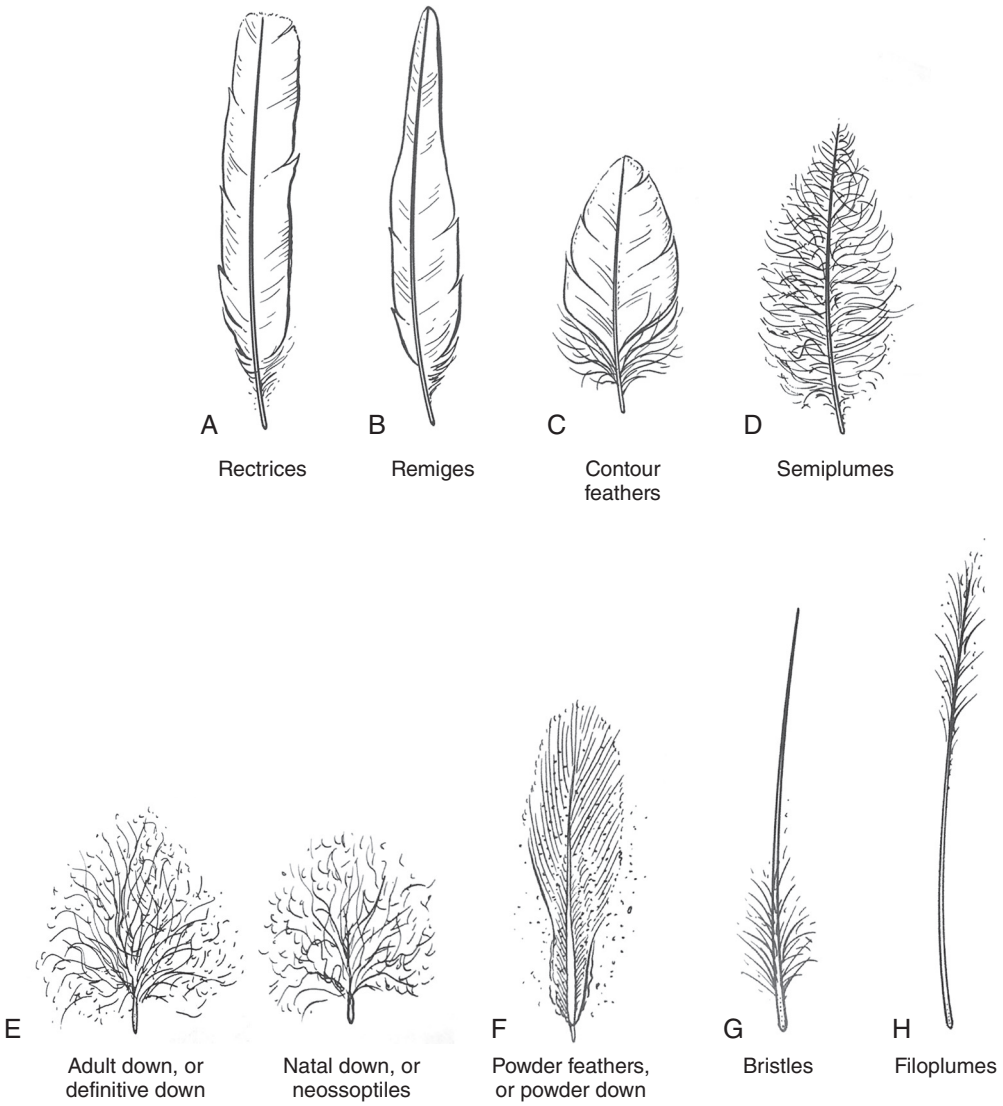

FIGURE 32.1 The main feather types that can be distinguished in birds include (A) tail feathers or rectrices, which have a symmetrically shaped vane; (B) the primary flight or wing feathers or remiges that have an asymmetrically shaped vane; (C) contour or covert feathers; (D) semiplumes; (E) down feathers; (F)powder down feathers, which are a specialized type of down found in few groups of birds; (G) bristle feathers; and (H) filoplumes.

secondaries. Some birds, such as vultures, have tertiary remiges that arise from the humerus. The primary feathers are closely and firmly attached to the periosteum of the bones of the hand (metacarpals plus major and minor digits). The secondary feathers are more loosely attached to the ulna, although in some flighted bird species (e.g., turkey vultures [*Cathartes* spp.], magnificent frigatebird [*Fregata magnificens*], pink-backed pelican [*Pelecanus rufescens*], rock pigeon [*Columba livia*]), there are bony prominences (quill knobs) on the ulna where the follicles arise.[11–13] In many groups of birds (i.e., Anseriformes, Caprimulgiformes, Charadriiformes, Ciconiiformes, Falconiformes, Gaviiformes, Gruiformes, Pelecaniformes, Phoenicopteriformes, Podicipediformes, Procellariiformes, Psittaciformes, Sphenisciformes, Strigiformes, Suliformes) there is a space *(diastema)* between the fourth and sixth secondary feathers on the wing that seemingly corresponds to a missing fifth feather (*diastataxy*; Figure 32.8), while this gap is absent in most Galliformes, Passeriformes, Coliiformes, Coraciiformes, Cuculiformes, Piciformes, and Trogoniformes *(eutaxy)*. As the remiges are attached to the dorsal aspect of the wing bones, it is impossible for the bird to move the flight feathers on the wing without moving the bones of the wing. The feather follicles are linked together subcutaneously by a complicated set of elastic ligaments and various aponeuroses, which ensures that the remiges are correctly spaced and oriented when the wing is flexed, extended, and in use.

Conversely the rectrices (tail feathers) are very mobile either by the bird moving its caudal vertebrae or by a set of intrinsic muscles that allow the tail to be spread as a fan. The rectrices steer the bird during flight and can also be used for communication/display. The caudal vertebrae end in a special bone, the pygostyle, which supports the feathers, and there is a set of complicated muscles that are used to support and move the tail feathers. In the peacock *(Pavo cristatus)*, the massive and

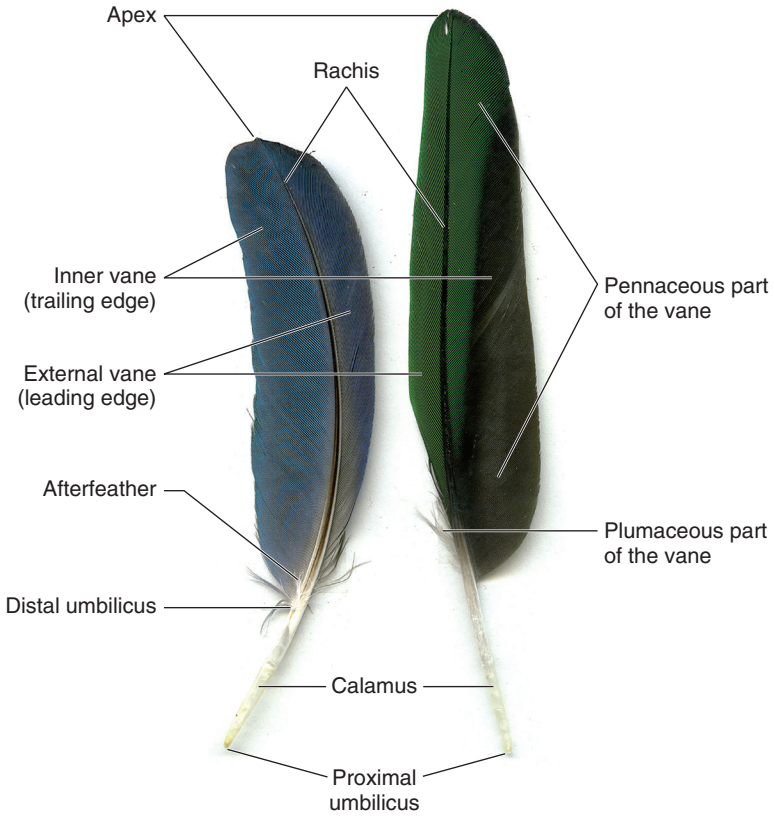

FIGURE 32.2 Remiges from bronze-winged parrot, *Pionus chalcopterus* (ventral secondary feather, blue), and scaly-headed parrot, *Pionus maximiliani* (dorsal primary feather, green). Irrespective of the feather's position on the body, the part of the feather that faces the body is the ventral surface; the dorsal surface faces outwards. In most birds, the exposed parts of the feather are colored whereas the unexposed parts are not. The primary feather in this illustration shows green barbs on the leading edge up to where it is covered by the overlapping adjacent (green) feather when the wing is extended. The ventral aspect of this feather is colored on the trailing edge where it is no longer covered by the adjacent feather, this can be seen where the edge of the feather is curled on the trailing edge. Secondary feathers are colored more extensively. (Photo courtesy Nigel Harcourt-Brown.)

gaudy tail fan is made from dorsal tectrices (coverts), while the rectrices are brown, relatively short, and support the fan.[14]

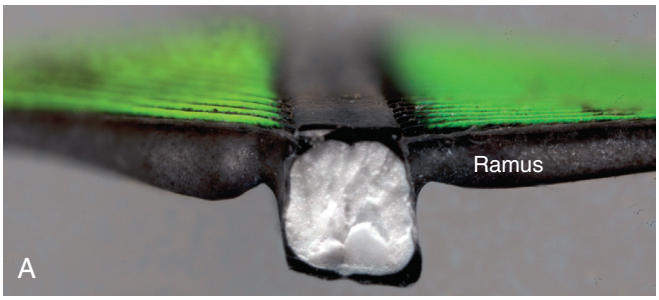
Down feathers have a short rachis and long, soft barbs (Figure 32.9). They are often the first feathers on a newly hatched chick. The down feather either occupies the same follicle as the contour feather, in which case it breaks away from the tip of the contour feather as the bird fledges, but mostly down feathers arise from a separate follicle. In adult birds, down feathers are found under the contour feathers, where they form an insulating undercoat. Their distribution varies with families, for instance covering the whole body in ducks (Anatidae) and penguins (Sphenisciformes), showing an uneven distribution in gulls (Laridae) and owls (Strigiformes), or being completely absent in hummingbirds (Trochilidae) and passerines (Passeriformes).[15]

Semiplumes are characterized by a wholly fluffy (plumaceous) vane and a long rachis, which is always longer than the longest barb (Figure 32.10). They are found along the margins of the contour feather tracts or sometimes singly in the feathered areas. They are insulative and in some aquatic species aid buoyancy. The spectrum of changes between down, semiplumes, and contour feathers makes it impossible to classify intermediate forms.

Powder down feathers are found in pigeons (Columbiformes), parrots (Psittaciformes), as well as birds from several other orders (Figure 32.11).[16–19] While they can have the basic structure of contour feathers or semiplumes, they usually resemble down feathers and are modified to grow slowly. As part of their normal maturation, these feathers shed particles of keratin as a fine waxy dust that can coat the whole bird, including its beak; this is very noticeable in white cockatoos *(Cacatua alba)*. Powder down feathers are usually found in dense patches, as in cockatoos on the body under the wing, or are scattered over the body as, for example, is seen in *Pionus* spp. The feathers are white to gray and are replaced more regularly than normal feathers. They also grow slowly so that there is a continued supply of shedding particles. Most birds produce some powder from normal contour and down feathers, but this is minimal compared to powder down feathers. The distribution of powder down feathers was previously used as a taxonomic classification feature, but this was not found to be reliable.

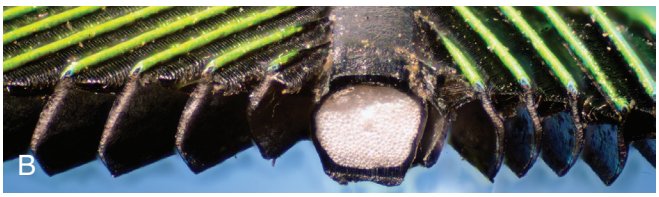
FIGURE 32.3 Ventral view of a contour feather from a Eurasian griffon vulture *(Gyps fulvus)* showing the well-developed plumaceous portion; the hypopenna is also well developed (compare with Figures 32.1 and 32.4). (Photo courtesy Nigel Harcourt-Brown.)

Hypopennae, also known as afterfeathers, are usually small and attached to the ventral aspect of the contour feather (Figure 32.4). They are not usually associated with remiges and rectrices. In emus *(Dromaius novaehollandiae)* and cassowaries (*Casuarius* spp.), the hypopenna is often as large as the main feather forming a double body feather.[20]



Bristle feathers *(seta)* are the short spiky feathers that only have barbs at the base, if any are present. They are found variably around the eye and loral region, also as eyelashes (Figure 32.12). They are protective and have lots of sensory nerve ends attached to their follicles to aid this function.[17,21–23]

Filoplumes are present in nearly all birds (excluding ratites), although they are not usually apparent (unless the bird is plucked; Figure 32.13). When the filoplume first grows, the long rachis is often surrounded by barbs, but these usually break off, leaving a long spike with a tassel of barbs at its tip. Filoplumes are usually associated with a contour feather and are assumed to serve as sensory detectors as they are closely associated with sensory nerve ends and Herbst corpuscles. It is thought that these feathers probably assess the strains and movement of the contour feathers, which is considered vital for flight.[24] Each flight feather has a number (up to 10) of closely associated filoplumes. A few birds (e.g., bulbuls, Pycnonotidae) have long modified filoplumes in their neck regions that extend beyond the contour feathers, which are thought to serve a decorative purpose only.[25]



Feathers are important tactile organs. Not only the filoplumes and bristle feathers serve a sensory function, but the feather follicle wall is supplied with numerous sensory nerve endings as well.

FIGURE 32.4 (A) Ventral view of a contour feather from a red grouse *(Lagopus lagopus scotica)* showing a well-developed hypopenna. The hypopenna has a central hyporachis supporting a plumaceous hypovexillum. (B) Lateral view of the same feather showing the relationship between the contour feather and its hypopenna. Feather barbs on the trailing edge | Rachis | Feather barbs on the leading edge

Feather barbs on the trailing edge | Rachis | Feather barbs on the leading edge

FIGURE 32.5 (A) Secondary remex from a scaly-headed parrot *(Pionus maximiliani)*, viewed toward the apex. The rachis has a hard melanin-rich cortex (mainly formed by β-keratin). The medulla is white and full of pith that adds strength to the feather with little extra weight. The pith is a firm spongy tissue formed from the keratinized walls of what were large polygonal epithelial cells. Because of the air inside these cells the rachis is opaque in contrast to the calamus. The barb consists of a ramus which has proximal and distal barbules along its length. (B) Primary remex from the same species, viewed from the apex. The barbs on the external vane *(vexillum externum)* are closer together and at a narrower angle to the rachis than those on the internal vane *(vexillum internum)*. This arrangement makes the leading edge stronger at the expense of slightly extra weight. The distal barbules overlie the proximal barbules. In these and the next illustrations from parrots, the colors of the remiges and rectrices are produced by the dorsal and ventral parts of the barbs. The ramus is usually not colored. The center is pith and the outer keratin layer, being melanin rich, is usually black to brown. Contour feathers in parrots usually have the rachis and the whole barb colored by pigment (psittacofulvin).[10] (Photo courtesy Nigel Harcourt-Brown.)

Pionus chalcopterus

Pionus maximiliani

FIGURE 32.6 (A) The barbs are attached to the rachis and are arranged regularly; they are more prominent on the ventral surface of the feather than the dorsal, as is the rachis. The barbs maintain their position by hooklets on each distal barbule which overlap and latch onto the flange of the proximal barbule (i.e., the barbule closest to the calamus). All these features form the smoothest, strongest surface to each feather. (B) The barbules can become separated while flying or foraging and the birds use their beak while preening to reunite the barbules. Feathers that have grown with adequate nutrition and are covered with normal sebum return to their perfect form very easily. (Photo courtesy Nigel Harcourt-Brown.)

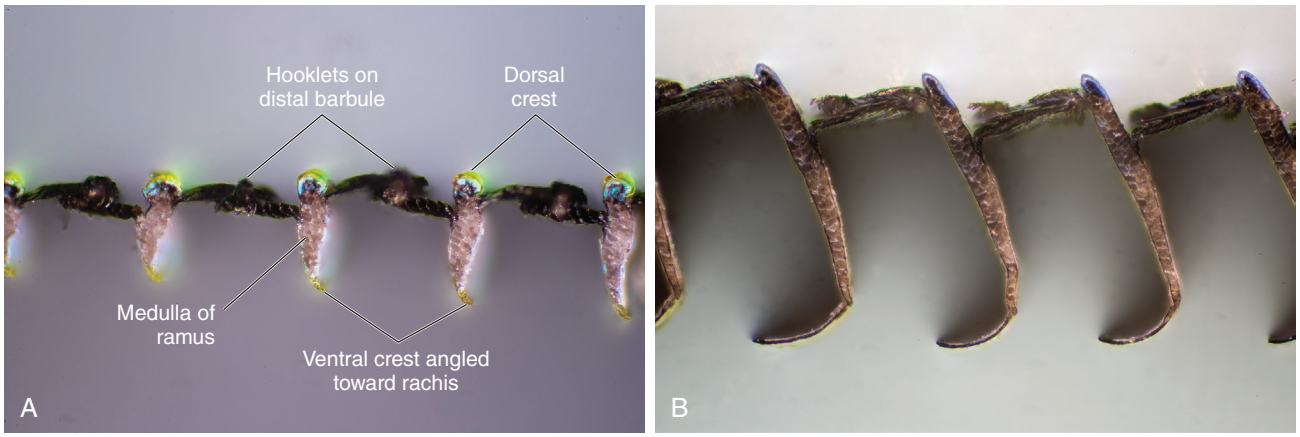

FIGURE 32.7 These illustrations are sections through (A) a green secondary remex and (B) a blue primary remex. In all the remiges and rectrices the shape of the barbs differs, seemingly to share the load on the flying wing and keep an aerodynamic shape. The hooklets on the barbules can be seen to be inserted into the flange of the proximal barbules. The secondary remex barbs are short with color produced by the dorsal and ventral extremities. Like the rachis, the barbs are much less prominent dorsally, keeping the surface as smooth as possible. The primary remex has a much deeper ramus and the ventral crest is bent over. In some birds this is extreme e.g., mute swan *(Cygnus olor)* where it is known as the tegmen. In the illustrated part of this primary remix the dorsal crest is colored; the ventral crest is not. (Photo courtesy Nigel Harcourt-Brown.)

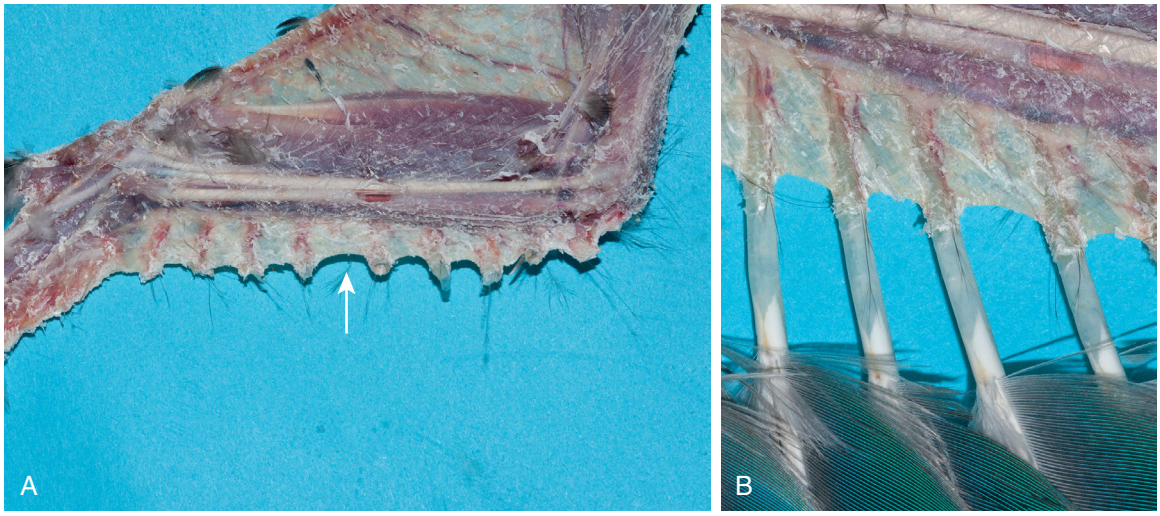

FIGURE 32.8 (A) Two features in the plucked wing of this bronze-winged parrot *(Pionus chalcopterus)* are the filoplumes associated with many of the empty feather follicles and the obvious diastataxic gap between the fourth and fifth secondary feathers (as indicated by the *arrow*). (B) The secondary feathers of this bronze-winged parrot show filoplumes emerging from very close to the feather follicle of each secondary feather. It is likely that some of the filoplumes were removed when the coverts were plucked. (Photo courtesy Nigel Harcourt-Brown.)

Pterylosis

Pterylosis is the arrangement of contour feathers within tracts *(pterylae)* over the body of the bird. Down feathers also occur with the contour feathers in these tracts. Areas between the pterylae are regarded as featherless tracts *(apteria)* and are either featherless or contain only down feathers and occasionally a semiplume. These apteria can at times be misinterpreted as regions of feather loss, or even skin lacerations, by inexperienced owners and veterinarians. Within the class of Aves, several patterns of pterylosis can be distinguished (Box 32.1).[26] In most birds, except those that do not have apteria (i.e., certain Struthioniformes, Sphenisciformes), there are usually eight pterylae involving about half the body surface (Figure 32.14), though the size of these can vary across species.[28–30] The contour feathers are shaped and arranged so that the bird has a continuous covering of feathers that would

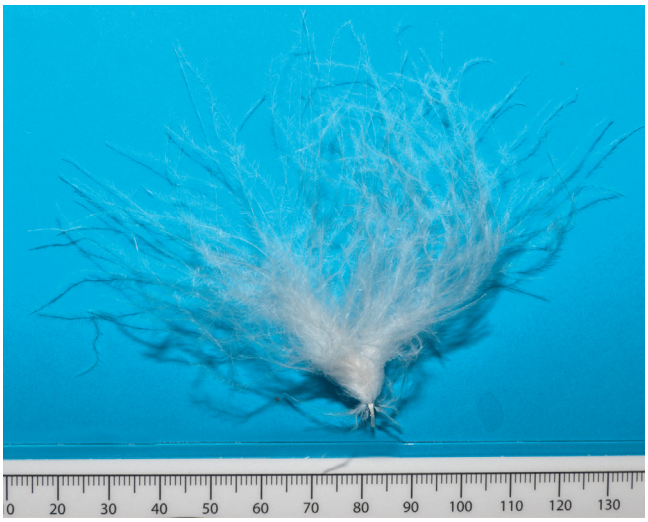

FIGURE 32.9 A down feathers has completely fluffy (plumaceous) barbs with its rachis when present shorter than its longest barbs. These feathers can be very large as from this Rüppell's griffon vulture *(Gyps rueppelli)*. Scale in millimeters. (Photo courtesy Nigel Harcourt-Brown.)

FIGURE 32.10 This ventral view of a semiplume from a Rüppell's griffon vulture *(Gyps rueppelli)* shows a relatively long rachis supporting fluffy pennaceous barbs. (Photo courtesy Nigel Harcourt-Brown.)

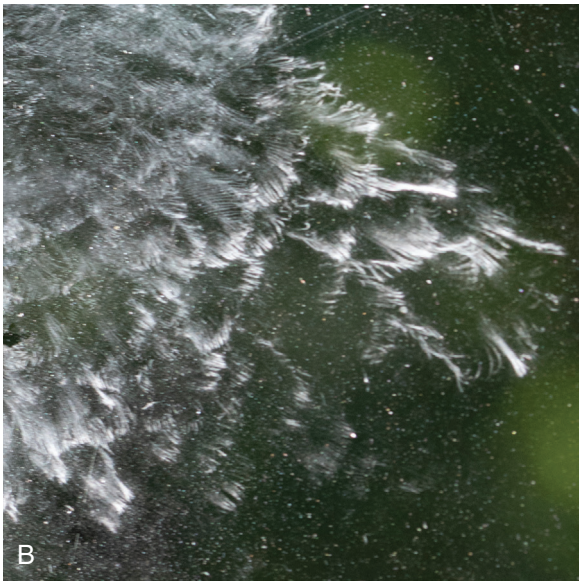

FIGURE 32.11 Powder down is shed from special feathers and covers the whole bird. (A) A window collision by a wood pigeon *(Columba palustris)* gives an obvious outline of the bird. (B) In close-up, the feathers are well defined. The powder has sebum mixed with it so the imprint lasts for some time. (Photo courtesy Nigel Harcourt-Brown.)

need to be parted to reveal the apteria. The area of the body under the wing and the adjacent wall of the abdomen often have reduced numbers of feathers. The skin of the apterium is thinner than the skin of the pteryla.

Molt

Full-grown feathers are inert structures and one of their roles is to absorb damage from external sources. They are not being continuously renewed, unlike beaks and claws, but become worn by life as well as affected by pathogens, such as ectoparasites, bacteria, or fungi. Sometimes they are lost traumatically and must be replaced as soon as possible. The parts of feathers that contain melanin are more resistant to wear, as well as damage by some bacteria. This might be because the area that contains the melanin is thicker. Melanin also protects against ultraviolet (UV) damage.

The plumage is made almost completely of dried protein, and there is a significant energetic cost to replacing it. Most passerines' feathers are 18% to 39% of total lean dry body mass (or approximately 6% of normal body mass) and the energetic cost has been calculated to be around 12% to 36% of resting energy output.[31] Small birds, for example, barn

FIGURE 32.12 Bristle feathers can be seen on the eyelids and periorbital region of this newly fledged cinereous vulture *(Aegypius monachus)*. The eyelid feather is just a stiff rachis; the periorbital feathers have small barbs at their base. There are some (5) natal down feathers still attached to the juvenile feathers on the top of the bird's head *(arrows)*. They will wear off in the next 10 days. (Photo courtesy Nigel Harcourt-Brown.)

swallows *(Hirundo rustica)*, have 1500 feathers but large birds have more, for example, mute swans *(Cygnus olor)* have 25,000. Small birds usually change all their plumage annually and do this outside the breeding season and at a time when they are not migrating—both high–energy cost activities.[32,33] The process of molt in birds requires the investment of substantial amounts of energy and nutrients in replacement feather production. Flight performance may be reduced with attendant risk to the individual, but it may affect the next generation too. To demonstrate this, researchers cut off the last two primaries on both wings of some pied flycatchers (*Ficedula hypoleuca*, a long-distance migrant) to reduce flight performance.[34] Just before fledging of the young, manipulated males and females, as well as the fledglings, had a lower body condition score than the group of control birds. Next year, less of the flight-impaired males returned (the females were unaffected), and the number of nestlings that returned was significantly lower for the group with flight-impaired parents. The reproductive performance in the groups of returning nestlings and old females was unaffected, as was the feather quality of the returning birds.

Birds have developed strategies to minimize the energy costs while molting. Molting birds tend to reduce their level of activity and in some instances, this can completely offset the energy costs of the molt. This reduction in activity should be considered in captive falcons and other birds as it could increase the potential for bumblefoot.[35] Molt tends to occur during a period when there is adequate food and minimal energy output. It is unusual for a bird to molt during the breeding period or migration. Molting large feathers is usually done in regulated stages.[33] Fledgling birds do not leave the safety and constraint of their nest, or try to fly, until the feathers (and bones) have almost completely matured. Growing feathers are much heavier and will cause deformation of the wing if used before they have finished growing.[36,37]

Large birds tend to change only a proportion of their plumage annually. In the wild, and captivity, large vultures and eagles take around 4 years to change all their remiges and rectrices[38,39]: clinicians must therefore try to protect and preserve them during examinations and medical/surgical procedures.

Anatidae (ducks and swans) have a different molting strategy.[40–44] At the end of the breeding season, they molt their body feathers, and the breeding plumage is replaced by

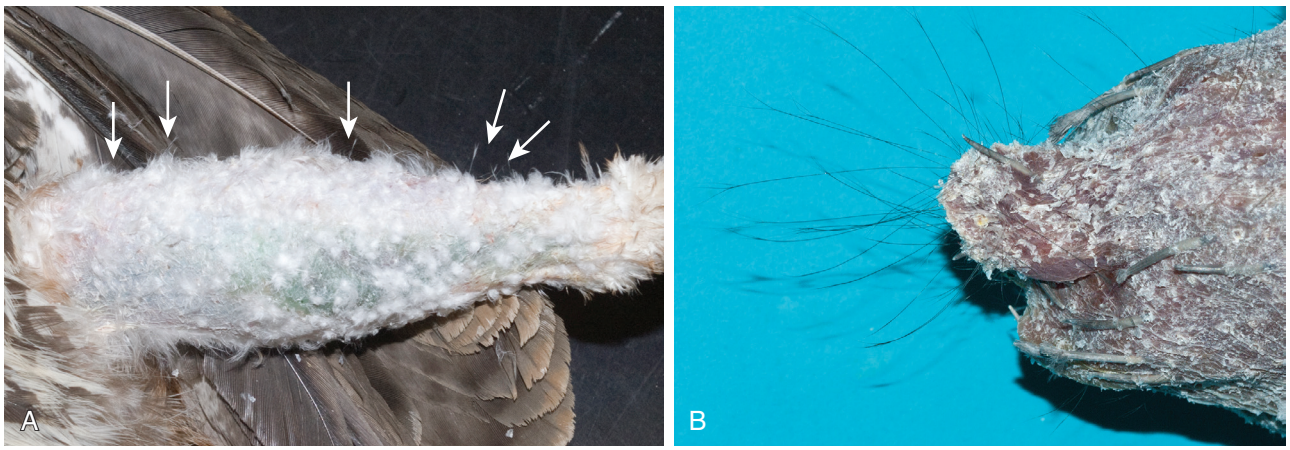

FIGURE 32.13 (A) A Harris hawk *(Parabuteo unicinctus)* had a fracture of the proximal third of the tibiotarsus. Surgical preparation requires feather removal. Plucking all the contour feathers leaves the down and also several filoplumes *(arrows)*. (B) This bronze-winged parrot *(Pionus chalcopterus)* has had all its contour feathers removed. There are many filoplumes left that were associated with the remiges. Birds use their tail to steer during flight but *Pionus* spp. use their tails to signal to each other so presumably feedback from the sensory filoplumes is useful. Note: *Pionus* spp., like *Amazona* spp., have no uropygial (preen) gland. (Photo courtesy Nigel Harcourt-Brown.)

BOX 32.1 PATTERNS OF PTERYLOSIS IN BIRDS[26]

Pattern	Characteristics	Examples
Struthioniform	◆ No apteria in the emu or cassowary; apteria are present in the ostrich and rhea, despite some references claiming otherwise[27] ◆ Uropygial gland is absent ◆ Plumage is soft and lax, intermediate between down and contour feathers	Ostrich, rhea, emu, cassowary
Sphenisciform	◆ No apteria in the adult bird ◆ Uropygial gland is present ◆ Dense plumage	Penguins
Columbiform	◆ Upper and lower cervical tracts are only separate near the shoulder ◆ Deeply forked upper cervical tract, without diverging branches ◆ Broad dorsal tract that is separate from the cervical tract and is without any apterium ◆ Broad, distinct humeral tracts ◆ Small femoral tracts that are mostly separate from the dorsal tract ◆ Broad sternal tracts that are directly continuous with branches of the (quire deeply forked) lower cervical tract and have no side branch ◆ Broad ventral tracts that are directly continuous with the sternal tracts ◆ Narrow ventral apterium that is broadest at the most caudal end	Loons, grebes
Anseriform	◆ Upper and lower cervical tracts are only separate near the shoulder ◆ Forked cervical tracts with somewhat diverging branches ◆ Dorsal tract that is directly continuous with upper cervical, thereby enclosing a variably elongated apterium ◆ Broad, strong humeral tracts that are sometimes connected with the dorsal tract ◆ Large femoral tracts that are united with the dorsal tract ◆ Sternal tracts that usually have a prominent side branch and are directly continuous with the lower cervical tracts ◆ Broad ventral tracts that are directly continuous with sternal tracts ◆ Narrow ventral apterium that is not notably broader toward the caudal end	Petrels, albatrosses, pelicans and other totipalmate birds, auks, geese, ducks, swans
Falconiform	◆ Well-marked, usually narrow upper cervical tract that is strongly forked between the shoulders with diverging branches, and only slightly or not at all connected with the dorsal tract ◆ Variable dorsal tract: can be broad or narrow, forked, or solid ◆ Strong but not very broad humeral tracts ◆ Absent or weak femoral tracts; usually full feathering of the tibia, sometimes with a strongly marked patch that runs along the femur, crossing the head of the tibia ◆ Considerably forked lower cervical tract ◆ Strongly marked sternal tracts ◆ Narrow ventral tracts that are widely separated over the abdominal area, wider on the chest area, and more or less fused with the sternal tracts; tracts may sometimes unite at the furcula only *(Asio)*, touch at the edge of the sternum *(Strix)*, or unite across the full sternal length *(Pandion)*	Vultures, hawks, owls, and other birds of prey, psittacine birds
Pelargiform	◆ Deeply divided upper cervical tract in the neck area, no diverging branches ◆ Solid or deeply forked (rear) dorsal tract that is variably connected with the cervical tract ◆ Well-marked humeral tracts ◆ Long, narrow, not very strong femoral tracts ◆ Lower cervical tract like upper, but with a less deep division and branches that tend to diverge ◆ Comparatively broad sternal tracts that are either continuous with or separate from the lower cervical tract ◆ Broad ventral tracts that are continuous with the sternal tracts, though sometimes separated from those for some distance, while joining near the furcula	Rails, cranes, storks, herons, bustards, flamingos
Charadriiform	◆ Sharply defined upper cervical tract that is not very deeply forked, and with diverging branches ◆ Variably forked dorsal tract (toward rear) that is slightly—if at all—connected with the forks of the upper cervical tract ◆ Narrow humeral tracts ◆ Fairly strong femoral tract that is usually narrow and distinct ◆ Deeply forked lower cervical tract that is continuous with the sternal tracts ◆ Moderately sized yet strong sternal tracts ◆ Narrow or moderately wide ventral tracts that are well separated over the abdominal area and join the sternal tracts across the chest, usually near the furcula	Gulls, terns, plovers, snipes, sandpipers, other waders

BOX 32.1 PATTERNS OF PTERYLOSIS IN BIRDS—cont'd

Pattern	Characteristics	Examples
Galliform	◆ All tracts broad, but usually well-defined ◆ Variably forked upper cervical that can be merged with the dorsal tract ◆ Broad dorsal tract broad, often with a mid-dorsal apterium, that is occasionally connected with the femoral tracts ◆ Broad, strong humeral tracts ◆ Large femoral tracts that sometimes unite with the dorsal tracts ◆ Deeply forked lower cervical tract of which the branches are continuous with the sternal tracts ◆ Strong sternal tracts, which are widest anteriorly, with or without connection to the ventral tracts near the furculum ◆ Narrow ventral tracts that are most narrow anteriorly, unite posteriorly (just cranial to the cloaca), and sparse distancing in between the tracts over the abdominal region	Gallinaceous birds, curassows, tinamous
Columbiform	◆ Wide upper cervical tract that is strongly forked between the shoulders, and often united with the lower cervical tract up to the level of the shoulders ◆ Broad and diffuse dorsal tract that is fairly separable from the cervical tract, but inseparable from the femoral tracts ◆ Broad and strong humeral tracts ◆ Large femoral tracts that are not clearly distinct from the dorsal tract ◆ Slightly or no forked lower cervical tract that is continuous with the sternal tracts ◆ Broad sternal tracts that are completely united with the ventral tracts ◆ Broad ventral tracts that are nonunited at the posterior end and have sparse distancing	Pigeons, sand grouse
Passeriform	◆ Narrow but well-defined upper cervical tract that is continuous with the dorsal tract ◆ More or less widened dorsal tract (often enclosing a prominent apterium) that is not clearly distinguished from the cervical, and generally narrowed near the tail area; frequently the tract is distinctly divided into two parts, i.e., anterior part which is usually forked, and the posterior part which is less commonly forked ◆ Moderate, frequently narrow humeral tracts ◆ Usually weak and small femoral tracts; sometimes these can be absent, while in other species they are more clearly defined ◆ Variably forked lower cervical tract ◆ Usually strong and well-marked sternal tracts ◆ Ventral tracts are rather narrow, widely separated over the abdominal area, and not reaching the cloaca; they are usually not separated from the sternal tracts, but sometimes they can be partly distinct	Cuculiformes, Coraciiformes, Passeriformes

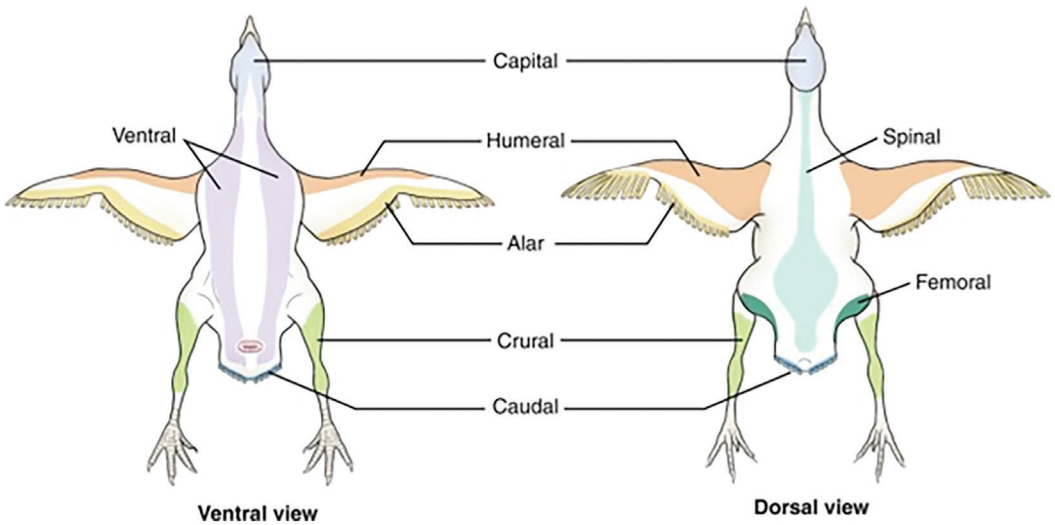

FIGURE 32.14 Unlike hair in (most) mammals, feathers do not cover the entire skin surface of birds. Instead, feathers are arranged in symmetrical tracts (pterylae) and are separated by areas of bare skin (apteria). Each species has its own characteristic arrangement of feather tracts. Represented are the feather tracts that can be recognized in the chicken including the (single) capital, and spinal tract, and the paired ventral, humeral, alar, femoral, crural, and caudal feather tracts.

a subdued (eclipse) plumage. Next, they lose all their flight feathers at once and are unable to fly while these feathers grow back; during this time, they use the water as a refuge. Once they can fly (after 3–4 weeks in smaller ducks, and 6–8 weeks for swans), the males molt their body feathers and grow their normal bright plumage in time for courtship.

Age and Feathers

Young birds are usually covered in down feathers that change to contour feathers as the *pullus* grows. Because the growing feathers are relatively heavy in many birds, the remiges and rectrices grow last—once the skeleton has formed sufficiently to cope with the weight of a heavy growing feather (Figure 32.15). Most birds have a juvenile plumage, which is characterized by feathers that are often smaller than those of the adult and have subdued colors—both of which are features having a lower energy cost. Smaller feathers grow to maturity more quickly, allowing the fledgling to be able to fly sooner. Juvenile psittacids tend to start to lose their juvenile feathers from 6 weeks of age. This is obvious in budgerigars *(Melopsittacus undulatus)* where the bars on the forehead are replaced with solid color feathers. *Pionus* parrots start to lose their head feathers at this time too and have replaced all the contour feathers on their head, neck, and shoulder region by spring the next year, while molting the rest of their juvenile feathers over the following 4 months.[34]

Feather Growth and Molt

In the embryo, each feather germ arises as an outpushing of the epidermis which encloses a core of the dermis. As it develops, the base of this structure invaginates to form a follicle. Once the follicle has grown, the dividing epidermis that lines the follicle remains active at the base of the follicle, forming a collar which becomes a germinal region for the cells that produce the feather. This area gives rise to the intermediate cells that form the rachis, barbs, and barbules by growth and then keratinization. It is a complicated process and while the mature feather can be seen arising from a cylinder of epidermis that eventually dries out and falls away the growing part of the feather is supplied through the umbilici with cells and blood vessels until the feather is fully formed (Figure 32.16).[45]

FIGURE 32.15 In the developing bird, the feather groups tend to grow at the same time. In many birds the wing feathers start growing after the leg bones have reached sufficient development to support the extra weight. This is particularly obvious in precocial birds who run around from a few days old. This wing of a 35-day-old bronze-winged parrot *(Pionus chalcopterus)* shows the growing wing feathers erupting from their sheath and uncurling. At this time, the weight of both wings is a significant proportion of the bird's total body mass. Strain on the skeleton is avoided by behavior as well as development.[37] The primary and secondary remiges in the illustrated species are light blue on the ventral aspect and dark blue dorsal. The coverts are bronze. (Photo courtesy Nigel Harcourt-Brown.)

The mature calamus fits closely within the follicle. The inner layer of the follicle, the epidermis, is continuous with the proximal umbilicus, and it surrounds the dermal papilla which projects into the calamus, holding it place. When the bird is stimulated into molt, the mesenchymal pulp that has been lying dormant over the dermal papilla is activated and starts to divide to produce the feather pulp. This activity pushes the old feather out of the follicle. The trigger for this process has been studied in many species, with significantly differing results.[32,46–50] Molts can occur either before or after breeding, and in many passerines they occur before or after migration. Juvenile plumage must be changed to adult plumage and in some species an adult winter plumage must change to breeding/summer plumage. All these molts can be complete or partial, so it is hardly surprising that the triggers and control can be so variable. It is generally accepted that thyroxine stimulates feather growth and estrogens inhibit it, but there seem to be a lot of different triggers to start the process that can vary tremendously between species. Once molt is underway, local factors come into play to control the sequence. In most of the birds molting their remiges, the molt starts at the carpus and works along the sequence of feathers to both the wing tip and the elbow. The next feather in the sequence is not lost until the adjacent feather is reasonably well grown. The process tends to be a mirror image between both wings. A new flight feather needs support from mature feathers on either side to prevent the relatively weak growing point at the feather's base from being damaged when the bird flies. This is important to realize as it can influence wing trim strategies that may be utilized with companion birds. (See also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 22, Advancements in Management of the Welfare of Avian Species.)

Traumatic loss of a feather initiates the growth of a replacement feather only if the dermal papilla is broken when the whole feather is removed.

FEATHER COLOR

Birds have tetrachromatic (or even pentachromatic) vision and their feathers reflect this. Only the trichromatic plumage characteristics of birds are obvious to human observers (Figure 32.17).[51] For instance, in one study, the application of UV-blocking sunscreen to the throat region of male bluethroats *(Luscinia svecica)* caused no obvious change in color to the human observers, but sexual and territorial displays went relatively unnoticed by other birds.[52] It diminished their hierarchical status and decreased their ability to select and hold a territory and mate.

Feathers distinguish between adult and immature birds by coloration and pattern, the coloration changing by molting and growing new feathers. Some birds molt twice yearly, and the breeding plumage is different to the off-season plumage.

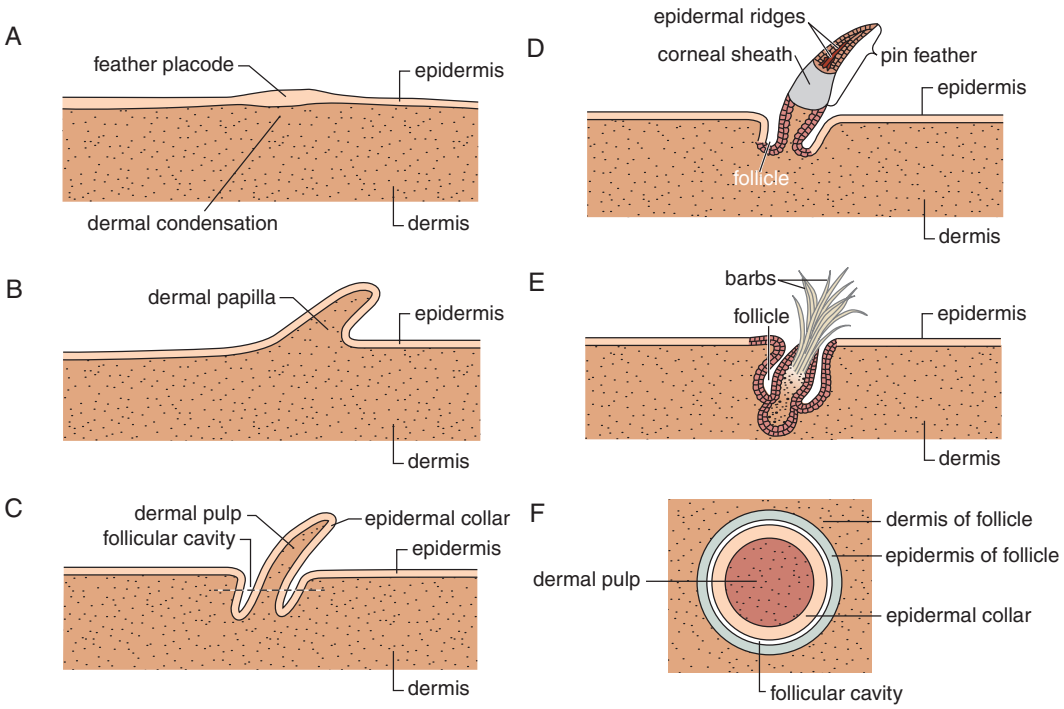

FIGURE 32.16 Schematic of the development of a feather follicle: (A) Formation of the dermal papilla which begins with the development of the epidermal feather placode and the dermal condensation. (B) Development of a feather papilla (or elongated feather bud) via the proliferation of dermal cells. (C) Formation of the feather follicle by the invagination of a cylinder of epidermal tissue (epidermal ridge) around the base of the feather papilla. (D) Keratinocyte production forces older cells up and out, eventually forming the entire feather that erupts from its protective sheath (E). (F) Cross-section of the feather follicle as indicated by the *dashed line* in (C). The follicle consists of a series of tissue layers (from peripheral to central), including the dermis of the follicle, the epidermis of the follicle (outer epidermal layer), the follicle cavity or lumen (the space between epidermal layers), the follicle (epidermal), collar (or inner epidermal layer), and the dermal pulp (tissue at the center of the follicle). The proliferation of feather keratinocytes and most of the growth of the feather occurs in the follicle or epidermal collar. (Adapted from Prum RO: Development and evolutionary origin of feathers, *J Exp Zool* 285:291–306, 1999.)[17]

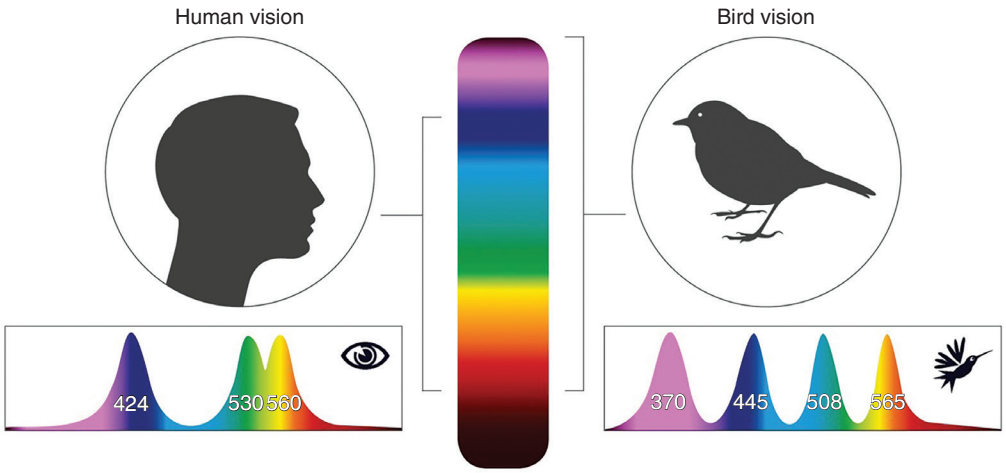

FIGURE 32.17 Comparison of human and avian vision. The human retina has three types of cones (red, green, and blue) resulting in trichromatic vision. Birds, on the other hand, have four or five types of photoreceptors, resulting in tetrachromatic or pentachromatic vision, which allows birds to detect wavelengths near the ultraviolet (UV) electromagnetic spectrum (400 nm). The ability to detect UV light is thought to be important for many biological processes including finding mates, finding materials to build nests, removing nest parasites, finding food, and (intra- and interspecies) communication.

This is very noticeable in, for example, whydahs and weavers (*Euplectes* spp.)[53–55] and black-headed gulls *(Larus ridibundus)*.[56] Some birds only molt once a year and their coloration changes after winter as the feather tips, which are lighter in color, wear down to reveal a more strident breeding coloration, as can be seen in, for example, brambling *(Fringilla montifringilla)*[54,57] and snow bunting *(Plectrophenax nivalis)*.[58] It also seems that the quality of the sebum can change the coloration of the feathers.

Coloration of the plumage is achieved in several ways. There are pigmentary colors *(biochromes)* and structural colors *(schemochromes)*; some colors are produced by a combination of these two methods.

Pigmentary Colors

Melanin is a tyrosine-derived pigment. It is bound to a tough protein component that forms the basis of a granule. These granules have a definite size, shape, and color that varies between species.[59] Work done on melanin granules in fowl showed they were larger than those of mice. Melanins are the most common pigments in feathers; they have been shown in fossil feathers.[60–62] On their own, melanin granules produce subdued colors but combined with other pigments or structural modifications they create many colors and vivid hues. Four types of melanin can be distinguished:

- eumelanin, which is the commonest and produces black or dark brown;
- phaeomelanin, which is lighter brown, reddish brown, or yellow;
- a trichosiderin-like pigment, which produces red, brown, and buff feathers and can be separated into purple I and II;
- erythromelanin, which produces chestnut red colors.

The color density is related directly to the granule density. For example, black and gray are formed by different concentrations of the same pigment.

Carotenoids are bright red, orange, or yellow pigments that are dissolved in fats (lipochromes) and occur in the feathers as colloidal globules. Birds, like other animals, cannot synthesize these pigments and must obtain them directly or indirectly from plants.[63–65] Carotenoids are found in two groups: carotenes and xanthophylls. Birds take up more xanthophylls than carotenes. The pigments are absorbed and carried into the body, where they are deposited either unchanged or, more often, altered, probably into oxidative intermediates. These new pigments often have distinct and sometimes unique properties. While dull yellows are caused by small amounts of phaeomelanin, bright yellows are carotenoid in origin. The principal yellow pigment is the xanthophylls—lutein. The principal red pigments are astaxanthin, rhodoxanthin, and canthaxanthin; these are transformation products of yellow carotenoids.

Carotenoids in body fat, egg yolk, and in the uropygial gland are diffused in lipoid droplets. In feathers the pigment is transferred into the cells of the growing feather and builds up until the "correct" color is formed. As the cells start to keratinize the fat solvent moves out of the cell and the pigment remains trapped in the keratin. Sometimes the deposit is formed as scales or layers. In some feathers, the pigments become hugely concentrated and the feather swells, for example, a red (astaxanthin) wax on the tip of the rachis of the secondary remiges of waxwings *(Bombycilla garrulus)*.[66]

Parrots have a novel set of yellow to red pigments (psittacofulvins) that are lipid soluble but differ from carotenoids by solubility and absorption spectra; some are fluorescent.[10] The pigments appear to be derived from carotenoids but have not been isolated from blood at the time of maximum feather production indicating that the pigment is made in the feather-producing cells.

Melanins and carotenoids are commonly seen in the same feather.[64,67] This combination forms various colors, for instance, olive green can be produced by a juxtaposition of tiny spots of yellow and black, as is seen in the greenfinch *(Carduela chloris)* and great tit *(Parus major)*. Generally, the exposed portions of the feathers are more pigmented than the covered portions. Melanins tend to occur in all types of feathers. Carotenoids, on the other hand, tend to occur in parts of feathers that are exposed, such as the contour feathers and the tips of semiplumes. They do not occur in feathers that are associated with flight and are also absent from the small interlocking parts of the feathers. Melanins can be found in all these structures.

Porphyrins have been found in red or brown feathers in a few families.[68] They characteristically fluoresce red under UV light and are a copper-containing pigment based on a porphyrin ring. In various embryos, coproporphyrin I is present in increasing quantities as hemoglobin increases. Porphyrins are abundant in owls and bustards (Otididae) as coproporphyrin 3[69] and have been found to be a positive indicator of how well the young bird was reared—body condition and quality of rearing territory. In adult bustards, they were found to allow females to select the "best" mate. These porphyrins occur in the down feathers but degrade quickly in UV light.

Some members of the turaco family (Musophagidae) have two porphyrins that color their plumage.[68,70] There is a dark red pigment, turacin, that is present in the remiges and a green pigment, turacoverdin, that occurs in most of the contour feathers. The amount of turacoverdin present in each green turaco species corresponds to their habitat: those that live in the greenest forest have the most turacoverdin in their plumage. These two pigments are based on copper-containing porphyrins. Some birds have up to 20 mg of copper in their plumage and based on analysis of their diet they need to eat 20 kg of fruit to obtain this. Some Galliformes (*Ithaginis* spp., *Rollolus* spp.), Anseriformes (*Somateria* spp., *Nettapus* spp.), and a jacana (*Jacana spinosa*) have feathers that contain a similar green pigment.[71] The yellow color in penguins is sphenisicin.[64,72]

Adherent Colors

There is a reddish secretion from the preen gland of some pelicans, which colors the plumage. The preen gland secretion in pied hornbills (*Anthracoceros* spp.) is bright yellow, which colors the beak. Some birds become a rusty brown shade from amorphous iron oxide in muddy soil, for example, the bearded vulture *(Gypaetus barbatus)*, common crane *(Grus grus)*, and some ducks.[18]

Structural Colors

Structural color production in feathers has been the subject of a huge range of research leading to what often appears to be confusing and even conflicting results. There are basically three classes of structures that produce color in feathers[73–76]:

1. Unspecialized, unpigmented keratin produced appears white because of incoherent scattering of light by the

keratin surface of the feathers and by air-filled, irregularly shaped, and randomly distributed vacuoles within the feather. This can be very efficient—a white ptarmigan *(Lagopus mutus)* can produce a reflectance that approaches 80% of that of fallen snow combined with the blue tinge of fresh snow (by Rayleigh scattering). Pure keratin fluoresces a light blue color which is usually masked by the presence of melanin granules.

2. Feather barbules in many birds have arrays of melanin granules which either alone or in combination with air spaces in the barbules can produce iridescent structural colors. The iridescence changes hue with the angle of observation. Hummingbirds are good examples of this type of structural color production.
3. Specialized, spongy, medullary layer in the feather barbs. This includes noniridescent blue, violet, green, as well as UV. In combination with carotenoids or similar pigments, structural barb colors are an essential component of almost all green bird plumages. Although the brightly colored feathers of *Amazona* spp. contain a range of biochromes, psittacofulvins, in both barbs and barbules, specific feather areas contain spongy nanostructured barb cells that reflect blue or blue-green wavelengths.[6] These blue-green spongy structures (or cloudy cells[1]) are partly enveloped by a blue-absorbing, yellow-coloring pigment which acts as a filter and gives a green color to the barb. Melanin granules act as reflectors to enhance the green color production (Figures 32.7, 32.18, and 32.19).

Structural colors are produced by light scattering from interfaces between structures of different refractive indices. This can occur as incoherent or coherent scattering.

Incoherent scattering is caused by structures where the space between them is greater than the wavelength of the light. This causes random scattering of light. The most cited models are Rayleigh and Tyndall scattering. Mie scattering is a better model but is far more complicated and requires a computer and complex program.[77,78]

Coherent scattering of light produces summation of light waves as they pass through the tissue. The light can shift in phase. Scattered waves that are approximately out of phase will cancel each other out while others that are in phase, or close to being so, will reinforce each other and produce color. The phase relationships among scattered waves are determined by the size and spatial distribution of the scatterers.

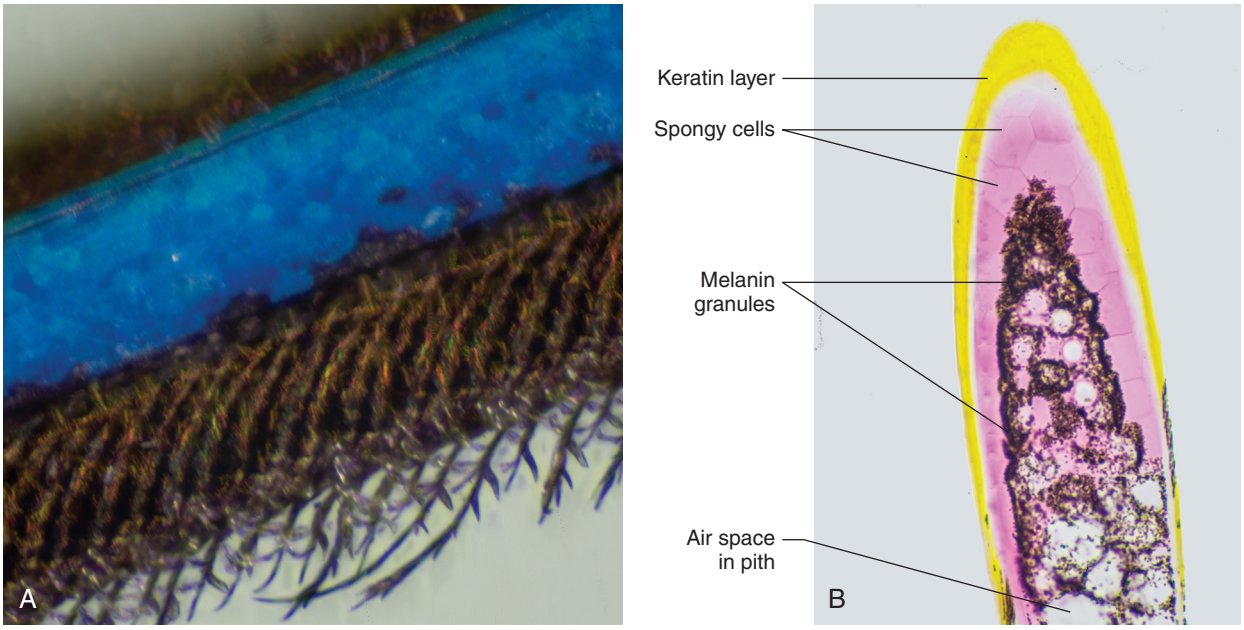

FIGURE 32.18 (A) Using blue feathers from a bronze-winged parrot *(Pionus chalcopterus)* and (B) green from a scaly-headed parrot *(Pionus maximiliani)*, it is easy to demonstrate the layer of spongy cells and show their importance in color production. A view of the dorsal aspect of a single blue barb shows the distal surface of the ramus and the distal barbules and their hooklets. The spongy cells can be seen to form a mosaic of slightly disparate shapes with differing depths of blue color. Areas where the cells are absent are dark because of the melanin showing from below the spongy cell layer. (B) A section of the dorsal aspect of the barb from a green feather, prepared in the usual manner for histology and stained with hematoxylin and eosin (H&E). Although the spongy cells have been shown to contain a fine spongy structure,[8] this is not shown on the H&E section; the cells are a homogeneous pink (eosin) although the cell walls can still be seen. In a green feather the spongy cells lie on top of a layer of melanin granules. This combination along with the overlying psittacofulvin pigment layer gives rise to a reflected green color. The space between the pigment layer and spongy cell layer may be artifactual but possibly the pigment in this area is more loosely held in sebum and has been removed by the xylene used in processing. In brown to black parts of the feather, the variation in melanin particle density gives rise to the depth of color. (Photo courtesy Nigel Harcourt-Brown.)

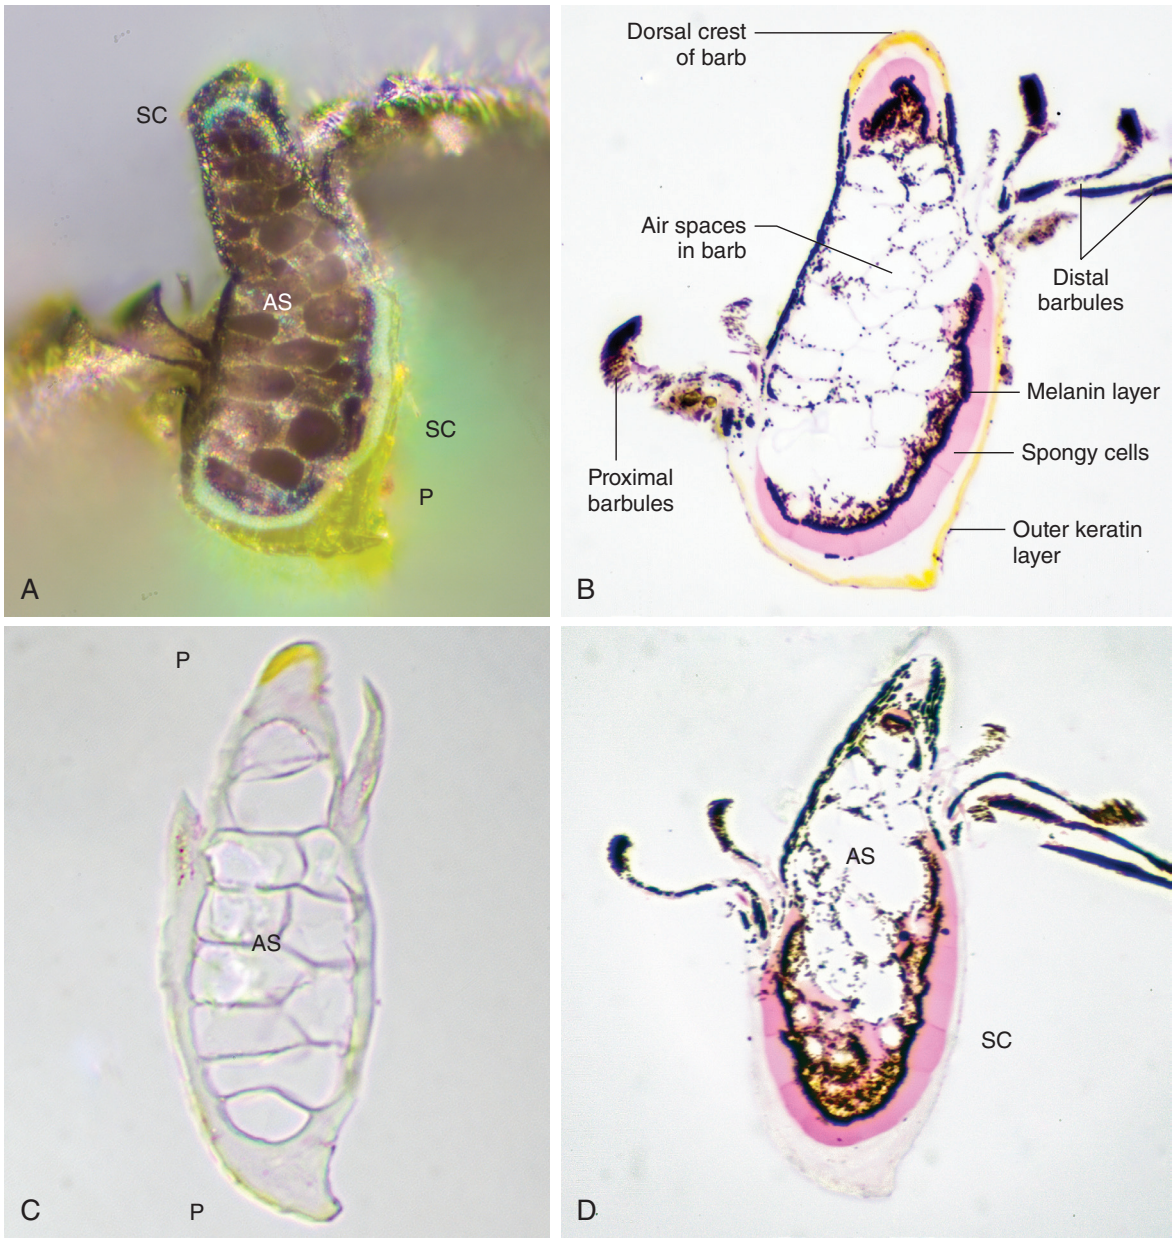

FIGURE 32.19 (A) Barb from the trailing edge *(Vexillum internum)* of a secondary remex of a scaly-headed parrot *(Pionus maximiliani)*; dark dorsal and green ventral crests. The barb has been cut and cross-illuminated to show the yellow psittacofulvin and melanin; because the section is cross-lit, the spongy layer shows some of the blue effect. The dorsal crest on this barb is very dark due to melanin granules mixed in with the carotenoid. (B) Section from a similar feather, except both dorsal and ventral crests are green. This barb has been cut and processed as a histological section stained with hematoxylin and eosin (H&E). In this section the area missing yellow pigment is obvious, compare with (A). (C) A feather from an area of old injury on a slender-billed conure *(Enicognathus leptorhynchus)*, cut as a histological section and stained with H&E. Trauma has left a scar and also affected the feather's color. This feather would normally be green but is completely yellow when viewed in normal light. Melanin granules have not been laid down and the spongy cells are also affected. (D) Barb from the trailing edge from a secondary remex from a bronze-winged parrot *(Pionus chalcopterus)*; dark dorsal and light blue ventral crests. There is an obvious lack of the yellow psittacofulvin pigment. The dorsal crest has a layer of melanin granules and no spongy cell layer; the loose distribution of the melanin granules gives a light black color. *AS,* air space, *SC,* spongy cells, *P,* psittacofulvin. (Photo courtesy Nigel Harcourt-Brown.)

The scatterers would need to be arranged regularly. If they are arranged randomly, there will be no wavelength reinforcement and the light will be incoherently scattered.

In biological tissues, coherent scattering is usually caused by structures of one refractive index immersed in a medium of different refractive index. Thin film reflectors are the best-known model. A thin film system produces the iridescent color of the feather barbules of hummingbirds[79] and the quetzals (*Pharomachrus* spp.).[77]

In any structurally colored tissue somewhere there must be an interface between the schemochrome and the supporting anatomy of the tissue. This supporting structure would normally interfere with color production. Therefore most tissues have a barrier, usually melanin granules, but occasionally a layer of carotenoid, which absorbs incident light that has passed through the entire color-producing system.

White, unpigmented feathers

White is a structural color that is a result of incoherent scattering in unpigmented feathers by the keratin surface of the feathers and by air-filled, irregularly shaped, and randomly distributed vacuoles within the feather. In the rock ptarmigan *(Lagopus mutus)* a feather from the winter plumage can reflect 50% of all wavelengths of visible light, compared to 15% to 18% by a white chicken's feather. In the rock ptarmigan, feathers overlap, giving a depth of color reflectance that approaches the 80% reflectance of the fallen snow in which they forage. The smaller wavelengths of light are slightly better reflected, giving the genuine blue tinge that characterizes fresh snow. Pure keratin fluoresces a light blue color. This is usually masked by the presence of melanin granules.[80,81]

Blue feathers

Gas-filled vacuoles in spongy cells[6] (also known as cloudy cells) within the rami in the cortex or medulla cause the distribution of light and it is reflected as a blue color (Figures 32.18 and 32.19). Light of long wavelengths is absorbed after passing through this layer by a layer of melanin. When dry, the cells reflect blue or violet light; when impregnated with liquid with the same refractive index as keratin (1.54) they become transparent. Xylene, cresol, Canada balsam, and oil of cedar wood (immersion oil) all have a refractive index of close to 1.54.

Structural colors of feather barbules

Schemochromes are usually produced by scattering from arrays of melanin granules, or melanin granules and air arranged through the keratin of the feather. These structures are best seen using transmission electron microscopy. The greater the number of scattering layers or depth of arrays, the more vivid the color.

Structural colors of feather barbs

The medulla of the barbs is filled with specialized light-scattering boxy or spongy cells. These cells scatter the light. The cells are made of a matrix of keratin rods interspersed with air vacuoles of varying shapes. Backscattering of incoherent light is prevented by underlying feather structures or by a layer of eumelanin (black to brown) or in a few species phaeomelanin (reddish brown).

Structural absorption by feather barbules

Feathers of some birds of paradise have highly modified contour feather barbules arranged in vertically tilted arrays, which increase multiple scattering of light and thus structural absorption. This causes extreme directional reflectance, giving an intense black feather when viewed from in front of the displaying bird.

Genetics of Bird Color

Many species of birds are maintained in captivity by the breeding of successive generations. In time, various color anomalies occur, which in the wild would be removed by predators or diluted in a large gene pool. However, many bird breeders are keen to propagate color mutations. Pigeons and poultry were among the first. Canaries *(Serinus canaria)*, budgerigars, cockatiels *(Nymphicus hollandicus)*, lovebirds (*Agapornis* spp.) and other parrots, and Gouldian *(Chloebia gouldiae)* and zebra finches *(Taeniopygia guttata)* have also been bred for color variations for a long time. In fact, any captive bird that is bred regularly has been "improved" by bird keepers in shape and plumage color. The mode of inheritance differs between species. Some colors are a direct Mendelian inheritance. Others are far more complicated. For those interested in learning more on breeding for color in the various bird species, a multitude of books are available.[82–84]

FEATHER ABNORMALITIES

Introduction

The integument is the largest organ system in the body, and the most obvious. Clients will commonly notice changes in their birds' plumage before they notice other health problems. Feather abnormalities can include changes in structure or changes in color. These abnormalities may be specific to the integument and plumage but can also often reflect more generalized health issues.

Changes in Feather Structure

Changes in feather structure (feather dystrophies) include any abnormalities of the feathers caused by genetic influences, trauma, disease, or malnutrition. These can include breaks in the feather vane, weakness in the rachis, retained sheaths, abnormal colors, feather cysts, clubbed feathers, and other abnormalities.

Genetic Influences on Feather Structure

During domestication of various bird species, a tremendous variety in hereditary features has arisen, with several of these genetically modifying the structure, distribution, and arrangement of feathers. Certain breeds have been specifically bred for those characteristics and need to adhere to specific descriptions detailing the ideal standard (e.g., American Standard of Perfection, British Poultry Standards, Deutscher Rassegeflügel-Standard, etc.). Selective breeding for these characteristics may significantly reduce the genetic diversity of the population. In addition, some mutations can have direct or indirect negative effects on the bird's health and/or reproductive capacity[85]:

- structural alterations of the vane or feather length (e.g., silky-feathering in domestic chickens, lace-feathering in

domestic pigeons) can affect the bird's flying ability or even lead to flightlessness;
- vane alterations (e.g., frizzle-feathering in domestic chickens) can result in a reduction or loss of the feathers' close-knit texture, thereby impairing thermoregulation and/or affecting the bird's ability to cope with weather conditions such as heat, cold, and rain;
- feather crests and/or vortices (e.g., in chickens, pigeons, and canaries) can impede the bird's sight;
- leg-feathering (e.g., muffed legs in domestic pigeons) and hypertrophies of single feather tracts or of the entire plumage can hinder mating, egg incubation, and rearing of the chicks;
- partial feather loss (e.g., loss of neck hackles in naked neck chickens), pleiotropic effects of a feather-altering trait (e.g., reduction in wattle size in chickens), or alterations in feather structure can negatively impact intraspecific communication due to loss of optical signaling functions;
- due to pleiotropic effects of single genes or close linkages with hereditary defects, modifications to the feathers and plumage can be associated with (semi)lethal effects or lowered vitality in homozygous individuals, and—to a lesser extent—in heterozygous individuals (e.g., feather crests in domestic ducks and canaries, ear tufts in domestic chickens);
- expression of specific phenotypes (e.g., long tail feathers in Onagadori roosters) may require specific environmental factors and housing conditions.

Feather duster or chrysanthemum syndrome in budgerigars

Feather duster syndrome is seen occasionally in juvenile budgerigars that exhibit continued growth of flight, tail, and contour feathers, with the feathers continuously growing to become long, soft, and curled, giving the bird the appearance of a "feather duster" (Figure 32.20).[85,86] The contour feathers often grow four to six times longer than the remiges and rectrices, whereas the remiges and rectrices are twice as long as in birds with a normal plumage. The elongated feathers hamper the vision of the birds, rendering them unable to fly, and the ongoing feather growth drains energy and nutrients from the body. Affected birds barely make an audible noise and many have microphthalmia. Most birds die before reaching adulthood, generally within the first few weeks of life, although some may live for several years. This has been suggested to be the result of a therapy-resistant protein deficiency related to the hypertrophied development of the feathers.[87,88] Feather duster syndrome is believed to be a lethal recessive genetic disorder with a strong correlation between affected birds and buff feathering.[89]

FIGURE 32.20 Feather duster disease or chrysanthemum disease refers to a condition seen occasionally in juvenile budgerigars *(Melopsittacus undulatus)*. Affected birds exhibit continued growth of flight, tail, and contour feathers, with the feathers continuously growing to become long, soft, and curled. (Photo courtesy Bob Doneley.)

Straw feathers in canaries

Straw feather disease is an unusual, lethal disorder, where the feathers fail to emerge from the feather sheath and the barbs and barbules fail to develop. This gives the feathers a straw-like appearance. It may occur in first-molt or adult birds.[90,91] The disease is believed to be hereditary in canaries, although viral causes have also been postulated. It has also anecdotally been reported in other passerine species, including zebra finches.[92]

Porcupine feathers

Porcupine feathers have been reported in Japanese quail *(Coturnix japonica)* and in homer and fantail pigeons. The condition resembles "straw feather disease" in canaries. The shafts of the feathers of affected birds appear normal, but the barbs fail to uncoil, giving the feathers the appearance of porcupine quills. Gross examination under light microscope reveals that both distal and proximal barbules are present and appear normal. Affected feathers are predominantly noticeable on the wings (i.e., the primary and secondary remiges) and on the back. As the birds grow older, the barbs partially uncoil so that the trait can be clearly observed only on the wings.[93]

Baldness in cockatiels, canaries, and zebra finches

A bald patch is often present behind the crest feathers on the crown of the head in lutino cockatiels (Figure 32.21). As this alopecia is not seen in most other color mutations of cockatiels, it is believed to have a sex-linked genetic origin. Baldness, characterized by loss of feathers at the back of the head, is also recognized in canaries and zebra finches. Certain canary breeds, such as the Giboso Espagnol or the Gibber Italicus, not only have a partially featherless head but also have a reduced number of feathers in the ventral pteryla and nearly featherless tibiotarsi and thighs.[94,95] In canaries, aside from hereditary factors, endocrine or hormone deficiencies have also been proposed. Since the baldness tends to be more common in males than in females, a gender-linked predisposition has been suggested. In finches, baldness on the head can be seen in both genders and is believed to also be caused by feather picking by a dominant individual from the group. In this case, the bird believed to be the picking bird should be separated from the group to see if this results in improvement. Supplementation with L-thyroxine (0.02–0.04 mg/kg q24h PO) or testosterone has also been attempted to diagnose or rule out endocrine disease. For genetically related baldness, no treatment is necessary (or available).[90]

FIGURE 32.21 Alopecia on the crown of the head of lutino cockatiels *(Nymphicus hollandicus)* is quite common and should be considered normal for this color mutation.

Featherlessness in other bird species

A hereditary decrease in the number of feathers, resulting in partial or complete featherlessness, is noted in various domesticated species of birds, including chickens, pigeons, and waterfowl.[85] Scaleless chickens, for example, are almost completely devoid of feathers, scales, foot pads, and spurs.[96] The condition renders them useful as research models for examining the role of epidermal-dermal tissue interactions but also makes them susceptible to temperature changes, and because of an impaired sense of balance they cannot copulate normally. Partial featherlessness in the neck region is characteristic of certain breeds, such as the Romanian Naked Neck Tumbler, Canard Cou-nu, and Transylvanian Naked Neck chicken. As the trait in the Transylvanian Naked Neck chicken is autosomal inherited and incompletely dominant, heterozygous individuals are characterized by an isolated tuft of contour feathers on the ventral side of the neck above the crop, while this tuft is absent or reduced to very few pinfeathers or small contour feathers in homozygous individuals.[97] While the reduced feather coverage results in increased heat loss from the body, hence allowing the bird to cope better with higher temperatures, it also exposes the featherless skin to potentially harmful UV radiation and hinders intraspecific communication due to missing neck hackles that are important in threat postures.

Feather cysts in canaries

Feather cysts appear as in-grown feathers, forming hard, yellow nodules on the skin of type canary breeds (i.e., canaries that are bred for their shape and/or stance) such as the Norwich, Border, and Gloucester strains (Figure 32.22). Affected canary strains have been genetically selected to produce an extra down-type feather (double buff) that may predispose them to cyst formation. It has been hypothesized that the feather cyst formation results from an altered expression of molecules that regulate feather morphogenesis and feather growth. For example, Widelitz et al. proposed that an abnormally high level of β-catenin in the skin leads to enlarged feathers with abnormal shapes.[98] The mode of inheritance of feather cyst formation is not clear.[89,90] In canaries, the cysts are believed to be benign neoplasms of the feather follicle (folliculomas or basal cell tumors). Several dermal papillae form in each follicle, resulting in a tangle of feathers that fail to erupt from the skin.

The dorsal thoracic area is a frequent site of multiple cysts, but they can occur anywhere on the body and wings. Cysts often occur in several sites along a feather tract and appear as hard, yellow nodules containing the trapped curling feathers (Figure 32.23). Badly affected birds have irregularly directed feathers all over their bodies. Actively growing feather cysts will have vascular walls and contain blood and gelatinous material. Mature cysts will contain drier keratinous material, and the cyst wall may be more expansive, thickened, and reduced in vascularity.

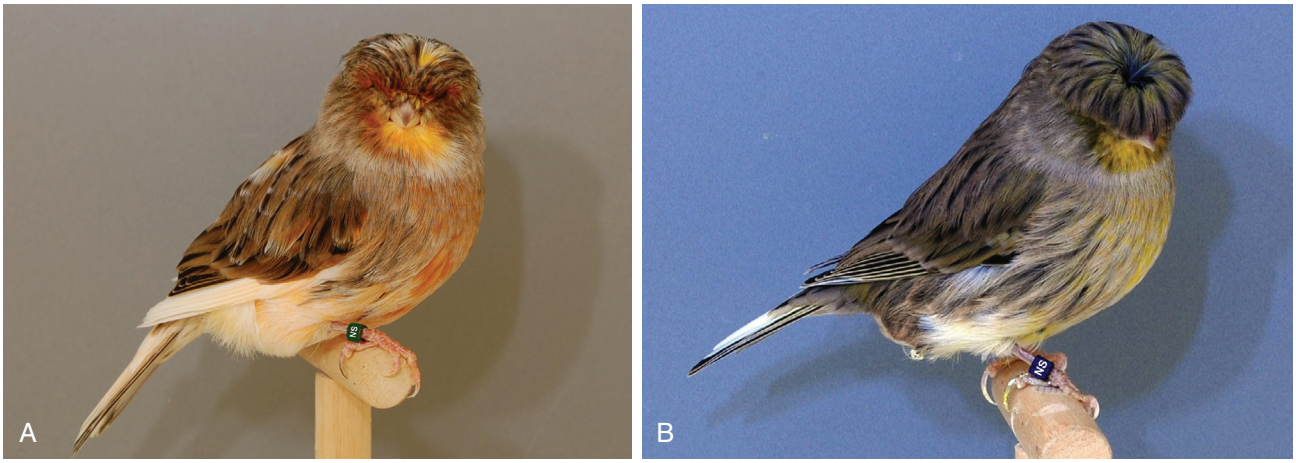

FIGURE 32.22 Examples of soft-feathered canary breeds: (A) Norwich. (B) Gloster. These canary breeds are prone to developing feather cysts. (A, from Wikipedia: https://commons.wikimedia.org/wiki/File:Norwich_gescheckt.jpg; B, from Wikipedia: https://commons.wikimedia.org/wiki/File:Gloster_corona_melanin.jpg.)

FIGURE 32.23 Close-up of a feather cyst on the left chest area in a Norwich canary *(Serinus canaria)*. Feather cysts can develop anywhere along a feather tract and typically present as a hard, yellow nodule containing feather keratin. (Photo courtesy Yvonne van Zeeland.)

Diagnosis is usually based on the clinical signs and appearance of the mass. Cytology may reveal erythrocytes, erythrophagocytosis, mixed-cell inflammation with a marked amount of background debris, multinucleated giant cells, and/or the presence of feather fragments. Treatment of individual cysts can be conservative by simply lancing and expressing the contents of the cyst. Recurrence is common, however. Surgical excision of the affected follicle(s), on the other hand, is generally curative. When multiple cysts are present, surgical excision of the affected pteryla(e) may be required. Cysts on the wings may not be amenable to surgery without partial wing amputation, making repetitive conservative therapy warranted.

Silkiness and lace-feathering

In silky-feathered chicken and lace-feathered pigeon breeds (Figures 32.24A and 32.25A), the contour feathers have no interlocking barbules and therefore do not form closed pennaceous vanes. Silky feathers obtain their characteristic hairy structure from the loss of hooklets on the distal barbules combined with an increased plumaceous portion of the vane. This typical change in feather structure can also be induced by thyroidectomy[99,100]; however, no differences have been found in thyroxine secretion rates of silky-feathered chickens compared to that of normal individuals.[101] In lace-feathered pigeons *(Columbia livia* f. *domestica)* and ring-neck doves *(Streptopelia roseogrisea* f. *risorii)*, the lace feathering is inherited by an autosomal, incompletely dominant gene,[102,103] hence resulting in heterozygous and homozygous individuals differing in the degree of lace-feathering. In the heterozygous birds, the feathers are plumulose, but in the homozygous individuals, the feathers appear tattered, rough, and brittle.

Frizzled feathers

Frizzled feathers have a peculiar upward-turning shape, which gives the appearance of the plumage having been brushed against the normal feather orientation. The condition results from an altered shaft morphology of the contour feathers, which results in an upward curving. Other structural abnormalities, such as thickening of the barbs and barbules and modifications of the hooklets, can also be present. Rectrices and remiges are less often affected but commonly have a ragged appearance. Secondaries also frequently lack inner vanes. Although this type of feathering has been described in various domesticated bird species, it has solely been established as a breed characteristic in domestic chickens. In these frizzled chickens (Figure 32.24B), several organ and physiologic changes (e.g., enlargement of the heart, spleen, and intestinal tract, lack of subcutaneous fat depositions, delayed sexual maturity, and decreased fertility) have been associated with a continuous, elevated loss of body heat that results from the abnormal plumage.[100]

Curled feathers

In certain breeds of domestic pigeons, such as the Frillback pigeon (Figure 32.25B), feather modifications like those seen in the frizzled chickens can be seen. These birds typically have wavy feathers as a result of uneven growth during feather development,[104] which leads to curling of the individual feathers. The curling is most pronounced on the wing coverts, where the distal parts of the contour feathers roll up like corkscrew spirals, but is less visible in the remiges, rectrices, and contour feathers of the neck and back.

Spiraled feathers

Elongated, spiraled feathers are found in the Sebastopol (Figure 32.26) and Lockengänse breeds of the domestic goose *(Anser anser* f. *domestica)*. This spiraling is caused by changed growth processes and disturbed keratinization during feather development, which lead to a lack of closed vanes in affected feathers. As the shafts of these feathers are soft and fragile, they are often fissured or cleaved and droop.[105]

Henny feathering

The so-called "henny-feathering trait," as can be seen in domestic chicken breeds such as the Sebright and Campine (Figure 32.24C), has been associated with a cutaneous hormonal defect that results in conversion of testosterone into estrogen in the male. As a result, the secondary male sex characteristics of the plumage are not formed, leading to affected roosters having a feather structure like hens.[106,107]

Fat quills

In some pigeon breeds (e.g., Nuremberg swallow, Thuringian swallow; Figure 32.25C), so-called "fat quills" are developed, which are modified powder downs that remain enclosed within a persistent feather sheath.[108] Transitional stages between fat quills and normal pulviplumae also occur. The "fat" in the quills originates from a fatty degeneration of the inter-radiogenic (non-feather-building) epithelium of the developing feather and has been hypothesized to assist in conditioning and waterproofing of the feathers, like preening oil produced by the uropygial gland.

Ear tufts

Ear tufts, which can be seen in, for example, the Araucana chicken as peduncular, feather-covered skin appendages positioned near the ear opening (Figure 32.24D), are inherited as an autosomal, incompletely dominant trait with variable expression. In homozygous individuals, the ear tuft gene leads to dead-in-shell embryos, whereas elevated fetal and postnatal mortality is observed in heterozygous specimens. As ear tuftedness also

affects the size and shape of the ear opening and the length of the ear canal,[109] hearing ability of these individuals may be impaired though this has not yet been confirmed.

Feather crests

Feather crests are seen in many of the domestic bird species, including chickens, ducks, and geese. Among chicken breeds, two phenotypes of feather crests can be distinguished, that is, the helmet-shaped, forward-inclining feather crest (e.g., in the Appenzeller chicken) and the full crest (e.g., in the Polish chicken). The full crest is inherited as an autosomal, incompletely dominant trait, with homozygous crested chickens lacking filoplumes in their crest compared to the heterozygous individuals.[110] Gender differences also exist, with contour

feathers being long and pointed in the male and rounded in the female. The scalp area in which the crest is vertically inserted is thickened and has a conspicuous hypodermal fatty layer. Crested chicken breeds also commonly have anomalies of the skull, including protuberant and vaulted frontal bones, and deformities of the nasal, intermaxillary, and other cranial skeletal bones.[100,110] These anomalies are caused by dysmorphogenesis of the brain, and in particular a bulging of the cerebral hemispheres. Furthermore, certain cerebral areas (e.g., the optic tract, diencephalon, telencephalon, parts of the hyperstriatum, and neostriatum) are significantly enlarged in crested chickens compared to noncrested individuals.[111] While the formation of skull protuberances is not causally connected to the formation of a feather crest, it is closely linked to the crest locus.[110] In some crested breeds of chicken, such as the Polish crested, Silkie, and Crevecoeur chickens (Figure 32.24E), the formation of a crest has been linked to cerebral herniation. This herniation, which results from a defective skull formation during incubation that allows the telencephalon to bulge out through a hole in the skull (Figure 32.27), is inherited as an autosomal recessive trait and can lead to a variety of neurological signs (e.g., ataxia,

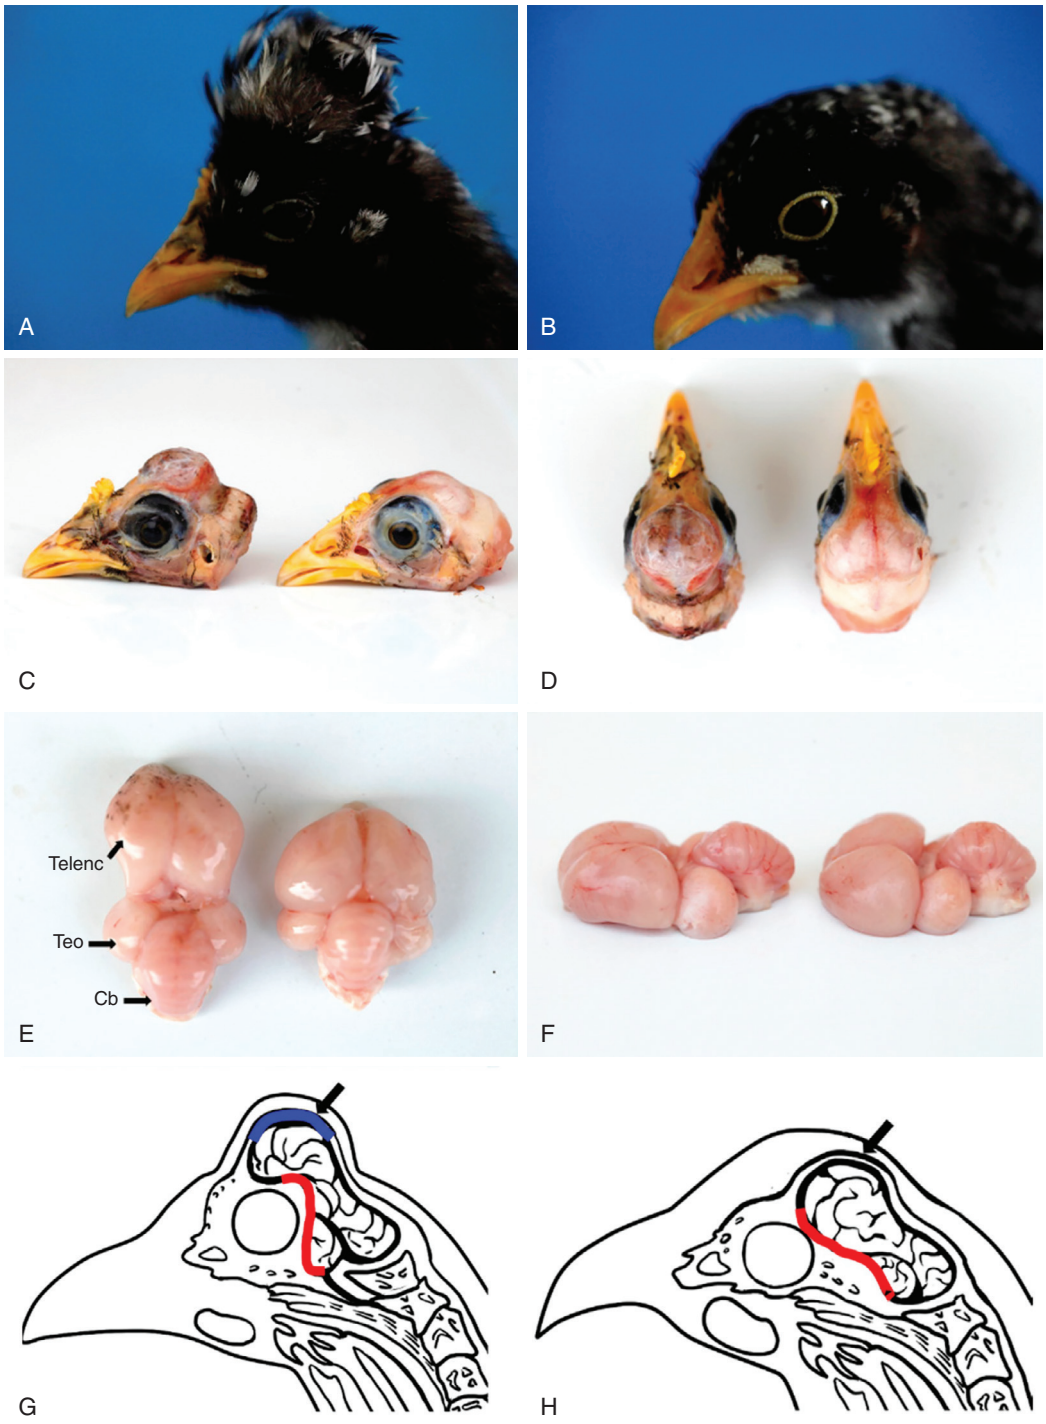

FIGURE 32.27 Anatomy and morphology of cerebral hernia-type and wild-type chickens. (A, B) The appearance of chickens (A) with cerebral hernia (cerebral hernia type) and (B) without cerebral hernia (wild type). torticollis) due to the bulging brain being susceptible to trauma and damage.[112,113]

Similar to chickens, crested ducks have a crest consisting of proportionally enlarged contour feathers and downs which arise from a thickened hypodermis of the occiput. In crested ducks, the underlying skull bones are rarely closed but rather show numerous perforations in the junctions of the frontal, occipital, and parietal bones *(Sutura supraoccipitoparietalis*, *Sutura interparietalis*, and *Sutura frontoparietalis)* and in the caudolateral region of the parietal bones *(Ossa parietalia)*. Originally, it was hypothesized that fat and connective tissue from the crest could protrude into the skull through these perforations, leading to compression of the cerebellum and other brain structures with subsequent onset of neurological signs such as ataxia and blindness.[110–111] However, it was later discovered that the intracranial fat bodies represent intracranial lipomas that can develop in both crested and plain-headed individuals that have at least one parent descending from a crested specimen.[114,115] In addition to these problems, increased mortality among offspring with craniocerebral malformations or malformations associated with duplication of body parts has been reported in crested ducks.[116] A phenotype similar to that in crested ducks (i.e., feather crests arising from hypodermal thickenings of the occiput, and perforated skull roof) can be observed in crested (tufted) breeds of geese (e.g., Tufted Roman, Emporda).[117]

Feather vortices

The feather crests as can be observed in some pigeon breeds (e.g., Bokhara Trumpeter, Komorner Tumbler, Oriental Frill), budgerigars (crested budgerigars), and passerines (e.g., Gloster, crested, and German crest canaries, crested varieties of the zebra finch and Bengalese finch, *Lonchura striata*) are termed feather vortices (Figure 32.22 and Figure 32.25C).[85] These vortices differ from the crests in chickens and ducks in several aspects:

1. They are formed by proportionally enlarged yet normal contour feathers.
2. Their location is variable across species, that is, above the beak in, for example, the beak-crested German trumpeter, on the forehead in, for example, the Harzburger Trommeltaube, on the back of the head in, for example, the Oriental Frill, or central on the top of the head with feathers radiating from the center in passerines. In addition, feather vortices can occur in other body regions such as the lateral neck in, for example, the Jacobin pigeon, or on the back, breast, and flanks in "frilled" type canaries or Bengalese finches.
3. Their appearance can be variable, for example, tufted, semicircular, or circular, which are the three forms that are recognized in budgerigars.[118]

In budgerigars, it has been suggested that vortices are inherited by an incompletely dominant autosomal gene, leading to one (in heterozygous birds) or two centers of vortex formation (in homozygous individuals).[119] Like the crests in ducks, the vortex trait in budgerigars has been associated with increased fetal mortality resulting from internal hydrocephalus and cerebral hemorrhage in both homozygous and heterozygous individuals. In addition, a relative high proportion of the (live) birds display abnormal behavior, ataxia, and tremors.[119]

In canaries, zebra finches, and Bengalese finches, the vortices are inherited by an autosomal incompletely dominant gene which leads to mortality of the homozygous chicks just before or shortly after hatching.[120,121] Aside from increased mortality and neurologic signs, vortices can also lead to impaired vision when they envelop the top and sides of the head (e.g., in Jacobin pigeons). This requires breeders to clip the vortex feathers to allow the pigeons to successfully raise their chicks.

Muffs and beards

Muffs and beards are feather modifications that can be seen in chickens and always occur in conjunction with a reduced wattle size.[122] Muffs are formed by elongated contour feathers that project horizontally from both sides of the face, while the beard consists of elongated contour feathers that project downward under the chin (Figure 32.24F).

Ptilopody and vulture hocks

Several chicken and pigeon breeds are characterized by ptilopody or "feet feathering," which is the result from a genetic mutation that leads to a transformation of the scales on the tarsus, feet, and toes into feathers.[107] Feet feathering can be expressed in various degrees. For example, "groused" feet are covered with small contour feathers, whereas "slippered" legs have enlarged feathers on the feet, and "muffed" legs develop primary-like feathers on the feet and toes. "Vulture hocks," which are characterized by elongated, stiff, and caudally projected contour feathers covering the tibia, can be found, for example, in the Booted Bantam and Sultan chicken breeds (Figure 32.24G) and Old Holland Pouter and Saxon Fairy Swallow pigeon breeds.

Longtail

Some Japanese chicken breeds, for example, the Onagadori breed (Figure 32.24H), are characterized by extremely long tail feathers, which can grow up to 13 m long with a growth rate of approximately 1 m per year.[123] While the trait is genetically determined, it is also influenced by environmental factors, for example, restricted housing.[124]

Hypoplastic tail feathers. In the so-called Ingie breed of chicken, rectrices and tail coverts are underdeveloped, showing a slender rachis as well as abnormal anterior and posterior barbules with a reduced number of hooklets.[107]

Increased number of tail feathers. Certain pigeon breeds (e.g., Danzig Highfliers, Oriental Rollers, Fantails; Figure 32.25D) have an increased number of tail feathers compared to the normal 12 that are present in the rock pigeon.[125] In Fantails, which can have >30 rectrices, the rectrices are kept spread out and are carried erect, forming an expanded fan. As such, they cannot assume a normal mating posture and copulate successfully unless the lateral rectrices are trimmed.

Physical Influences on Feather Structure

Physical conditions can also temporarily affect the appearance of the feathers. These feathers will eventually molt out and be replaced with normal feathers.

Stress lines

Stress lines are translucent lines across the vane of a feather, oriented perpendicular to the shaft (Figure 32.28). They represent segmental dysplasia that occurred in the developing

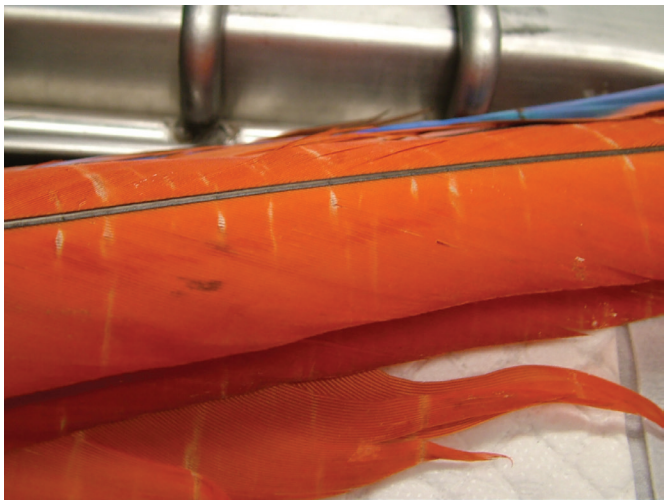

FIGURE 32.28 Stress lines, as seen in this scarlet macaw *(Ara macao)*, are translucent lines across the vane of a feather, oriented perpendicular to the shaft. They represent segmental dysplasia that occurred in the developing barb and barbules due to a brief period of dysfunction in the epidermal collar from which the feather arises. (Photo courtesy Bob Doneley.)

FIGURE 32.29 Damage or trauma to the feathers can be the result of inappropriate housing, damage by other birds, animal attacks, or through trauma such as heavy falls or impacts. This sulphur-crested cockatoo *(Cacatua galerita)* was housed in an inappropriately sized cage for an extended period. (Photo courtesy Bob Doneley.)

barb and barbules due to a brief period of dysfunction in the epidermal collar from which the feather arises. This dysfunction is generally the result of the release of corticosteroid hormones as a result of a stressful event (e.g., transport, restraint, nutritional deficiencies, food deprivation, or environmental stressors) that occurred while the feather was growing. The barbules do not form, resulting in a line of weakness at the same level. Stress lines may also develop following exogenous corticosteroid administration during feather growth. They are commonly noted in young birds and may be associated with illness or a change in diet or disruption of their feeding schedule when they are being weaned (see Chapter 41). Stress marks are easily identified upon inspection of the plumage or spreading the wing and/or tail feathers and holding them against the light. Their clinical relevance depends largely on the number of stress marks that are present and the bird's overall condition. A few stress marks in an otherwise healthy bird may have mere aesthetic impact. A larger number of stress bars generally warrants further investigation into the underlying cause, but this is often difficult as the marks are the result of a problem that occurred during feather development in the past that may not be present any longer. The underlying cause has to be identified & eliminated; no further treatment for the feather abnormalitiy is needed as it will now be able to correct itself at the next moult.[89,90]

Damage or trauma to the feathers

Damaged feathers are relatively common in companion, aviary, and wild birds (Figure 32.29). They can be the result of inappropriate housing (e.g., too small an enclosure so that the bird brushes its feathers against the side constantly), damage inflicted by other birds (particularly over-amorous mates), predator attacks (e.g., birds of prey, dogs, or cats), restraint, or through trauma such as a heavy fall or collision impact. Often the primary feathers on the wings, the alular and carpal covers, and/or tail feathers will be abraded, broken, or removed. Malnutrition may predispose the bird to such damage as nutritional deficiencies may weaken the feathers, rendering them susceptible to damage. Elimination of the predisposing factors may help to prevent problems in future, but a molt is necessary to shed the damaged feathers. If an early return to function is required (e.g., for the release of a wild bird), a falconry procedure (imping) can graft replacement feathers onto the stump of damaged feathers (Box 32.2).[90]

Damage to newly erupted (blood) feathers may be more problematic as this can result in severe hemorrhage, especially if the bird has an underlying coagulopathy (e.g., hepatic lipidosis). These newly emerged feathers, known as "blood feathers" (because of the blood vessels in the calamus and rachis; Figure 32.30), are enclosed in a soft keratin sheath which is easily damaged. Such damage is often associated with improper wing trims exposing the blood feathers to damage. If the damage is mild (e.g., a longitudinal split in the keratin sheath), hemorrhage may be controlled by manual pressure or applying a paste of flour and water to the split. Chemical or thermal cauterization should not be used. If the bleeding is severe or cannot be controlled, removal of the feather may be required. This is achieved by administering appropriate analgesia, with or without sedation or anesthesia, followed by grasping the feather at its base and pulling it from its follicle, along the line of feather growth, and then applying manual pressure to the follicle until the bleeding is stopped.[90]

BOX 32.2 CLINICAL TECHNIQUE: IMPING PROCEDURE

1. Anesthetize the bird (e.g., using isoflurane) to reduce stress and prevent the bird from destroying the freshly repaired feather through movement and struggle. Analgesia is not required; this feather repair technique is painless because noninnervated and nonvascularized parts of the avian integument are manipulated.
2. Place the anesthetized bird on a towel or paper cloth, and provide thermal support with conductive (e.g., heating pad) and/or convective (e.g., warm air) equipment.
3. Assess the damaged primary feathers (Figure 32.2.1) and retract the covert feathers away from the broken flight feather with masking tape; this will expose the base of the affected shaft (calamus; Figure 32.2.2).

4. Compare the length and shape of the possible replacement feathers (Figure 32.2.3) with the damaged one. If the length and shape of the replacement feather are acceptable, align it in proper position relative to the adjacent feathers (Figure 32.2.4). Make sure to maintain bilateral symmetry with the opposite side of the tail or wing when replacing a feather.

5. After determining the correct length of the replacement feather, mark the cutting line with a pen on both feathers (Figure 32.2.5). If more than one feather needs to be imped, replace the innermost feather first for optimum results.

6. Trim the damaged feather approximately 15 to 25 mm distal to the skin with a nail cutter (Figures 32.2.6 to 32.2.8).

BOX 32.2 CLINICAL TECHNIQUE: IMPING PROCEDURE—cont'd

7. Trim the new feather along the marked cutting line, leaving a clean, cylindrical shaft. Do not use scissors to trim the feather because this will cause the shaft to split.
8. Clean out the feather shafts with a blunt object (e.g., small drill bit, paper clip).
9. Shave a bamboo stick until it fits tightly within the feather shafts of both feathers. Confirm that the shaft of the donor feather has perfect alignment with the feather shaft of the recipient site.
10. Place a piece of paper or cardboard under the imping site to prevent glue exposure on adjacent feathers (Figure 32.2.9).

11. Prepare the fast-setting 5-minute epoxy glue (a mix of equal parts of epoxy resin and hardener), then lightly coat the implant with the glue and insert approximately 2.5 cm into the shaft of the new feather. Aspirate the remainder of the prepared glue with a 1-mL tuberculin syringe and inject into the old feather shaft. Insert the implant into the recipient feather shaft and connect both feather fragments (Figures 32.2.10 and 32.2.11).

12. Rotate the new feather for proper positioning, close the wing/tail in the natural anatomical position, and hold all the feathers in place with hair clips until the epoxy cures (Figures 32.2.12 and 32.2.13).

13. After the epoxy glue has cured, remove the paper or cardboard and recover the patient from anesthesia.

Adapted from Lierz M, Fischer D: Clinical technique: imping in birds, *J Exot Pet Med*, 20(2):131–137, 2011.[126]

FIGURE 32.30 Damaged blood feather in a Senegal parrot *(Poicephalus senegalus)*. In this case, excessively short-clipped primary remiges appeared to have signaled feather shaft automutilation by the bird as can be seen in the adjacent remiges. When these damaged plumes are molted and replaced, a single pin feather may extend out and beyond the others, rendering it more susceptible to mechanical trauma. These injured pin, or blood, feathers should be considered to be painful for affected birds. (Photo courtesy Bob Doneley.)

Disease Influences on Feather Structure

Noninfectious diseases

Malnutrition. Malnutrition remains a common problem in birds kept in captivity. The feeding of a predominantly seed-based diet, which is commonly high in fats and carbohydrates and low in protein, essential amino acids (particularly lysine and methionine), minerals (calcium, phosphorus, sodium, manganese, zinc, iron, iodine, selenium), and vitamins (most notably A, D, K, B_{12}, riboflavin, pantothenic acid, choline, and niacin),[127–130] can have a direct effect on feather quality, or an indirect effect through changes to liver function, skin infections and inflammation (related to hypovitaminosis A), and other systemic diseases. The normal molting process may be delayed or interrupted in birds, thereby giving rise to development of depigmented or discolored, poor-quality feathers that break easily and have a dull, ragged-looking appearance.[127,131] Changes in feather color will be discussed later. Changes in keratin, associated with essential amino acid deficiencies, may cause changes in feather structure and quality as well as cause dry, flaky skin, particularly of the face, feet, and legs. Feather structure that was adversely affected by malnutrition may be representative of an event in the past during its development and does not necessarily have to always imply ongoing malnutrition.

Although the previously mentioned abnormalities may not necessarily and specifically point to ongoing malnutrition, an underlying nutritional component should be suspected in any abnormally feathered captively maintained bird that is primarily fed seeds. Treatment in these cases should aim at correction of the malnutrition by conversion to a balanced (pelleted) diet, combined with a multivitamin injection (5000–20,000 IU/kg IM, once; based on vitamin A content) and/or oral supplements.

Lack of bathing opportunities. In the wild, most birds bathe regularly to ensure their feathers are maintained in optimal condition for flight, thermoregulation, waterproofing, camouflage, and communication. Bathing also stimulates preening, which helps to remove dirt, dander, and ectoparasites. Bathing may take place in standing water (standing-water bathing), in the rain (rain bathing), or the bird may rub its feathers against wet foliage (foliage bathing).[132–134] Alternatively, birds in environments where water is scarce may resort to dustbathing.

In captivity, restricted bathing (opportunities) can have a detrimental effect on the bird's skin and plumage. For example, in the zebra finch, restricting bathing opportunities was found to reduce plumage condition through increased lipids and dirt in the short term, while long-term bathing deprivation led to increased corticosterone,[135] which could affect the molting process and lead to immunocompromise.

It is therefore recommended to bathe birds regularly (i.e., at least weekly, but preferably daily) to keep the plumage and skin in optimal condition. More frequent bathing may be required in the winter months, especially in homes with central heating where relative humidity is low. Bathing opportunities can be provided in multiple ways:

- Wading in a birdbath, bowl or pan of water, or sink with the water running gently.
- Misting, whereby water is sprayed in such a way that the water falls gently onto the bird (note that the bird should not be sprayed directly in the face as this can be uncomfortable and frightening).
- Showering, which is preferably done on a perch with a nonslippery surface for grip that is placed off to the side (not directly under the spray).
- Rolling in wet leafy greens (e.g., lettuce leaves), which can be placed in the bottom of the cage of small birds.

Preference for one option over the other may differ according to species and per individual. When bathing a bird, care should be taken to use lukewarm to slightly cool water and to avoid drenching the bird's feathers as this could lead to significant heat loss. While some birds like a blow-dry after their bath, it is not necessary nor recommended as this may lead to drying of the skin and poses a risk of skin burns if using too high temperatures. Similarly, the use of (bird-friendly) shampoo is rarely required, unless the bird is severely soiled or greasy. For birds that are fearful of bathing, systematic desensitization and counterconditioning may need to be employed (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). If using a birdbath, pan, or bowl of water, this should be removed from the enclosure when bathing is complete, and any wet cage bedding should be removed to prevent mold growth.

Feather cysts. In species other than canaries (e.g., parrots, chickens), feather cysts most often represent an acquired condition, resulting from an infection, trauma, or other conditions that interfere with the normal feather growth (Figure 32.31). These cysts usually occur as solitary masses that develop due to curling of a new, growing feather within its follicle. While they can develop anywhere on the body, they are most found on the wings, tail, or neck. Baker described three types of cysts in budgerigars: variably sized spherical cysts containing

FIGURE 32.31 A feather cyst, as seen in a sun conure *(Aratinga solstitialis)*, may be an acquired condition or the result of an infection, trauma, or other conditions that interfere with the normal feather growth. (Photo courtesy Bob Doneley.)

FIGURE 32.33 An inability to preen, for any reason, can result in retained feather sheaths, especially in powder down feathers over the thighs, as can be seen in this cockatiel *(Nymphicus hollandicus)*. (Photo courtesy Bob Doneley.)

FIGURE 32.32 Multiple feather cysts in a budgerigar *(Melopsittacus undulatus)*, likely to be a hereditary condition. (Photo courtesy Bob Doneley.)

caseous material and the remains of one or more feathers, encased in a fibrous capsule; similar cysts but with the surrounding skin inflamed and thickened; and long, narrow cysts on the wing, often found side by side, with each cyst corresponding to the follicle of one primary feather (Figure 32.32).[89] These cysts contain caseous material like the other types but often have a malformed feather protruding from the tip of the cyst. Diagnosis and treatment are like that described for the genetic feather cysts in canaries.

Delayed molt ("stuck in molt"). Delayed molt is frequently caused by a combination of malnutrition, abnormal diurnal rhythm (especially for companion birds kept indoors and exposed to extended hours of artificial lighting), concurrent illness, and/or hormonal disorders (e.g., hypothyroidism).[90] Excessive egg laying in cockatiels and budgerigars may cause abnormal or delayed molting due to endocrine effects on feather growth. Affected birds have untidy plumage, bald spots, and damaged, brittle feathers. The ends of the feathers often become frayed and lose their reflective coloration. Other (nondermatological) signs may include decreased vocalization in male canaries, excessive or decreased egg production, and general lethargy. A thorough history and physical examination will reveal whether and which predisposing factors are involved. Treatment is primarily aimed at eliminating and correcting these conditions. Normal diurnal rhythms should be re-established by ensuring the bird gets at least 12 to 14 hours of "sleep time" in a darkened, quiet environment. Simply covering a cage in a busy family area is insufficient to meet the sleep requirements for most birds, as most of these covers do not block all light or sound. Nutritional problems must be corrected. Egg production should be controlled through nutritional, environmental, social, and possibly reproductive hormonal manipulation.

Inability to preen. Inability to preen can result in retained feather sheaths and is common in birds that have an Elizabethan collar in place to stop self-mutilation or are unable to preen due to spinal or beak problems. In cockatoos (*Cacatua* spp.), Grey parrots (*Psittacus erithacus*), and cockatiels, retained sheaths are especially seen in the powder down feathers over the thighs, which can become very elongated and friable, thereby breaking easily (Figure 32.33).

Chronic liver disease. Chronic liver disease can cause feather changes (Figure 32.34). The hyperbiliverdinemia associated with liver disease will cause keratinocytes to excrete biliverdin, resulting in yellowing of feathers, particularly in lutino cockatiels.[136] Birds with chronic hepatopathies may show feather structural changes including loss of barb and barbule interlocking, giving the feathers

FIGURE 32.34 Chronic liver disease can cause feather and beak changes, especially in older birds. It needs to be distinguished from psittacine beak and feather disease and possibly hypothyroidism. This galah *(Eolophus roseicapilla)* shows darkening of the plumage and loss of the barbule structure. Without diagnostic testing, the cause cannot be elucidated.

FIGURE 32.35 Polyfolliculosis/polyfolliculitis, as can be seen in this peach-faced lovebird *(Agapornis roseicapilla)*, is a chronic pruritic condition that can cause multiple short feathers to erupt from one follicle. There is some discussion as to whether this condition is the cause of the bird's intense pruritus or is the result of damage done by the bird in response to the pruritus. (Photo courtesy Bob Doneley.)

more of a hair-like appearance. Feathering in birds with chronic liver disease is often dull and the plumage unkempt. Delayed molt or failure to molt is not uncommon with chronic disease of many forms, not specific to liver disease. There may be a degree of pruritus leading to feather damage and loss, particularly over the torso. Nails and beaks are often overgrown, possibly due to derangements in carbohydrate and protein metabolism.

Diagnostic tests that can be performed to confirm a suspicion of liver disease can include serum/plasma biochemistry (including aspartate aminotransferase, creatine kinase, γ-glutamyl transferase, glutamate dehydrogenase, lactate dehydrogenase, alkaline phosphatase, and bile acids), imaging (e.g., radiography, ultrasound), endoscopy, and/or collection of (ultrasound-guided or endoscopic) fine needle aspirates or liver biopsies (see Chapter 2 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 13, Advances in Clinical Pathology and Diagnostic Medicine and Chapter 14, Advances in Diagnostic Imaging). Treatment should aim at supporting the patient, treating the specific condition, and creating an environment that allows the liver to heal and regenerate.[137,138]

Polyfolliculosis/polyfolliculitis. Polyfolliculosis or polyfolliculitis refers to a chronic pruritic condition that can cause multiple short feathers to erupt from one follicle (Figure 32.35). It is most encountered in lovebirds and budgerigars.[139] While the etiology is still currently unclear, some veterinarians have hypothesized a viral or genetic origin. There is some discussion as to whether this condition is the cause of the bird's intense pruritus or is the result of damage done by the bird in response to the pruritus. Affected birds are presented for pruritus predominantly over the neck, back, and tail. Diagnosis can be made based on the clinical appearance of the feather follicles, which typically reveal several feathers with short, stout quills and retained sheaths emerging from a single, enlarged follicle. Histologically, there is the appearance of multiple short feather shafts growing from the same follicle, with a thin layer of epidermis separating the shafts. Chronic inflammation occurs beneath the pulp cap and the feather sheath is thickened. Surgical excision or electrocautery of affected follicles or feather tracts may be of benefit. Nonsteroidal antiinflammatory drugs such as meloxicam, as well as other analgesics, may also be helpful to alleviate associated pain.[136] Collars may be considered in birds that mutilate their skin.

Hypothyroidism. Hypothyroidism has been documented in poultry with immune-mediated thyroiditis demonstrating changes in feather quality and color. Black, brown, and yellow feathers become red, longer, and more pointed and have fewer pennaceous barbules than normal. These changes are reversible with thyroid supplementation.[140]

An obese scarlet macaw *(Ara macao)* with confirmed hypothyroidism had nonpruritic feather loss, mild nonregenerative anemia, mild leukocytosis, heterophilia, hypercholesterolemia, and sparse feathers, and had not molted in over a year. It responded well to thyroxine therapy.[141] Hypothyroidism has also been suspected in eclectus parrots *(Eclectus roratus)*, galahs *(Eolophus roseicapilla)*, lovebirds, budgerigars, and cockatiels with plumage changes including elongation of powder down feathers (in cockatoos and cockatiels), narrowing and elongation of outer primary feathers, and generalized feather color changes (Figures 32.36and 32.37).[142] Galahs develop a pink-red discoloration of the gray plumage and the normally pink feathers deepen in color intensity. Lutino cockatiels with suspected hypothyroidism may show deepening color intensity and a loss of barbs and barbules in the feathers, giving the

FIGURE 32.36 Hypothyroidism is suspected in galahs *(Eolophus roseicapilla)*, budgerigars *(Melopsittacus undulatus)*, and cockatiels *(Nymphicus hollandicus)* with plumage changes including elongation of powder down feathers, narrowing and elongation of outer primary feathers, and generalized feather color changes. This cockatiel shows the darkened, often "greasy," appearance of the feathers and slight beak overgrowth. (Photo courtesy Bob Doneley.)

bird a "greasy" deep yellow color. Hypothyroidism in parrots nevertheless tends to be much overdiagnosed (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 10, Clinical Endocrinology of the Protein Hormones). Diagnosis is difficult because normal resting thyroxine (T4) levels in birds (5–15 ng/mL) are much lower than in mammals and are often below the detectable limits of many laboratory techniques and equipment. Additionally, Triiodothyronine (T3; 0.5–4 ng/mL) may be as important as T4 in overall thyroid function, therefore measuring only T4 may not present an accurate picture of the health of the thyroid gland. The half-life of both hormones is shorter in birds than in mammals, resulting in a significant diurnal variation in a normal bird. There is also a seasonal variation, with higher baseline levels in spring. Diagnosis of hypothyroidism therefore requires demonstration of a failure to respond to thyroid-stimulating hormone (TSH). As avian TSH is not commercially available, mammalian TSH must be used. After obtaining a baseline T4, the bird is given 1 IU/kg of TSH and T4 is determined 4 to 6 hours later. A positive response in a normal bird will result in a 2.5-fold or greater increase in the resting T4 level.[143]

Supporting evidence for a diagnosis of hypothyroidism includes elevated cholesterol, triglycerides, liver enzymes, and a mild nonregenerative anemia. It has been suggested that, in

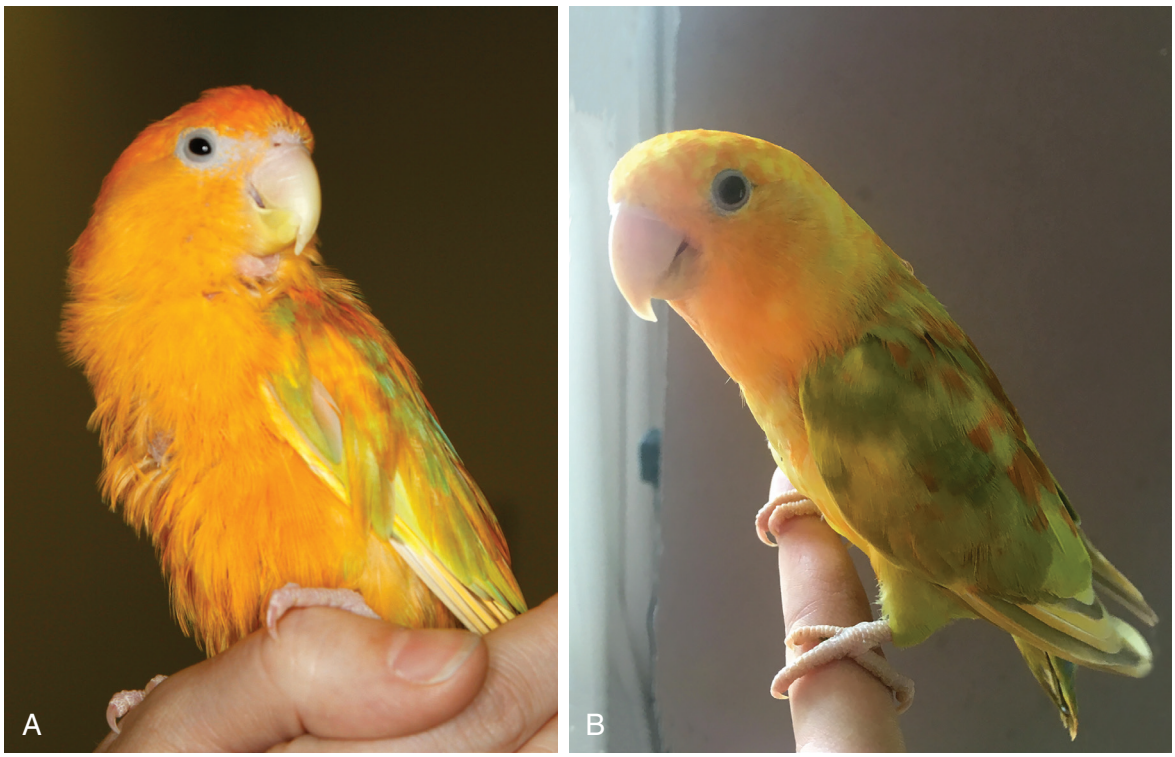

FIGURE 32.37 Peach-faced lovebird *(Agapornis roseicollis)* with suspected hypothyroidism. (A) The bird was presented with obesity, decreased activity, and progressive color changes of the feathers. (B) Following supplementation with L-thyroxine the bird lost weight, became more active, and the plumage gradually returned to normal coloration over a course of several months, as can be seen in these two serial images. (Photo courtesy Yvonne van Zeeland/Nico Schoemaker.)

larger birds, endoscopic biopsy of the thyroid gland may lead to a diagnosis of hypothyroidism.[142]

Despite the lack of laboratory confirmation, some obese birds that demonstrate a lack of weight loss following a rigid diet, accompanied by poor-quality feathers and infrequent molts, respond favorably to thyroxine therapy. It must be noted that no pharmacologic data exist to confirm the proper administration of thyroid hormone replacement in birds and that response to thyroid hormone supplementation does not confirm the diagnosis (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 10, Clinical Endocrinology of the Protein Hormones).

Toxic effects of drugs. Certain drugs can cause weakened, twisted feathers if administered during molting. The best-known example of this is fenbendazole. Silver sulfadiazine, used as a topical antibacterial cream, and colloidal silver have been reported to cause agyria (e.g., silver poisoning) after excessively prolonged application or administration. It causes a bluish discoloration of the skin, feathers, and oral mucosa.[143]

Pinching off syndrome

Pinching off syndrome (POS) refers to a condition in which all remiges and rectrices become malformed and are lost during the nestling stage, thereby rendering the bird unable to fly.[144] Contour feathers can sometimes be more or less malformed as well. The syndrome was first reported in 1975 in a juvenile white-tailed sea eagle *(Haliaeetus albicilla)*,[145] but has since been described in several species of birds of prey in both Europe and North America.[146–150] In birds with POS that were temporarily held captive, feather abnormalities worsened, with new flight feathers becoming progressively shorter with each new feather generation. Though various (viral, parasitic, genetic, endocrine) causes have been postulated, researchers have thus far failed to determine the underlying etiology for this condition.

Infectious diseases

Psittacine beak and feather disease. Psittacine beak and feather disease (PBFD) is caused by a circovirus (PBFDV), a nonenveloped single-strand DNA virus measuring 14 to 17 nm. The virus has a minimum incubation period of 21 to 25 days, but incubation periods could be up to several years. It is shed in feces, crop secretions, and feather dust. Vertical transmission is suspected but not confirmed. Following infection, the virus is disseminated hematogenously, residing in the feather follicle epithelium, the thymus, and the bursa. In cockatoos, it also resides in the growth areas of the beak (Figure 32.38). The result is feather dystrophy, immunosuppression, and, in cockatoos, overgrowth and underrunning of the rhamphotheca. All parrots are susceptible, but New World parrots and cockatiels appear to be rarely affected. PBFD is more common in juveniles than in adults, but naive adults are susceptible. There are two forms of PBFD: acute and chronic (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).

Acute PBFD is seen in juveniles (especially Grey parrots) around weaning age. Following infection, they become lethargic, fluffed, and anorexic. Hematology may show pancytopenia and nonregenerative anemia. Affected birds often die (within a few days) with severe hepatic necrosis before feather abnormalities develop. However, feather lesions have been noted in fledgling birds at 28 to 32 days old.[151]

FIGURE 32.38 Psittacine beak and feather disease (PBFD) in two wild-caught sulphur-crested cockatoos *(Cacatua galerita galerita)* showing the classical presentation of overgrown beaks and lost/dystrophic feathers. (Photo courtesy Bob Doneley.)

Chronic PBFD causes progressive replacement of normal feathers with dystrophic feathers, which can present as retained sheaths and blood supply, clubbed appearance, stress lines, constrictions, and abnormal shapes. The degree and location of the feather loss may depend on the state of molt that the bird was in when it was initially infected. Typically, lesions develop first in the powder down feathers, followed by the contour feathers, primaries, secondaries, tail, and then the crest. *Poicephalus* species and lorikeets may only lose tail feathers and primary flight feathers (Figure 32.39). These feathers may then regrow. Neophemas (*Neophema*

FIGURE 32.39 Psittacine beak and feather disease (PBFD) in a juvenile wild-caught rainbow lorikeet *(Trichoglossus moluccanus)* showing the loss of primary flight feathers on the wings. (Photo courtesy Bob Doneley.)

spp.) may develop untidy plumage and will easily lose feathers when handled. Many parrots develop feather color changes, for example, blue feathers become white, green feathers become yellow. Beak lesions, which include palatine necrosis, ulceration, elongation, and fracturing of the beak, are seen only in cockatoos. Immunosuppression is common in all species.

A presumptive diagnosis can usually be made based on the characteristic clinical signs, with further testing confirming the suspicion. Testing for evidence of infection with PBFDV can be done via polymerase chain reaction (PCR), serology, or histopathology (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease.

Since no treatment exists for PBFD, affected birds may be euthanized once the disease progresses. Some birds (especially cockatoos) may live for 10 to 30 years despite showing clinical signs, but most infected birds die within 2 years due to developing secondary diseases related to immunosuppression. Lorikeets and lories appear to mount an effective immune response and recover to look clinically normal. However, many of these birds become unapparent carriers.[90,152]

In Australia, where the disease is endemic, experimental inactivated vaccines are available, but these do not prevent infection (see Chapter 13 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).[153] Prevention therefore primarily aims at reducing the spread of the disease by maintaining closed flocks, quarantine measures, and (repeated) testing. Proper hygiene and disinfection protocols are also recommended to reduce the risk of transmission (see Chapters 11 and 12).

Circovirus infection in other birds. While primarily recorded in psittacine birds, circovirus infections have been suspected or confirmed in several nonpsittacine birds (Table 32.1).[154] Similar to circovirus infection in psittacine birds, disease is

TABLE 32.1

Circovirus Infections in Nonpsittacine Birds

Taxonomic Order	Species	Type of Circovirus	Clinical Features	Reference
Anseriformes	Pekin *(Anas platyrhynchos domestica)* and mulard ducks (sterile hybrid between a Muscovy duck, *Cairina moschata*, and Pekin duck)	Duck circovirus (DuCV)	Growth retardation, poor body condition, feather dystrophy (hemorrhage of the shaft), particularly in the dorsal region, increased mortality in young ducklings related to immunosuppression	Atterman et al., 2003[155]; Soike et al., 2004[156]; Hong et al., 2018[157]
	Goose *(Anser anser)*	Goose circovirus (GoCV)	Runting syndrome associated with a feathering disorder and increased mortality in young geese	Soike et al., 1999[158]; Ball et al., 2004[159]; Chen et al., 2006[160]
	Mute swan *(Cygnus olor)*	Swan circovirus (SwCV)	Wild swans, found dead. No further clinical presentation available	Halami et al., 2008[161]
Charadriiformes	Southern black-backed gull *(Larus dominicanus)*, herring gull *(Larus argentatus)*, black-headed gull *(Larus ridibundus)*	Gull circovirus (GuCV)	(Juvenile) birds that were found dead, with secondary infections (aspergillosis) suggestive of immunosuppression	Twentyman et al., 1999[162]; Smyth et al., 2006[163]
Columbiformes	Racing pigeon *(Columba livia)*	Columbid circovirus (CoCV)	Immunosuppression with associated increases in morbidity and mortality in young pigeons. Feather abnormalities are relatively rare but may include thickening of the feather pulp, quill congestion, pinching off, vane discoloration, feather deformation, feather growth retardation, and (symmetrical) loss of feathers	Woods et al., 1993[164]; Woods et al., 1994[165]; Gough and Drury, 1996[166]; Smyth and Carroll, 1995[167]; St. Leger et al., 1997[168]
	Senegal dove *(Streptopelia senegalensis)*	Columbid circovirus (CoCV)	Bilaterally symmetrical feather loss and dystrophy	Pass et al., 1994[169]; Raidal and Riddoch, 1997[170]
Coraciiformes	Rainbow bee-eater *(Merops ornatus)*	95.6% similarity to PBFDV	Dystrophic flight feathers with thickened feather shafts, broken remiges, bilaterally symmetric feather loss of primary feathers	Sarker et al., 2015[171]
Galliformes	Common pheasant *(Phasianus colchicus)*	Unknown	Circovirus-like particles found in a commercial pheasant flock, no clinical information retrieved	Terregino et al., 2001[172]

Circovirus Infections in Nonpsittacine Birds—cont'd

Taxonomic Order	Species	Type of Circovirus	Clinical Features	Reference
Passeriformes	Canary *(Serinus canaria)*	Canary circovirus (CaCV)	"Black spot" of neonatal canaries with coelomic distension, gallbladder congestion, failure to thrive and mortality (<7 days). Grossly normal feathering though microscopic changes have been identified	Goldsmith, 1995[173]; Phenix et al., 2001[174]; Todd et al., 2001[175]; Sheykhi et al., 2018[176]
	Gouldian finch *(Chloebia gouldiae)*	Finch circovirus (FiCV)	Progressive beak deformities (elongated beaks with rough surface), feather loss, mortality of young chicks showing weakness, lethargy and ruffling of the feathers	Shivaprasad et al., 2005[177]; Todd et al., 2007[178]; Circella et al., 2014[179]
	Zebra finch *(Poephila castanotis)*	Zebra finch circovirus (ZfiCV)	Mild to severe disease with high mortality caused by secondary infections (commonly *Macrorhabdus ornithogaster*) in nestlings, fledglings, and adult birds. Feathering abnormalities and feather loss can also be observed	Mysore et al., 1995[180]; Rinder et al., 2015[181]; Rinder et al., 2017[182]
	Common starling *(Sturnus vulgaris)*, and spotless starling *(Sturnus unicolor)*	Starling circovirus (StCV)	Detected in apparently healthy and diseased starlings during a mortality outbreak	Johne et al., 2006[183]
	Australian raven *(Corvus coronoides)*	Raven circovirus (RaCV)	Progressive feather defects in juveniles, bilateral feather depigmentation (white feathers) and dystrophy	Stewart et al., 2006[184]
Sphenisciformes	Adélie penguin (*Pygoscelis adeliae*)	Penguin circovirus (PenCV)	Feather loss in juvenile birds	Morandini et al., 2019[185]; Levi et al., 2020[186]
	Chinstrap penguin *(Pygoscelis antarcticus)*	Penguin circovirus (PenCV)	Feather loss in juvenile birds	Levi et al., 2020[186]
Strigiformes	Powerful owl *(Ninox strenua)*, tawny owl *(Strix aluco)*	Spillover BFDV from lorikeets? Tawny owl-associated circovirus (ToCV)	Feather lesions similar to PBFD, possible spillover from BFDV in lorikeets (prey species for the powerful owl); detected in the spleen of a tawny owl during routine evaluation	Sarker et al., 2015[187]; Legnardi et al., 2022[188]
Struthioniformes	Ostrich *(Struthio camelus)*	Circovirus detected on PCR in various tissues from young chicks, but not on histopathology; circovirus-like particles observed in the gut contents by negative contrast electron microscopy, but unknown whether this was of plant or animal origin	Early to late embryonic death, increased mortality and wasting in chicks; circovirus particles were also discovered in the gut contents of an ostrich; clinical presentation of this bird is otherwise unknown	Els and Josling, 1998[189]; Eisenberg et al., 2003[190]
Suliformes	New Zealand king shag *(Leucocarbo carunculatus)*	Suspected viral infection, but not confirmed	Juvenile bird with feather dystrophy, consisting of swollen and flaky calamus of outer four primaries, as well as some primaries that were missing or broken near the base	Melville and Schuckard, 2021[191]

PBFDV, Psittacine beak and feather disease virus; *PCR*, polymerase chain reaction.

observed mostly in juvenile birds, leading to immunosuppression and susceptibility to secondary infections. Upon histopathology, characteristic basophilic inclusion bodies can be found in various organs and tissues (e.g., bursa of Fabricius, liver, spleen). Feather dystrophy and (symmetrical) feather loss, if present, resemble the abnormalities as have been described for psittacine birds.

Avian polyomavirus. Avian polyomavirus (APV) is a nonenveloped virus that is relatively environmentally stable. While all species of parrots can be affected, disease is most common in macaws (*Ara* spp.), conures (*Aratinga* spp.), eclectus parrots, and caiques (*Pionites* spp.). In contrast, disease is rare in Grey parrots, cockatoos, and cockatiels. Passeriformes, including canaries, grass finches, goldfinches, and greenfinches, can also be infected (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).

In affected budgerigars, which are the primary reservoir of polyomavirus, signs include decreased hatchability and embryonic death, abdominal distension, subcutaneous hemorrhages, and feather dysplasia that may resolve after several months (see Chapter 41). Neurological signs may be seen if the cerebellum is affected. Over the course of the disease, primary and secondary feathers on the wings and tail are lost or fail to erupt. In the budgerigar fancy, birds with this presentation are referred to as runners or creepers, and the condition is known as French molt (Figure 32.40).

In other species, the virus typically causes sudden death (especially in chicks <15 days old) at around 10 to 14 days after exposure. In larger parrots, most deaths occur between 20 and 140 days old.

In estrildid finches (grass finches), the virus causes acute mortality in 2- to 3-day-old fledglings, young adults, and mature finches. Survivors may demonstrate poor feather development and misshapen lower beaks.[143]

A presumptive diagnosis is usually based on the history, clinical findings, and pathological features. Definite diagnosis requires serology or PCR testing of cloacal swabs, blood, or tissues. However, due to the short viremia and irregular shedding, many false-negative results are obtained. Definite diagnosis may therefore sometimes require histopathologic examination of tissue samples which identifies the presence of basophilic intranuclear inclusion bodies in various tissues (e.g., liver, spleen, kidney, and feather follicles).[192] No specific treatment for polyomavirus infection currently exists. A commercially available polyomavirus vaccine is available in the United States to protect nestlings of large parrots in aviaries. To prevent the spread of the disease, hygiene and quarantine measures like those discussed for PBFD are recommended. PCR testing will help to identify viremic and/or shedding birds. Temporary cessation of breeding in flocks of affected budgerigars can also help to reduce horizontal and vertical transmission of the disease (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).

Bacterial infections. Folliculitis (inflammation of the feather follicles) can develop in response to invasion with (secondary) bacterial pathogens. Bacteria that have been implicated in folliculitis include *Staphylococcus* spp., *Aeromonas* spp., and *Mycobacterium* spp.[193,194] Birds with folliculitis typically present with perifollicular swelling and erythema. Often, multiple feathers are affected. Birds may furthermore show signs of pruritus and/or pain, which may be expressed by restlessness, shivering, and/or feather-damaging behavior (FDB). If the bacterial organisms invade the skin, signs of dermatitis can also be present (Figure 32.41). To identify which bacteria are involved, an affected feather may be pulled and aseptically opened, after which the pulp may be cytologically examined using specific stains (e.g., Gram stain) and/or cultured. Alternatively, histologic examination of feather follicle biopsies may be considered. Choice of antibiotics is preferably based on results of a culture and sensitivity testing.

Fungal infections. Fungal infections affecting the feathers are uncommon but can be seen in all avian species. Fungal species involved include *Candida albicans*, *Malassezia pachydermatis*, dermatophytes (*Microsporum gallinae*, *M. gypseum*, *Trichophyton verrucosum*, other *Trichophyton* spp.), *Cryptococcus*

FIGURE 32.40 Avian polyomavirus infection in a juvenile budgerigar *(Melopsittacus undulatus)*. Known as "French molt" this condition causes the loss of remiges and rectrices, rendering the bird unable to fly (they are known as "runners" or "creepers").

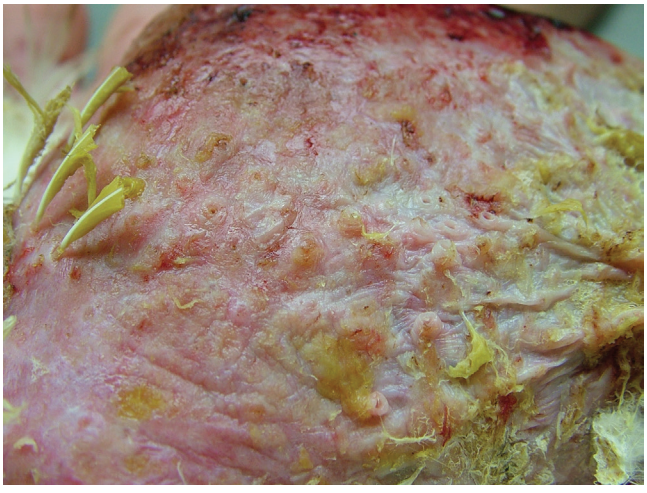

FIGURE 32.41 Bacterial dermatitis developing following a dog bite in a galah *(Eolophus roseicapilla)*. (Photo courtesy Bob Doneley.)

bacillisporus (formerly *C. neoformans* var. *gattii*) and *C. neoformans* var. *grubii* (formerly *C. neoformans* var. *neoformans* serotype A), and *Aspergillus* spp.[90]

Candida causes lesions around the commissures of the mouth and nares and occasionally around feather follicles on the head, back, and ventral abdomen. *Malassezia* results in generalized pruritus, sometimes with crusting and folliculitis.[90] Dermatophytes are a slow-spreading infection causing scabs, crusts, and alopecia on the body and thin-skinned areas of the head and upper beak, and a rough, porous appearance of the podotheca. In gallinaceous birds the characteristic scaly, crusty lesions of the wattle, comb, and legs are known as "favus" (Figure 32.42).[90] *Cryptococcus* has been reported to cause subcutaneous nodules on the head and body and raised nodular lesions on the face and beak (see Chapter 21).[90] Cutaneous aspergillosis has been associated with focal ulcerative pruritic lesions.[90]

Diagnosis generally requires biopsy and culture. Cytology must be used with caution: feather dust stains similarly to yeast organisms and can be nearly impossible to distinguish from yeast bodies. In affected birds, a systemic treatment with antifungal drugs such as voriconazole, itraconazole, fluconazole, clotrimazole, and terbinafine is often initiated, though topical therapy (e.g., miconazole) may be considered if lesions are localized. Depending on the pathogen involved, treatment periods of 3 weeks or more are required to clear the infection.

External parasites. Ectoparasites are commonly found on wild and aviary birds, but somewhat less common on companion birds. These parasites may inhabit the skin and/or feathers and are usually detected upon microscopic examination of the pulp and/or vane of a damaged or developing feather.

Mites are the most important and commonly encountered external parasites of birds. Adult mites have eight legs; the larval stage has six legs.[143]

FIGURE 32.42 Ringworm (or favus) in a chicken *(Gallus gallus domesticus)* showing feather loss and characteristic skin changes that give the appearance that flour is sprinkled over the bird. Ringworm or dermatophytosis in chickens is usually caused by the dermatophytic fungus *Trichophyton megninii*, although infections with *Trichophyton simii, Microsporum gypseum,* and *Microsporum gallinae* have also been reported. (Photo courtesy Bob Doneley.)

Knemidocoptes pilae (scaly face mite). Many species of mites cause mange in birds. The most common are *K. mutans* of poultry[195,196] and *K. pilae* in budgerigars,[197,198] other psittacines[199–202] and canaries.[91,203] The mites spend their entire life on the bird. The lesions can occur on any featherless part of the skin and are characterized by raised honeycombed encrustations on the cere, beak, eyelids, and feet (see Chapter 31). Occasionally it becomes generalized and affects feather follicles.[143] If left untreated for a longer time, severe and permanent beak deformities can occur, which could interfere with eating and may warrant regular trimming.[204] Occurrence of beak keratoacanthomas has also been associated with former *Knemidocoptes* infection.[205] Diagnosis can readily be made by means of cytology of superficial and deep skin scrapings of affected areas. Treatment consists of use of avermectins (e.g., ivermectin, selamectin), which generally results in clinical resolution of signs and negative scrapings within 2 to 4 weeks.[198,206,207] Fipronil is also effective against scaly mites.[207] In chickens, topical application of petrolatum products is commonly practiced by owners.[208]

Dermanyssus gallinae (red or roost mites). Red mites *(Dermanyssus gallinae)* live in the environment where they can survive long periods without feeding. The mite feeds on the host's blood at night and leaves it in the day to hide in cracks and crevices of the enclosure. The mites can cause skin irritation, scaliness, and anemia (especially in juveniles or small birds). Heavy infestations may kill chicks in the nest box. Because the mite is not permanently present on its host, it can be difficult to confirm the diagnosis. Elimination of the mites usually requires treatment of the host, contact birds, and environment with synthetic acaricides that have activity against *D. gallinae* (e.g., fluralaner, phoxim[209–211]; see Chapter 9). Other measures for control include the use of predatory mites (mainly in subclinical, mild infestations),[212] silica dusts, and changing the enclosure design such that hiding places for the mites are minimized by using slatted floors and laying nest floors with more open structures.[213–215]

Ornithonyssus spp. (fowl mite). Fowl mites (*Ornithonyssus* spp.) are host-dependent blood-sucking mites which remain on the bird, where they congregate at the eyelids and vent. They may cause anemia, pruritus, and damaged plumage. In contrast to red mites, fowl mites are easily observed on the bird. Over-the-counter insecticides, which are available in both powder and spray application, are effective to eliminate the parasites. Oral or injectable (200 μg/kg) ivermectin can also be used. Recently, fluralaner (Exzolt, MSD Animal Health, Macquarie Park, Australia) was registered as an in-water medication for poultry for ectoparasite treatment.

Epidermoptic mites. The group of epidermoptic mites includes *Myialges* spp., *Epidermotes* spp., and *Microlichus* spp. The hippoboscid fly may carry them mechanically. They cause depluming dermatitis with scale formation in passerines.[89,90] Diagnosis is based on the skin lesions, associated with the presence of mites. Treatment is like that of other mites (see Chapter 9).

Quill mites. The group of quill mites includes *Syringophilus* spp., *Dermoglyphus* spp., *Pterolichus* spp., *Analges* spp., and *Harporhynchus* spp. Their entire life cycle is spent on the host. They cause partial or complete feather loss. Quill mites predominantly live and reproduce inside the feather quills where they feed on the available tissue and secretions. When present

in large numbers, they may cause damage to the feathers by destroying the medulla from the quill to the rachis. Affected quills tend to break or bleed easily and may change in appearance from transparent to opaque. Although most quill mites primarily feed on the keratin and medulla of the feather quills, quill wall mites (e.g., *Syringophilus* spp.) primarily feed on feather follicle fluid and outer, nonkeratinized layers of the feather germ of developing feathers, thereby triggering hyperkeratosis of the feather sheath. They can be found by examining the pulp material within a developing or damaged feather.[9,10] Treatment consists of use of topical or parenteral avermectins (e.g., ivermectin, selamectin, moxidectin) and/or other topical acaricides (e.g., permethrin, pyrethrin, fipronil; see Chapter 9).[216] Alternatively, fluralaner, which was recently registered for use in poultry in several countries, can be added to the drinking water.

Feather mites. Feather mites (e.g., *Protolichus*, *Dubininia* spp.) live between the barbs of the contour, wing, and tail feathers and primarily feed on the feather fragments and skin debris (Figure 32.43). Feather mites are generally considered nonpathogenic but may cause problems when present in high numbers, in non-host-adapted species, or in birds with a compromised immune system. The mites, which may be identified as tiny dark spots of grains of sand on the ventral surface of feathers, may cause irritation (leading to FDB) and induce feather lesions such as darkened areas, dots or stripes on bright feathers, or bright dots and stripes on dark feathers. Diagnosis and treatment are like that described for quill mites.

Lice. Lice are six-legged, wingless, crawling external parasites with chewing mouthparts (note: sucking lice do not infect birds). They are species-specific and usually cause little feather damage.[90] There are many hundreds of species of lice found on birds, including the following:

- Biting lice of parrots include *Neopsittaconirmus*, *Psittaconirmus*, *Eomenopon*, and *Pacifimenopon*.
- Biting lice of pigeons include the Philopteridae and Menoponidae families.
- Biting lice of raptors include *Mallophaga* spp.
- Biting lice of chickens include Menoponidae lice (*Menacanthus* spp., *Menopon gallinae*), *Oxylipeurus* spp., *Goniodes* spp., *Cuclotogaster* spp., and *Lipeurus* spp.

Lice usually live on just the one host. Eggs are attached to feather shafts and hatch in 4 to 7 days. Nymphs go through three molts before maturing. The adults feed on skin scales, feather debris, and hair, and, in large numbers, may cause pruritus and poor feather quality. Diagnosis is made by direct visualization of the lice, nymphs, or eggs. As lice undergo a complete life cycle on the host, weekly treatments with topical acaricides (e.g., permethrin, fipronil), or fluralaner in the drinking water, usually suffice to eliminate the infection.

FIGURE 32.43 Unknown species of lice on the feathers of a budgerigar *(Melopsittacus undulatus)*. These are common and rarely cause problems. (Photo courtesy Bob Doneley.)

CHANGES IN FEATHER COLOR

Color in birds is the result of a combination of feather structure (affecting the passage or reflection of light) and a variety of pigments—melanins, carotenoids, and porphyrins (see section on Feather Color). The colors that these pigments produce are modified by how they are laid down in the feather; the presence, absence, and interactions between each other; and the air cells in the feather (affecting the passage of light). Anything that affects these combinations can change the color of the feathers (see also Box 32.3; Figure 32.44).

Genetically Acquired Color Mutations

Genetically acquired color mutations are often highly sought after by aviculturists and are the result of selective breeding. Most of these mutations are obvious at fledging, but some develop in intensity as the birds go through successive molts. The bird's genetic makeup may affect the deposition of feather pigments directly or indirectly (e.g., through the production of enzymes that alter dietary carotenoids).[218]

Molting

Molting may affect feather coloration. Hormonal influences (e.g., sex hormones, thyroxine) can induce a molt at the beginning and end of the breeding season and, in some species, the coloration of the birds may change dramatically just prior to the breeding season (the prenuptial molt)—an important social signal to other birds. Molting is, however, an expensive exercise requiring a lot of energy and resources. Consequently, not all avian species will show dramatic changes in coloration.

Black Marks

Black marks are commonly seen in green- or blue-colored companion birds that are given a lot of attention, involving physical and hand contact (Figure 32.45). The black marks are due to the owner's hand oils, passed on when cuddling the bird, and may be due to either a harmless fungal growth or, again, a change in reflected light. They are not seen on birds that produce powder down (cockatoos and Grey parrots).

Black/Brown Scalloping

Black or brown scalloping on the margins of feathers is often associated with a delayed or imminent molt. The ends of the vane become worn and tattered and lose their structure, that is, the barbules are no longer interlocking. This changes reflective color and gives a black or brown scalloping effect (Figure 32.46).

BOX 32.3 NOMENCLATURE FOR (GENETIC) COLOR ABNORMALITIES IN BIRDS[217]

Color Abnormality	Synonym(s)	Morphologic Appearance	Cause	Consequences
Total amelanism	(Total, complete, perfect, pure, or true) albinism, complete albinism, all white.	Absence of all melanin from the plumage, eyes, and skin, which results in an all-white plumage, pink eyes, and light, often pink, skin if other pigments are also lacking; if present, other pigments remain unaffected.	Genetic mutation blocking the production or activity of tyrosinase, a key enzyme in the synthesis of melanin pigment. Usually a recessive trait, which can both be autosomal and sex-linked.	Absence of melanin leads to light-sensitivity and reduced visual acuity, which can affect food-locating capacity and increase the risk of bird falling victim to predators, traffic or other hazards; may also affect attractiveness to potential mates, and reduce fitness as feathers are less resilient in absence of melanin.
Partial amelanism	(Partial, semi- or incomplete) albinism, leucism, schizochroism, piebaldism, white spotting, abnormal white, and Pealea phenomenon; individuals partial amelanism have been dubbed pied, splashed, or variegated.	Abnormal absence of all melanin from parts of the plumage, skin, eyes, or all three areas; expression can vary from a single white spot on a feather to an all-white plumage. Melanin usually remains to a certain extent in the eyes, aiding in distinction from total amelanism.	Diminished tyrosinase activity, resulting from both hereditary (genetic) and nonhereditary (environmental) factors. Hereditary forms are nonreversible and can be recessive or dominant, sex-linked or autosomal. Nonhereditary forms are reversible and can result from, e.g., malnutrition, intoxications, injury, (systemic) diseases, parasitic infections, hormonal influences (e.g., testosterone), shock, and old age.	Mostly similar effects to total amelanism except for reduced visual acuity as melanin pigment is often maintained in the eye.
Hypomelanism (total or partial)	Leucism, (partial, imperfect, dilute) albinism, dilution, dilutism, ghosting, paling, isabellism/isabellinism, chlorism/chlorochroism; individuals with the condition are referred to as faded, frosted, or bleached.	Abnormal reduction of melanin concentration from the plumage, skin, eyes, or all three areas, resulting in a faded appearance. Extent of pigment dilution is variable, ranging from slightly pale to nearly white plumage; distinct patterns (e.g., tail bands, eye lines) are usually retained.	Can be hereditary (recessive or dominant) or nonhereditary; one or both types of melanin can be affected.	Effects on survival and reproduction are likely to vary dependent on the species involved and the type and extent of the condition.
Aeumelanism	Schizochroism, schizochromatism, schizomelanism, imperfect albinism, and isabellism; individuals with this condition are referred to as buff, fawn, or cinnamon.	Abnormal absence of eumelanin from the plumage, skin, eyes, or all three areas, resulting in a pale plumage in which the melanic areas are usually some shade of fawn, brown, or rufous. Other nonmelanin pigments are unaffected.	Inherited as a sex-linked, recessive trait, thereby more common in heterozygous females.	Effects on reproduction and survival in the wild are likely to vary, but no deleterious effects proven.

BOX 32.3 NOMENCLATURE FOR (GENETIC) COLOR ABNORMALITIES IN BIRDS—cont'd

Color Abnormality	Synonym(s)	Morphologic Appearance	Cause	Consequences
Aphaeomelanism	Schizochroism, schizochromatism, schizomelanism, imperfect albinism, and isabellism; individuals with this condition are referred to as gray or silver.	Abnormal absence of phaeomelanin from the plumage, skin, eyes, or all three areas, resulting in a pale plumage in which the melanic areas are usually some shade of black or gray, often ash-gray. Other nonmelanin pigments are unaffected.	Inherited as an autosomal recessive trait with equal distribution among males and females.	Effects on reproduction and survival in the wild are likely to vary, but no deleterious effects proven.
Hypermelanism	Melanism, nigrism.	Abnormally high melanin concentration in the plumage, skin, eyes, or all three areas, resulting in a (fully or partially) darker than normal plumage.	Increase in concentration of one melanin type (hypereumelanism or hyperphaeomelanism). Both hereditary (usually autosomal, recessive, or dominant) and nonhereditary forms exist.	Effects on reproduction and survival in the wild are likely to vary, with nonhereditary forms (e.g., due to malnutrition) likely associated with reduced fitness. Certain hereditary forms could be advantageous (e.g., black morphs are less prone to bacterial degradation of feathers).
Carotenism (Figure 32.44)	Xanthism, xanthochroism, flavism, erythrism, cyanism, (partial) albinism; individuals with carotenism are referred to as lutinos.	Abnormal carotenoid pigmentation; occurs only in species that normally display carotenoids in their plumage or unfeathered areas.	Can result from one or more of four causes: (1) change in the normal distribution or extent of carotenoid pigments; (2) increase or decrease in carotenoid concentration, resulting in a change in color or color intensity; (3) change in carotenoid pigment type and therefore a change in color; and (4) total absence of carotenoids from all or part of the plumage or skin. Often results from dietary factors during or just prior to molt, but can also result from a genetic mutation disrupting the carotenoid metabolism.	Effects on survival and reproduction are likely to vary.

Malnutrition

Malnutrition will affect both the feather structure and the amount and type of pigments in the feather. Dietary deficiencies can result in a lack of carotenoids or enzymes to modify them and result in the yellowing of green plumage or fading of feather color. Choline and riboflavin deficiencies in cockatiels can cause achromatosis of primary feathers, and a deficiency in tyrosine or copper can interfere with melanin production causing dark feathers to become lighter. Malnutrition can also lead to changes in feather structure and therefore reflective color. It is not only nutritional deficiencies that can affect coloration; dietary excesses in some hand-rearing formulations and pelleted foods may be associated with yellow feathers and bands in eclectus parrots of both sexes (Figure 32.47). Most nutrition-related changes in feather color will correct after a diet change and the following molt.[90]

Viral Diseases

Viral diseases such as PBFD can also affect feather color through changing reflective color. Green birds such as

FIGURE 32.44 Yellow-naped Amazon parrot *(Amazona auropalliata)* with genetic color mutation resulting in complete absence of carotenoid pigment from the plumage, hence providing the bird with a blue-white rather than green-yellow-colored plumage. (Photo courtesy Yvonne van Zeeland/Nico Schoemaker.)

FIGURE 32.46 Worn margins on feathers are often associated with a delayed or imminent molt. The ends of the vane become worn and tattered and lose their structure, that is, the barbules are no longer interlocking. (Photo courtesy Bob Doneley.)

FIGURE 32.45 This moustache parrot *(Psittacula alexandri)* shows two color changes. The first is the genetically selected color change to blue (color mutation). The second is the black scalloping on the feathers associated with human hand oils after prolonged handling. (Photo courtesy Bob Doneley.)

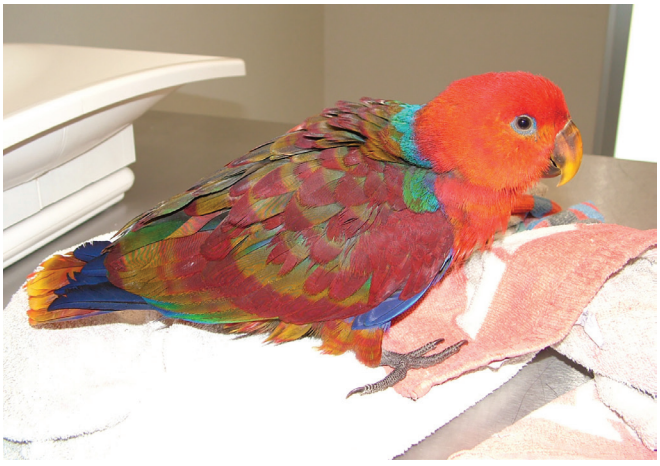

FIGURE 32.47 Dietary excesses in some hand-rearing formulations and pelleted foods may be associated with yellow feathers and bands in eclectus parrots *(Eclectus roratus)* of both sexes. (Photo courtesy Bob Doneley.)

lorikeets develop yellow patches; blue feathers in color mutation birds turn white; gray feathers in Grey parrots may turn red (Figure 32.48).[143]

Systemic Disease

Systemic diseases can affect feather coloration. Liver disease and hypothyroidism may affect the deposition of pigments in the feathers, altering their color. A lack of normal preening behaviors in an unwell bird may lead to structural changes, often giving the feathers a dull appearance.

FEATHER LOSS

In most companion birds presented with feather loss, the loss of feathers is the result from the bird (or a cage mate) pulling out its feathers. This behavior and its underlying medical and behavioral causes are considered in the next section (Feather-Damaging Behavior). Feather loss may occasionally also occur in the absence of this behavior. In most of these cases, the underlying disease damages the feathers or follicles in such a way that they are easily lost or shed.

The differential diagnosis for feather loss without the presence of FDB should include the following[92,193,219–221]:

- Normal apteria or normal molt (not recognized as such by the inexperienced parrot owner).

FIGURE 32.48 (A) Grey parrot with red discoloration of several of the coverts. This type of color change has been associated with various conditions including liver disease, psittacine beak and feather disease (PBFD), and malnutrition. However, it can also be seen in normal young Grey parrots and in areas of scarred skin. (B) A postmortem specimen of a lesser vasa *Coracopsis nigra* shows many randomly distributed white feathers. This bird contracted PBFD while being hand-reared with a group of other birds, including cockatoos. It died soon after fledging. (A, Photo courtesy Nico Schoemaker/Yvonne van Zeeland. B, Photo courtesy Nigel Harcourt-Brown.)

- Excessive or irregular molt induced by malnutrition or irregular photoperiod.
- Prior damage to the feather follicle resulting in cessation of feather growth.
- Genetic conditions (e.g., baldness in lutino cockatiels).
- Obesity, resulting in alopecia over the breast (particularly in budgerigars).
- Ectoparasites (e.g., *Knemidocoptes* spp., feather and quill mites, lice).
- Clinical manifestation of PBFD or polyomavirus infection.
- Mycotic infections, including candidiasis, *Malassezia* dermatitis, and dermatophytosis.
- Bacterial dermatitis and abscesses.
- Neoplastic skin disease including xanthomas.
- Systemic disease including hepatopathies and nephropathies.
- Endocrinopathies such as hypothyroidism.

Often, the feather loss will remain localized (e.g., in case of obesity or neoplastic disease), but generalized feather loss may also occur (e.g., in case of PBFD). Based on the distribution of feather loss certain diseases may be ruled out. In addition, diseases may be ruled out based on the presence or absence of skin damage or skin lesions.

Diagnostic workup of patients presented with feather loss should always begin with a thorough history and full physical and dermatologic examination. Additional diagnostic testing may be indicated based on the likely differential diagnoses established. In addition to specific treatment based on a diagnosis, contributing factors such as suboptimal diet, housing, environment, and management may be corrected as well.

Feather-Damaging Behavior

FDB can be broadly grouped into FDB inflicted by other birds and self-inflicted FDB.

Feather-damaging behavior inflicted by other birds

FDB inflicted by other birds is most seen in parrots, finches, and poultry. The following behaviors have been observed:

- Nestling parrots that have their feathers chewed by the parents, perhaps as a learned behavior (the parents were feather-picked themselves as chicks) or to remove the chicks from the nest so the hen can lay again. Mild cases involve removal of feathers, usually from the back, dorsal wings, and head. Severe cases will see the parent(s) remove wing tips or toes, or even kill the nestling. Affected chicks may be best removed for hand-rearing. They should not be used for breeding if possible.
- Breeding pairs that pull feathers from the head and face of their mate (Figure 32.49), often at the beginning of the breeding season, perhaps as the result of mismatched libido and readiness to breed. Both hens and cocks will pluck feathers from their mate.
- Overcrowding of enclosures holding finches, budgerigars, *Agapornis* spp., and *Neophema* spp. (particularly in pet shops) can lead to feather loss on the head and face, perhaps as a stress response by the birds inflicting the damage. Affected birds and, if possible, the offending bird(s) should be removed. Stocking density and stress factors need to be addressed and corrected. Foraging activities and toys should be provided and strategically enriched for birds that

FIGURE 32.49 Green-winged macaw *(Ara chloropterus)* with feather loss on the head as a result of plucking by its partner. (Photo courtesy Nico Schoemaker/Yvonne van Zeeland. Reprinted from van Zeeland YRA, Friedman SG, Bergman L: Behavior. In Speer BL, editor: *Current Therapy in Avian Medicine and Surgery*, Vol 1, St. Louis, MO, 2016, Elsevier, pp 177–251.)

FIGURE 32.50 (A) Excessive feather pecking and (B) cannibalism are commonly seen in poultry because of overcrowding. Similar injuries may also occur in other avian species when returning a recently deflighted individual back into the flock. (A, Photos courtesy Bas Rodenburg. B, Photos courtesy Elske de Haas.)

appear to be indulging in this behavior due to a lack of environmental enrichment.

- Poultry that are overcrowded will frequently display FDB toward other chickens, including the removal of feathers on the backs and pericloacal regions (Figure 32.50). Again, stocking density and stress need to be addressed.

Self-inflicted feather-damaging behavior

FDB, also referred to as feather-destructive behavior, feather plucking, feather picking, or pterotillomania,[222–224] has been reported in approximately 10% to 15% of captive parrots (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). FDB includes the chewing, plucking, biting, or pulling of feathers,[225,226] which can inflict more or less extensive damage to feathers in areas that are easily accessible to the beak (i.e., neck, chest, flanks, inner thighs, and wings; Figures 32.51 and 32.52).[222,227] While consequences of this self-inflicted feather damage may seemingly be merely aesthetic, medical issues can arise due to alterations to the birds' thermoregulatory abilities and metabolic demands and/or the development of hemorrhage and/or (secondary) infections.[227–229]

Although FDB may be noted in all psittacine species, it appears to be most common in Grey parrots, cockatoos, and eclectus parrots, with reported prevalence of up to 40%.[230] In contrast, it is less common in Amazon parrots (*Amazona* spp.), cockatiels, and budgerigars.[231–233]

Determining whether the feather damage is self-inflicted or due to a medically or environmentally related condition that causes loss or damage to the bird's plumage (irrespective of its behavior) can be difficult. First, birds are often left unobserved throughout a specific portion of the day, which limits the owner's ability to properly observe the bird's behavior. Second, it can be difficult for the owner to distinguish FDB from normal preening behavior, as both may follow the same pattern (Figure 32.53).[234]

In birds with self-inflicted feather damage or loss, it will be important to identify whether the behavior is primarily related to a medical condition that results in FDB due to the associated pruritus, pain, or other discomfort (which thereby acts as an antecedent to the behavior); whether that the behavior relates to an inadequate husbandry, management, and/or nutrition that affects the feather quality (hence signaling the behavior); or if there is a psychological underpinning to the behavior which stems from an attempt to deal with a suboptimal living environment (so-called *maladaptive behavior*) or an abnormal psyche or altered brain neurochemistry (i.e., an

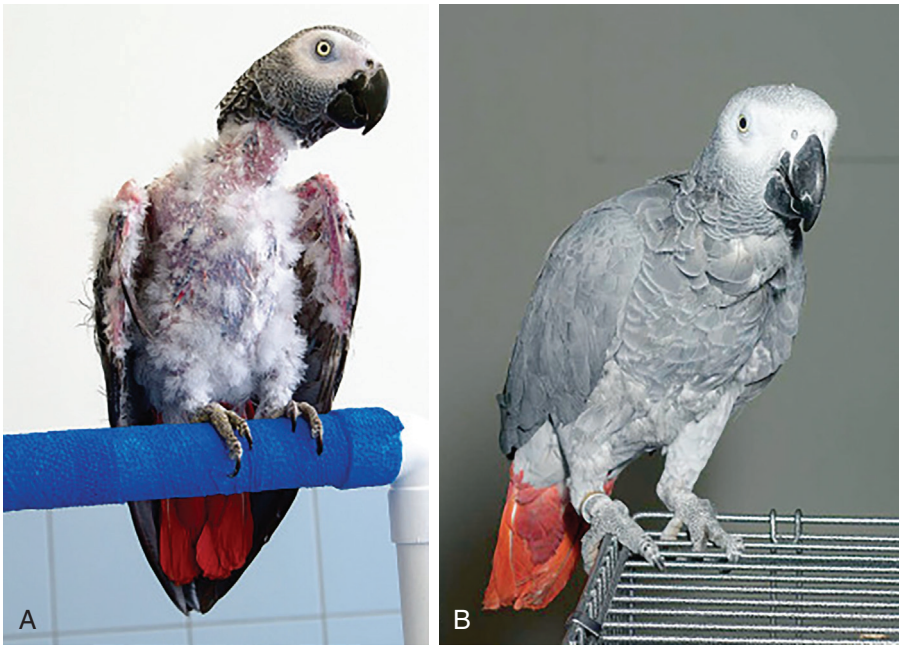

FIGURE 32.51 These two Grey parrots *(Psittacus erithacus)* demonstrate the typical appearance of a bird with self-inflicted feather-damaging behavior, as indicated by their normally feathered head. Severity of the feather damage may vary from case to case, resulting in (A) more or (B) less extensive loss of or damage to feathers. (Photo courtesy Nico Schoemaker/Yvonne van Zeeland. Reprinted from Paul-Murphy J, Wensley Koch V, Briscoe JA, et al: Advancements in management of the welfare of avian species. In Speer BL, editor: *Current Therapy in Avian Medicine and Surgery*, Vol 1, St. Louis, MO, 2016, Elsevier, pp 669–718.)

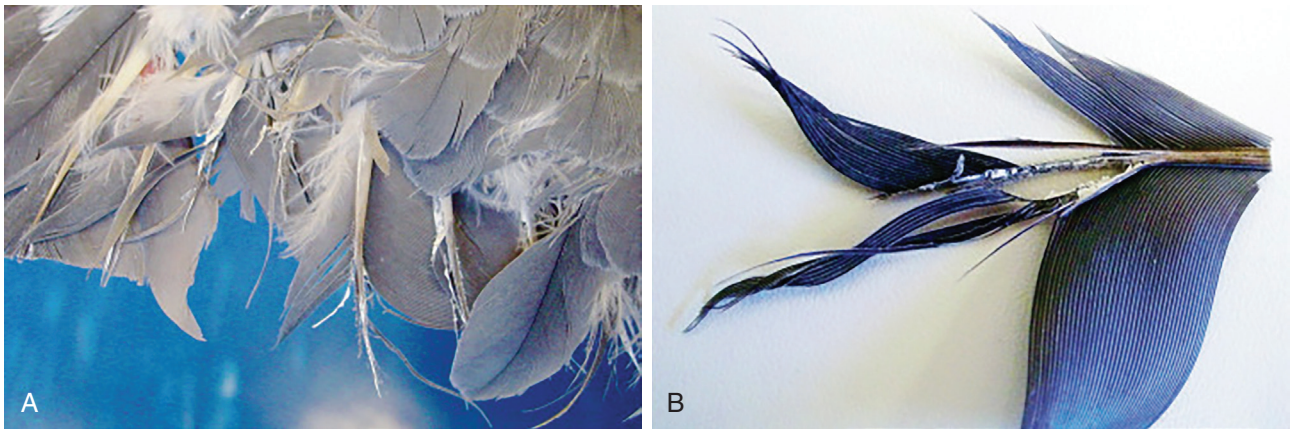

FIGURE 32.52 (A, B) Chewed and frayed feathers often have an irregular appearance, as can be seen in these feathers. (Photo courtesy Nico Schoemaker/Yvonne van Zeeland. From van Zeeland YRA, Friedman SG, Bergman L. Behavior. In Speer BL, editor: *Current Therapy in Avian Medicine and Surgery*, Vol 1, St. Louis, MO, 2016, Elsevier, pp 177–251.)

abnormal repetitive behavior or *malfunctional behavior*). Determining an exact cause often proves challenging, especially since multiple factors usually play a role and these behaviors do not reside in simple linear causality. These factors can make it challenging to effectively treat and reduce or eliminate the behavior.

Etiological Considerations

FDB often is a multifactorial problem, in which various medical, genetic, neurobiologic, and socioenvironmental factors can play a role (Table 32.2).[235] Numerous medical conditions have been associated with FDB, but in most cases it is difficult to prove a causal relationship. In essence, any disease or condition that causes pain, discomfort, anxiety, irritation, and/or pruritus could result in the development of FDB, which in turn can become a reinforced behavior due to a perceived consequential value that results from the behavior. Such conditions may both include primary feather and skin diseases as well as systemic diseases (Table 32.2).[193,233,235–243] In case of systemic disease, feather damage may either be

FIGURE 32.53 Grey parrot *(Psittacus erithacus)* in the process of removing a tail feather. Without the owner directly witnessing the removal of a feather, it might be hard to distinguish feather-damaging behavior from normal preening. (From van Zeeland YRA, Friedman SG, Bergman L: Behavior. In Speer BL, editor: *Current Therapy in Avian Medicine and Surgery*, Vol 1, St. Louis, MO, 2016, Elsevier, pp 177–251.)

TABLE 32.2

Factors Suggested to Be Involved in Feather-Damaging Behavior in Parrots

Environmental/Extrinsic Factors	Medical Factors	Intrinsic (Psychological) Factors
◆ Inadequate enrichment, lack of opportunities to perform species-specific behaviors, e.g., foraging, social interaction, flying ◆ Lack of choice or control over the environment ◆ Sudden changes to the environment ◆ Exposure to aversive, threatening stimuli (e.g., predators, novelty) ◆ Small cage or poor cage design with little space for the parrot to move around or fly ◆ Social isolation ◆ Overcrowding ◆ Reinforcement by actions of the owner ◆ Airborne and/or topical toxins, including cigarette smoke, scented candles, air fresheners, hand lotions, and creams ◆ Low humidity levels, lack of bathing opportunities ◆ Abnormal photoperiod ◆ Poor wing trim ◆ Trauma	◆ Ectoparasites (e.g., feather or quill mites, lice) ◆ Bacterial or fungal dermatitis/folliculitis (e.g., *Staphylococcus, Aspergillus, Malassezia*) ◆ Chlamydiosis ◆ Viral infections (e.g., polyomavirus, PBFD, avian bornavirus) ◆ Skin neoplasia (e.g., xanthoma, lipoma, SCC) ◆ Hypersensitivity, skin allergy ◆ Airsacculitis, pneumonia ◆ Cardiovascular disease (e.g., atherosclerosis) ◆ Liver and/or renal disease ◆ Hypocalcemia ◆ Endocrinopathy: hypothyroidism/diabetes mellitus ◆ Reproductive disease (e.g., egg binding) ◆ Heavy metal toxicosis (e.g., lead, zinc) ◆ Nutritional deficiencies (e.g., hypovitaminosis A) and/or dietary imbalances ◆ Gastrointestinal disease, e.g., colic, endoparasitism (particularly giardiasis in cockatiels) ◆ Obesity ◆ Orthopedic disorders (e.g., osteosarcoma, fracture, osteomyelitis, osteoarthritis) ◆ Neuropathy (e.g., spinal disorders)	◆ Hand-rearing and imprinting on humans ◆ (Sexual) hormones ◆ Boredom ◆ Frustration ◆ Stress ◆ Anxiety ◆ Attention seeking behavior ◆ Abnormal repetitive behavior resulting from neurotransmitter deficiencies and/or excesses (e.g., serotonin, dopamine, endorphins), similar to obsessive-compulsive or impulsive disorders

PBFD, Psittacine beak and feather disease.

diffuse and generalized or localized directly over the region of discomfort. Renal disease, for example, may appear to induce FDB in the region of the synsacrum,[244,245] whereas hepatic disease may either induce feather damage that is limited to the ventral portion of the body or follows a more diffuse, generalized pattern.[138,246]

A commonly encountered risk factor for FDB also includes inappropriate husbandry, management, or nutrition (Table 32.3). A small cage or poor cage design may cause damage to the feathers, in particular the primaries and tail feathers. As a result, the bird may remove the damaged feathers, which should be considered as normal behavior.[236] Other environmental risk factors that have been implicated in FDB include nutritional deficiencies and dietary imbalances; airborne and topical toxins; low humidity levels and abnormal photoperiods, which can all affect the quality of the plumage and thereby stimulate the bird chew, pluck, or over preen its feathers.[221,235,236]

Almost regardless of whether a medical or environmental basis can or cannot be found for FDB, behavioral and/or psychological factors should always be considered. In general, two possibilities should be taken into consideration when a psychogenic FDB is suspected: (1) the behavior concerns maladaptive behavior, which results from an attempt of the animal to adapt to a suboptimal, inadequate living environment that either lacks appropriate stimuli to allow normal, species-typical behavior(s) or exposes the bird to aversive stimuli; and (2) the behavior represents an *abnormal repetitive* or *malfunctional behavior* which results from an abnormal psychology, brain development, or neurochemistry (potentially induced due to long-term exposure to an inadequate living environment).[247,248] Although the two are not separate entities per se and may even represent consecutive phases of the same disorder, the ability to make a distinction between the two may be of particular importance when considering the success of future therapeutic interventions. Whereas maladaptive behavior may benefit from changes to the environment that help to optimize the bird's living conditions, malfunctional behavior may show a lack of response to these measures and will more likely require the use of psychopharmaceutic drugs to reduce the behavior.

The list of factors that contribute to the development and maintenance of psychogenic FDB is numerous and includes

TABLE 32.3

Diagnostic Tests to Be Performed in Birds With Feather Abnormalities, Including Their Indications

Diagnostic Test	Indication(s)
Complete blood count and biochemistry	Hepatopathy, nephropathy, generalized infection or inflammatory process, diabetes mellitus, hypocalcemia
Toxicology	Suspected lead or zinc toxicosis. Collect heparinized whole blood (lead) or plasma/serum in nonrubber plastic or glass tubes
TSH stimulation test	Hypothyroidism
Fecal cytology (including wet mount and/or flotation)	Giardiasis (common in cockatiels), helminth infection, candidiasis, *Macrorhabdus ornithogaster* infection (avian gastric yeast), bacterial gastroenteritis
Radiology	Heavy metal intoxication, reproductive disorder (e.g., egg binding), hepato-, spleno- or renomegaly, proventricular dilatation disease, pneumonia, airsacculitis, neoplastic conditions, musculoskeletal disease (e.g., osteoarthritis, osteomyelitis, fractures, osteosarcoma)
Ultrasound	Hepatomegaly, reproductive disorders (e.g., egg peritonitis, cystic ovary), neoplastic conditions, cardiac disease, ascites
Endoscopy	Airsacculitis, hepato- or nephropathy, splenomegaly, pancreatic disorders, reproductive disease
Skin scrapings	Ectoparasites, in particular mites (e.g., *Knemodicoptes*)
Impression smear, swab cytology, or tape strip	Bacterial or fungal dermatitis, dermatophytosis, *Malassezia*, *Candida*, ectoparasites (e.g., feather mites, lice), pox virus
Fine needle aspirate	Skin neoplasia, xanthomatosis, feather follicle cyst, hematoma, bacterial dermatitis or abscess
Feather digest (using potassium hydroxide)	Ectoparasites (quill mites)
Feather pulp cytology	Bacterial or fungal folliculitis, PBFD or polyomavirus infection, quill mites
Culture	Bacterial or fungal dermatitis, folliculitis
Skin and/or feather follicle biopsy (histopathology)	Various infectious, inflammatory, and/or neoplastic skin diseases, e.g., PBFD, polyomavirus, bacterial and fungal folliculitis, quill mite infestation, xanthomatosis, squamous cell carcinoma, feather follicle cysts
Intradermal skin testing	Hypersensitivity reactions, allergic skin disease. Thus far not found to be reliable due to the bird's diminished reaction to histamine
Tests for specific causative agents	◆ PCR testing on whole blood, feather pulp or tissue for PBFDV ◆ PCR testing on fecal swab or tissue for presence of polyomavirus ◆ PCR on cloacal swab/feces and/or serologic testing for ABV ◆ PCR on conjunctival/choanal/cloacal swab and/or serologic testing for *Chlamydia psittaci*

ABV, Avian bornavirus; *PBFDV*, psittacine beak and feather disease virus; *PCR*, polymerase chain reaction; *TSH*, thyroid-stimulating hormone.

many socioenvironmental factors (Table 32.2).[233,235,249–253] In addition, the behavior may be exacerbated by inappropriate responses by the owner (e.g., punishing or attempting to distract the bird while it is damaging its feathers) as these responses may serve to reinforce the behavior.[254,255] Intrinsic reinforcements of the behavior should also be considered. Neurotransmitter deficiencies and/or excesses (e.g., dopamine, serotonin, endorphin) and a genetic background have also been proposed.[235,256]

FDB has particularly been linked to the lack of foraging opportunities in a captive environment. As a result, time spent foraging is drastically decreased: whereas wild parrots spend up to 6 hours daily on searching, selecting, and manipulating food,[257] captive birds usually consume their daily food ration within 30 to 72 minutes.[258,259] The lack of appropriate target stimuli to engage in species-specific foraging behaviors may subsequently lead to the onset of behavioral problems such as FDB.[227,251] Although the onset of this behavior may in part be the result of the altered time budget of captive parrots, some studies have demonstrated that parrots are motivated to forage and will contra-freeload (i.e., work for food even when identical food is freely available), thereby suggesting that foraging may be a "behavioral need."[260–262]

For most other factors that have been implicated in FDB, a causal relationship is less clearly established, thereby demonstrating the use for further epidemiologic and experimental studies into the etiology and risk factors associated with FDB.

Diagnostic Approach

In general, the diagnostic workup of FDB is primarily aimed at identifying or ruling out any medical or environmental factors that may be involved. For this purpose, a thorough history and complete physical examination are deemed essential. During the physical examination, the self-inflicted nature of the feather damage and/or loss may be confirmed by the absence of feather abnormalities on the head, which is inaccessible to the bird's own beak.[222] In addition to the history taking and physical examination, a thorough dermatologic examination of the skin and feathers is warranted, after which diagnostic skin and feather samples may be collected (Table 32.3). If an underlying systemic cause is suspected, diagnostic workup may be further expanded with, for example, a hematologic and/or biochemical blood panel, urinalysis, diagnostic imaging, and/or endoscopy (Table 32.3).[235,263] Intradermal skin testing for diagnosis of allergic skin disease has been described, but thus far been found unreliable in part due to the birds diminished reaction to histamine.[264,265] Definite diagnosis of allergic skin disease may therefore be difficult, although the collection of paired skin biopsies from affected and unaffected areas of the same patient may identify the presence of inflammation consistent with delayed-type hypersensitivity reaction.[266,267]

Any and each diagnostic test should always be carefully weighed for its merit and necessity for the particular case to prevent a plethora of tests from being run as this can pose health and welfare risks for the bird and be a financial burden to the owner. Should the history, physical examination, and additional tests fail to identify feather damage related to the physical environment or a medical problem that is likely to function as a strong antecedent for the behavior, a psychological or primary behavioral origin of the disorder becomes likely. It then becomes important to identify the potential signals (antecedents) and reinforcing factors (consequences) that may result in the behavior being maintained.[255] This can be a difficult and time-consuming task that could be further complicated by the limited reliability and accuracy of the owners' observations and their willingness to learn and commit to environmental adaptations, offering enrichment and behavior modification techniques.[235]

Therapeutic Considerations

Management of FDB can be challenging, especially in chronic cases, where it can be difficult to determine the antecedents and consequences that are associated with FDB, and ritualization of the behavior may have occurred, resulting in the behavior occurring irrespective of the initiating events. It is therefore important to initiate treatment as soon as possible, whereby the approach will largely depend on the findings of the history, physical examination, and diagnostic tests. An initial therapeutic plan will often be aimed at correction of the diet and modification of the bird's housing and living conditions to address any environmental factors that may be involved.

If any medical issues are encountered, these should be appropriately addressed, which may include the use of topical and/or systemic antibiotics, antifungals, and antiparasitic drugs to treat any underlying parasitic or infectious disease. In case allergies are suspected (e.g., based on histopathological findings that indicate a delayed hypersensitivity response), dietary and/or environmental modifications should be made to decrease or eliminate exposure to the suspected allergen(s), if and where possible. In addition, the use of antihistamines (e.g., hydroxyzine hydrochloride, 2 mg/kg PO q8h)[268] and/or corticosteroids may be considered. However, as histamine does not seem to be involved in the inflammatory response in birds, the value of antihistamines in the control of allergies remains questionable. Similarly, corticosteroids should be used with caution in birds because of their potential to induce profound immunosuppression which renders the bird susceptible to develop secondary infections in the absence of appropriate (preventive) antibiosis and antifungal treatment.

Promoting a more stimulating environment by means of social contact, perches, chewing toys, puzzle feeders, and other forms of environmental enrichment may be considered as an important part of the treatment regimen to alter the behavior (see Chapter 47 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).[235] In particular foraging enrichment has been shown to effectively reduce FDB.[224,234,242] Providing such enrichment may be as simple as providing complicated food items such as corn on the cob, pineapples, or pomegranates, providing food in larger chunks or pellets, using multiple feeding stations, scattering the food through the enclosure and/or mixing it with inedible it ems.[235,259,269] Owners may also use paper bags, cardboard boxes, plastic bottles, and other materials to create their own foraging toys or, alternatively, buy one or more of the more complicated foraging devices and puzzle feeders that have become commercially available throughout the past years. Although most of these foraging enrichments appear effective

to significantly increase foraging time of captive parrots, they do not appear capable of naturalizing foraging times to levels comparable with those of wild conspecifics (i.e., 4–6 hours per day).[269] New, more effective foraging enrichments may therefore need to be developed and tested for their efficacy to naturalize foraging behavior and reduce abnormal behavior.

In addition to providing environmental enrichment, behavior modification techniques such as differential reinforcement of other behaviors may be employed to alter the behavior of the bird (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).[232,255,270] Training may furthermore also help to provide the bird with a mentally stimulating challenge or task, provided the owner is able and willing to employ the techniques in a proper and consequent manner.

Other treatments that have been used to treat (psychogenic) FDB include the use of Elizabethan collars and neck braces, fabric "ponchos," "jackets," or "vests," and/or local application of foul-tasting substances (Figures 32.54 and 32.55).[235] It should, however, be remembered that these interventions are primarily aimed at preventing the behavior rather than eliminating the underlying causes. Even their use as a tool to help "break habitual FDB," which was considered an acceptable approach in the past, is nowadays highly questionable from an ethical standpoint as it could lead to "learned helplessness" through "flooding" (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). However, sometimes collars, braces, or ponchos may be necessary to stop the bird from self-mutilating. When opting to use one of these devices, care should be taken to select the device that will be effective yet poses the least amount of burden to the bird from both a physical and mental perspective. If and where possible, devices should be designed such that as much of the normal behavior is possible. For example, pieces of tape can be stuck to a collar or brace, and ponchos can be made from multiple layers of lightweight bird-friendly cloths of which the upper layers are cut into strips to allow preening activity. When placing a collar, poncho, or brace, one should also take into consideration that many birds respond well to the placement; as a result, administering tranquilizers such as midazolam (0.3–0.5 mg/kg IM) could be helpful to facilitate placement, while also ensuring adequate monitoring and supportive care (e.g., gavage feeding and fluid therapy in birds that will not eat and drink) until the bird is properly acclimatized to the device.

Pharmacologic intervention has also been proposed to treat (chronic) FDB. In the authors' opinion, this type of intervention is primarily indicated in those cases that appear refractory to treatment with behavior modification therapy and environmental changes. Options that can be considered include (1) anxiolytic drugs such as diazepam[271]; (2) antipsychotic drugs such as the dopamine antagonist haloperidol[272,273]; (3) tricyclic antidepressants such as amitriptyline, clomipramine, and doxepin[271,274,275]; (4) serotoninergic reuptake inhibitors such as paroxetine and fluoxetine[271,276,277]; and (5) opioid antagonists such as naltrexone (Appendix 1).[271,278] In cases of suspected sexual or hormonally related FDB (e.g., seasonal occurrence and presence of [hyper]sexual and nesting behaviors) treatment may be initiated with a depot gonadotropin-releasing hormone (GnRH) such as deslorelin or leuprolide acetate, or medroxyprogesterone acetate.[279] For more in-depth information on the various psychoactive drugs and their use in birds, the reader is referred to reviews by Seibert (2007),[271] van Zeeland (2018),[280] and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior.

The preferred drug to be used in a given case will be the one that is most likely to be effective in treating the behavioral problem but poses the least risk of adverse side effects. This not only requires knowledge of the mechanism of action, (contra)indications, and side effects of the various classes of drugs available but also warrants an accurate analysis and diagnosis of the underlying motivation for FDB prior to initiating a treatment, and a thorough monitoring and follow-up with detailed instructions being provided to the owner on what can be expected (Box 32.4). It should furthermore be emphasized that, while psychoactive drugs can be useful in the treatment of FDB, they are not expected to provide a cure on their own. The likelihood of beneficial outcomes following drug therapy is greatest when using these as an adjunct therapy to appropriate behavior modification therapy, environmental adjustments, and adequate treatment of any concurrent medical illnesses. When thoughtfully applied, medications are likely to benefit the treatment plan because they can help attenuate an animal's response and increase its receptiveness to the environment. In general, starting at a low dose and gradually titrating it to effect (or until adverse effects are observed) is recommended. Unless a patient exhibits adverse effects, treatment should be attempted for at least the time period that is needed for the drugs to take effect (i.e., 1 week for benzodiazepines and 1 month for most other drugs). If, after this period, insufficient response without adverse effects is seen, the dose can be gradually increased. Should the maximum dose be reached, or adverse effects encountered without adequate resolution of FDB, switching to another drug (from the same or a different class) could be attempted following (gradual) weaning of the original drug and allowing a drug-free interval of approximately 2 weeks before initiating the new medication.

Monitoring and Follow-up

To evaluate whether the treatment has the desired (and no adverse) effects, regular monitoring and follow-up are recommended. Ensure that regular contact with the owner is established to discuss the effects of the interventions, as well as challenges encountered during their implementation. Although the owner is able to directly observe the bird's behavior,[275] this method may not always provide reliable results since it can be difficult to distinguish normal preening from abnormal FDB and bouts of FDB may be missed as these may occur during the night.[234] As such, it could be important to educate the owner to, for example, evaluate (changes in) the number of feathers found on the bottom of the enclosure. In addition, regular checkups in the clinic are advised to evaluate the bird's plumage condition, and adjust the plan, if necessary. To objectively evaluate the changes in plumage condition, feather scoring systems (Box 32.5) and (serial) photographs can be useful.[251,281]

FIGURE 32.54 (A) Many different types of Elizabethan collars are available for parrots and are preferably only used as a component of treatment if the parrot is mutilating itself. The collar this Grey parrot *(Psittacus erithacus)* is wearing has an extension that prevents the bird from reaching even the most distal areas of its body. A great disadvantage is that these collars commonly weigh around 20% of the body weight of the birds and prevent normal preening behavior and other important maintenance behaviors of the bird. (B) In this Grey parrot *(Psittacus erithacus)* a ball-shaped collar is used to prevent the parrot from chewing on the esophageal tube, which was placed because of an extensive crop burn. The great advantage of this "ball" collar is that the curvature of the neck fits within the inner side of the ball. These collars are therefore often better tolerated compared with the one shown in (A). The disadvantage is that the birds can still reach the feet and parts of the wings when wearing these types of collars. Neither of these mechanical blocking devices should be viewed as acceptable substitutes for appropriate pain management of these types of wounds and for promoting alternative chewing behaviors. (C) Besides the commercially available Elizabethan collars, home-made collars are also frequently used. The collar that this lovebird is wearing was made out of insulation tubing that is used to protect warm-water pipes. These collars are not only very inexpensive, but they are easy to make, lightweight, effective, and well tolerated by the birds. (A–C, Photos courtesy Nico Schoemaker/Yvonne van Zeeland. From van Zeeland YRA, Friedman SG, Bergman L: Behavior. In Speer BL, editor: *Current Therapy in Avian Medicine and Surgery*, Vol 1, St. Louis, MO, 2016, Elsevier, pp 177–251.)

FIGURE 32.55 (A) Alternatives to the use of Elizabethan collars are "ponchos" or "socks," which owners frequently fabricate themselves. Alternatively, socks can also be purchased online and customized to the size and color of the parrot, as is the case with this sulfur-crested cockatoo *(Cacatua sulphurea)*. These garments provide a safe, nonrestrictive, and comfortable alternative to collars. Moreover, a sock helps protect against heat loss that may occur as a result of lack of insulating contour and down feathers. Birds generally tolerate socks surprisingly well. (B) In case of self-injurious behavior to the wings, socks will not suffice. However, a jacket, such as the one that was made by the owner of this Grey parrot *(Psittacus erithacus)*, may be helpful to protect the wing area from further damage inflicted by the parrot's beak. (A, Photo courtesy Suzanne Freeman [www.thesockbuddy.com]. B, Photo courtesy Nico Schoemaker/Yvonne van Zeeland. From van Zeeland YRA, Friedman SG, Bergman L: Behavior. In Speer BL, editor: *Current Therapy in Avian Medicine and Surgery*, Vol 1, St. Louis, MO, 2016, Elsevier, pp 177–251.)

BOX 32.4 CHECKLIST FOR ADMINISTERING PSYCHOACTIVE DRUGS[280]

Veterinarians should ask themselves the following questions when considering the use of pharmacologic intervention for behavior modification and ensure all these can be answered with yes before initiating treatment.

1. Has a thorough behavioral and medical workup been performed to identify the potential underlying causes for the problem behavior? Has a working diagnosis or differential diagnoses been established?
2. Have the potential underlying medical issues and environmental stressors been adequately dealt with? Has or will an appropriate behavior modification plan be(en) put into place?
3. Is it possible for the owner to medicate the bird without causing additional stress that may exacerbate the existing problems?
4. Does the drug of choice's mechanism of action correspond with the hypothesized neuropathophysiologic processes that underlie the behavioral problem (e.g., reduction of anxiety, compulsiveness, or hormonal influence)?
5. Did the medical workup reveal no contraindications for use of the medication? If the bird is receiving any other medication, is there no interaction with these drugs that warrants caution or adjustment of the dose?
6. Has the owner been informed properly about effects of the therapy and the potential risks (i.e., side effects) of the treatment?
7. Has a proper monitoring and follow-up protocol been set in place (e.g., frequency of rechecks, monitoring of plasma concentrations, evaluation for presence of side effects)?

BOX 32.5 FEATHER SCORING SYSTEM FOR ASSESSING PLUMAGE CONDITION IN BIRDS

(A) Score Determination Table for Coverts and Down Feathers; Used for Chest/Neck/Flank, Back, Legs, and Dorsal and Ventral Surface of Wings

	Down Feathers			
Coverts	**No Down Removed**	**<50% of Down Removed**	**>50% of Down Removed**	**All Down Removed**
All coverts intact	100	85	70	60
Fraying or breakage	95	80	65	55
<25% of coverts removed	90	75	60	50
25%–50% of coverts removed	80	65	50	40
50%–75% of coverts removed	70	55	40	30
75%–90% of coverts removed	60	45	30	20
>90% of coverts removed	50	35	20	10

The percentage of damage to the covert and down feathers is assessed for each body part separately.
Deduct 10 points from the score if skin damage is present.
Total body plumage score (0–100)[a] = 0.25 × chest/flank + 0.17 × back + 0.10 × legs + 0.28 × dorsal wings + 0.20 × (ventral wings).
[a]To determine the total body plumage score, the scores for each body part are corrected for their relative body surface percentage, similar to scoring systems used in human burn victims. These percentages (expressed as % of the total body surface area excluding the surface area of the head and unfeathered parts of the legs) were determined in six Grey parrots. Mean (± SD) values for the various body parts were 25 ± 1.2% (chest/neck/flank), 17 ± 1.5% (back), 10 ± 1.2% (legs), 28 ± 2.2% (dorsal wing surface, up to the level of the tertiaries), and 20 ± 1.9% (ventral wing surface, up to the level of the tertiaries).

(B) Score Determination for Flight Feathers; Used for Tail, Primary and Secondary Feathers (Wings)

Score	**Description**
0	Flight feather with signs of fraying and/or breakage over >50% of the original length
1	Flight feather with signs of fraying and/or breakage over <50% of the original length
2	Flight feather with little or no damage present

Damage to individual flight feathers is assessed.
Total flight feather score (0–100)[b] = (primary + secondary feathers left wing) + (primary + secondary feathers right wing) + (tail feathers).
[b]The maximum score is dependent on total number of flight feathers of the bird. In general, each wing has 10 primary feathers and 10 secondary feathers (remiges), whereas the tail has 10–12 flight feathers (rectrices). As each individual flight feather is awarded a score from 0 to 2, the score will range from 0 to 40 for each wing and from 0 to 20 (or 0–24 in the case of 12 tail feathers) for the tail, respectively.

SUMMARY

A variety of different conditions may affect the plumage of birds, resulting in various feather abnormalities, including changes to the feather structure, coloration, and growth. Feather loss, particularly related to self-inflicted pulling, plucking, biting, chewing, or fraying of the feathers, is common in psittacine species and can be a difficult and frustrating problem to deal with due to the complex interplay between medical (i.e., dermatologic as well as systemic diseases), environmental, nutritional, psychological, and genetic factors. Due to the myriad of factors that can be involved, any condition affecting the plumage of a bird warrants thorough behavioral and medical workup, whereby treatment is targeted at eliminating all the risk factors involved. Proper education of clients is also important, as it may take time before the effects of the treatment will be visible (i.e., several weeks to months in case of feather loss, or—in case of feather abnormalities—until the next molt, when the new feathers regrow).

CHAPTER 33

Pododermatitis

INTRODUCTION

Pododermatitis is the most frequently encountered foot disease of captive birds and a cause of significant welfare concerns. Pododermatitis is rarely seen in free-living birds, and consequently, management of cases frequently requires identification and correction of husbandry, nutritional and/or environmental deficiencies that have causal roles in the condition. Several bird groups appear predisposed, with the taxonomic orders Falconiformes, Anseriformes, Sphenisciformes, and Phoenicopteriformes seemingly being particularly susceptible.

Pododermatitis can be simply defined as inflammation of the skin of the foot. In avian medicine it is considered a degenerative, inflammatory condition of the plantar surface of the foot, most commonly involving the plantar metatarsal pad or plantar digital pads. It is best considered a disease syndrome—where disruption of the plantar epithelium allows microbial invasion and secondary infection. If not identified quickly and managed effectively, pododermatitis can progress and affect deeper tissues, resulting in tendon necrosis and osteomyelitis of the distal tarsometatarsus and digital bones. This chapter provides an overview of the etiological and pathophysiological considerations, diagnostic workup, and treatment of pododermatitis in birds. As knowledge of the anatomical and physiological characteristics of this region is essential for gaining a thorough understanding of the pathology and the seriousness of its effects, these will first be discussed.

ANATOMY AND PHYSIOLOGY

There are a number of species-specific differences between the anatomy of avian feet; however, some similarities exist between all birds. These anatomical similarities and differences will be discussed in the later sections.

Epidermis

The skin covering the feet of birds is constructed of heavily modified dermis and epidermis (Figure 33.1). The epidermis is avascular and thin and consists of two layers:

- *Stratum corneum*—the most superficial, horny layer
- *Stratum germinativum*—this layer is split into three distinct layers:
  - *Stratum basale*—the deepest layer, which is separated from the dermis by a basal membrane. Dividing cells in the *stratum basale* move superficially forming the *stratum intermedium*.
  - *Stratum intermedium*—these epidermal cells are held together by desmosomal junctions. Nutrients are transported from the vascular dermis and transported within the extracellular fluid, which is found between the cell plasma membranes.
  - *Stratum transitivum*—the most superficial layer of the *stratum germinativum*. This transitional layer contains keratohyalin granules found in the cytoplasm, closely associated with the cell nucleus. In the most superficial layer of *stratum transitivum*, keratinization occurs below the horny *stratum corneum*.[1]

In the domestic fowl, at their thinnest, the *stratum corneum* and *stratum germinativum* are only two to three cells thick. However, it is substantially thicker over the featherless areas of the body, such as the face, and is at its thickest in the podotheca of the foot. In most species the transition to modified thicker skin starts at the region of the intertarsal joint—although some variation exists. The degree of cornification of the modified skin depends on the species—with terrestrial birds having heavily cornified structure, while in water birds it is softer and more flexible.[2]

Dermis

The dermis is found directly under the epidermis and is composed of connective tissue. It is separated from the subcutaneous tissue by a layer of elastic connective tissue—*lamina elastica*. This layer enables the dermis to remain flexible and pliable, which is needed for flight, particularly in the axillary region. The superficial layers of the dermis are characterized by increased numbers of fibroblasts. The superficial compact layer of dermis is made up of dense network of collagen—predominately with horizontal orientation and elastic fibers. On microscopy, this collagen structure is more organized and structured in birds compared to mammals. In the deep loose layer, the connective layer is less structured, and adipose cells and lymphatic vessels are present.[3]

Podotheca

The integumentary covering of the feet, termed the podotheca, is a layer of scales from approximately the distal tibiotarsus to the ends of the digits. While the podotheca is heavily cornified in land birds, it is softer and more flexible in water birds. Feathers tend to diminish distally on the legs as scales arise and become prominent, the transition usually occurring

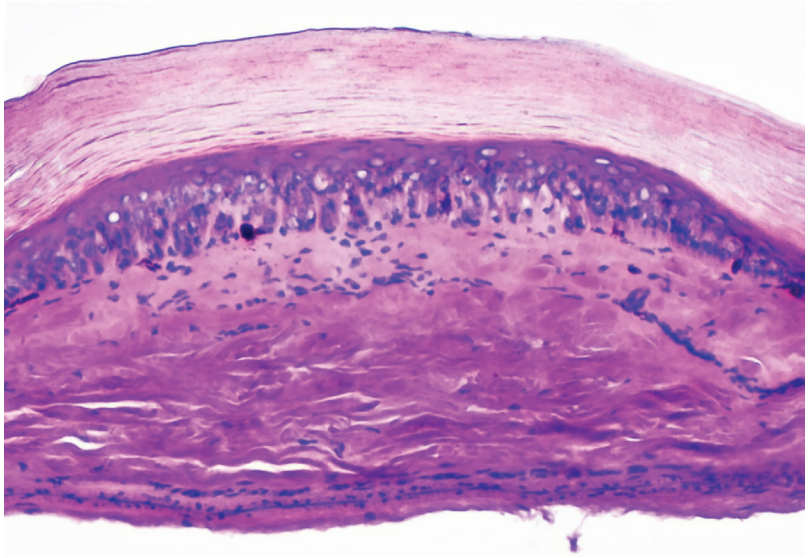

FIGURE 33.1 Scaly skin from lateral tarsometatarsal region and removed to the underlying bone. Frozen section cut 6- to 9-μm thick, manually stained with hematoxylin and eosin (slender-billed parakeet, *Enicognathus leptorhynchus*).

about the intertarsal joint (but varying greatly between species). Eagles and some other eagle-like raptors, such as the ferruginous buzzard *(Buteo regalis)*, are feathered below the intertarsal joint—often described as being "booted." Feathers and scales are variously situated in relation to each other in parts of the foot and among birds, but they never intergrade.

Scales are flat, rounded, or conical raised thickenings of highly keratinized epidermis, separated by inward folds of thinner, less keratinized epidermis (Figure 33.2).[3] They vary in size, shape, amount of overlap, and degree of fusion on different parts of the foot, not to mention among species. The main types of scales that can be distinguished are as follows:

- *scutes* (large scales)
- *scutella* (intermediate scales)
- *reticula* (small scales)

Scutes are seen most frequently on the dorsal aspect of the tarsometatarsus distal to the intertarsal joint. The plantar surfaces (and occasionally the anterior surface) of the tarsometatarsus and the dorsal surface of the digits are typically covered by scutella scales—being more rectangular and more regularly arranged than those on the remaining surfaces (reticulate scales). Metatarsal scales, not needing flexibility, are often fused, especially on the anterior surface. Overlapping or imbrication of scales is species specific—being found in kingfishers (Alcedinidae) and woodpeckers (Picidae).

The scale types differ embryologically and histochemically as well as morphologically. Scutellate (scutes and scutella) scales contain beta-keratin, similar to the rhamphotheca and the claws, whereas reticulate scales are composed of alpha-keratin. These differences indicate that they have different evolutionary histories. Scutellate scales, being very similar to crocodilian scales, appear to have come directly from reptilian scutes, whereas reticulate scales are apparently a later-derived form with different properties.[2]

The reticulate scales on the plantar aspect of the digits and the distal end of the tarsus cover the thick plantar and digital pads. These pads, formed from connective tissue, provide protection to the flexor tendons and joints and are designed to withstand compression, especially in terrestrial species. They underlie the joints and are separated by transverse furrows or gaps, which open and close as the digits are bent. The

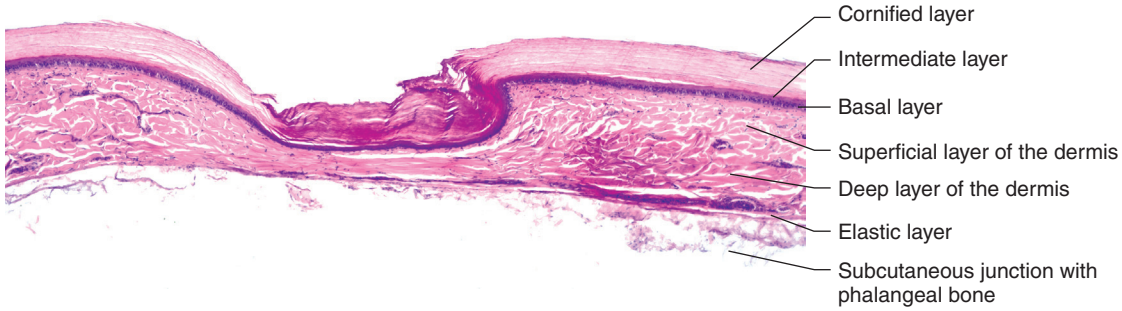

FIGURE 33.2 Section of full-thickness skin showing two small scutes (hard keratin) and their more flexible (soft keratin) junction. Lateral digit of Harris' hawk *(Parabuteo unicinctus)*. Frozen section cut 6- to 9-μm thick, manually stained with hematoxylin and eosin.

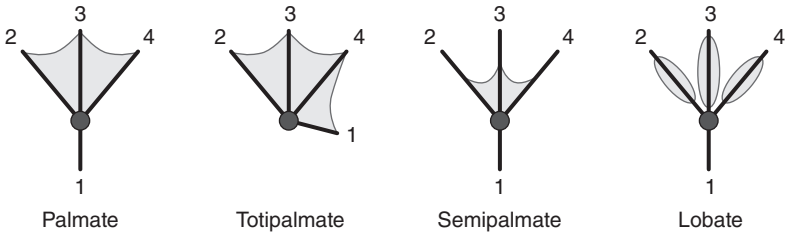

FIGURE 33.3 Type of feet webbing recognized in birds: (A) palmate, (B) totipalmate, (C) semipalmate, and (D) lobate.

pads and papillae vary morphologically and histologically among the digits and among species according to the length of the digits, their need for support, and the natural history of the bird.

Young woodpeckers, barbets, toucans, kingfishers, jacamars, and trogons develop an extra-thick pad that is located on the distal-ventral aspect of the tarsus. During the nesting period, while confined to the nest cavity, they rest on this pad and shed it when they fledge (see Chapter 44, Figure 44.8).[2]

Most waterbirds have a palmate foot structure and have a web present between the digits that is formed from reticular scales, resulting in paddle-like feet (Figure 33.3). This web is composed of thin, flexible, leathery integument. Pelecaniformes have full webs connecting all four digits (totipalmate); Anseriformes, Procellariiformes, lari, loons, and alcids have full webs between the three forward digits (palmate); and plovers and some sandpipers have basal webs between the forward digits (semipalmated). Grebes, rails, and finfoots (Heliornithidae) accomplish the same end with flat lobes on independent digits (lobate).

Ptarmigans have digit feathering that increases the surface area of the foot, acting as natural snowshoes that allow easier ambulation in winter climates. For example, the winter plumage of willow grouse *(Lagopus lagopus)* includes digit feathering that increases the surface area of the foot fourfold, thereby reducing the sinkage into snow by 50%, thereby also saving considerable energy. Black grouse *(Tetrao tetrix)* and capercaillie *(T. urogallus)* have pectinations (combs), which are extensions of the foot scales on the digits that also increase the surface area of the feet. Digit feathering often develops in autumn and molts out in spring.[1,4]

Claws

Avian claws are formed over the germinal epidermis at the terminal phalanx of each digit. They share many similarities with the rhamphotheca (beak covering) with both having a highly keratinized structure that contains hydroxyapatite crystals (see Chapter 31). A digit's claw is composed of a dorsal plate *(scutum dorsale)* that is the hardest, containing heavy deposits of beta-keratin plus calcium salts and curves downward at the tip and sides, and a plantar plate *(scutum plantare)* that fills the space between the sides underneath (Figure 33.4).[3] The curved shape of the claw comes from the faster dorsal growth in comparison to the plantar plate and has advantages for grasping prey, perching, and climbing. Digit claws vary in length, curvature, and pointedness in relation to their usage and the substrate where a bird lives. For example, claws are less developed in diving and water birds, whereas they are much larger in Falconiformes, and are

FIGURE 33.4 Sagittal section of a steppe eagle *(Aquila nipalensis)* claw.

flattened in grebes, contributing to the foot paddle. Claws have pectinate (comb) edges, used for grooming feathers, in nightjars, herons, frigatebirds, and pratincoles.[2] The same function is suggested to be present in hawks, in which the claw on digit 3 has a flatter profile that may serve as an adaptation for grooming feathers.

Digits

The foot of a "typical" avian species has four digits. While no birds have more than this number, several species have fewer. The ostrich is the only species that has just two digits—with digits 1 and 2 being lost. Other ratites, many waders, petrels, auks, and woodpeckers have three digits, with digit 1 being vestigial or absent. In kingfishers, it may be the second digit that has been lost in development.

The arrangement of digits depends on function and is highly species specific (Figure 33.5). Among the arrangements that can be distinguished are:

- Anisodactyl feet—three digits pointed forward, one digit (digit 1) pointing back; this arrangement is seen in, for example, passerines (Passeriformes), gallinaceous birds (Galliformes), and Falconiformes (falcons, caracaras).
- Zygodactyl feet—two digits (digits 2 and 3) pointing forward; two digits (digits 1 and 4) pointing back; this arrangement is seen in toucans (Rhamphastidae), parrots

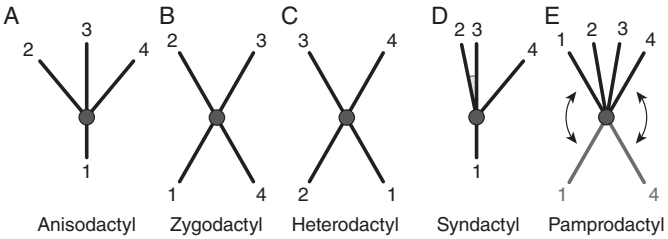

FIGURE 33.5 Digital arrangements of the feet in birds: (A) anisodactyl, (B) zygodactyl, (C) heterodactyl, (D) syndactyl, and (E) pamprodactyl.

(Psittaciformes), and cuckoos (Cuculidae) and is beneficial for climbing and grasping. Owls (Strigiformes), osprey (Pandionidae), and turacos (Musophagidae) have a variation on zygodactyl feet where digit 4 can face either forward or back.

- Heterodactyl feet—this arrangement is much like that for zygodactyl feet, but here digits 1 and 2 face backward, as is the case in trogons (Trogonidae).
- Syndactyl feet—here, digits 3 and 4 are partly united, as can be seen in Coraciiformes (kingfishers, bee-eaters, rollers, motmots, and todies.), and hornbills (Bucerotidae).
- Pamprodactyl feet—all four digits face forward in an adaptation for climbing; this arrangement is seen in mousebirds (Coliidae) and swifts (Apodidae).

Feet can further be classified as grasping, walking/wading, or swimming feet, based on the function to which they have specialized.

Grasping Feet

Grasping feet are adapted for perching or holding prey or food items. The function is most common in species with anisodactyl and zygodactyl feet. In the anisodactyl feet, the hallux (digit 1) is fully opposable to provide a firm grip, whereas the grip in zygodactyl feet is developed further due to two pairs of opposable digits.

Walking/Wading Feet

In species with walking/wading feet, digit 1 is often absent or vestigial, leading to the foot having limited or no grasping capacity. In wading birds, full or partly webbed feet can be seen. In certain species, the digits may be elongated to increase the ground/surface contact and spread the load.

Swimming Feet

Swimming feet all have a significant development of webbing or lobes. Some species have totipalmate feet, that is, all four digits are fully webbed, whereas others have palmate feet in which digit 1 is vestigial or absent and the other three digits are webbed. Grebes and coots have broad lobes on the side of the four digits, forming a lobate foot, but lack a web that joins the digits.[1]

PATHOPHYSIOLOGY OF PODODERMATITIS

Regardless of the species, pododermatitis typically starts with mechanical breach of skin surface. Most of these cases occur due to pressure and/or abrasion, which results in an area of avascular damage. The initial ischemic insult progresses to the development of necrosis and inflammation of the soft tissues, leading to the release of inflammatory mediators. This not only aggravates the lesion but also causes thrombosis of small blood vessels and provides a point of entry for pathogenic, commensal, or opportunist bacteria which then lead to further inflammation and tissue damage. In grade 1 and early grade 2 diseases, which are characterized by inflammation, erythema, scabs, and moist lesions, bacterial infection has yet to develop. As such, these cases are mostly amenable to treatment.

Hyperkeratosis appears when the lesion becomes chronic, reducing the epithelium thickness followed by tissue ulceration. Lesions can also advance toward the subcutaneous tissue and cause secondary infections, most notably of *Staphylococcus* spp. In animals in which the condition is left untreated, osteomyelitis, tendinopathies, and arthritis may develop. At this stage, the prognosis is unfavorable and can also lead to systemic pathologies such as endocarditis and polyarthritis.

Recognizing the factors that predispose to pododermatitis is essential. Factors known to increase the risk of pododermatitis include excess weight or obesity, larger-sized birds, inappropriate perching (i.e., size, texture, materials), substrate or bedding, inactivity or sedentary lifestyle, malnutrition (e.g., hypervitaminosis or hypovitaminosis A in psittacine birds, biotin deficiency in turkeys), and lack of cage hygiene. In addition, birds with unilateral lameness (e.g., arthritis, fracture) may develop pododermatitis on the contralateral leg due to a shift in weight bearing. Trauma can also predispose to development of pododermatitis, as primary penetration allows direct inoculation of bacteria into the foot or creates a wound that serves as an entry point for bacteria. Examples include talon penetration (in raptors), bite injuries, or puncture wounds from sharp objects. Finally, pododermatitis has been linked to repeated exposure to nicotine residues on the hands of a smoker, strong cleaners/disinfectants, or allergens, which all can cause local irritation and dermatitis of the feet.[5]

CLASSIFICATION OF PODODERMATITIS

No classification scheme for pododermatitis in birds has been universally accepted. However, the most used ones involve grading from either 1 to 5 or 1 to 6, with 1 representing the least severe condition, and 5 or 6 constituting "end-stage" disease. A scheme originally proposed for classifying raptor pododermatitis is commonly used (see Box 33.1 and Figure 33.6) and can be adapted and applied to other species.[6] In addition, specific classification schemes have been developed for certain species such as flamingo[7] and poultry.[8]

HISTORY AND CLINICAL EXAMINATION

A combination of signalment, clinical examination, diagnostic imaging, and microbiology is frequently employed in the diagnosis of pododermatitis. A clinical history and examination are important to determine the severity of the pododermatitis and identify any predisposing factors that contributed to its development. This information is essential to determine an appropriate treatment plan and establish a prognosis.

History should include information about the diet (including any treats or supplements provided), housing/enclosure, perches (if applicable), substrate/bedding, cleaning and disinfection protocols, and exercise. In addition, attention should be paid to possible trauma or medical conditions that could lead to unilateral lameness or altered weight bearing.

BOX 33.1 GRADING SCHEME FOR PODODERMATITIS (FIGURE 33.6A–E)

Grade 1: Erythema and smoothing of the skin on the plantar aspect of the feet. Flattening of the papillae. Slight discoloration, most frequently a darkening of the skin, can also be seen.

Grade 2: Hyperkeratosis and thickening of the plantar skin may be seen. Localized inflammation and the beginning of necrosis. Crusts may be seen.

Grade 3: Moderate to severe hyperkeratosis. The feet will often feel warm to touch, with moderate to severe swelling and mild to moderate pain. The necrotic and hyperkeratotic core penetrates the skin to full thickness, and a caseous abscess forms.

Grade 4: Infection spreads to adjacent soft tissues, including joints and tendons. Tenosynovitis is often present, resulting in ascending infections and inflammation extending from the foot toward the tarsometatarsus. Swelling will commonly be seen on the dorsal and plantar aspect of the feet. Mild to moderate pain can be observed.

Grade 5: Involvement of skeletal structures. Osteomyelitis and/or septic arthropathies of one or more of the intertarsal, tarsophalangeal, and interphalangeal joints. Marked swelling with moderate to severe pain is often observed.

FIGURE 33.6 Examples of various grades of pododermatitis. (A) Focal hyperemia and loss of integrity of the epidermis in grade 1 pododermatitis. (B) Grade 2 pododermatitis affecting the digital pad of digit 2. (C) Grade 3 pododermatitis in a snowy owl *(Bubo scandiacus)*. (D) Grade 4 pododermatitis in which the infection has spread to the underlying tendons and bony structures. (E) Grade 5 pododermatitis in which septic arthritis has resulted in significantly impeded function of the foot. (Photos A and B courtesy Neil Forbes.)

When obtaining a history regarding the enclosure or perches, asking the client to provide photographs and videos is very useful. Where possible, on-site examination of the bird in its environment should be performed as the bird's perching preferences and behavior can help identify more subtle risk factors. In nocturnal species such as owls it may be necessary to observe the birds during the night. Night vision web-cameras or closed circuit television (CCTV) can help to facilitate this procedure.

A systematically performed physical examination is helpful to discover concurrent diseases or predisposing factors for pododermatitis. First, the patient should be observed in its cage or carrier, whereby any changes in gait or weight bearing, as well as abnormal posture while perching should be noted.

To facilitate the clinical examination, sedation or anesthesia may be required, especially in untrained or fractious patients (see Chapter 46); however, in many species, manual restraint may suffice. A weight and body condition score should be obtained and compared to previous values, if applicable. Physical examination findings may include erythema, erosions or ulcerations, swelling, lameness, reluctance or inability to move, and pain on palpation. Lesions are most commonly found on the metatarsal pad or digital pads and should be graded according to their severity (see section on Classification of Pododermatitis). Photographs can be helpful to monitor progression. Aside from a visual inspection of the lesions, the feet should be palpated for swelling, crepitus, and range of movement of the joints. Gloves should always be worn—firstly to prevent inoculation of skin bacteria into lesions, but also to protect the examining veterinarian from exposure to bacteria. In addition to examining the affected foot, the clinician should always examine the other leg and foot closely to evaluate for the presence of problems on the contralateral leg leading to a shift in weight bearing.

Differential diagnoses for pododermatitis include the following:

- trauma (soft tissue, fracture, dislocations);
- gout;
- septic arthropathy (hematological spread).

With the majority of these, there will not be disruption to the plantar skin, thereby facilitating the establishment of a diagnosis.

DIAGNOSTIC TECHNIQUES

To determine whether infection has spread to underlying tissues and differentiate between grade 3 and 5 pododermatitis, imaging will often be required. Radiography or computed tomography (CT) imaging is best used to assess skeletal changes (e.g., osteomyelitis, Figure 33.7; see also Chapter 2). Moreover, these allow the clinician to assess injuries that may contribute to uneven weight distribution between the feet (e.g., degenerative joint disease, previous misaligned fracture healing, metabolic bone disease, intraabdominal disease–causing sciatic nerve compression). Ultrasound, on the other hand, can be used to assess soft tissue structures such as tendon sheaths and tendons—particularly in larger birds, though the scales may hinder proper visualization of the structures (Figure 33.8). CT or magnetic resonance imaging (MRI) may

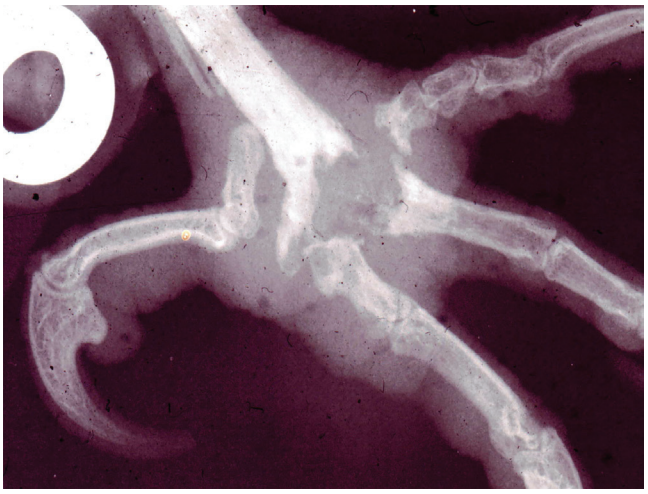

FIGURE 33.7 Radiograph showing severe osteomyelitis in a case of a grade 5 pododermatitis.

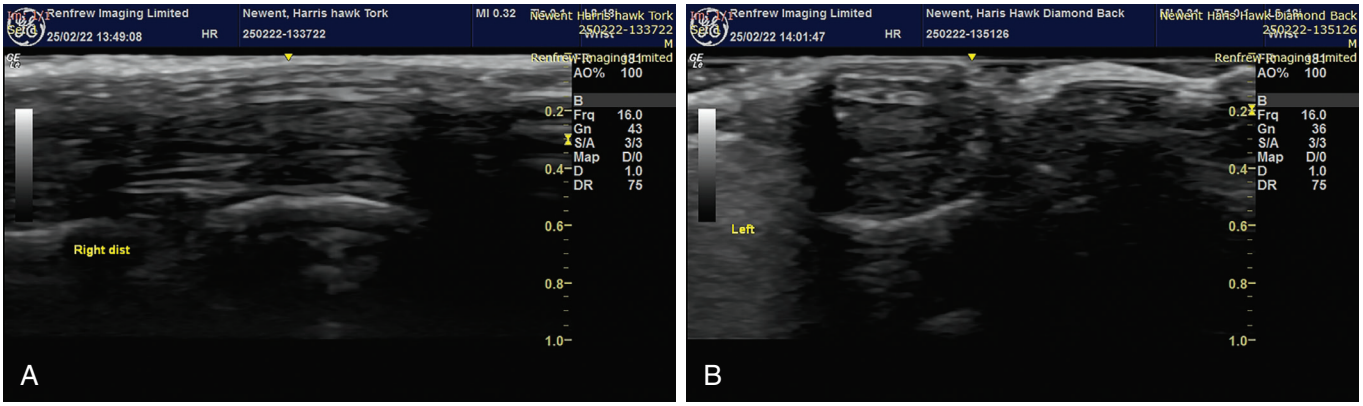

FIGURE 33.8 Longitudinal (A) and transverse (B) images of a normal gastrocnemius tendon in a Harris' hawk *(Parabuteo unicinctus)*.

also be used to detect more subtle bone and soft tissue pathologies.

From the lesions, material can also be collected for cytology and/or culture. Cytological samples should be stained with a Gram stain as this can help with the selection of first-line antimicrobial therapy while awaiting culture results (see Chapter 7). Culture and sensitivity performed on a deep portion of the lesion or a piece of infected tissue will generally lead to the best results. Frequently, *Staphylococcus aureus* is isolated from such lesion, though other bacteria, such as *Escherichia coli*, *Corynebacterium* spp., *Pseudomonas* spp., and yeasts are regularly cultured from the lesions as well.[9–12]

A complete blood cell (CBC) count and biochemistry panel can be performed to identify concurrent diseases or predisposing factors. If blood work is performed as part of a complete clinical investigation in the more advanced stage of disease, there is frequently elevation of the white blood cell (WBC) count with a heterophilia. Fibrinogen is also elevated to boost clotting (hyperfibrinogenemia).

TREATMENT OF PODODERMATITIS

Management of pododermatitis will generally require a multimodal approach. Dependent on the grade of pododermatitis, a combination of medical and surgical interventions may be needed that aim at relieving pressure on the affected area(s), reducing swelling, establishing drainage (as needed), and treating any secondary infections and associated pain and inflammation (Table 33.1). Regardless of the severity and species, treatment should aim at correcting the underlying causes. Concurrent disease conditions as well as any stress and/or anxiety should also be addressed.

REVIEW AND CORRECTION OF HUSBANDRY AND MANAGEMENT

Treatment of pododermatitis is doomed to fail unless the underlying causal management problem or problems are identified and corrected. While a clinical history can be very useful, nothing is quite as beneficial as an on-site examination of the housing. The detail is vitally important, and subtle problems can easily be missed in conversation. Where an on-site evaluation is not possible, photographs and videos can be used. Time-lapse footage of birds in an aviary space or enclosure can be useful to assess the proportion of time spent at certain locations, or on certain perches. It may allow assessment of group dynamics which may be a factor in the onset of pododermatitis.

TABLE 33.1

Summary of Grade and Treatment Options for Pododermatitis in Avian Species[a]

Grade	Identification	Treatment Options	Prognosis
1	◆ Erythema/smoothing skin ◆ Flattened papillae ◆ Discoloration—either darkening/pink erythema	◆ Environmental/husbandry changes ◆ Pressure-relieving dressings/casts ◆ Topical treatments (emollients, footbaths/soaks) ◆ No indication for antibiotics	Excellent if underlying cause can be identified and corrected
2	◆ Hyperkeratosis/thickening plantar skin ◆ Localized inflammation ◆ Early necrosis ◆ Crusts	◆ As above for grade 1 disease ◆ Systemic antiinflammatories ◆ Topical antibiotics ◆ Systemic antibiotics (rare cases where secondary bacterial colonization is likely) ◆ Surgery considered in refractory cases	Good
3	◆ Progressed hyperkeratosis ◆ Diffuse swelling feet ◆ Mild to moderate pain ◆ Necrotic and hyperkeratotic core ◆ Abscess formation	◆ As for grades 1 and 2 ◆ Surgical debridement necrotic/avascular tissues ◆ Remove caseous material and pyogenic membranes ◆ Systemic antibiotics based on culture ◆ Topical antibiotics, that is, absorbable calcium sulfate impregnated beads ◆ Topical dressings promoting granulation	Fair
4	◆ Spread of infection into tendon sheaths, joints, and adjacent tissues	◆ Flush tendon sheaths and surgical debridement as required ◆ Advanced imaging food can help with surgical planning ◆ Local/regional antibiotics particularly beneficial ◆ Regional limb perfusion antibiotic administration ◆ Long courses of treatment required where bone and synovial structures effected	Guarded
5	◆ Involvement of skeletal structures ◆ Osteomyelitis and/or septic arthropathies ◆ Marked swelling with moderate to severe pain is often observed	◆ Viability and ethics of treating need to be assessed ◆ Even if infection is controlled long-term secondary degenerative joint disease will affect welfare ◆ Euthanasia may need to be considered	Poor

[a]Species-specific variations are discussed in section on Species-Specific Considerations.

Reversal of early stage pododermatitis is often possible following correction of the underlying predisposing factors. These may include dietary changes, stimulating exercise, frequent exposure to sunlight, improved cleanliness, and adjusting the enclosure design. For animals that are overweight, a weight loss program should be initiated which includes measures to stimulate the bird to exercise and move around (e.g., by offering foraging enrichment) as well as a reduction of the daily caloric intake. For psittacine birds, a gradual transition from a seed-based diet to a formulated diet with additional fresh fruits and vegetables that contain vitamin A (e.g., peppers, squash, sweet potatoes) is commonly advised. Birds of prey should be fed with a varied (supplemented) whole-prey diet, whereas for poultry and waterfowl a commercial maintenance diet appropriate for the species is recommended.

Perches of variable sizes and types should be offered to perching birds and rotated on regular basis to encourage birds to perch on different surfaces. Surfaces should be kept clean and dry and can be wrapped with safe, soft materials such as cotton padding or foam covered with Vetrap bandaging tape (3M, St. Paul, MN, USA) during the management of pododermatitis. For birds of prey, shape and configuration of the perch should be appropriate for the species involved. For example, falcons should be housed on flat surfaces (e.g., shelves covered with artificial turf), whereas eagles, hawks, and owls are preferably housed on round or elliptical perches (e.g., made of hemp or sisal rope).[13] For waterfowl, it is essential to provide access to water for swimming, which must be kept clean and free of organic matter. For most species, a large pond with a minimum depth of 2 feet should be provided, though for the diving species, a depth of at least 4 feet is recommended.[14] Gradual slopes in and out of the water are important, as is the provision of islands for resting, and areas of shade and sunlight.

TOPICAL MEDICATION

Many topical products have been used in the treatment of pododermatitis, albeit without little scientific evidence to promote the use of one product over another.

Examples include silver sulfadiazine 1% cream, Collasate postoperative dressing (PRN Pharmacal, Pensacola, FL, USA), and nontoxic antimicrobial products such as triple-antibiotic ointment (Neosporin; Johnson & Johnson Consumer Companies, Inc., New Brunswick, NJ, USA; Table 33.2; see also Chapter 36).[15] Whenever using topical antibiotics, care should be taken to avoid products that are toxic following ingestion. Similarly, oil-based products can potentially affect feather quality and impair thermoregulation. Topical corticosteroids should be avoided because of their immunosuppressive effects and delayed wound healing.

SYSTEMIC ANTIBIOTICS

Systemic antibiotics may be indicated in case of persistent or deep infections. Ideally, the choice of antibiotic is based on the results of a culture and sensitivity testing, but if this is unavailable, a broad-spectrum antibiotic with activity against both gram-positive and gram-negative bacteria can be selected. An antibiotic that is able to penetrate tendons, joints, and/or bones should be selected in case of tendinitis, arthritis, and/or osteomyelitis (see Chapters 6 and 7).

TABLE 33.2

Commonly Used Topical Treatments for Pododermatitis[15–19]

Active Ingredient	Mode of Action	Use
Manuka—methylglyoxal	High osmolarity—reducing edema and inflammation. Gluconic acid production contributes to low pH and antibiotic activity. Hydrogen peroxide production. Provides a moist and favorable environment for wound healing.	Useful particularly with resistant bacterial infections. Activity against biofilm-producing organisms such as *Staphylococcus aureus*.
Silver	Compromising phosphomannose isomerase and components of the microbial electron transport system as well as impairing some DNA function of microorganisms.	Multispectral topical antimicrobial action. Care delay wound healing with extended use.
Dimethyl sulfoxide (DMSO)	Changes the scope of penetration of chemical compounds in biological membranes. Increases membrane fluidity.	Addition of DMSO in the dressing is suggested to facilitate the penetration of topical antibiotics and may help to reduce swelling.
Sodium fusidate	Fusidic acid is a bacteriostatic antibiotic with bactericidal properties at higher concentrations. Its mode of action is via inhibiting bacterial protein synthesis. The ointment base reduces the amount of dry, hyperkeratotic skin.	Antibacterial, particularly against *Staphylococcus* spp. infections. Reported to penetrate intact skin.
Povidone iodine	Action against both gram-positive and gram-negative bacteria. Ability to penetrate biofilms with minimal cytotoxicity. Oxidative damage of bacterial cell structures.	For either footbaths or topical wound cleansing.
Benzalkonium chloride, polyhexanide (F10 Barrier Ointment)	Broad-spectrum antimicrobial properties from disruption of cell membranes.	Topical administration to the foot or incorporated in footbaths or lavage solutions.
Yeast extract and shark liver oil	Shark liver oils contain alkylglycerols which modulate the inflammatory response, enhancing macrophage activation.	Found in topical human hemorrhoid preparations, applied to the plantar skin to treat low-grade pododermatitis (grades 1–2).

ANALGESIA

Analgesia is important to provide for patients with pododermatitis, as even the superficial lesions can be painful. Meloxicam is a commonly used analgesic, but dependent on the severity, opioids such as butorphanol and tramadol may be considered (see Chapter 35).

REGIONAL LIMB PERFUSION

Regional limb perfusion administration of antibiotic treatments has recently received significant attention in avian species (see Chapter 6, Figure 6.5; see also Chapter 36). Relative ease of intravenous access into the medial metatarsal vein makes this technique achievable in medium to large species. The higher tissue concentrations achieved locally are particularly useful where resistant infections are present or when using antibacterials that have greater risk of systemic toxicity (e.g., aminoglycosides).[20] Amikacin has been used in cranes. Ceftiofur regional limb perfusions have been investigated experimentally in chickens, and showed synovial concentrations of ceftiofur to exceed therapeutic concentrations for most pathogenic bacteria.[21,22]

A tourniquet or manual vessel occlusion is performed proximal to the site of infection, following which an infusion of intravenous antibacterials is performed distal to the tourniquet for approximately 15 minutes. Most commonly, cannulation of the medial metatarsal vein and placement of the tourniquet are performed just proximal to the intertarsal joint. In large species, placement of a digital cannula may be possible.

LASER THERAPY

Laser therapy has been used in a number of species as an adjunctive treatment for pododermatitis. The difficulty of setting up control trials and multimodal treatment of most patients make it difficult to demonstrate its added value, although empirical case reports have shown promising results.[23–25]

MEDICAL VERSUS SURGICAL INTERVENTION

Low-grade (grade 1 or 2) pododermatitis is frequently managed with husbandry changes and topical therapies, with or without the addition of pressure-relieving dressings (Figure 33.9). Overall aims of this treatment are to:

- provide analgesia;
- control swelling and inflammation;
- prevent formation of (further) necrotic tissue;
- prevent progression of pododermatitis to higher-grade disease;
- prevent colonization of pathogens;
- promote granulation and healing (thus avoiding cytotoxic therapies).

Higher-grade (i.e., grades 3–5) pododermatitis frequently requires more extensive therapy to be successful (Figure 33.10). Surgical intervention is often required and aims to:

- debride necrotic and avascular tissues and remove caseous material and pyogenic membranes;
- minimize disruption to the normal foot structure;
- allow primary closure, where possible; many cases, however, will require healing by granulation and secondary intention;
- expedite healing and allow the limb to return to full function as soon as possible;
- prevent spread of infection into bone, tendons, tendon sheaths, or joints.

FIGURE 33.9 Grade 1–2 pododermatitis in a small falcon following 1 week of topical treatment and correction of husbandry. Callus is starting to lift at the periphery.

FIGURE 33.10 Severe grade 3 digit pododermatitis. Progression can lead to avulsion of the digital flexor tendon.

In severe cases, with extensive involvement of underlying tissues and functional limb dysfunction, amputation of the affected leg may be considered. However, in wild birds or birds of prey, the procedure would not be recommended.

Surgical debridement will vary significantly from case to case. The species, chronicity of disease, previous treatment attempted, importance of (remaining) limb functionality, and so on will all affect how a surgeon manages a case. The timing of surgery is important. Premature surgery will lead to unnecessary disruption of the foot architecture (Figure 33.11) versus a surgery that is delayed for too long leading to progression of lesions and development of irreversible septic arthropathies, osteomyelitis, or tendinitis with risk of tendon rupture. Typical surgical steps involved in most cases are summarized in Box 33.2 and Figure 33.12.

FOOT DRESSINGS

Bandages or foot dressings are required in most, except the milder cases. There is a wide range of foot dressings utilized in the management of pododermatitis (Figure 33.13). The technique selection will depend on species, lesion location and severity, and—to a degree—on personal preference. There is very little published material in which techniques are compared, hindering the ability to provide evidence-based guidance on the efficacy of

FIGURE 33.11 Brite-Vue enhanced computed tomography images of the anatomy and unique vascular supply of the foot of various bird species. (A) Bald eagle *(Haliaeetus leucocephalus),* dorsal and ventral view; (B) African goose *(Anser cygnoides),* dorsal and plantar view; (C) pigeon *(Columba livia domestica),* dorsal view.

BOX 33.2 STEPWISE SURGICAL PROCEDURE FOR TREATMENT OF PODODERMATITIS

1. Assess plantar skin and plan surgery (Figure 33.12A). If possible, incisions should be made to reduce tension and allow primary healing.
2. Surgical preparation of skin—the preference is chlorhexidine, although povidone iodine can be used (see *Current Therapy in Avian Medicine and Surgery Vol 1, Chapter 21, Surgery*). A toothbrush can be useful to remove debris from between scales. If no crust is present, samples for culture and sensitivity should be taken before surgical preparation of the foot.
3. Crusts, if present, are removed, following which samples can be taken for bacterial and fungal culture. Culture swabs should be sampled from deep tissue to prevent culturing of surface commensals (Figure 33.12B)
4. A temporary tourniquet can be placed proximal to the intertarsal joint and left on for a maximum of 10 minutes per foot. This helps to prevent blood contamination of the surgical field and allows easier visualization of the structures of the foot.
5. Necrotic material and caseous material with associated pyogenic membrane are removed to leave a healthy, bleeding wound bed (Figure 33.12C). Where present, the pyogenic membrane should be removed in its entirety, and ideally be left intact. A small Volkmann spoon can be useful for curetting material. The surgeon's aim is for one single and thorough surgical procedure rather than leaving contaminated tissue and requiring repeat procedures. Care should be taken to maintain the structural integrity of the foot and minimize formation of scar tissue (Figure 33.12D).
6. The wound bed is soaked and/or lavaged with warm saline or lactated Ringer's solution. Alternative irrigation solutions include dilute povidone iodine and dilute benzalkonium chloride (F10 sc). These would preferably only be used in the initial phases of treatment as these solutions can be cytotoxic to fibroblasts and may reduce white blood cell viability and phagocytic efficiency, hence leading to delayed wound healing (see Chapter 36).

BOX 33.2 STEPWISE SURGICAL PROCEDURE FOR TREATMENT OF PODODERMATITIS—cont'd

7. Small (2–4 mm) antibiotic-impregnated beads can be used to locally obtain a high concentration of antibiotics, which generally will exceed the minimum inhibitory concentration (MIC) of the organisms involved. Commonly used antibiotics for this purpose include aminoglycosides, cephalosporins, penicillins, fluoroquinolones, and clindamycin, with the choice depending on culture and sensitivity of the lesion.[26] If antibiotic-impregnated beads are placed, they should be sited so that they can ideally be removed from a dorsal incision rather than requiring a repeat disruption to the plantar skin. The surgeon should accurately record where they have been placed to help expedite removal, once needed. Modern alternatives of absorbable calcium sulfate beads (Kerrier LLC) do not require removal and are preferable to Polymethyl methacrylate (PMMA) when available. Antibiotic-impregnated substrates are most useful in cases with grade 3 and higher-grade pododermatitis or those with resistant bacterial infections where high concentrations of antibiotics are required to overcome the MIC. Local antibiotic therapy is also considered appropriate in cases sensitive to potentially toxic antibiotics (e.g., aminoglycosides).
8. Avascular and devitalized skin should be removed and, where possible, apposition of the skin should be accomplished with monofilament interrupted sutures to allow first intention healing (Figure 33.12E). In some cases, a tension-relieving suture pattern (mattress or "far-near-near-far") suture may be required.

different dressings. In general, the aims of a foot dressing or casting are to:

- relieve pressure on pododermatitis lesions;
- prevent desiccation and provide favorable conditions for granulation and healing;
- shield the wound from contamination and prevent microbial contamination;
- in some cases, allow continued application of topical therapies;
- avoid softening and thinning of the epidermis.

With early pododermatitis lesions (e.g., flattening of the papilla), liquid bandages, cyanoacrylate skin protectants, or skin toughners (e.g., camphor and benzoin) can be placed on the lesion. In the case of more extensive lesions, bandaging can be applied to the lesion. Such bandages are generally

FIGURE 33.12 (A) An adult female steppe eagle *(Aquila nipalensis)* was presented with chronic bilateral pododermatitis. (B) After a 5-day course of enrofloxacin, the bird was anesthetized and the scab removed to allow the foot and tendons to be assessed. Once cleaned, the foot lesions were covered with propylene glycol, salicyclic acid (Dermisol, Zoetis) and bandaged with a nonadherent dressing that was held in place with zinc oxide tape. (C) Once the wounds had started to granulate with no signs of purulent discharge from the tendon sheaths, the bird underwent surgery to close the wounds. Excess granulation tissue and fibrous tissue were removed. (D) During surgery, the wound was regularly assessed to ensure that the skin edges would oppose without undue tension and that the shape of the foot was returned to as close to normal as possible.

Continued

FIGURE 33.12, cont'd (E) Polydioxanone suture swaged onto a round-bodied needle was used to repair the wound. Initially, a series of mattress sutures were placed to reduce the dead space as well as the tension on the skin edges. These sutures were subsequently opposed by simple interrupted sutures. (F) The wounds were covered with a sheet of hydrophilic (Granuflex) dressing to help keep the wound clean and reduce tension and movement on the suture line. The dressing was held in place with zinc oxide tape. If this bird had been a falcon, a foot cast would have been used, but hawks are known to healwith just a well-padded perch. The bird was exercised by flying on a creance daily. (G) Dressings were changed every 7 to 14 days. The sutures remained present until the wound looked healed. This process can take up to several weeks to complete. (H) After 8 weeks, the skin was healed but still quite thin and easily injured. A small wound was still present over an area where the foot had not been returned to the correct shape. However, with time and care, this wound eventually healed. This case clearly demonstrates that it may take a long time for the foot surface and function to return to normal. Once unbandaged, lanolin-based hand cream can be applied to the dry skin to allow it to return to normal faster.

composed of three layers: (1) a primary layer that contacts the wound, (2) a secondary layer that has absorptive properties, and (3) a tertiary layer to hold the other layers in place (see Chapter 36).

The primary layer of the dressing must be carefully chosen to provide the ideal environment for wound healing and greatly depends on the stage of healing (see Chapter 36). In raptors, for example, wet-to-dry bandages or a seton with ball bandage are used in the initial stage to facilitate drainage of the wound, followed by a ball bandage without the seton in the granulation stage, polypropylene shoes in the early healing stage, and an interdigital bandage in the later stages of healing. A lightly absorbent, nonadhesive dressing such as Melolin (Smith & Nephew, Watford, UK) is preferred by the author in the initial treatment as it is of particular use where mild, moderate discharge is present from the wound. Hydrocolloid dressings have been recommended; however, these should only be used in noninfected wounds. Their use can promote a moist wound environment that has been proposed to increase the risk of secondary mycotic infections. Hydrocolloid-type dressings may also lead to softening of the skin surrounding the wound—particularly if used for protracted periods of time. Hydrocolloid dressings (e.g., Granuflex, DuoDERM - Convatec, Deeside, UK) help to promote epithelialization and protect and strengthen the suture line (see Chapter 36).

Pressure-relieving foot casts in their many different forms should be used where feasible (Figures 33.13–33.15). Ongoing pressure at the lesion or surgical site is a major reason for poor resolution and wound healing. One of the authors' preferred techniques is a "snowshoe" style dressing constructed of yoga matting (Figure 33.14A). Portions of the snowshoe mat can be cut away full or partial thickness to remove pressure away from the tissue below (Figure 33.14B). Later in the treatment course where a primary dressing is not required,

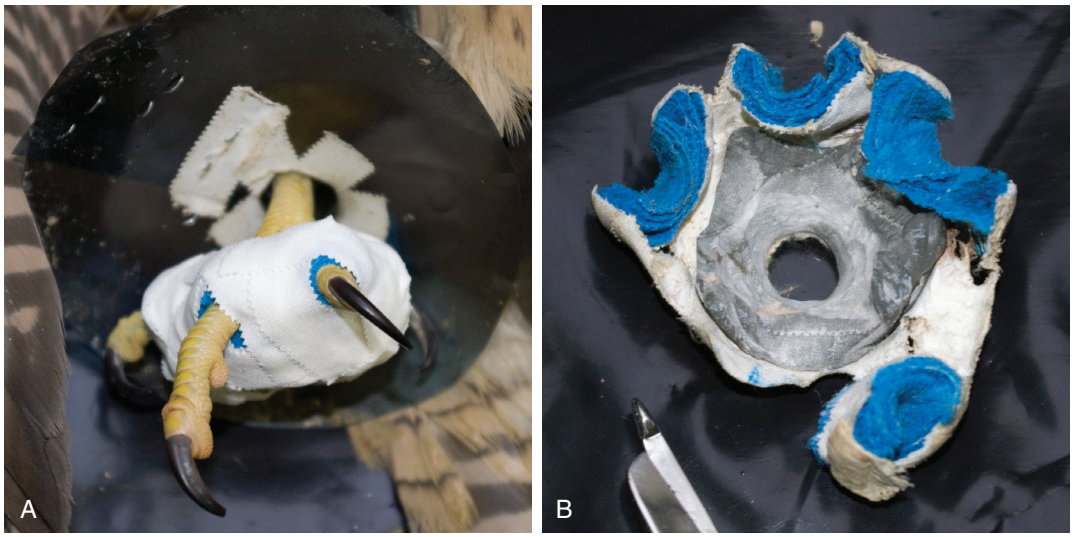

FIGURE 33.13 A saker/gyr falcon hybrid *(Falco cherrug × F. rusticolus)* had surgery for bilateral bumblefoot. For this bird, foot casts were made from car-body filler that was modeled in the correct shape using a Dremel drill with a 9.5-mm grindstone. The toes were padded with sections of loosely wrapped conforming bandage of approximately 1-cm width. As this type of bandage compacts and tightens with time, it must be replaced at least every 10 days. The bird interfered with the bandages, which was prevented by an "Elizabethan collar" on each leg, in this case old radiography film (A). A view of the contact surface of the dressing following removal from the birds foot (B).

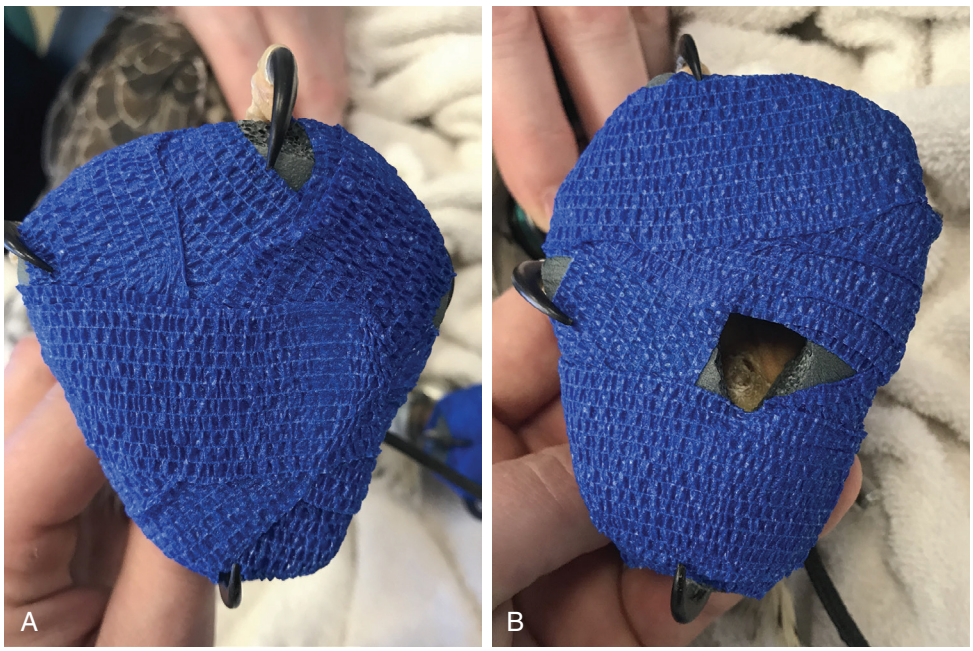

FIGURE 33.14 (A) Pressure-relieving dressing constructed of 12-mm-thick "yoga mat" and cohesive bandage. (B) A central "cutaway" in the yoga mat dressing allows direct application of topical treatments to the central callus of the (grade 2) pododermatitis lesion.

this can also facilitate direct examination and application of topical medication while keeping a dressing in place.

The client/owner will need to keep any foot dressings clean and dry. Should dressings become wet or contaminated or slip out of position, these would need to be changed as soon as possible. Dressings should initially be changed daily to two to three times per week and at least every 5 to 7 days in the later stages of wound healing. Suture removal should be carefully planned and is often best performed in a staged removal (which is why interrupted suture patterns are preferred) to allow the sutures to continue to provide some support for 1 to 2 weeks after wound healing has completed. After removing dressings, the healed skin should be monitored closely (i.e., at least every 4 weeks) for several months

for evidence of recurrence. Intervals of reexaminations would be case specific, but intervals of at least every 4 weeks for the first 3 months are recommended as recurrence is common, and treatment is far more successful if recurrence is quickly identified.

FIGURE 33.15 Doughnut dressing can also be used to relieve pressure from a pododermatitis lesion. (Photo courtesy Neil Forbes.)

While this general treatment guide can be applied to most captive avian species, species-specific treatment recommendations exist and are summarized in the following sections.

SPECIES-SPECIFIC CONSIDERATIONS

Falconiformes

Introduction

The Falconiformes, together with the Strigiformes, integrate a group of birds commonly referred to as birds of prey or raptors. This term originates from the Latin word "*rapere*," meaning to size or grab, and describes how these birds hunt using the large, strong talons and sharp, hooked beaks.

The order of the Falconiformes comprises five families, that is, Cathartidae, Pandionidae, Accipitridae, Sagittariidae, and Falconidae (Box 33.3).

Birds of prey are among some of the most popular species kept in captivity. Many species are maintained in zoological collections and used in exhibitions, others are maintained in breeding centers, as part of propagation and reintroduction programs, while others are bred intensively to supply the needs of the falconry market worldwide (see Chapter 55). This trade involves the Harris' hawk *(Parabuteo unicinctus)*, the goshawk *(Accipiter gentilis)*, as well as falcon species such as the

BOX 33.3 OVERVIEW OF THE VARIOUS FAMILIES BELONGING TO THE ORDER OF FALCONIFORMES[27]

Family	Characteristics
Cathartidae (New World vultures)	◆ Comprises 3 genera, 7 species, and 13 taxa ◆ Medium to large diurnal birds of prey, with bare heads, a powerful hooked beak, and large wingspan to allow gliding and soaring in search of carrion ◆ Habitat: widely variable, ranging from desert, grasslands, and savannas to lowland tropical forests to high mountains of North America, Central America, and South America ◆ Largest species: California condor *(Gymnogyps californianus)* with a weight of 8.0–14.0 kg, length of 1.17–1.34 m, and a wingspan of 2.7 m ◆ Smallest species: lesser yellow-headed vulture *(Cathartes burrovianus)*, with a weight of 950–2550 g, a body length of 0.58–0.66 m, and a wingspan of 1.6 m
Pandionidae	◆ Comprises one single species: osprey *(Pandion haliaetus)*, a relatively large, piscivorous bird of prey ◆ The male and female weigh between 1.2 and 1.6 kg and between 1.6 and 2.0 kg, respectively, and have a body length between 55 and 58 cm and a wingspan of 1.45–1.70 m
Accipitridae	◆ Hawks, eagles, and Old World vultures ◆ Comprises 237 species, 64 genera, and 535 taxa ◆ Worldwide distribution ◆ Largest species: lappet-faced vulture *(Torgos tracheliotus)*, with a weight of 5.4–9.4 kg, a body length of 1.15 m, and a wingspan of 2.80 m ◆ Smallest species: pearl kite *(Gampsonyx swainsonii)* from Central America and South America, of which the male weighs approximately 94 g, has a body length that measures 20–28 cm, and has a wingspan of 54 cm
Sagittariidae	◆ Comprises one single species: the secretary bird *(Sagittarius serpentarius),* a large bird of prey which is characterized by long legs, a loose crest of long feathers, and long central tail feathers ◆ Secretary birds weigh 2.3–4.3 kg, are 1.25–1.50 m height, and have a wingspan of 2.12 m
Falconidae	◆ Small- and medium-sized birds of prey (caracaras to falcons) ◆ Comprises 10 genera, 61 species, and 149 taxa ◆ Worldwide distribution; birds inhabit all geographical regions of the world with the exception of the Antarctic ◆ Largest species: gyrfalcon *(Falco rusticolus).* The male and female of this species weigh 0.96–1.32 and 1.26–2.10 kg, respectively, are 0.48- to 0.60-m long, and have a wingspan of 1.20–13.5 m ◆ Smallest species: black-thighed falconet *(Microhierax fringillarius)* from Southeast Asia, which weighs 28–55 g, has a body length of 14–17 cm, and a wingspan of 30–34 cm

gyrfalcon *(Falco rusticolus)*, the saker falcon *(Falco cherrug)*, the peregrine falcon *(Falco peregrinus)*, and their hybrids (particularly gyr-peregrine hybrids and gyr-saker hybrids), which are mainly destined for the markets of the Middle East, where they are used extensively for hunting and, more recently, for falcon races.

Pododermatitis is a condition commonly encountered in captive birds of prey, particularly the larger species.[28–30] Different etiological factors have been proposed as responsible for the development of pododermatitis in birds of prey including increased body weight, inadequate perches, lack of exercise, sudden cessation of exercise, bruising of the plantar surface of the feet, unequal weight bearing on one foot, overgrown talons,[28–30] and inadequate diets (Figures 33.16 and 33.17).[31] Members of the Falconiformes, but in particular the gyrfalcon *(Falco rusticolus)*, and saker falcon *(Falco cherrug)* are more likely to develop pododermatitis (Figure 33.16).[32] Owls are the next most commonly presented, with larger species such as snowy owls *(Bubo scandiacus)* particularly susceptible. Hawks and eagles have a significantly lower prevalence and typically only develop significant pododermatitis due to concurrent injury or significant husbandry limitations (Figure 33.17A).

Pathophysiology

Pododermatitis in birds of prey begins, in almost every case, with focal to diffused pressure sores to the weight-bearing surface of the plantar pad affecting one or both feet. Pressure sores develop gradually, causing devitalization of the integrity of the epidermis and dermis, and eventually the hypodermis (Figure 33.18).[33] This is mainly caused by diminishing blood circulation due to reduced exercise and activity,[34] increased body weight of the bird, inadequate perches, trauma from bating repeatedly on hard surfaces, and dietary regimens.[35] The resulting ischemia ultimately leads to necrosis and the formation of scabbing and, in many cases, callus of different diameters with associated swelling, increased focal temperature, and pain (Figure 33.19).[36] Invading bacterial infection

FIGURE 33.16 Mild reddening and flattening of the epithelium of the plantar pad in a gyrfalcon *(Falco rusticolus)* at the beginning of the training season. This is the result of standing for long periods of time on falconry stands during training sessions, even if lined with artificial turf.

FIGURE 33.17 (A) Puncture wound due to overgrown talons in a hawk. (B) Dorsal digit 1 pododermatitis lesion which developed as a result of poorly fitted and conditioned anklets. The leather had become hard and abrasive. (A, From Blair J: Bumblefoot: a comparison of clinical presentation and treatment of pododermatitis in rabbits, rodents, and birds, *Vet Clin North Am Exot Anim Pract* 16(3):715–735, 2013, with permission.)

FIGURE 33.18 Grade 1 pododermatitis in a peregrine falcon *(Falco peregrinus).* Lesions often develop gradually as a result of diminished circulation, which leads to devitalization and loss of integrity of the epidermis, dermis, and eventually the hypodermis. (Photo courtesy Neil Forbes.)

FIGURE 33.19 Stage 3 bilateral bumblefoot in a saker falcon *(Falco cherrug)* with bilateral bumblefoot. The right plantar pad exhibits extensive necrosis of the epithelium with a large superficial scab and the left foot, smaller scab with the formation of clavus. Even such chronic cases respond well to conservative treatment without the need for any surgical intervention.

occurs as a sequela to focal necrosis. Bacteria commonly isolated from plantar and interdigital abscesses in birds of prey include *S. aureus*, *E. coli*, *Klebsiella*, and *Proteus* spp.[37] Secondary mycotic infection has been reported and appears to be much more prevalent in warm, humid climates (Figure 33.20).

Clinical and pathological findings

Different classifications of the stages of pododermatitis have been proposed. This has resulted in classifications distinguishing pododermatitis into three,[28] four,[38] or five grades or stages,[6] dependent on the severity of clinical and pathological findings. Currently, the most accepted grading system for pododermatitis in birds of prey is the five-stage classification as developed by Remple (see also Table 33.3).[39]

FIGURE 33.20 Infection with *Candida albicans* of the plantar pad in a saker falcon *(Falco cherrug).* The falcon was operated for stage 2 bumblefoot and a dressing was applied. The bandage and the dressing were not replaced as often as they should have with the resulting infection. Such infections are responsible for a number of nonhealing bumblefoot surgical cases but generally respond well to the use of topical antifungal agents.

TABLE 33.3

Pododermatitis Grading Scheme for Birds of Prey by Remple (2006)[39]

Stage	Characteristics
1	◆ Mild reddening of the plantar epithelium ◆ Flattening of the papillae of the weight-bearing surfaces, and plantar pad in particular
2	◆ Mild hyperkeratosis ◆ Necrosis ◆ Formation of scabbing Mild swelling and pain
3	◆ Moderate to severe hyperkeratosis ◆ Necrotic epithelium ◆ Development of medium to large clavi (corns) ◆ Formation of caseous abscess with related moderate to severe swelling ◆ Mild to moderate pain
4	◆ Spreading infection to the tendon sheaths and tendons with ascending infection to the intertarsal joints ◆ Mild to moderate pain
5	◆ Infection affecting the bones including osteomyelitis and osteolysis and/or septic arthritis of the phalangeal and/or tarsometatarsal joints ◆ Severe swelling ◆ Moderate to severe pain

Treatment and prevention

It is always preferable to prevent pododermatitis in captive birds of prey by eliminating or minimizing the causative etiologies rather than having to attempt treatment (Figure 33.21). Different techniques and approaches for the surgical resolution of pododermatitis in birds of prey, and falcons in particular, have been described over the years.[26,28,30,38–41] Prior to surgery, it is essential that a full assessment of the blood

FIGURE 33.21 Early stage 2 bumblefoot in a saker falcon *(Falco cherrug)* with mild to moderate formation of scabs in both the plantar and digital pads. Such cases respond well to improved husbandry allowing the falcon to stand for long periods of time on clean, soft sand such as washed marine sand alternating with salt/disinfectant footbaths.

FIGURE 33.22 Foot secured in surgical restraint. (Photo courtesy Neil Forbes.)

supply and integrity of the surgical site is carried out as it is vital to create edges with full thickness and with adequate blood supply to ensure healing. In all cases, surgical resolution of pododermatitis involves an incision around the scab and clavi and excision of all necrotic tissue through surgical debridement and curettage of the subcutaneous and interdigital spaces. The collection of bacteriological swabs of purulent caseous material for culture and antibiotic-sensitive testing is important to institute adequate antibiotic therapy. Gram stain cytology can also be used to guide first-line therapy. Given the common etiologic agents involved, amoxicillin and clavulanic acid is commonly the first choice of treatment for the authors, pending results of sensitivity testing. Necrosis and inflammation reduce the blood supply to the area thereby limiting the delivery of systemic antibiotics to the region. This, together with granuloma formation, further shields the pathogens from systemic antibiotics.[31] Remple[39] described a four-step approach for the surgical resolution of pododermatitis in falcons. This approach includes the use of systemic antibacterial therapy, intraoperative antibacterial administration, surgical debridement, and postoperative foot casting.[39] The use of custom-made operating tables with foot support to secure the digits intraoperatively may be useful to facilitate the surgical procedure, if available (Figure 33.22).[39,42] Surgical intervention, as described under section Medical Versus Surgical Intervention, is possible in stage 4 pododermatitis cases but with a reserved prognosis. Stage 5 pododermatitis cases, in contrast, are often candidates for euthanasia on humane grounds as digital function will likely remain permanently impaired, with chronic discomfort.

Daily footbaths using a 5% salt solution together with a disinfectant, for example, chlorhexidine or quaternary ammonium compounds, are also beneficial. These can be prepared by procuring an 8-inch diameter plastic tray, such as those used for pot plants. This is firmly secured to a falconry stand with a heavy base to which the bird is tethered. Daily foot bathing can only be performed realistically in tame falconry birds. The footbath is filled with about 1 inch of the solution and the bird is left to stand for 30 to 60 minutes twice daily. A piece of AstroTurf can be placed at the bottom of the tray for comfort. It is important to ensure that birds are fed the correct diet. Any deficiencies identified should be corrected, although these are uncommon if whole carcasses are fed. Balanced vitamin supplements containing vitamin A and biotin have been proposed, with the latter being largely extrapolated from studies in poultry.[43]

Eagles commonly present with pododermatitis, which has been anecdotally suggested to be related to hyperkeratosis and accumulation of flaking skin (Figure 33.23). This accumulation in turn can lead to fissures and secondary infection. For these cases, the authors have found the use of lanolin-based hand cream or ointments to be beneficial.

FIGURE 33.23 Resolving pododermatitis, right foot, following surgical debridement and primary healing in an eagle. On the left foot, a grade 2 pododermatitis with central callus is present. In eagles, these lesions are anecdotally suggested to be related to hyperkeratosis and accumulation of flaking skin. Early stages may respond favorably to lanolin-based topical creams or ointments.

Various forms of foot casting have been proposed for the postoperative care of pododermatitis in birds of prey.[38,41,44,45] The earliest form of foot casting in the postoperative care of pododermatitis in birds of prey included the use of thermoplastic bandaging tape.[38,40] This was followed by custom-made shoes manufactured from bandaging and epoxy-resin[44] or from automotive body filler[41] or the use of composite silicone dental impression material (Figure 33.24).[45] High-grade foam used in the construction of yoga matting or Hexalite is inexpensive, readily available casting materials that are commonly used and favored by the authors.

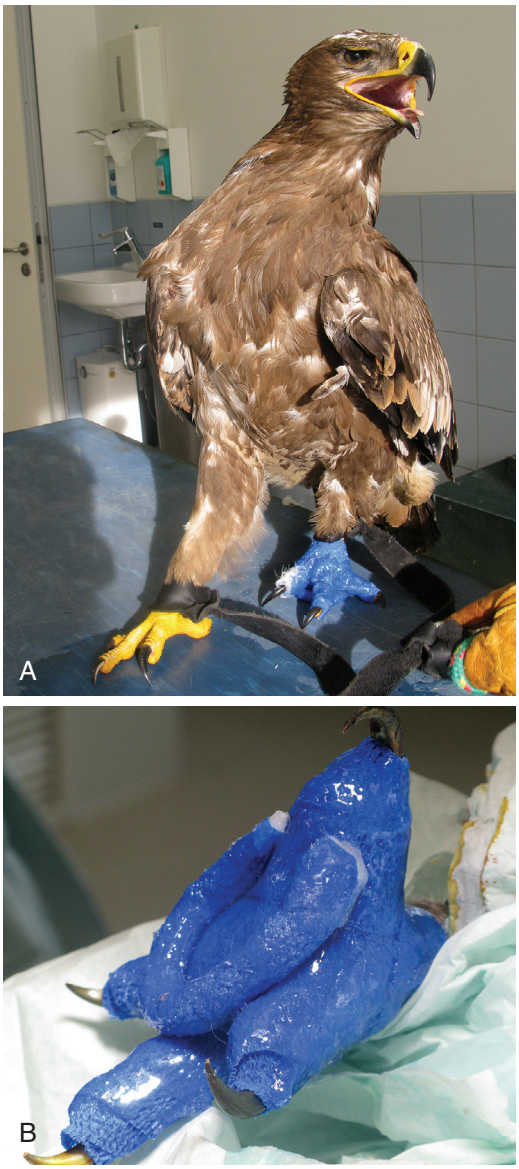

FIGURE 33.24 (A) A 1-year-old female golden eagle *(Aquila chrysaetos)* was presented for bumblefoot. Postsurgically, a custom-made shoe, manufactured from bandaging material and epoxy-resin, was placed around the left foot and was left in place for 2 weeks. After removal of the bandage the wound had almost completely healed. (B) Close-up of the bandage. On the plantar surface a "doughnut" ring was placed to alleviate pressure from the surgical site.

The use of antibacterials, antiinflammatories, and antifungal agents, if necessary, is an essential component in the treatment of pododermatitis in birds of prey.[36] Antifungals are only used in case of cytological or culture evidence of secondary mycotic infection. The use of intralesional antibacterial therapy in pododermatitis in the form of antibiotic-impregnated[26] calcium sulfate beads, or antibacterial gels[46] appears to be effective in controlling localized infections together with systematic antibiotics. This concept was originated from the use of antibiotic-impregnated polymethyl methacrylate beads in the treatment of chronic osteomyelitis and cellulitis in a juvenile bald eagle *(Haliaeetus leucocephalus)*.[47] Beads should be removed after treatment to prevent them from acting as a foreign body and potentially decreasing foot comfort. If beads can be removed from a dorsal-lateral/medial approach, this is preferred as it prevents the need for a further plantar surgical wound.

Dressings and bandaging are also essential in the postoperative care of cases of pododermatitis in birds of prey.[48] Zsivanovits and Monks[31] suggested that the addition of dimethyl sulfoxide (DMSO) in the dressing facilitates the penetration of topical antibiotics and helps reduce swelling. However, *Candida albicans* is a yeast commonly invading surgical sites covered with dressings and protected by bandaging if sterility of the surgical site was not preserved or if the dressing was not changed and replaced with more frequency. While not proven, the authors suggested that secondary fungal overgrowth of bandaged pododermatitis lesions is more common in hot and humid climates. Recent studies in cadaver peregrine falcon *(Falco peregrinus)* feet have used force pressure sensors to suggest that snowshoe dressings are preferable to interdigital bandages at relieving pressure from the plantar pad.[49] However, it has yet to be determined if this finding is repeatable in live birds and clinical cases.

Some species of raptors, particularly those considered more intelligent species such as Harris' hawks and caracara (*Caracara* spp.), will often chew and remove protective and supportive foot dressings. A smooth, round orthotic formed from dental acrylic (Kooliner, GC Europe, Leuven, Belgium) and molded around the tip of the maxillary beak limits a raptor's ability to pick successfully at dressings (Figure 33.25).[50] As this will affect a bird's ability to tear at the food, hand feeding or chopping of the food will be required. One author has used a film/plastic disk fixed around the tarsometatarsus to reduce the incidence of self-trauma.

Exercise, perching, and environment are all important factors in managing pododermatitis in raptors. Excessive body condition, inactivity, and inappropriate perching all predispose and will delay recovery. If possible, a raptor should be flown and/or exercised while under treatment as this promotes circulation and ensures body condition is managed. If daily treatment (particularly topical administration of medication) is required, it may be appropriate to tether a (trained) raptor during treatment (see Chapter 55). However, as minimal welfare intrusiveness is the goal, each case needs to be individually assessed for its potential adverse effects on the patient. Perching should be critically analyzed. If pressure-related pododermatitis has developed, then perching changes will be required—and if these are not made recurrent disease will almost certainly occur. Molting, which typically occurs in the spring/summer at the end of the breeding season, leads to

FIGURE 33.25 Dental acrylic maxillary blob is used to prevent dressing interference. This technique appears particularly useful in Harris' hawks *(Parabuteo unicinctus)* to prevent picking at a foot dressing.

FIGURE 33.26 Image of the skin 21 days postoperatively and 7 days after suture removal following surgical debridement of grade 3 pododermatitis in a Chaco owl *(Strix chacoensis)*.

reduced activity in captive birds. The authors have seen a pattern where birds who have been affected by pododermatitis had an increased chance of reoccurrence if free lofted in a pen to molt. Encouraging owners to continue to exercise their birds during the molt may thus help prevent this problem.

Conclusion

Pododermatitis in birds of prey is only observed in captive birds used in captive breeding programs and those used for falconry and is best described as a management-related medical condition. Surgical failure and recurrence of pododermatitis in birds of prey are high and have been attributed to the failure of the operator to recognize the granulomatous nature of this condition and the etiological causes.[39] A four-stage therapeutic approach has been proposed as the most successful in resolving pododermatitis in birds of prey.[39] This includes (1) systemic antibacterial therapy, (2) direct intralesional antibacterial therapy, (3) surgical debridement, and (4) postoperative protective foot casting.[39] When managing the condition, the anatomy and structure of the plantar aspect of the foot should be returned as close to the normal shape as possible, with as little scar tissue as feasible, which helps prevent recurrence of the condition (Figure 33.26).

In almost every case of stage 1 and stage 2, and in many cases of stage 3 pododermatitis, the best intervention is not to intervene surgically and to opt for conservative treatment (Figure 33.27). This is probably the most indicated form of therapy in the long term.

Anseriformes

Introduction

Incorporated within the order Anseriformes are three families: Anhimidae, Anatidae, and Anseranatidae. The family Anatidae contains over 170 species of waterfowl including ducks, geese, and swans, which are the most common Anseriformes kept in captivity. The pygmy geese (*Nettapus* spp.) are the smallest, weighing only 300 g, whereas the trumpeter swan *(Cygnus buccinator)* is the largest of the waterfowl and can weigh up to 17 kg. Anatidae are found all over the world apart from the Arctic.

Different waterfowl use different feeding strategies: some spending the majority of time on water, with others spending significant periods on land. This needs to be considered when evaluating husbandry and environmental conditions in cases of pododermatitis. Birds whose wild ancestors predominately spent time on the water in their natural range would be at high risk for pododermatitis if they are forced into terrestrial living and unable to freely spend time on water.

Dabblers are waterfowl that feed primarily on the surface of water or graze under shallow water. Traditionally, this group is assigned to ducks from the subfamily Anatinae. These birds rarely dive and tend to have their legs placed more centrally on their body, walk well on land, and even feed terrestrially. Mallards *(Anas platyrhynchos)*, teals (*Anas* spp.), widgeons (*Mareca* spp.), and most swans (*Cygnus* spp.) are dabblers.

Divers, as their name suggests, feed primarily under the water. Their legs and feet are situated more caudally, and they spend little or no time on the ground. Examples include the ruddy duck *(Oxyura jamaicensis)*, marbled teal *(Marmaronetta angustirostris)*, and the rest of the *Aythya* genus. Captive management schemes that result in having these species spending excessive periods on land is a risk factor for developing pododermatitis.

The most common grazers are geese (*Anser* spp.). These birds are terrestrial spending most of the time on land. In the wild, geese are frequently found grazing arable land where

FIGURE 33.27 Grade 2 pododermatitis before (A) and directly following (B) 2 weeks of treatment with topical Preparation H and changed perching. In early stage pododermatitis, conservative treatment can lead to full resolution (C).

they can be considered a pest species such as Canada geese *(Branta canadensis)* in Europe.

The final classification is perching ducks—which typically are long legged and are adapted to allow perching or roosting in trees. Mandarin *(Aix galericulata)* and wood ducks *(Aix sponsa)* are typical examples.[51]

General risk factors for pododermatitis in waterfowl include housing with excessive areas of hard standing (e.g., concrete), abrasive surfaces, interspecies disturbance/bullying and introducing new birds to existing group (leads to increased exercise/chasing), poor hygiene, excessive body condition, and skeletal deformities leading to uneven pressure.

Pathophysiology

Waterfowl have palmate feet to help them swim. The first digit or hallux is vestigial, and the birds have a relatively large plantar pad.

In captivity, one or more husbandry or environmental factors are often responsible for the development of pododermatitis. Among these are a lack of opportunity for swimming, obesity, contralateral limb injury causing uneven weight bearing, and standing on hard/abrasive substrate (concrete/compacted earth).[52] The disrupted epidermis and presence of gradual avascular necrosis, predominately affecting the plantar pad but on occasions also the digital pads, provide favorable conditions for microbial entry and allow for invasion of secondary pathogens. In the authors' experience, this most commonly includes bacteria such as *E. coli*, *Staphylococcus* spp., *Proteus* spp., *Aeromonas* spp., and *Pseudomonas aeruginosa*, although occasionally fungal organisms (e.g., *C. albicans*) are also involved. Poor hygiene also predisposes to such secondary infections.

Clinical and pathological findings

Pododermatitis in Anseriformes can be graded into five classifications, as has been described for raptors (Table 33.3). However, many authors simplify the classification system into three grades—mild, moderate, and severe (Table 33.4)[52]—as treatment options vary little between grades 1 and 2 or grades 4 and 5. It is very common to find grade 1 or mild pododermatitis as an apparent "asymptomatic" finding in captive waterfowl, with the birds showing no apparent discomfort and the condition only being noted on close inspection of the foot. Educating owners and keepers to closely monitor foot health and instigate measures before the disease progresses beyond this stage is vital in preventing more serious diseases. In early disease, hyperemia and erythema are associated with a shiny appearance of the metatarsal and digital pads. As disease progresses to moderate disease, fissures and large callous formation of the foot pads are particularly common as hyperkeratosis develops and lesions often become proliferative (Figures 33.28 and 33.29).

Treatment and prevention

Collection of a thorough history is vital when managing a case of pododermatitis in waterfowl. Any potential husbandry deficiencies should be identified and corrected. On-site visits can be very useful—if not, photographs or videos of the enclosure/housing can be used. In cases where substrate is too hard, sharp, or abrasive, this should be corrected. In many cases, natural substrates such as grass or sand are preferable to

TABLE 33.4

Three-Grade System for Pododermatitis in Waterfowl

Mild		Hyperkeratosis and erythema but no Infection
Moderate		Callous and infection but no skeletal involvement
Severe		Osteomyelitis

FIGURE 33.28 Grade 3 pododermatitis with hyperkeratosis, moderate swelling, and central caseous core in a Sebastopol goose *(Anser anser domesticus)*. In waterfowl, the plantar pad is most commonly affected, though on some occasions the digital pads can be involved too.

FIGURE 33.29 Radiograph shows periosteal reaction and severe soft tissue swelling of the proximal phalanx of digit 4 in a domestic goose *(Anser anser domesticus)* resulting from severe, grade 3 pododermatitis. Morphologic appearance is shown in Table 33.4.

artificial materials.[31] The birds should be observed to assess the duration of time in water and on land, ensuring it is appropriate for the species. If water is not being utilized by the birds, this warrants further attention and investigation; factors such as excessive stocking density, flock hierarchy, (aerial and terrestrial) predators, and multispecies interaction can affect

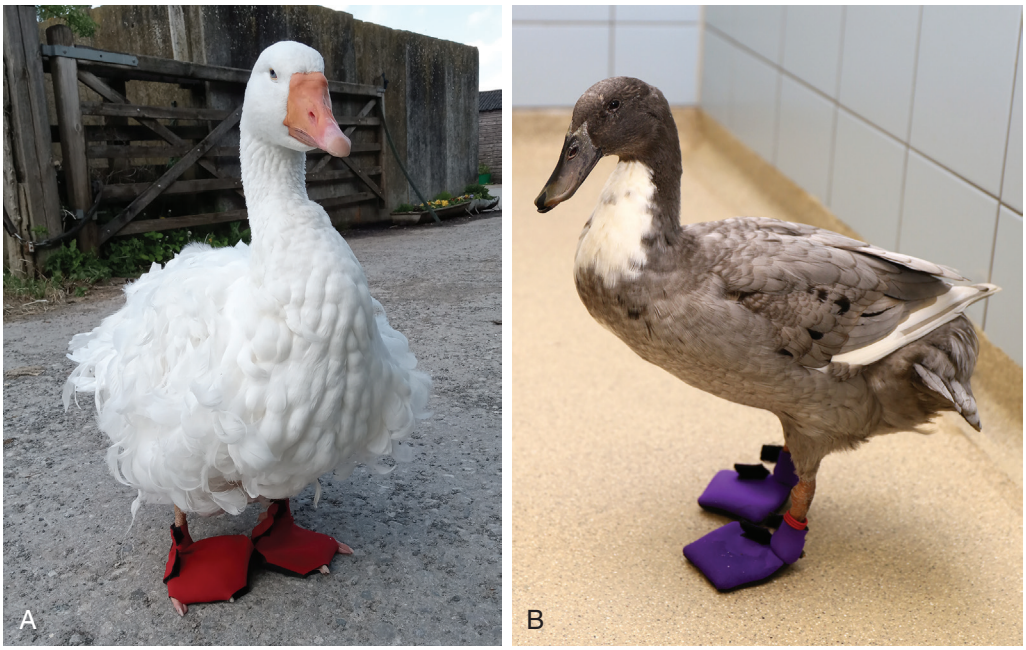

FIGURE 33.30 Sebastopol goose *(Anser anser domesticus)* (A) and female Indian runner duck *(Anas platyrhynchos)* (B) wearing removable waterproof neoprene protective shoes (Birdy Bootie, Crazy K Farm Pet and Poultry, USA). Such neoprene shoes are particularly useful in waterfowl where contact with hard abrasive surfaces like concrete is possible. In addition, the shoes can be beneficial to alleviate pressure in the case of (chronic) bumblefoot, as was the case in the Indian runner duck.

the use of available swimming water. Diet should be assessed and supplemented or converted if required. Vitamin A deficiency has been associated with chronic epithelial conditions such as pododermatitis and is associated with feeding a high-grain diet.[53] The body's condition should be assessed, and feeding should be addressed in case of obesity.

If disease has progressed beyond mild/grade 1 lesions, husbandry modifications alone are unlikely to be effective to resolve the pododermatitis. In such instances, topical foot treatments with agents such as chlorhexidine, povidone iodine, and magnesium sulfate solutions can be utilized. However, little data exist to support the use of one over the other. Topical antimicrobial treatments such as silver sulfadiazine may be sufficient in early cases, but systemic therapy is required for moderate and severe cases. Systemic antimicrobials should be selected based on culture and sensitivity, where possible. Bimodal antibacterial therapy (e.g., aminoglycosides combined with penicillamine or trimethoprim-sulfonamide) may be indicated, although restrictions may apply in food-producing animals. Pressure-relieving dressings such as doughnut type or ball bandages can help the skin to heal and keep the area clean and free from environmental contamination. However, maintaining dressings can be particularly challenging in waterfowl that need regular access to bathing facilities for maintaining plumage quality. If ambulation on hard and/or abrasive surfaces cannot be avoided, neoprene boots can be fastened to the feet to protect the plantar and digital pads. These are used frequently, particularly by owners of heavier bodied waterfowl. Velcro fasteners allow easy fitting and removal. These are commercially available in the US (Birdy Bootie, Crazy K Farm Pet and Poultry; crazy-k-farm.myshopify.com; Figure 33.30). One big advantage of neoprene is that it does not need to be removed before swimming. Commercial and home-made devices can be made to the correct size for bird feet. Each bird should ideally have two pairs so that one can be washed and disinfected while the other is in use, as this will help prevent the boot from becoming a fomite for infection. Allowing birds to continue to swim takes weight off the feet and may thus expedite lesion resolution. In advanced cases, surgical debridement may be required to debride necrotic tissue and remove caseous material with its associated pyogenic membrane. The decision to operate on waterfowl is a difficult one, as surgical wounds can be challenging to heal in aquatic birds. Modern waterproof dressings or artificial skins can be applied to surgical wounds. Equally, delaying surgery can allow the progression to deeper infection, osteomyelitis, and septic arthropathy. Following surgery, a period of minimally 5 days, in which swimming is avoided, is recommended to allow the open wound to heal and prevent secondary contamination of the wound bed. Dependent on the complexity of the case, this period could be extended. Given the well-developed medial metatarsal vein and featherless skin below the intertarsal joint, limb perfusion antibiotics are also an excellent option to consider in Anseriformes (see section on Regional Limb Perfusion and Chapter 36).

A technique has been presented for the surgical lavage of chronic septic arthritis lesions in the foot of Anseriformes. The procedure is done separately to planter approach to the pododermatitis lesion to avoid causing disruption to the blood supply. A dorsal approach is made to the affected interphalangeal joint(s)—or tarsometatarsal phalangeal joint (Figure 33.31). Inspissated material is curetted, and samples

FIGURE 33.31 Pekin duck *(Anas platyrhynchos)* with severe grade pododermatitis of the plantar pad, and concurrent osteomyelitis and septic arthritis (A). Such cases can be successfully treated with surgical lavage. For this purpose, the affected joint is accessed from (latero)dorsal, following which the necrotic/purulent debris can be removed from the joint using a curette. If needed, multiple incisions can be made. Once all debris is removed, a small silicone tube (e.g., butterfly catheter tubing) is tunneled through the joint and sutured in place to enable repeated flushing of the joint (B). A protective layer of bandage can be used to prevent the bird from chewing the tubing. Flushing of the joint for several days will help clear the joint infection and can result in complete resolution of the infection (C). (Photos courtesy Scott Echols and Avian Studios.)

are collected for cytology and culture. Sterile plastic giving set tubing with a luer attachment and preplaced ports is sutured in place between the surgical sites allowing repeated lavage to be performed over several days.

Galliformes

Introduction

The order Galliformes contains 290 species across five families. The most common in captivity are Phasianidae (including the domestic fowl, quails, partridges, pheasants, turkeys, peafowl, and grouse), Odontophoridae (New World quail), and Numididae (guineafowl). Cracidae (including chachalacas and curassows) and Megapodiidae (megapodes) are certainly less common.

Galliformes are kept in captivity for many reasons; the largest percentage of captive birds are domestic poultry kept for food production, typically on a commercial scale; however, backyard poultry keeping has boomed in recent years. Galliformes are also kept in zoological collections or as ornamental pets. Husbandry varies widely from commercial environments to more naturalistic enclosures. Within commercial poultry there is a move toward free range production—although cage and barn systems still exist in many countries.

Husbandry will vary depending on the species being housed. The majority of commonly kept poultry (chickens, guinea fowl, turkey) roost at night and will require appropriate daytime floor-level substrate and suitable perching, both having an effect on foot health. When choosing floor substrate, often a compromise between easy to clean/biosecure options and comfort for birds is required.

As well as being a significant welfare concern in commercial poultry, pododermatitis can cause severe economic losses during production. Severe cases can lead to secondary infections, poor carcass development, and carcass rejection at slaughter. Chicken feet are a commonly exported byproduct of broiler production but will be rejected where pododermatitis is present.

Pathophysiology

As in many other species, galliform pododermatitis features hyperemia, hyperkeratosis, and avascular necrosis of the epidermis. If disease is allowed to progress, ulceration and inflammation of the subcutaneous tissues occur with or without abscessation and fistula formation. Rather than pressure necrosis due to poor perching being the primary etiology, as seen in many avian species, it has been proposed that frequently, poultry disease is caused because of contact dermatitis due to poor bedding/substrate. Lesions have, on occasions, been termed ammonia burns and are believed to be caused by a combination of moist litter and chemical irritation of the skin due to a high ammonia content of the litter. Organic material in urine and feces accumulating in litter is converted to ammonia under anaerobic conditions and to nitrate under aerobic conditions. Wet substrates and a humid environment will provide conditions that favor attachment of litter to the feet and formation of ammonia due to the anaerobic conditions.[54] Bedding materials with sharp edges (large particle size wood chips, chopped straw, etc.) may contribute to foot pad dermatitis (FPD) through their abrasive action, however.[55]

Proven risk factors for development of pododermatitis include:

- bedding deeper than 5 cm;
- wet litter;
- use of drinking cups instead of nipple drinkers;
- winter weather;
- poor ventilation;
- genetic susceptibility (within lines of commercial chickens).[56,57]

Broiler birds are at higher risk of pododermatitis due to their high body condition scores and conformation. Pododermatitis incidence and severity were found to be increased following feeding with high-protein diets in broilers. When managing litter ammonia levels associated with higher stocking density, sodium bisulfate used as a litter amendment reduced volatile ammonia levels and significantly lowered the incidence and severity of pododermatitis. Male broilers have been shown to be more predisposed to pododermatitis than females.[58]

Many lesions show no histological evidence of bacterial or fungal infection.[55] Where secondary bacterial infection occurs, *S. aureus* (68%), *Enterococcus faecalis* (14%), and *E. coli* (9%) have been shown to be most prevalent.[59] Secondary mycotic pathogens are also reported, with *Cryptococcus* spp. and other opportunistic fungal pathogens have been cultured from pododermatitis lesions.[12] Most pathogens (whether bacterial or fungal) will be secondary to the underlying cause of pododermatitis. However, they require appropriate treatment—ideally based on culture and sensitivity for successful management. Choice may be limited due to antibiotic restrictions that apply to poultry. Topical treatment with betadine combined with trimethoprim-sulfonamide or amoxicillin-clavulanic acid is a common first-line treatment used in poultry by the authors.

Clinical and pathological findings

Pododermatitis lesions in Galliformes are described similarly to other avian species (see Table 33.3). Lesions can be varied, with hyperkeratosis, abrasion, ulceration, necrosis, and abscess formation, with or without the formation of a fistula canal being most common (Figure 33.32).[60] In commercial poultry, similar lesions are also seen on the hock and overlying the pectoral muscle and have been associated with wet/high ammonia litter and high body condition in boiler birds.[61]

FIGURE 33.32 Various grades of pododermatitis in the domestic chicken *(Gallus domesticus)*. (A) Mild, grade 1 pododermatitis with a small surface lesion and hyperkeratosis of the plantar foot pad. (B) Moderate, grade 2 pododermatitis with a medium-sized lesion, with erosion of the surface and central callus formation. (C) Severe, grade 3 pododermatitis with significant soft tissue swelling and central callus formation. These lesions are usually large, deep, and ulcerated.

One of the commonly utilized foot scoring systems was described by Berg[62] who classified pododermatitis lesions in poultry into a three-point system:

- 0—no lesion;
- 1—mild erythematous lesion;
- 2—severe erosive lesions.

Many other systems exist with three-, four-, and six-grade systems being proposed.[63,64] Visual scoring systems are unable to assess the depth of lesions—and it is suspected that depth is more significantly correlated with lesion discomfort than width. Depth is more readily assessed microscopically. However, this renders this type of grading scheme more suited to post-slaughter assessment than for companion birds such as the five-grade histological scoring system.

A recent publication described the attempts that were made to validate a four-point grading scheme by comparing macroscopic and microscopic findings of pododermatitis lesions in poultry (Box 33.4). Results of this study showed presence of a strong correlation between lesion width and lesion depth, and between hyperkeratosis and lesion depth. In addition, the study evaluated intra- and interrater reliability, which showed the greatest variability between assessors when having to distinguish between grade 3 and 4 lesions. This strengthens the arguments for use of a three-grade system.[8]

In commercial production units, automated foot scoring systems now exist which are less subjective and shown to be more accurate than human scoring. Thermography has shown to be more sensitive than visual examination alone at detecting early or subclinical pododermatitis lesions (see Chapter 3).[65]

Treatment and prevention

If a deficiency in substrate or environment is noted, this should be corrected. A study investigating substrate in the broiler industry found that substrate that was either highly absorbent (e.g., wood shavings) or quick-draining and easily able to release moisture (e.g., rice husks) provided the best results regarding preventing pododermatitis.[55] Good litter management and hygiene will help to reduce the risk of secondary infection. Wood or paper-based bedding materials designed for horses that are low dust, hypoallergenic, and resist mold growth can be effective choices.

As with other species, obesity and limb injury resulting in uneven weight distribution to the feet can predispose to pododermatitis. Backyard poultry in particular are kept up to much greater ages than commercial poultry.[66] Degenerative arthropathies can alter weight bearing and predispose to pododermatitis lesions. Exercise can be useful to both stimulate blood flow to the feet and contribute to weight loss, which removes the load on the feet.[67]

BOX 33.4 FOUR-POINT GRADING SCHEME FOR VISUAL SCORING OF PODODERMATITIS IN GALLIFORMES

Score 1: No lesion, no hyperkeratosis, no ulcers (original score 0).
Score 2: Small lesion on the surface (original score 1).
Score 3: Medium lesion, with erosions only in individual cases (original score 2a).
Score 4: Large and deep lesion, ulcers, and scars (original score 2b).

Many pododermatitis lesions—particularly low grade—are not secondarily infected. Litter management, pressure-relieving dressings, and topical antiseptics/antimicrobials can be used. Where secondary bacterial or mycotic infections are identified, treatment should be based on culture and sensitivity. Long-term antimicrobial administration has been facilitated in poultry by using a vascular access port.[68] Intravenous and intraosseous regional limb perfusion has also been tested in poultry and is another method of delivering high concentrations of antibacterials to the foot while decreasing the risk of systemic side effects.[69]

Surgical management should be restricted for high-grade lesions where necrotic tissue and caseous abscess require removal. Lesions should be debrided with care so as not to damage important soft tissue structures such as flexor tendons but should also remove pyogenic membranes as completely as possible. Primary closure following debridement is preferable to allow more rapid healing—but is not possible where insufficient skin is present—and healing by secondary intention may be required. Advanced flaps have been used in Falconiformes and can be adapted for use in Galliformes.

The use of vitamin and mineral supplementation has been investigated for their role in preventing pododermatitis lesions. The picture is unclear, with early studies showing biotin supplementation as potentially effective in reducing onset of lesions,[70] whereas in turkey poults, biotin supplementation made no difference to lesions.[71]

Psittacine and Passerine Birds

Introduction

Psittacine birds are very popular cage and aviary birds. They are equipped with strong legs, upright stance, and zygodactyl foot structure, giving them a strong grip and ease of perching. There are nearly 400 species of psittacine birds, weighing from <50 g up to 2 kg. Psittacine birds are known for their social nature and high levels of intelligence and are commonly kept within the home, resulting in potential exposure to some unnatural substrates on which to perch, and feeding of unlimited quantities of energy-rich diets, which predisposes to obesity and nutritional deficiencies that can increase the risk for pododermatitis.

The order of passerine birds covers over 50% of known avian species. Only a small number of species are kept in captivity—these being common aviary birds in private and zoological collections. Canaries *(Serinus canaria)* and finches (*Fringillidae* spp.) are the most frequently kept passerine species. They have an anisodactyl foot structure to give stable perching. Corvids, in particular the common raven *(Corvus corax)* are the largest passerines—weighing up to 2 kg body weight, with the smallest passerines weighing only a few grams. The taxonomic orders of Psittaciformes and Passeriformes include a large number of species that each have their unique, species-typical behaviors, but the heavy bodied birds (e.g., *Amazona* spp.) that are prone to a more sedentary lifestyle when maintained in captivity are predisposed to pododermatitis.

Pathophysiology

The most common cause of pododermatitis is poor perching or cage floor substrate. Perches with too narrow or too wide diameters can lead to poor weight distribution on the foot.

Typical recommendations include a diameter size where the foot is wrapped for approximately two-thirds to three-fourths around the perch. It is advisable to have variable perching surface and diameters within this range to provide choice and variety for the bird. Smooth perches that tend to create focal pressure are also linked to the development of lesions. An area of pressure necrosis develops, the reticulate scales become noticeably smooth and flattened, and marked erythema is seen. Sandpaper perches, while commonly recommended to keep nails short, may create areas of pressure and avascular necrosis on the skin, particularly in smaller passerine birds.[72,73] As lesions progress, ulceration and hyperkeratosis are frequently seen. Many birds will prefer a particular perch location over an appropriate perch type or size, requiring perch rotation. For communally housed birds, care should be taken to ensure that sufficient perching space is provided.

Dynamics between groups of housed birds can lead to subordinate birds being forced off the most comfortable perching. Overgrown claws can lead to punctures of the plantar surface or altered weight bearing on the feet. Many owners use sandpaper or concrete perches with the aim of correcting overlong claws, but these may exacerbate pododermatitis due to abrasion causing irritation and erythema. Sandpaper cage floor coverings are commonly used with small passerines and may exacerbate foot disease.

Both psittacine and passerine birds are prone to malnutrition in captivity. Seed-based diets have been shown to be deficient in vitamin A.[74] Hypovitaminosis A in turn can predispose to hyperkeratosis, loss of skin elasticity, and a weakened immune system.[75]

As with many avian species, excessive weight is a factor. Large bodied psittacine birds, for example, *Amazona* spp. appear predisposed to the development of pododermatitis.[76] Pain associated with lesions often leads to further reduction of activity and worsened situation. Many pet psittacine birds suffer from obesity due to a combination of excess nutrition and inactivity. Wing clipping of birds (a largely outdated practice) prevents flight, which is one of the most effective forms of exercise. As birds enter the geriatric life stage, the prevalence of osteoarthritis significantly increases. The resulting uneven use of the pelvic limb and feet is another leading cause of pododermatitis.

Clinical and pathological findings

Although pododermatitis is a frequent clinical finding in psittacine birds and occasionally passerine birds, no specific grading or classification of lesions has been accepted for either order. Most clinicians therefore adopt the 1 to 5 scale as used in Falconiformes (see Table 33.3), although it is uncommon to see advanced grade 4 to 5 lesions in psittacine and passerine birds.

Two lesion types seem to predominate in low-grade psittacine pododermatitis, empirically with some species developing one more frequently than the other. *Amazona* spp., in particular, seem to develop thinning of the skin with a loss of keratinization (Figure 33.33A). *Psittacus* spp., in contrast, develop hyperkeratosis and fissures (Figure 33.33B).

In psittacine and some passerine birds, plantar foot lesions are frequently accompanied by lesions on the plantar aspect of the intertarsal joint. Birds with sore feet, arthritis, or inadequate perching will frequently sit down on their hocks, predisposing to the tarsal lesions (Figure 33.34).

FIGURE 33.33 Typical low-grade pododermatitis lesions in parrots include thinning of the skin with loss of keratinization, as is seen in an Amazon parrot (*Amazona* spp., A), and hyperkeratosis and fissures, as seen in a conure (*Pyrrhura* spp., B).

Treatment and prevention

Treatment involves correcting underlying husbandry deficiencies and managing the lesions. Perching should be selected to provide a choice of varying diameters. Generally, the digits should grasp roughly two-thirds to three-fourths around the perch. Natural surfaces such as fruit tree branches promote better foot health then smooth doweling type perches. In some cases, it may be necessary to wrap the perch with soft padded material (e.g., Vetrap) to relieve the pressure. In some instances, pressure-relieving bandages (as used in raptors) may be required. Perch rotation can encourage perching on different surfaces.[73] Perch and substrate hygiene should be kept optimal to reduce the chance of secondary bacterial infection. Remote observation is key to investigate the bird's use of perches as well as its behavior in its environment, based on which behavior change can be instigated to promote appropriate use of perches,

FIGURE 33.34 Pododermatitis affecting the hock in a Senegal parrot *(Poicephalus senegalus)*. Such lesions are typically seen in birds with arthritis or painful feet but can also result from inadequate perching.

if required (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).

The prevalence of pododermatitis in psittacine birds increases with age. Arthritis, particularly affecting the stifle and intertarsal joints of psittacine birds, affects weight bearing. Modified perches may be required for geriatric birds—some manage better on shelf perches, or with padded perching surfaces.

If weight is identified as a contributing factor to the pododermatitis, a gradual weight loss program will be required. Dietary conversion away from a nutrient-deficient diet, or addition of reliable supplementation, may also need to be considered. Environmental enrichment should be assessed and implemented. Enriched birds will be more active, less sedentary, and likely have improved body conditions. Foot toys, foraging toys, and the provision of a foraging tree encourage the bird to move around the enclosure (see Chapter 47).[77]

Psittacine and passerine birds with pododermatitis very rarely require surgery as most birds will respond to medical treatment. Topical or, in more advanced cases, systemic antibiotics can be used and follow guidelines such as listed for Falconiformes. Effective analgesia is vital and reduces the risk of self-mutilation.

One complicating factor to consider when treating psittacine birds is that they will frequently interfere with and remove dressings. In cases where dressings are required, strategies may therefore need to be employed to prevent interference. While (temporary) collar placement can help to effectively prevent bandage destruction, the use of less-intrusive options that redirect the behavior (e.g., distractor tabs, enrichment of chewing/foraging behaviors) is highly preferred and should be used as the first-choice method, whenever possible.

Sphenisciformes

Introduction

Penguins are a group of flightless aquatic birds belonging to the order of the Sphenisciformes living primarily in the Southern Hemisphere, with the exception of the Galapagos penguin *(Spheniscus mendiculus)*, which lives north of the equator. The order of the Sphenisciformes comprises one family, the Spheniscidae, comprising 6 genera, 17 species, and 26 taxa. Penguins are among the most popular birds kept in zoological collections. The largest living species is the emperor penguin *(Aptenodytes forsteri)* weighing 19 to 46 kg and standing 1.12 to 1.15 m in height, whereas the smallest species is the little blue or fairy penguin *(Eudyptula minor)* that weighs on average 1 kg and stands 0.40 to 0.45 m in height.[78]

Penguins are pelagic birds that spend up to 75% of their lives living in the open sea, coming to shore only during the breeding and molting seasons.[78] In captivity, however, penguins are confined mostly to small enclosures provided with ponds and a beach and rockery with concrete flooring. Under such conditions, penguins are predisposed to pododermatitis due to the sedentary lifestyle, reduced time swimming, prolonged length of time spent standing on hard and abrasive flooring, and nutritional deficiencies.[79–82]

Pathophysiology

Penguins possess palmate webbed feet with four digits, but the first digit or hallux is only vestigial, and a relatively large and voluminous plantar pad. The tarsometatarsi are short, and the legs are placed far back on the body, which makes the birds stand upright.[78] The increased pressure of the weight of the bird on the plantar pad of the foot makes penguins more predisposed to develop pododermatitis.[79]

In captivity, penguins develop pododermatitis as a result of gradual avascular necrosis of the weight-bearing surfaces, mainly of the plantar pad and, less commonly, of the digital pads. This is mainly due to the lack of exercise and the result of standing on hard and abrasive flooring for long periods of time. Other predisposing factors include poor floor hygiene and nutritional deficiencies.[79,82] While concrete surfaces are commonly listed as a risk factor, pododermatitis is a seemingly rare phenomenon in certain zoos, despite the penguins being housed in a concrete surfaced enclosure. Possibly, this is due to the unlimited access to a large, long swimming pool that promotes swimming activity (Adam Naylor, personal communication, 2023). As such, these observations emphasize the multifactorial origin of the condition.

Clinical and pathological findings

Pododermatitis of penguins is a progressive clinical disease affecting the weight-bearing plantar pad of the foot and digital pads. The condition in penguins is characterized by the presence of flattened and thinner epithelium, hypertrophy of the epithelium, superficial to deep ulcerations leading to clavi, single central caseous to multiple digital abscesses, mild to severe swelling, increased localized temperature, and mild to severe pain (Figure 33.35). In penguins, the three-stage classification has been favored by several authors as this seems to conform well to the clinical and pathological findings commonly observed in individuals from the different penguin species maintained in captivity (Table 33.5).[79,81]

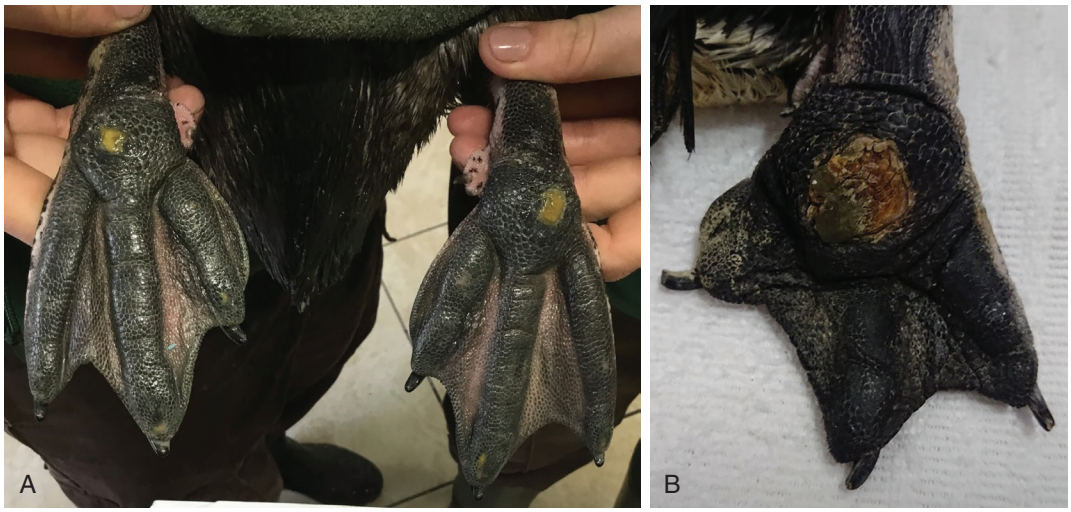

FIGURE 33.35 (A) Bilateral, mild to moderate ulcers on the plantar pad of a 5-year-old captive Humboldt penguin *(Spheniscus humboldti)*. This could be considered a transition stage between grade 1 and grade 2 bumblefoot. This type of bumblefoot should be treated as early as possible to stop developing into a more serious condition. (B) Severe and extensive necrosis of the plantar pad with the formation of deep infected clavus in an African penguin *(Spheniscus demersus)* admitted to a rescue and rehabilitation center. Such rescue centers should provide different flooring surfaces and increase activity in order to prevent the occurrence of bumblefoot and delay releasing individuals back to the wild.

TABLE 33.5

Three-Stage Classification Scheme for Pododermatitis in Penguins

Stage 1	Flattening and thinning of the epithelium of the weight-bearing surface, most commonly, of the plantar pad. Hypertrophy of the epithelium leading to clavi can also be present.[79]
Stage 2	Presence of infection of the dermis and soft tissue of the plantar pad with a variety of bacteria. Foot temperature can be increased and mild to moderate pain and subsequent lameness are usually present.
Stage 3	(Chronic) infection which not only affects the pad but also extends to the tendons, bones, and/or joints.[79]

The lack of uniform and universal description and classification of pododermatitis in penguins has made identification of early detection of disease difficult, resulting in the delay in the establishment of adequate therapy measures.[82] It has also been suggested[79] that the etiological factors leading to the development of pododermatitis in penguins may be similar to those described in detail by Harcourt-Brown[36] in raptors.

Treatment and prevention

Over the years, different treatment protocols have been undertaken, including cleansing the feet with a 2% chlorhexidine solution, footbaths with chamomile tea followed by the application of a cream containing DMSO, escin 20% solution, dexamethasone, prednisolone, and lidocaine hydrochloride.[81] The possible immunosupressive affects of steroidal medication must be considered before prescribing, even when used topically. In addition, other more invasive protocols have included the use of surgery and debridement, followed by bandaging and dressing containing a topical solution of enrofloxacin, DMSO, and dexamethasone and the use of neoprene shoes fitted with Velcro straps for a period of up to 3 months to ease the healing process (Figure 33.36).[79]

Currently, environmental enrichment seems to be the most popular long-term option to manage pododermatitis in collections of captive penguins (Figure 33.37).[81,83–85] Measures introduced into the environment and changes into the daily routine included reinforcing the penguins to stay one additional hour in the water through the provision of play objects such as colored balls and rings, ice blocks with fish, natural shells, and live fish, gradually introducing such items on a daily basis.[81] Another measure is the placement of structures within the enclosure and stimulation for the penguins to climb or swim through these. This has been used with different degrees of success to increase the time spent in the water.[84]

Behavioral husbandry has also been proposed as an aid to manage pododermatitis in captive penguins.[86] This consists mainly of reinforcement of voluntary participation by individuals in their routine care and using operant conditioning through the development and reinforcement of desirable human-animal interactive relationships.[86]

Phoenicopteriformes

Introduction

Flamingos are large birds with long necks and legs and a distinct pink plumage. One unique anatomical feature particular to flamingos is the downcurved beak adapted for filtering feeding. The neck and the legs are longer in relation to the body size than in any other group of birds. The extreme

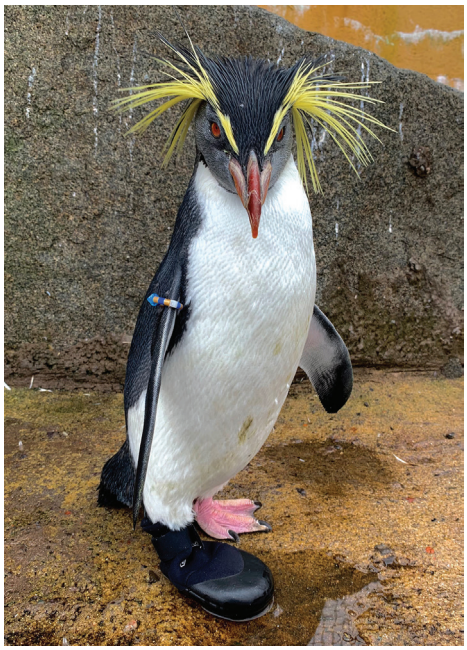

FIGURE 33.36 In penguins, neoprene protective boots that are commercially sold for small dogs are a suitable option for providing cushioning for mild pododermatitis lesions and for additional protection of dressings that may be applied in cases of severe pododermatitis or following surgery. In this elderly rockhopper penguin *(Eudyptes chrysocome)* the boot was placed unilaterally to aid healing of a pododermatitis lesion that was suspected to have developed as a consequence of osteoarthritis and associated abnormal posture and uneven weight bearing. The bird was restricted from swimming while wearing the boot. (Photo courtesy Adam Naylor, Royal Zoological Society of Scotland, Edinburgh Zoo.)

FIGURE 33.37 A captive 27-year-old African penguin *(Spheniscus demersus)* was previously affected with severe, stage 2 bilateral bumblefoot. The feet developed extensive necrosis of the plantar pad occupying over 50% of the total surface after years of standing on hard and abrasive flooring. The image shows the feet greatly improved after 4 months of environmental enrichment and improved behavioral husbandry.

length of the legs and the reduced feathering on the tarsometatarsi allow flamingos to wade deeper than any other wading bird, allowing them to go as far as the lower abdomen. The order Phoenicopteriformes is composed of one single family, the Phoenicopteridae, comprising three genera, five species, and six taxa. Flamingos have a worldwide distribution with the exception of Australasia and the Antarctic. In some species males are larger than females, but in some species the size difference is minimal. The largest species is the greater flamingo *(Phoenicopterus ruber)* weighing 2.1 to 4.1 kg and standing 1.20 to 1.45 m in height. The smallest species is the lesser flamingo *(Phoeniconaias minor)* that weighs 1.5 to 2.0 kg and stands 0.80 to 0.90 m in height.[87]

Flamingos are one of the most popular birds maintained in bird gardens and zoological collections worldwide. In a survey carried out in European zoos in 2013, 65% out of 139 members of the International Species Inventory System (ISIS) held greater flamingos, representing a total of 5,500 birds.[88]

Flamingos live and thrive in medium to large colonies of hundreds and thousands of individuals in highly specialized habitats consisting of mangrove swamps, shallow lagoons, and lakes with pH value as high as 10.5 and very often, with twice the salinity of seawater.[87]

Pododermatitis did not seem to occur in free-living flamingos as observed in the Camargue, France, in different studies.[89,90] In captivity, flamingos are housed in open enclosures provided with medium-sized shallow ponds and beaches. Due to convenience and to ease the cleaning procedures, most water ponds and beaches for housing flamingos are built of rough and abrasive concrete surfaces. The type of flooring appears to be a possible contributing factor in the development of pododermatitis.[89,91,92] Flamingos housed in collections north of the 53rd degree latitude are viewed to be at a higher risk of developing pododermatitis since the birds are maintained mostly indoors due to the prevailing climatic conditions.[7]

Pathophysiology

The feet of flamingos are small in relation to the size of the body and are provided with four digits, except for the Andean flamingo *(Phoenicoparrus andinus)* and the James's flamingos *(Phoenicoparrus jamesi)* in which the hallux or first digit is absent. There is a relatively large and thick interdigital web between the three front digits starting from the joint between the first and second phalanx. This type of foot webbing (palmate) provides support and allows flamingos to walk across soft mud and silt.[87]

Pododermatitis in flamingos develops gradually. Hyperkeratosis in the proximal pads of the digits is first commonly observed, reflecting an increased weight bearing in such areas. In a study carried out in European and American zoological collections, 100% of the flamingos included in the study were affected by such hyperkeratosis in the digital pads.[7] Hyperkeratosis of the digital pads does not appear to cause pain or discomfort to the bird. However, in the same study, up to 87% of the flamingos presented fissures with up to 46% showing deep fissures (Figure 33.38). There is no clinical information to support this, but it is believed fissures may be painful and may allow a port of entry to bacteria.[7] The presence of nodular growths was relatively small (19%), with only 6% of such birds showing severe nodular growths (Figure 33.39).[7]

FIGURE 33.38 A lesser flamingo *(Phoeniconaias minor)* showing bilateral superficial and deep fissures in all digital pads classified as stage 2 with fissures substage 1 and fissures substage 2. This bird was maintained in a rescue and rehabilitation center on concrete flooring. Such cracks are believed to be painful and serve as port of entry to bacteria.

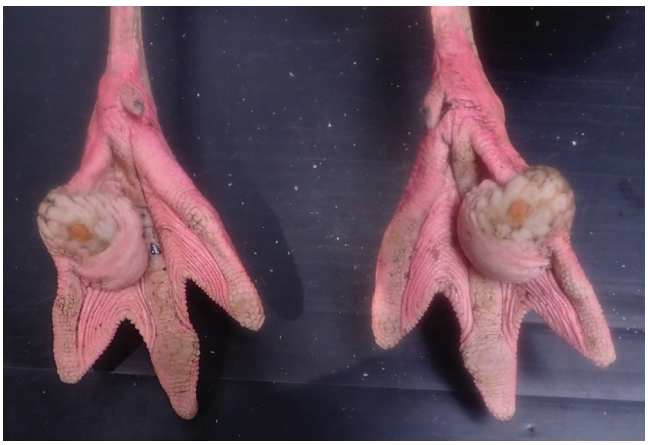

FIGURE 33.39 Greater flamingo *(Phoenicopterus roseus)* with a large abscess in the plantar pad. Such cases should undergo surgery to debride all necrotic tissue and to attempt first intention healing. Postoperative care of such cases can be challenging as the feet have to be kept dry at all times.

Papillomatous growths were observed in 46% of all the flamingos examined, with only 11% of the birds showing severe growths (Figure 33.40).[7]

In a study carried out at Basel Zoo in Switzerland, a novel bacterium was isolated from skin scrapings from several flamingos. The organism was identified as *Arsenicicoccus dermatophilus*.[93] In addition, *Micrococcus*-like bacteria invading the stratum corneum and exocytosis of heterophils into the epidermis were observed in a group of captive juvenile flamingos.

FIGURE 33.40 Greater flamingo *(Phoenicopterus roseus)* with stage 4, substage 2 bumblefoot showing cauliflower papillomatous growths on the plantar pads of the feet. Such cases of severe bumblefoot require radical excision surgery and long postoperative care with a moderate prognosis.

The exocytosis was attributed to reaction to the presence of the bacteria.[90]

It has long been suspected that papillomavirus could be involved in the development of papillomatous growths in the feet of flamingos. In support of this hypothesis, virus-like particles were observed in a northern gannet *(Morus bassanus)* with proliferative pododermatitis[94] and in several waterfowl species with verrucous hyperkeratotic pododermatitis.[95] Similarly, poxvirus has been associated with wart-like cutaneous growths in Chilean flamingos.[96] In a study using the polymerase chain reaction (PCR) carried out in 20 samples obtained from flamingos at Basel Zoo, no evidence was found for the presence of papillomavirus or poxvirus.[90] However, herpesvirus DNA of an unknown strain, but 69% identical to gaviid herpesvirus 1, was amplified in three samples obtained from flamingos affected with cauliflower papillomatous growths and fissures.[90]

Clinical and pathological findings

Pododermatitis in flamingos is classified into four stages, with two substages each according to the abovementioned pathological observations on the plantar pad and digits (Table 33.6).[7,89]

Treatment and prevention

Comparative studies carried out in zoological collections in France and Switzerland have shown that flamingos maintained in ponds provided with natural flooring have significantly less severe pododermatitis presentation than those kept on concrete flooring.[7,89] There are few species-specific recommendations for the treatment of lesions in flamingos. As a result, treatment of pododermatitis in flamingos is largely extrapolated from general treatment guidelines as listed for other species.

The exact etiology of pododermatitis in flamingos has not been identified to date; however, the type of flooring (concrete) used in ponds and dietary deficiencies, in particular dietary zinc, have been identified as possible causes of development of pododermatitis in captive flamingos.[89,91,92] Access to sunlit areas within the enclosure helps to increase natural

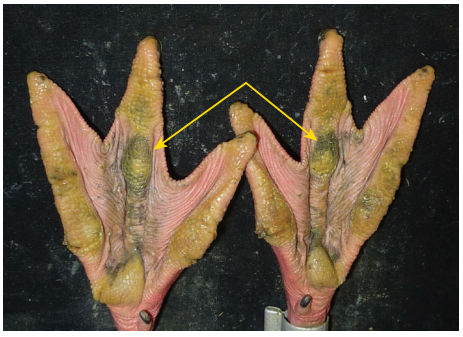

TABLE 33.6

Classification Scheme for Pododermatitis in Flamingos[7,89]

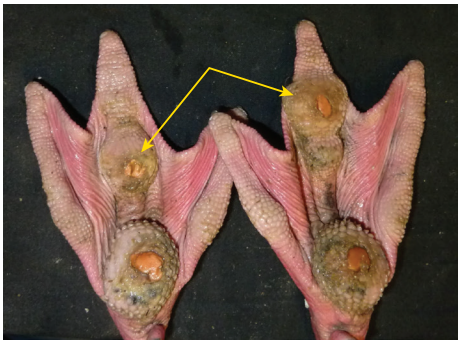
Stage 1 pododermatitis: hyperkeratosis

Substage 1: slight hyperkeratosis

Substage 2: marked hyperkeratosis

Stage 2 pododermatitis: fissures

Substage 1: superficial fissures



Substage 2: deep fissures

Stage 3 pododermatitis: nodules

Substage 1: nodules without ulceration

Substage 2: nodules with ulceration

Stage 4 pododermatitis: papillomatous growths

Substage 1: finger-like papillomatous growths

Substage 2: cauliflower-like growths

behaviors, including foraging and swimming, with a potential benefit to foot health.

SECTION 8 THE TRAUMA PATIENT

CHAPTER 34

Triage and Stabilization

Angela M. Lennox • Jennifer E. Graham • Natalie Antinoff

INTRODUCTION

Birds presenting after trauma may show behaviors ranging in extremes from normal to increased activity and responsiveness to nonresponsive. Due to innate tendencies to hide signs of illness, many birds with catastrophic injuries can appear bright and alert, including (in the authors' experience) those with multiple fractures and even complete beak avulsion. It must be assumed that despite appearances, any bird with evidence of trauma is experiencing pain, and appropriate analgesia is a mandatory part of immediate treatment.

ASSESSING THE PATIENT—INITIAL HANDLING AND TREATMENT

Examination

All trauma patients should be observed at rest, undisturbed, prior to handling if possible. Evaluate the bird's ability to move about the enclosure, body position, respiratory effort (open-beak breathing or tail bobbing can be signs of increased respiratory effort), fluffed feathers, and overall level of responsiveness. Take note of color and consistency of droppings, any regurgitated material, and the presence of any blood or discharge. Observe the bird for normal behaviors in relation to the species and environment; for example, a bird of prey or wild bird should be very alert and not expected to eat, whereas a parrot may exhibit preening and eating. Injured birds still aware of their surroundings may experience stress with handling, which can cause rapid decompensation. During any handling and restraint, constantly look for indications that the bird should be released at once and the examination or procedure postponed; these include increasing dyspnea, inability to grasp, increasing weakness, and decreased response to stimuli. These birds should be offered oxygen and warmth while formulating a plan for the next steps.

Physical examination is best performed systematically, thoroughly, and in a timely fashion to minimize stress. It may be safest to perform the examination in stages if the patient is unstable. Have all materials, including any needed for the examination or diagnostics, organized prior to handling the bird. Work in a small room with locking doors and covered windows to minimize the potential for additional trauma with any escapes. Darkening the room can reduce movement of particularly fractious patients to facilitate initial capture. An appropriate scale (1-g increments of measure for small birds, with a range of over 1 kg to accommodate larger species) should be used to determine the weight of the patient prior to or immediately following the examination. While some birds will willingly step onto a tared perch, placing the bird in a small container for weighing is preferable to avoid further injury in cases of trauma.

Evaluation of the head should include examination of the external ear canals, nares, eyes and surrounding tissues, beak, and the oral cavity including mucus membranes and choanal slit. The beak is a common site for trauma and should be closely inspected for fractures or bleeding, particularly from the tip of the rhinotheca. Rhinothecal tip fractures can be incomplete and difficult to detect (Figure 34.1). Head trauma can result in ocular trauma, hemorrhage, or bruising (Figure 34.2). In birds of prey or in cases of head trauma, perform a fundic examination to evaluate for retinal detachment, hemorrhage, or other indicators of trauma. If the bird's condition permits, separate the feathers over the skull and assess for bruising, and palpate the orbital rim for fractures. Palpate the crop at the base of the neck and note any distention or evidence of wounds. Body condition should be assessed by palpation of the pectoral muscling and palpation of the body for any excess fat stores. The abdominal region between the ventral keel and the pelvis should be gently palpated for any evidence of distention. Wings and legs should be evaluated for symmetry, bruising, or instability, along with

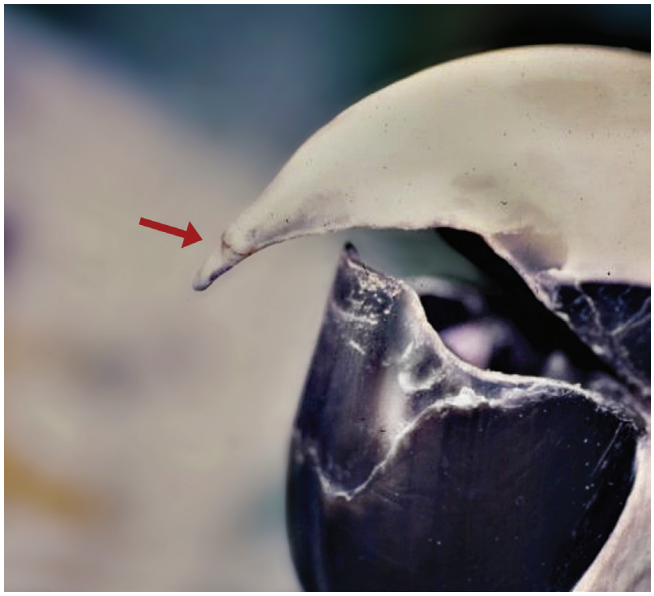

FIGURE 34.1 Traumatic rhinotheca tip incomplete fracture *(arrow)*. These fractures often require careful close inspection to detect.

FIGURE 34.2 A budgerigar *(Melopsittacus undulatus)* with suspected head trauma. Note marked depression and ruffling of the feathers of the head.

the overall quality of the skin and feathers. The presence of a wing droop or leg lameness warrants further investigation (Figure 34.3). Auscultation of the heart is best performed over the keel while the respiratory tract can best be auscultated across the dorsum. Note any heart murmur, arrhythmia, or increased respiratory sounds. Any crackles, wheezes, or clicking can indicate pathology as respiratory sounds are normally minimal. Note that there can be a normal clicking sound in some birds from the uncinate processes (projections off the caudal aspect of each rib) hitting one another—this is most common in cockatiels in the authors' experience. Ruptured air sac, fracture of pneumatic bones, and penetrating bite wounds can result in subcutaneous emphysema, which can produce a crackling sound and crepitus when palpating the skin. Skin

FIGURE 34.3 A subtle right-wing droop in a double yellow-headed Amazon parrot *(Amazona ocrocephala oratrix)* with suspected wing trauma. Wing carriage in a normal bird is symmetrical at rest.

turgor can be assessed by gently pinching or lifting the eyelids—if the skin stays tented, this can be a sign of dehydration. Observe and palpate the brachial artery for strength, regularity, and quality; this may be difficult to evaluate in smaller species. The oral cavity can be dry and pigmented in many species, so evaluation of the cloacal mucosa can give a better idea of mucous membrane color and hydration. Perfusion status can be assessed by refill time of the basilic vein. Complete neurologic examination can be challenging in some patients but should be attempted for any bird with suspected head trauma (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 9, Clinical avian neurology and neuroanatomy). At any point in time, a stressed bird can be given a break or placed in oxygen with the remainder of the examination completed later. Evaluate the recovery of the bird and note excessive recovery time, dyspnea, or weakness. Overweight birds and birds with coelomic distention can easily become overheated and may display panting and holding the wings away from their body to facilitate cooling during recovery. Be cognizant of other conditions that may contribute to overheating such as sun exposure when injured, especially for outdoor birds and wildlife.

Common Trauma Presentations

Birds are relatively fragile when compared to the size of their human companions and other traditional pets that may live in the same household. Common traumatic injuries include bite wounds, collision injuries with walls, windows, and ceiling fans (especially in free-flying birds), compression injuries from entrapment in furniture or closing doors, and blunt

trauma from falls in nonflighted, often overweight birds. Even birds that are maintained in cages are not immune to predators; there are many anecdotal reports of cats and even wildlife such as raccoons pulling parrots, poultry, and exhibit birds through cage bars resulting in severe wounds and even traumatic amputation of limbs. Immediate life-threatening conditions include moderate to severe hemorrhage, upper airway and pulmonary trauma, and internal organ damage and bleeding.

Analgesia is important for the trauma patient and is presented in Chapter 35 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 20, Recognition, Assessment, and Management of Pain in Birds.

ASSESSING THE PATIENT—BASIC LIFE SUPPORT

Before taking a complete history, determine if the bird needs immediate care. As in mammals, the ABCs (airway, breathing, cardiovascular status) should be immediately assessed in avian patients with trauma. Stabilization efforts should be made in situations of hemorrhage, respiratory distress, severe neurologic signs including seizures, open fractures, or if the bird is weak and/or on the bottom of the enclosure. If immediate care is needed, place the bird in a warm and oxygenated incubator, ideally 85°F to 90°F (29°C–32°C). Supportive care measures including fluids, nutritional support, analgesics, or antibiotic therapy can stabilize the patient and allow for additional diagnostics and treatment later. Avoid high temperature if head trauma is suspected.

The nonresponsive patient may require basic life support (BLS) and should be evaluated immediately, and cardiopulmonary resuscitation (CPR) rendered if necessary. Guidelines for BLS in birds are based on those considered most effective in other veterinary patients, with adaptations made for significant anatomic and physiologic differences (Table 34.1).[1] The Reassessment Campaign on Veterinary Resuscitation (RECOVER) campaign is an initiative of the Veterinary Emergency and Critical Care Society (VECCS) and the American College of Veterinary Emergency and Critical Care (ACVECC) to continually assess and review scientific literature in an effort to provide evidence-based and consensus guidelines for CPR for dogs and cats.[2] While RECOVER does not include data for nontraditional pet species, the guidelines are an excellent starting point for improving CPR efforts in special species, including birds. A recent study described CPR outcomes in hospitalized birds.[3] The study included 41 birds that experienced arrest either during anesthesia or during handling or hospitalization. Various CPR techniques were attempted, including ventilation, external compressions, vascular access, fluid administration, and drug administration. There were three documented cases of return of spontaneous circulation (ROSC) and one cardiopulmonary arrest (CPA) survivor. Two of the survivors were undergoing minor procedures, and one a more invasive coelomic surgical procedure. Protocols used to successfully resuscitate the patients differed in all three patients. Because of this high variability and low number of successful CPR attempts, it is currently not possible to form specific recommendations intended to improve success in future cases; however, the low number of successful attempts does demonstrate that while chances for ROSC are poor, positive outcomes demonstrate that coordinated and vigorous attempts should be made.[3] Resuscitation wishes should be discussed in advance for critical patients and CPR efforts made accordingly. Successful resuscitation requires staff preparedness, which includes frequent CPR drills, and consolidating all necessary equipment into specific designated areas of the hospital with available oxygen and where CPR is most likely to take place.

For birds, specialized equipment includes multiple sizes of endotracheal tubes (1.0 mm and larger) and tight-fitting masks for ventilation, emergency drugs, and appropriately sized needles and syringes. Modified red rubber tubes, 18- to 22-gauge (G) intravenous (IV) catheters (with stylet removed), or other tubing may be used for intubation of small

TABLE 34.1

ER, Emergency room.

birds and should be prepared in advance and kept with standard endotracheal tubes for easy access in an emergency.

All equipment for BLS is kept in a designated "crash cart," which is separate from regular hospital supplies, clearly marked, and regularly inspected. Crash carts are sealed and dated with tape. When the cart is opened, supplies are replaced when the BLS event ends and resealed to ensure it is ready for the next emergency. A summary of useful equipment for the avian crash cart is presented in (Box 34.1).

BOX 34.1 SUGGESTED SUPPLIES FOR THE AVIAN EMERGENCY AND CRITICAL CARE "CRASH CART"

Drugs

Epinephrine (1:1000, 1 mg/mL)
Vasopressin (20 U/mL)
Atropine (0.54 mg/mL)
Naloxone (0.4 mg/mL)
Flumazenil (0.1 mg/mL)
Atipamezole (5 mg/mL)
Lidocaine 2%
Hypertonic saline 7.3%
50% Dextrose
Furosemide
± Norepinephrine
± Dobutamine
± Dopamine
± Calcium gluconate

Supplies

ET tubes (appropriate size for birds, 1.0–4.0 mm)
Tight-fitting anesthetic face masks (various sized appropriate for birds)
Sterile cotton tip applicators
Syringes, needles, flush, catheters (appropriate size for birds)
Suture (sizes 5-0 to 2-0, absorbable and nonabsorbable)
IO catheters (25-18-G hypodermic needles or small, short spinal needles with stylet)
ECG with atraumatic clips and/or small ECG pads
Capnograph
Prewarmed fluids (replacement crystalloids-LRS, saline, etc.), hypertonic saline, hydroxyethyl starch (e.g., hetastarch)
Air sac tube (commercial or made from shortened endotracheal tubes)
Bandaging supplies (basic vet wrap, rolled gauze, cast padding, tape [cut to size])
Tourniquet (rubber band, hemostat, or small commercial product)

Ideal Equipment Available in Close Proximity

O_2 flow meter + humidifier and/or oxygen cage (with heat and humidity control)
Multiparameter monitor with ECG, BP, $ETCO_2$, Pulse-OX
Doppler unit (used to monitor heart directly or for BP with appropriate cuff sizes)
Glucometer, PCV tubes, slides for blood smear
Ideal: point-of-care ultrasound unit

The crash cart is positioned in close proximity to an oxygen source. Crash cart contents should be replaced immediately after use and inspected regularly.

BP, Blood pressure; *ECG*, electrocardiogram; *ET*, endotracheal; *$ETCO_2$*, end-tidal carbon dioxide; *LRS*, lactated Ringer's solution; *PCV*, packed cell volume; *Pulse-OX*, pulse oximeter.

Respiratory Arrest

Birds are relatively easy to intubate, as the position of the glottis is clearly visible at the base of the tongue (Figure 34.4). Birds under 100 g are more challenging to intubate due to size. A small endotracheal tube can be fashioned from a 3.5- or 5-mm red rubber tube in small birds if an appropriately sized tube is not readily available. The glottis of chickens and other poultry is relatively deep and should be gently pushed rostrally to visualize it. Cotton-tipped applicators are very useful to help remove mucus and debris from the oral cavity and in some cases depress or advance the rostral portion of the tongue. Avoid inflation of cuffed endotracheal tubes in birds as their complete tracheal rings predispose them to stricture. If intubation is complicated and takes more time than anticipated, consider forced mask ventilation with a tight-fitting mask. A variety of masks with small openings to create a tight seal are required for forced mask ventilation in birds. A syringe case can also be modified to fit over the beak and nares and sometimes is necessary in some species. In both cases, a ventilation rate of 15 to 20 breaths per minute has been suggested, but the ideal ventilatory rate for birds in the face of respiratory arrest has not been determined.

In cases of suspected tracheal injury, avulsion, or obstruction (as indicated by the presence of stridor, open-beak breathing, and increased inspiratory effort), an air sac tube should be placed (see section on Respiratory Distress and Chapter 29).

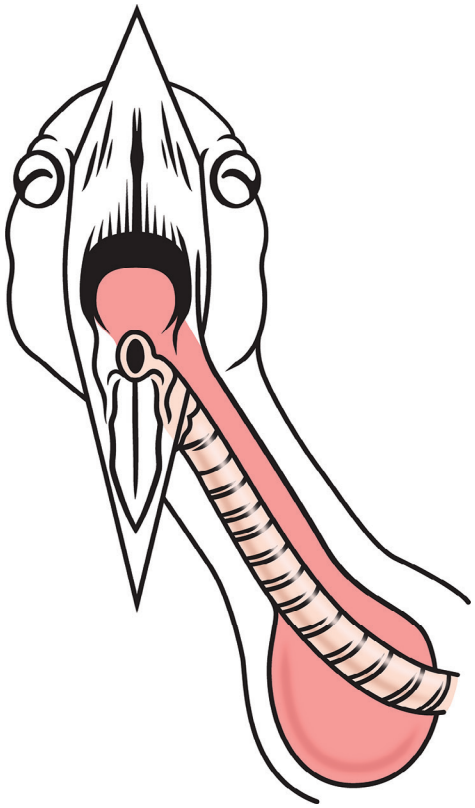

FIGURE 34.4 Line drawing of the general placement of the glottis in relation to the tongue.

Cardiac Arrest

If cardiac arrest is identified, start cardiac compressions. Note that there are limited data on the efficacy of compressions in birds because of the large keel of flighted birds and the high compression rates that are likely required. Chest compressions in birds may work on the principle of a thoracic pump, increasing the intrathoracic pressure to encourage blood flow out of the heart and great vessels. The wide sternum "shields" the heart and the coracoids prevent depressing the cranial sternum during traditional cardiac compressions. Therefore, adopting a different technique than mammals for cardiac compression may be more effective. A recent study evaluating the arterial blood pressure during three different types of cardiac compressions was performed in chickens.[4] Cardiac compression techniques include keel compressions, lateral compressions, and keel compressions with interposed caudal coelomic compressions (ICCC). Keel compressions with ICCC consistently resulted in higher arterial blood pressures compared to lateral compressions or keel compressions alone. Although this study was performed in poultry, keel compressions with ICCC should be considered in psittacine species. When compressions are attempted, more than 120 compressions/minute have been suggested. When performing compressions in the intubated patient, compressions and ventilation can be performed simultaneously. When using forced mask ventilation, discontinue compressions temporarily during ventilation (Table 34.1)

Cardiac activity should be monitored with electrocardiography (ECG) and effectiveness of compressions with a Doppler probe. ECG leads should be attached to the skin at the base of both wings and both thighs. This can be done using hypodermic needles, paper clips, gel-soaked gauzes, or self-adhesive patches. The Doppler probe can be placed near the proximal ulna or medial tibiotarsus, with a cuff for blood pressure monitoring placed on the humerus or femur, respectively. The width of the cuff should be 30% to 40% of the circumference of the limb. Indirect blood pressure measurements in birds are not very accurate; however, they can be used to monitor trends. Every 1 to 2 minutes, discontinue compressions and assess for ROSC via the ECG, Doppler probe, and auscultation.

Epinephrine and atropine have been described for use in birds, but specific research focusing on ideal dosages is lacking.[5] Table 34.2 lists some suggested dosages. Ideal route of administration is IV, or in case of vascular collapse, rapidly place an intraosseous (IO) catheter, which is discussed in greater detail in the section on Vascular Access.

Once cardiac and respiratory arrest are resolved, evaluate for shock and begin appropriate treatment.

SEDATION FOR THE TRAUMATIZED PATIENT

Many traumatized but responsive birds benefit from low-dose sedation to decrease anxiety; this is of particular benefit for the bird in respiratory distress. The most described sedation protocol combines midazolam (0.25–2 mg/kg) with butorphanol (1–2 mg/kg), which provides the added benefit of analgesia.[6] Another option is lower-dose midazolam and butorphanol with the addition of 1 mg/kg alfaxalone intramuscularly (IM). Dosages are chosen based on overall patient condition, with lower dosages chosen for sicker patients. The authors prefer the delivery of sedation drugs in a trauma patient by combining them into a single syringe and injecting IM using minimal handling techniques. Intranasal administration of midazolam and midazolam-butorphanol has been described and may be useful in some situations as well.[7]

Analgesia is discussed in detail in Chapter 35 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 20, Recognition, Assessment, and Management of Pain in Birds.

Vascular Access

Vascular access is required for effective delivery of emergency drugs, for blood transfusion, and to treat shock. Ideally, oral or subcutaneous fluids should be reserved for stable, standing patients that are suspected to be less than 5% dehydrated. However, the risk of catheter placement due to stress and handling in some patients may outweigh benefits. Therefore, it may be beneficial to administer subcutaneous fluids along with other stabilization measures prior to catheterization. Oral fluids should not be administered if there is significant risk of aspiration, in a recumbent patient or in patients with evidence of marked gastrointestinal dysfunction. Vascular access in birds can be performed via two routes: IV and IO; the choice depends on patient size and condition and personal preference.

Intravenous catheters are more difficult to maintain than IO catheters due to the thin skin of the bird. Locations for IV catheters include the jugular vein, basilic (or ulnar) vein, or the medial metatarsal vein (Figure 34.5A–C). The area for catheter placement is plucked and scrubbed. A small catheter (generally 24- to 26-G over-the-needle catheter) is guided into the vein and secured to the skin with glue or tape sutured

TABLE 34.2

Cardiopulmonary Resuscitation (CPR) Drug Dosages Suggested for Use in Birds

Drug	Dose	Concentration	Route
Epinephrine	0.01 mg/kg	1:1000, 1 mg/mL	IM, IV, IO, intratracheal
Atropine	0.02 mg/kg	0.54 mg/mL	IM, IV, IO
50% Dextrose	0.25 mL/kg	1:1 dilution with saline	IV
Calcium gluconate	50–150 mg/kg	10%, 100 mg/mL	IV (bolus slowly)
Doxapram	2.0 mg/kg	20 mg/mL	IV, IO
Vasopressin	0.8 U/kg	20 U/mL	IV, IO
Naloxone	2.0 mg	0.4 mg/mL	IV

Dosages are based on extrapolation from other species and anecdotal reports.
IM, Intramuscular, *IO*, intraosseous, *IV*, intravenous.

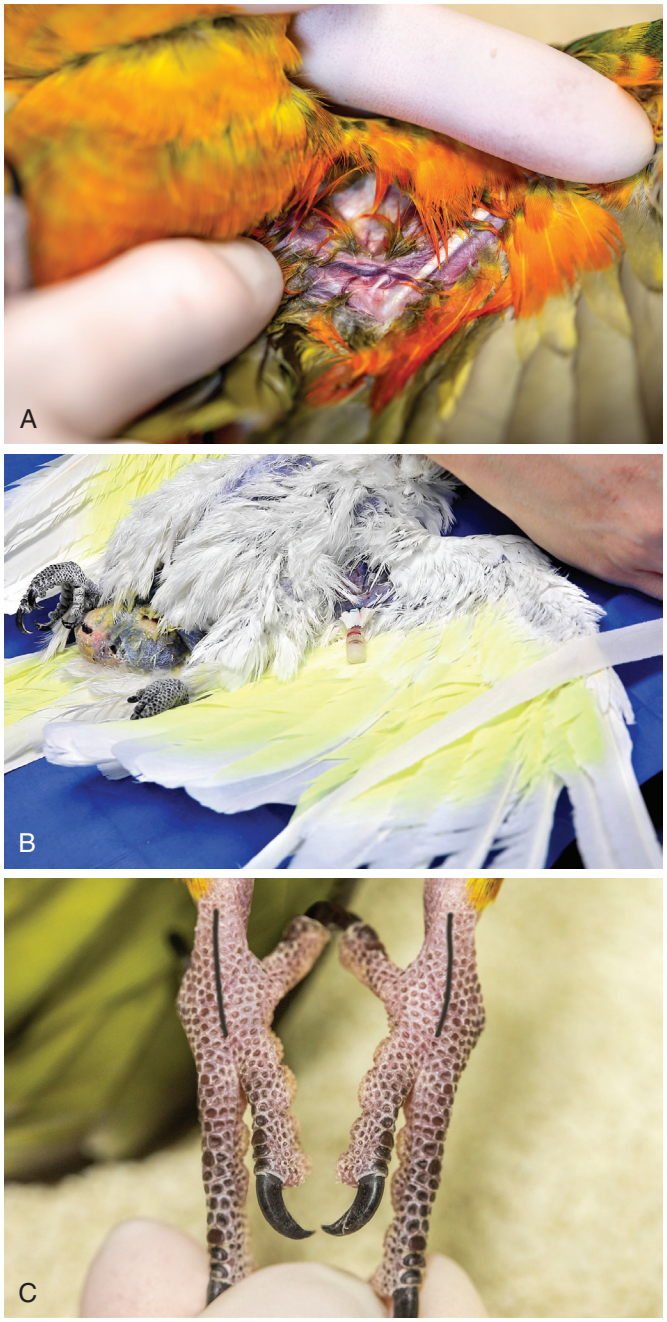

FIGURE 34.5 (A) The location of the left ulnar or basilic vein in a conure (*Aratinga* sp.). (B) An anesthetized cockatoo with a catheter placed in the left ulnar or basilic vein. A butterfly-style tape is applied to the catheter and is sutured to skin. (C) Location of the medial metatarsal veins, which can be used to collect a very small amount of blood (e.g., for evaluation of packed cell volume [PCV]) or in larger birds for placement of an IV catheter.

to the skin. A small piece of transparent film dressing (Tegaderm; 3M Company, Maplewood, MN, USA) followed by a figure-of-eight bandage can be used to protect and secure basilic vein catheters. A neck wrap can be used to help secure jugular catheters. Catheters in the medial metatarsal vein are easy to place and maintain in larger birds and generally wrapped in place. A syringe pump or fluid pump that can

FIGURE 34.6 Postsurgical image of a bird after amputation of the left leg that was crushed by another household pet. Note the use of intradermal sutures, and the placement of an IO catheter in the right tibiotarsus for intermittent fluid administration, and, if needed, delivery of emergency drugs.

administer small volumes is ideal to control slow delivery of fluids in smaller birds. In very large patients, such as larger poultry, regular drips may also be safely used.

Intraosseous catheters can be placed either in the distal ulna or in the proximal tibiotarsus through the cnemial crest (Figure 34.6; see also Box 19.1 in *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 19, Anesthesia). A potential complication of IO catheters is osteomyelitis; therefore, sterile surgical preparation of the area is essential. Analgesia is important, as placement is uncomfortable. The site (skin, subcutaneous tissue, and periosteum) can be blocked with lidocaine at 2 mg/kg prior to catheter placement. Medium- to large-sized birds can accommodate a 20- to 22-G, 1.5 to 2.5-inch spinal needle, or similarly sized hypodermic needle. Smaller size hypodermic needles (25–27 G) are used in smaller birds. A stylet can be made for the hypodermic needle using sterile cerclage wire or 3-0 to 6-0 stainless steel suture. Stylets prevent obstruction of the needle lumen with cortical bone.

FLUID RESUSCITATION

Most studies evaluating fluid resuscitation in avian patients use chickens and ducks as a model.[8] There is very little information on ideal fluid requirements for birds in shock. One study compared the effects of three fluid types (hetastarch [HES], a hemoglobin-based oxygen carrier [Hemospan; Sangart Inc., New York, NY, USA], and whole blood) for resuscitation in chickens *(Gallus gallus domesticus)* after removal of 50% of their blood volume via phlebotomy under general anesthesia. Four of 10 birds in the nontreated control group died, whereas 2 of 10 birds in the whole-blood group died, and 3 birds died in both the HES and Hemospan groups.[9] While results were not considered statistically significant in any group, mortality was lowest in the group treated with whole blood. During blood removal, arterial blood pressure decreased in all groups and increased in the three treatment groups.[7] The drop in packed cell volume (PCV) created by phlebotomy was corrected in 7 days in all groups.

Current anecdotal recommendations include the following: for early decompensatory phase, give crystalloid bolus

(10 mL/kg) and HES bolus (hydroxyethyl starch, 3–5 mL/kg IV or IO). In the decompensatory phase, give hypertonic saline solution (HSS) bolus (hypertonic saline, 3–5 mL/kg IV or IO) over 10 minutes. The rapid effects of hypertonic saline can be maintained with the addition of HES, which can be given at 3 mL/kg IV or IO if needed. Warm the patient and administer crystalloids (10 mL/kg) and HES (3–5 mL/kg) bolus IV or IO. All fluids administered should be warm. Repeat for three to four boluses or until blood pressure is greater than 90 mm Hg and/or there is improvement in clinical markers (mentation, capillary refill time [CRT], mucus membrane color). If PCV is under 20% or the patient is hypoproteinemic, consider blood transfusion.

Crystalloids are the preferred treatment for dehydration. The fluid deficit equals the degree of dehydration (%) multiplied by the body weight *in grams*. Fluid deficit can be replaced over 6 to 8 hours in acute losses and over 12 to 24 hours in chronic losses in birds without cardiopulmonary compromise.[1] Up to 50 mL/kg can be administered as an IV bolus. Recommended maintenance dose of fluids is 40 to 60 mL/kg/day (depending on species).

Whole blood is indicated when albumin, antithrombin, coagulation factors, platelets, or red blood cells are required. It should be kept in mind that blood products do not promote blood flow as well as acellular fluids (e.g., HES, crystalloids); the density of erythrocytes impedes the ability of blood products to promote blood flow (a viscosity effect). Therefore, blood is rarely used for initial resuscitation unless the patient is exsanguinating or there is coagulopathy.

As in other species, continued blood loss, nonregenerative anemia in a weak, symptomatic patient with PCV 12% to 15% or below, and clotting disorders (such as rodenticide toxicosis) are indicators used to determine the potential need for a whole-blood transfusion. Whole blood can be administered at 10 to 20 mL/kg via the IV or IO route. Blood donors can be homologous or heterologous species. Limited studies in selected species suggest that the lifespan of red cells transfused between homologous species is greater than that between heterologous species; for example, 1 to 13.1 days for homologous transfusion between pigeons *(Columba livia domestica)* and cockatiels *(Nymphicus hollandicus)* but 12 hours for pigeon to red-tailed hawk *(Buteo jamaicensis)*.[10] Some practices maintain a relationship with a local bird rescue and keep a list of clients willing to bring in patients for blood donation in exchange for clinic credit.

Blood collection is performed in the carefully restrained or sedated healthy donor via the jugular vein, using a needle and syringe, or butterfly catheter. Collect blood into syringes with heparin (2 U/mL whole blood) or sodium citrate at product-recommended doses. As blood typing in birds is impractical, and in most cases multiple donors are not available, volume to transfuse is usually limited by the amount that can be safely collected from a single healthy donor, generally 10% of the body weight. Formulas to predict posttransfusion PCV in anemic dogs have been proposed and may be useful for birds as well (Box 34.2).[11]

While general recommendations are to administer blood over 1 to 4 hours, when need is urgent, the entire volume can be administered over 10 to 15 minutes, or even quicker in cases of massive hemorrhage. Use a pediatric microfilter to remove most of the aggregated debris.

BOX 34.2 PROPOSED FORMULAS TO PREDICT POSTTRANSFUSION-PACKED CELL VOLUME IN ANEMIC DOGS THAT MAY BE USEFUL FOR BIRDS[11]

Formula 1:
Volume to be transfused [VT] [mL] = 1 mL × % PCV rise × kg body weight [BW]

Formula 2:
VT [mL] = 2 mL × % PCV rise × kg BW

Formula 3:
VT [mL] = 90 mL × kg BW × [(desired PCV − Patient PCV)/PCV of donor blood]

Formula 4:
VT [mL] = 1.5 mL × % PCV rise × kg BW

BP, Blood pressure; *BW,* body weight; *PCV,* packed cell volume.

Administer blood transfusions within 4 hours of collection to prevent the growth of bacteria, according to standards set by the American Association of Blood Banks.[10]

Cross matching donor and recipient blood has been proposed to prevent transfusion reaction. However, in most cases the need for transfusion is urgent, and it is rare that there are multiple donors from which to choose. A single transfusion is unlikely to produce a serious reaction, and risk should be weighed against the risk of foregoing blood transfusion.[10]

SPECIFIC TRAUMATIC CONDITIONS

Respiratory Distress

Traumatic injuries may produce respiratory compromise in several ways. Tracheal trauma impairs airflow to the lungs, and diseases that produce hemocoelom or pulmonary hemorrhage directly impact the function of the lungs and air sacs. Blunt trauma can produce pulmonary contusions or hemorrhage. Suboptimal oxygenation can be produced by profound anemia or hypovolemia resulting in poor circulation. Rest in a warm oxygenated enclosure is important prior to any additional handling or treatment.

Classification of respiratory patterns can be very helpful to distinguish between upper and lower airway disease. As in other species, birds with traumatic injury of the nasal cavities or trachea often show inspiratory distress, while birds with traumatic injury to the coelom that produces respiratory compromise may present with expiratory distress.

Birds with tracheal injury or obstruction due to hemorrhage often present with an audible wheeze or "squeak" upon inspiration. Some may exhibit a voice change or exhibit neck stretching and open-mouthed gasping. Severe cases of suspected tracheal obstruction not responding well to oxygen therapy require emergent air sac cannula placement (see Chapter 29). These birds also may greatly benefit from the use of conscious sedation, or gas anesthesia, which supplies beneficial oxygen as well (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 19, Anesthesia).

Air sac cannulas can be made from red rubber tubes or standard small endotracheal tubes (Figure 34.7A). The diameter of the tube is selected based on the approximate size of

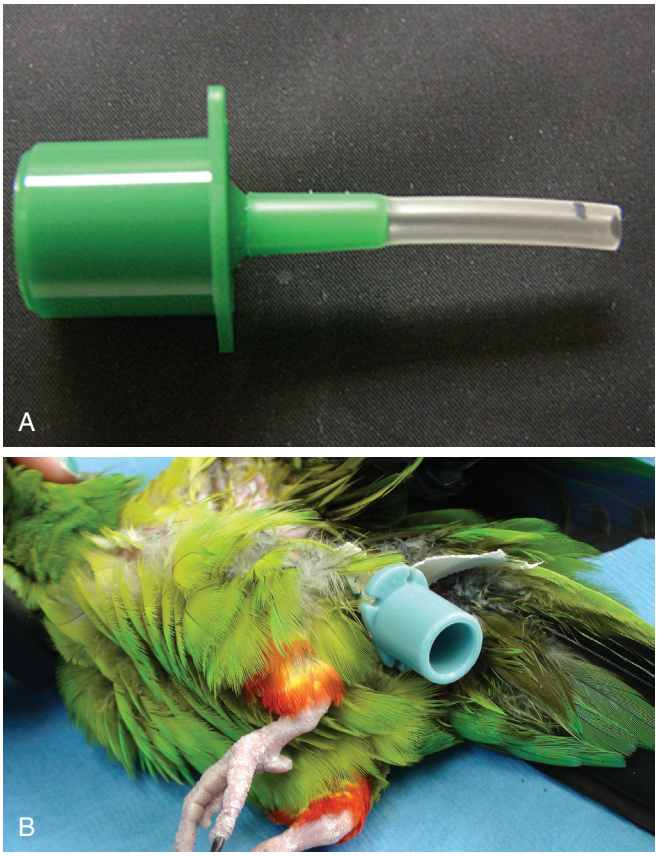

FIGURE 34.7 (A) A shortened endotracheal tube for use as an air sac cannula. (B)The cannula in place in an anesthetized bird.

the trachea in the species. A standard cuffed 3.0 mm inside diameter endotracheal tube can be used in larger birds. The position for the tube is the same as for an endoscopic approach to the caudal thoracic and abdominal air sacs. A small skin incision is made over the triangle created by the cranial muscle mass of the femur, ventral to the synsacrum and caudal to the last rib. The body wall is exposed by blunt dissection and penetrated with a pair of hemostats and the air sac cannula is inserted between the last two ribs or just caudal to the last rib (Figure 34.7B). The bird should immediately begin to breathe through the tube if placed correctly. A filter, such as the removed inner filter from a respirator mask, can be placed over the end of the tube to prevent entry of particulate matter.

After placement, test for airflow with cotton strands or a feather. Suture in place using a purse string and finger-trap suture technique. Patency should be tested again once the sutures are in place. Stay sutures can be used to attach the tube to the back; most birds do not chew these tubes, but an e-collar can be applied if necessary.

Once a patent airway has been established and the patient is stable, tracheal obstruction or trauma can be addressed. Birds can be anesthetized and maintained under anesthesia delivering inhalant gas and oxygen via the air sac cannula. Obstruction due to hemorrhage may require gentle flushing and aspiration of the trachea with an appropriately sized small red rubber catheter. One author (A.M.L.) removed a seed lodged in the midtrachea of a cockatiel by forcing it out with air injected proximal to the obstruction using a 27-G needle and 1-mL syringe directly through the wall of the trachea. These techniques may be useful for birds with more rostral obstructions due to hemorrhage.

Tracheal trauma may be amenable to tracheal surgery techniques described for other conditions in birds, such as tracheal stenosis (see Chapter 29). While tracheal surgery is often linked to poor outcomes, there are numerous reported cases of successful tracheal resection and anastomosis in larger bird species and a cockatiel.[12,13] One case report described the placement of a custom-made, nitinol wire stent in an Eclectus parrot *(Eclectus roratus)* suffering from multiple tracheal strictures spanning a length of 2.6 cm after repeated attempts to widen the trachea using fluoroscopic-guided balloon dilation were unsuccessful. Following stent placement, the bird continued to have intermittent episodes of mild to moderate dyspnea and eventually died because of complications that were suggestive of tracheomalacia.[14] While tracheal injuries often carry a good prognosis (provided the injury is not too extensive), injury to the syrinx carries a much poorer prognosis due to the complexity of the structure and difficulties related to surgical access.

In patients that have undergone airsacculotomy, air sac tubes should not be left in place for longer than 5 days and should be checked frequently to assure patency. To test the patient to see if an air sac tube is still required, plug the air sac tube with an adapter, end of a syringe, or other material appropriately sized to functionally block the opening. Observe the bird for several hours for dyspnea or distress. If no change in respiration occurs, and the patient breathes normally, then the air sac tube can be removed. Culture the tip of the air sac tube when removed. It is not necessary to close or cover the site of air sac tube placement.

Air Sac Rupture

Air sac rupture can occur in association with trauma, such as bite wounds or trauma, but can also be a result of underlying disease conditions such as airsacculitis. Air sac rupture may cause local subcutaneous emphysema, particularly in Amazon parrots (*Amazona* spp.), macaws (*Ara* spp.), and cockatiels. Needle aspiration of the air can aid in a diagnosis and reduce air accumulation, which may not reform in some cases. However, chronic recurring air accumulation may require creation of a temporary opening. In acute cases where air rapidly reaccumulates after aspiration, apply a local analgesic block, and make a small slit into the skin to allow air to escape; such incisions may remain patent for short periods of time.

Indwelling stents for palliative removal of air have been described as an option. Surgical means to address air sac hyperinflation or rupture are also described in Chapter 29.

It is possible for birds to develop persistent air sac hyperinflation or rupture without long-term complications.

Coelomic Disease

The most commonly encountered coelomic cavities with disease include those in the abdominal region, intestinal peritoneal, and hepatic peritoneal cavities, although pericardial and even pleural disease processes are also described (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 8, Pleura, Pericardium, and Peritoneum: The Coelomic Cavities of Birds and Their Relationship to the Lung–Air sac System). Ascites may be a result of trauma. Fluid may be urine/urates,

due to urinary tract injury, bile, or blood secondary to injury or rupture of the liver, kidney, or spleen. Larger accumulations may cause pronounced respiratory signs due to compression of the air sacs. Ultrasound or transillumination of the coelom is often useful to confirm the presence of fluid and may give information on the nature of the traumatic injury as well as the most optimal point to attempt centesis. Aspiration of coelomic fluid (preferably ultrasound guided) is often utilized to remove ascitic fluid from nontraumatic causes but is of questionable utility in traumatized birds. Aspirate only in the central third of the coelom to avoid lateral penetration and leakage of fluids into the air sacs. The feathers of the ventral abdomen are moved away from the aspiration site and the skin is aseptically prepared. A 27- or 25-G (butterfly) needle or catheter is inserted at the midline and directed to the right side of the peritoneal cavity (thereby preventing damage to the proventriculus) or into the fluid-filled region as identified by ultrasound or transillumination. Aspirate as much fluid as possible for complete analysis and to resolve the bird's dyspnea. Ascites resulting from egg yolk peritonitis can be viscous and may require a larger needle (22 G or larger). Continued hemorrhage, recurrence, or leakage of other fluids may be an indication for exploratory surgery (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 21, Surgery).

Head and Spinal Trauma

Flight injuries are a common cause of head trauma in pet birds. Patients with head trauma can present with evidence of bruising or bleeding, lethargy, and altered consciousness. There are several reports of Horner syndrome in birds, one in a parrot, and several in wild birds of prey (Figure 34.8).[15] Birds presented with unilateral ptosis and changes in the position and mobility of feathers. A case in a red-bellied parrot *(Poicephalus rufiventris)* was thought to be secondary to trauma to the base of the neck.[16] These birds should be placed in an oxygen-enriched, quiet, dark, well-padded environment. Additional thermal support is not recommended if intracranial hemorrhage is suspected, except to prevent hypothermia. Vascular access is ideal with placement of an IV or IO catheter. Hypovolemia can be managed with low-volume resuscitation (3 mL/kg) over 10 minutes with hypertonic saline with or without colloids. For cases of suspected increased intracranial pressure, hypertonic saline at 3 mg/kg IV or mannitol (0.25–1.0 g/kg) IV or IO as a slow bolus can be considered and given every 4 to 6 hours for a total of three doses in 24 hours. Maintenance fluid support should be reduced by 35% to 50% in these cases. Head elevation by 30% is recommended for recumbent patients. Analgesia, including opioids, can be given but should be used cautiously to avoid respiratory depression. If hydrated, meloxicam (0.5 mg/kg q12h) may decrease cerebral edema and intracranial pressure (see also Chapter 35 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 20, Recognition, Assessment, and Management of Pain in Birds). Benzodiazepines can be used to control seizures. Imaging including computed tomography (CT) scan can be performed once the patient is stable to evaluate for beak or skull fractures (see Chapter 2). The use of steroids with head trauma is not recommended, especially in birds that may be more sensitive to the effects of corticosteroids. Tranexamic acid (TXA) has been proposed in trauma, but too little information

FIGURE 34.8 (A) Left-sided Horner syndrome in a great horned owl *(Bubo virginianus)*. Marked ptosis of the left upper eyelid can be seen *(asterisk)*. Feather asymmetry is mainly characterized by depressed ear tuft feathers on the left side *(arrow)*. (B) Left-sided Horner syndrome in a northern goshawk *(Accipiter gentilis)*. Ptosis of the left upper eyelid *(white arrow)*, along with elevation of the lower eyelid *(black arrow)* can be appreciated. Feather asymmetry in the Accipitriformes and Falconiformes in this study was attributable to an erection of the head feathers on the affected side *(star)*. (From LaChance MK, Fitzgerald G, Lair S, Desmarchelier MR: Horner syndrome in birds of prey, *J Avian Med Surg* 33(4): 381–387, 2019.)

exists as to its utility in animals at this point. As potential side effects include seizures, thromboembolism, hypotension, and anaphylaxis, use of TXA is not without risk. Ophthalmologic examination of both anterior and posterior segments should occur upon patient stabilization. Topical and/or systemic administration of antibiotics is indicated for corneal ulceration or perforation. Topical ophthalmic nonsteroidal antiinflammatory drugs (NSAIDs) can be used to treat uveitis without corneal ulceration.

Spinal cord injuries can be caused by fractures, subluxation, or luxation of the spine (Figures 34.9 and 34.10). This may be difficult to detect radiographically but may demonstrate an air lucency in the affected area, particularly when the injury is caused by an altercation with an animal. Careful physical examination by gently wetting the area of the spine

FIGURE 34.9 Coronal slice CT image of a spinal fracture *(black arrow)* in a Quaker parrot. The *white arrow* demonstrates pulmonary contusions.

may demonstrate bruising in the affected areas (Figure 34.11). Hemorrhage, inflammation, edema, and ischemia secondary to the trauma may cause further damage. Serial neurologic examination is essential for monitoring recovery (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 9, Clinical avian neurology and neuroanatomy). Although prognosis for recovery is likely to be poor if deep pain is absent, one of the authors (J.G.) managed a case of spinal trauma in a great horned owl with absent deep pain for over a week that made a full recovery with cage rest. While rigid bandaging techniques are unlikely to be helpful in most cases, they can be beneficial in cases of cervical injury. Strict activity restriction is essential for spinal fractures. As with head trauma, there is no indication that steroids are warranted to manage avian spinal trauma but NSAIDs along with general supportive care measures are indicated. Surgical stabilization of spinal fractures has not been investigated in birds.

Fractures

Fractures can occur in association with flying accidents or crushing trauma and when pathology of the bone is present. Fractures should be immobilized in stable patients to prevent further trauma. Open fractures should be cleaned and reduced, taking care in the case of pneumatic bones not to introduce fluids into the air sacs. Antibiotic therapy should be initiated. The figure-of-eight bandage can be useful to manage wing fractures distal to the humerus, soft tissue injuries, and luxations. If there is a humeral or pectoral girdle fracture, a body wrap should be placed. A modified Robert Jones bandage (birds >200 g) or Altman tape splint (birds <200 g) can be used to stabilize fractures distal to the femur. Once the bandage is in place, the bird should be monitored to make sure there is no evidence of increased stress, dyspnea, or chewing/destroying the bandage. Appropriate fracture repair should follow when warranted (see Chapter 37).

Hemorrhage

Hemorrhage can be internal or external. Common sites of external bleeding include broken blood feathers, injured nails or beak, lacerations, and trauma to the ventral carpus from repeated beating of wings against the sides of the cage or another surface during an episode of panic. It should be noted that blood from the ventral wings will transfer to feathers on the lateral aspect of the body wall. When blood is seen in this location, the ventral wings should be inspected carefully. It may be necessary to thoroughly clean blood clots to identify if ongoing bleeding is present.

Broken blood feather

The larger primary rectrices and remiges can bleed significantly if the calamus is fractured during the time they are actively emerging. Small defects may effectively clot and require no additional therapy. Larger fractures may bleed significantly and require intervention. The entire feather can be gently removed from the follicle by grasping the base of the feather with hemostats; this procedure causes significant discomfort and requires appropriate analgesia. In some cases, simple ligation may be helpful as well. If the feather is removed, blood will continue to emerge from the follicle; direct pressure is recommended. Avoid applying styptic powders or other irritating substances into the feather follicles or surrounding skin. If hemorrhage from the follicle continues, tissue adhesive or a small absorbable suture can be placed to temporarily close the follicle.

Nail injury

Toes may become traumatized in toys, on cages, or by conspecifics. Styptic powder or cautery can be used on bleeding nail tips. In the case of complete nail avulsion, the exposed tissue should be cleaned and covered with a light bandage or tissue adhesive.

Beak trauma

Beak trauma can be seen in cases of head trauma or falls, toy entrapment, and bites from conspecifics. Simple rhinothecal tip fractures can be managed with manual pressure, styptic powder, or cautery. Small incomplete fractures may be managed by applying layers of surgical glue and baking soda. It should be kept in mind some bleeding rostral rhinothecal tomial fractures may be missed as blood may wick into the oral cavity and/or the bird continually licks the site. More complex fractures or avulsions may require surgical or acrylic stabilization. Analgesia is important and some birds may benefit from temporary gavage feeding or being fed a softer diet. See Chapter 31 for further details on management of beak injuries.

Laceration/other

Skin wounds can be self-inflicted or caused by conspecifics, falls, and predators. Wing tip trauma can occur with episodes of night fright and falls. Open wounds should be cleaned and closed if fresh and noncontaminated. Some wounds cannot be

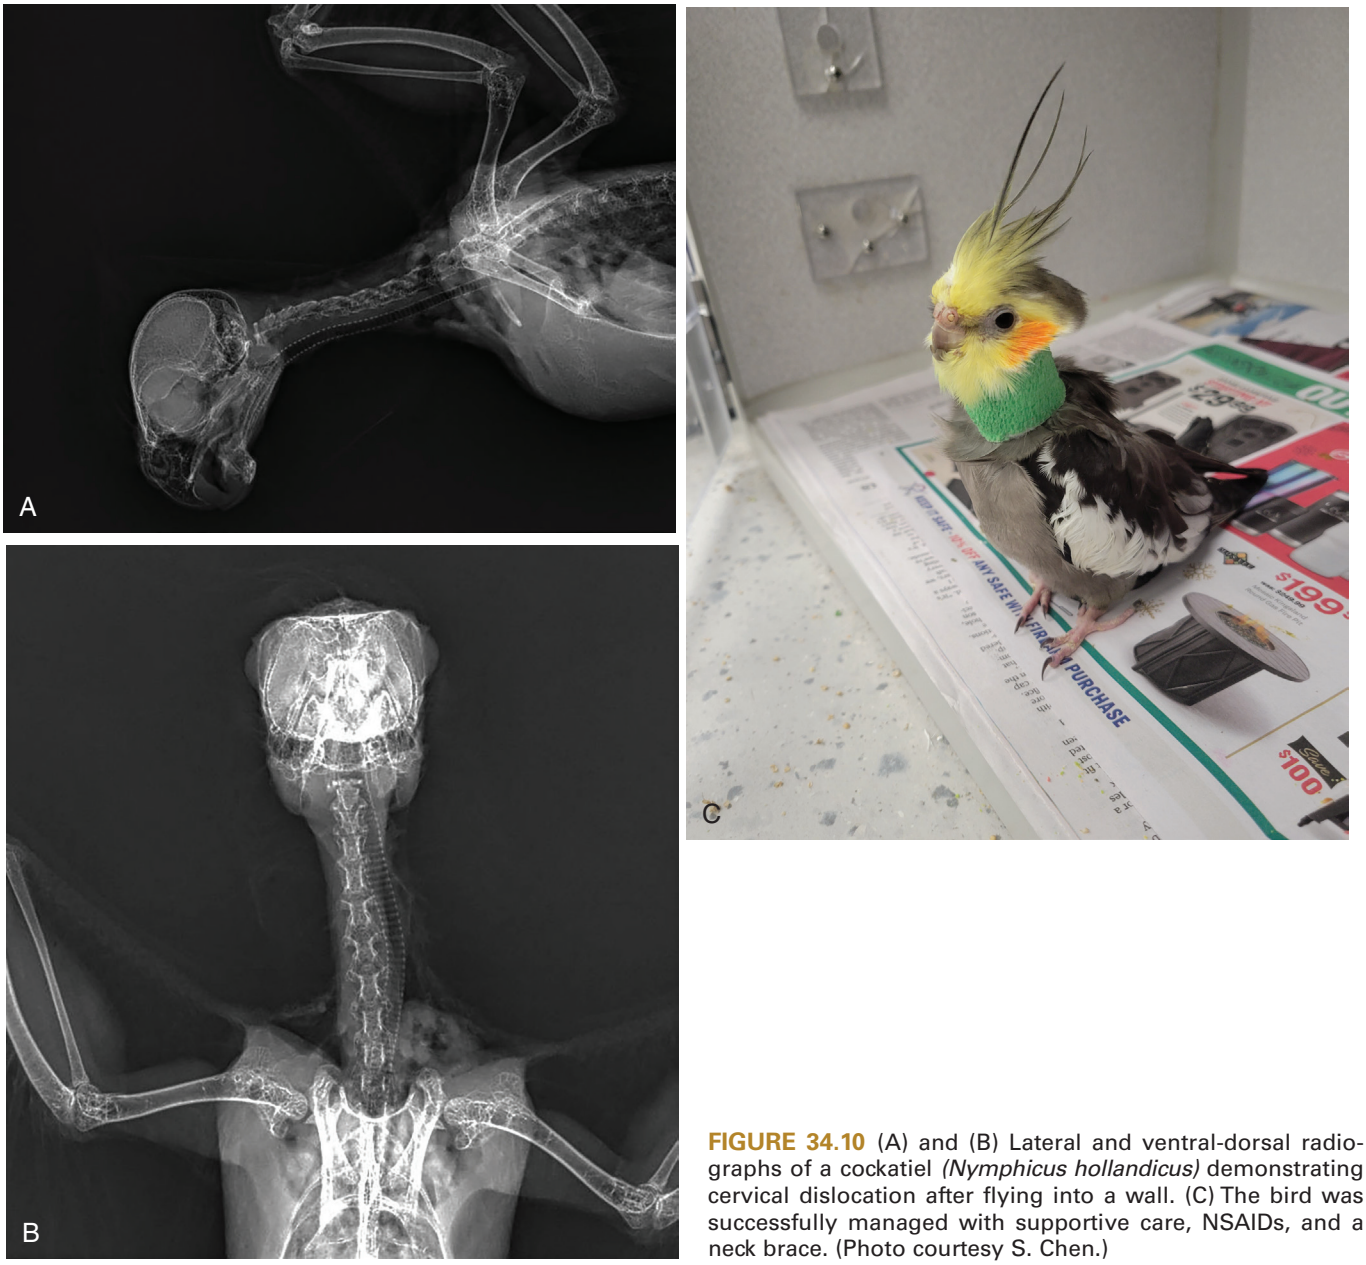

FIGURE 34.10 (A) and (B) Lateral and ventral-dorsal radiographs of a cockatiel *(Nymphicus hollandicus)* demonstrating cervical dislocation after flying into a wall. (C) The bird was successfully managed with supportive care, NSAIDs, and a neck brace. (Photo courtesy S. Chen.)

managed by primary closure, and collars or bandages may be required to protect the wound while healing (see Chapter 36).

Constriction injury

Constriction injuries can occur to an extremity from a leg band (Figure 34.12) or trauma from toys, strings, or nesting material, injuries, and skin hyperplasia secondary to malnutrition (see Chapter 41). Magnification can be helpful when removing constricting material and great care should be taken to avoid causing further injury. Kras leg band cutters (Vet Specialty Products, Fort Lauderdale, FL, USA), hemostats, wire cutters, or bolt cutters may be used to remove metal bands, taking care not to injure the leg. Appropriate wound care should follow removal of the constricting material. In some cases, constriction may be severe enough to cause loss of extremities. Pentoxifylline and/or peripheral vasodilators may be beneficial in acute constriction injury.

Soft tissue injuries

Bite wounds

Bite wounds can be minor to catastrophic and include coelomic cavity penetration or traumatic limb amputation. Bites can come from household pets, or for birds housed outside, wildlife predators such as raccoons and birds of prey (Figure 34.13). Of particular concern is the danger of septicemia from bite or scratch wounds from cats. Broad-spectrum antibacterial therapy should be initiated immediately, even if wounds appear to be minor (see Chapter 7 and Chapter 36). Bacterial septicemia is difficult to treat in any species. For these patients, IV antibiotics are recommended. One author uses piperacillin-tazobactam at

FIGURE 34.11 Close-up of the soft tissue adjacent to the spine in a bird with suspected spinal trauma. Dampening the feathers can help detect bruising.

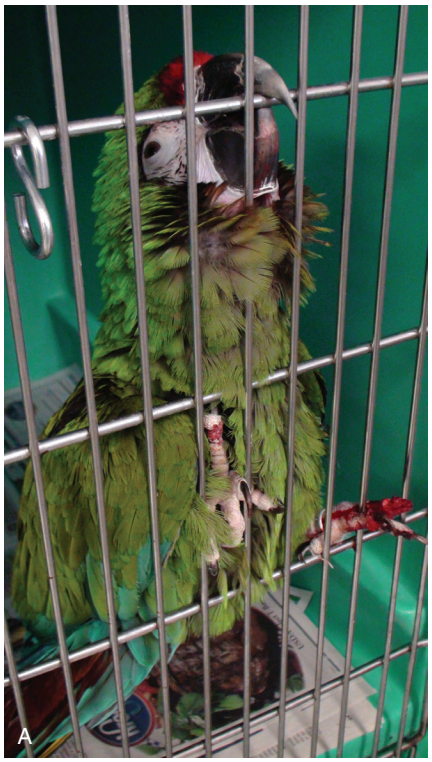

FIGURE 34.12 Constricting leg band injury of the left tarsometatarsal region in a cockatiel *(Nymphicus hollandicus)*. Once the aluminum band was cut transversely, it was able to be bent and removed from the leg without further injury including fracture occurring. With protective bandaging, pain management, and wound care, this injury ultimately healed well. (Photo courtesy Brian Speer.)

FIGURE 34.13 (A) Traumatic amputation of all toes of one foot due to a predator injury. A raccoon grabbed the bird through the cage bars when the bird was inadvertently left outside overnight. (B) A pet chicken *(Gallus gallus domesticus)* with a very large soft tissue wound caused by a predator. Despite the size of the wound, general wound care and surgical repair were successful. (A, Courtesy Angela Lennox. B, Courtesy Crystal Matt.)

FIGURE 34.14 (A) Traumatic tail avulsion in a Grey parrot *(Psittacus erithacus)* due to a falling injury. Note the position of the injury *(bottom arrow)* in relation to the vent *(top arrow)*. (B, C) Repair of a traumatic ventral tail avulsion injury in a cockatiel *(Nymphicus hollandicus)* that occurred several weeks prior to presentation. There is significant granulation tissue that required trimming prior to suturing and wound closure. Nonabsorbable suture was used in a mattress suture pattern to reduce tension. The procedure was performed in the sedated patient with a lidocaine/bupivacaine local block. (A, Permission Amy Boxberger, DVM. B, C, Courtesy Angela Lennox.)

100 mg/kg IV, IO, or, if vascular access is unavailable, IM every 4 to 6 hours for these cases. A pharmacokinetic study in Hispaniolan Amazon parrots *(Amazona ventralis)* demonstrated 87 mg/kg delivered IM q3–4h produced blood levels likely useful for susceptible infections.[17] Additional information on antibiotic therapy can be found in Chapter 6 and Chapter 7. Wound management may necessitate flushing, bandaging, suturing, or fracture repair; care should be taken to avoid flushing wounds that could connect to the air sacs or lungs.

Frostbite/freezing injuries

Most injuries of this type are seen in birds normally housed outdoors in colder climates, in particular, pet poultry. It can also be seen in birds that accidentally escape outdoors. Immediate therapy should focus on analgesia and acute management of tissue trauma, which can be minor (margins of the comb in poultry) to severe (loss of limbs). The use of pentoxifylline and/or peripheral vasodilators may be considered.

Traumatic tail avulsion

Falling and crashing injuries can cause avulsion of the tail and tearing of the tail base skin caudal to the vent. Some of these are the result of improper wing trimming (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 22, Advancements in Management of the Welfare of Avian Species). Owners often note bleeding from the tail area, and veterinarians may mistake the skin injury for trauma to the vent itself (Figure 34.14A). This injury appears most often in cockatiels but can happen in any bird, especially those that are overweight, with an inappropriately severe wing clip or other issue impairing flight. Some owners report intermittent bleeding as the scab forms and then is disrupted.

Traumatic tail avulsion is best repaired surgically. If the injury is not repaired, considerable granulation tissue often forms, preventing healing by second intention. The granulation tissue is trimmed, the skin margins freshened, and the injury sutured using nonabsorbable sutures and individual

mattress sutures taking relatively large bites of adjacent tissue (Figure 34.14B, C). In some cases, suture can be placed around the base of the primary rectrices to help reduce tension. A splint made from a tongue depressor spanning the tail and back may be applied over the dorsal aspect of the tail during the healing phase to prevent dehiscence during the healing period. Strict cage rest and prevention of additional falls are critical to prevent reinjury during the 2- to 3-week healing period. It should be noted there may be a link to future feather-destructive behavior and self-mutilation of the area, which may require eventual amputation.

Keel injuries

Hard falls can produce injuries to the skin and bone of the keel, even causing bone necrosis (Figure 34.15). Most injuries are in overweight birds, or those unable to perform a controlled landing (improper wing clip, wing injuries). Tension over the keel and movement during flapping results in poor healing by second intention, and most benefit from removal of necrotic skin and bone and suturing with tension-relieving suture patterns.

Thermal burns

Thermal burns can occur in household birds exposed to open flames or any hot surface. Aggressive supportive care is essential as there are substantial fluid and protein losses through burns. Analgesia and antimicrobial therapy are necessary during the healing process, as well as wound care. Silver sulfadiazine is beneficial for care of thermal burns, as well as frequent bandage changes. Hydrocolloid bandages may be useful but must be changed once to twice daily, and their use should be discontinued in the presence of infection. Feathers in the surrounding area should be cut rather than removed (unless caring for a wild bird) to prevent further contamination of the affected areas and allow for ease of wound care. Avian skin has the capacity to epithelialize over large areas once the burned areas have granulated. Skin grafts may be a viable option in some situations (see Chapter 36).

FIGURE 34.15 An umbrella white cockatoo *(Cacatua alba)* with a traumatic keel wound following a fall to the ground. (Courtesy L. Thielen.)

Electrocution injuries

Most electrocution injuries in household birds are from chewing on wires. Injuries may be difficult to detect in the acute phase but present as oral cavity swelling progressing to necrosis. Birds may be unwilling to eat, and supportive care may consist of tube feeding or in severe cases an ingluviotomy tube. Electrocution injuries in wild birds are addressed in more detail in Chapter 50.

Crop burns

Crop burns are addressed in Chapter 41.

CHAPTER 35

Advances in Management of Pain in Birds

David Sanchez-Migallon Guzman • *Michelle G. Hawkins*

Pain management is one of the areas of avian medicine that has advanced substantially in recent years. This chapter focuses on the most significant therapeutic advancements in pain management in birds and is presented as a continuation of a previous chapter on recognition, assessment, and management of pain in birds published in *Current Therapy in Avian Medicine and Surgery*, Vol 1.

OPIOID DRUGS

Opioids are mostly used for the treatment of moderate-to-severe pain. They act as agonists, partial agonists, mixed agonists/antagonists, or antagonists by reversibly and selectively binding to μ, κ, δ, and nociceptive receptors in the central nervous system (CNS) and peripheral nervous system. While distribution, number, and type of opioid receptors in the brainstem and spinal cord appear to have been conserved across species, more variation seemingly exists in other parts of the brain such as the forebrain, which could account for variation in the effects of opioids seen clinically. Recent studies looking at opioid receptors in chickens *(Gallus gallus domesticus)*,[1] pigeons *(Columba livia domestica)*, and cockatiels, *(Nymphicus hollandicus)*[2] together with a large number of recent studies on opioids in birds, are challenging the paradigm that κ-opioid receptor agonists (e.g., butorphanol, nalbuphine) are the opioids of choice, finding that in some species μ-opioid receptor agonists (e.g., morphine, hydromorphone, methadone, fentanyl, buprenorphine) might actually be the better choice when treating pain in some species. The results of these studies are described in the following paragraphs. Interestingly, when looking at the structure of opioid receptors (μ, κ, δ) in the peregrine falcon *(Falco peregrinus)*, snowy owl *(Bubo scandiacus)*, and blue-fronted Amazon parrot *(Amazona aestiva)*, nucleotide homologies with humans ranging from 77% to 82% were found, which might account for some of the differences seen in the efficacy of these drugs.[3] Most importantly, a large variability in the pharmacokinetics (PK) and pharmacodynamics (PD) between species, and in some cases also age and sex, has made it clear that generalizations within the class Aves and extrapolation between species need to be exercised with caution. Common opioids that have been studied and used in birds include morphine, hydromorphone, methadone, fentanyl, buprenorphine, and butorphanol (Table 35.1).

Morphine

Morphine is a μ-opioid receptor agonist that has been infrequently used in avian medicine because some of the early studies with this drug in domestic fowl yielded conflicting results.[19] In a recent study evaluating the analgesic efficacy of morphine, lame broiler chickens underwent an obstacle course (OC) and latency-to-lie (LTL) test before injection, and at 30 minutes and 2 hours after injection, to assess their walking ability and their standing ability.[4] Injection of 2 mg/kg IV of morphine resulted in an increased time to finish the OC as sedation occurred, resulting in the chicks tending to sit down rather than walk and confounding assessment of its analgesic effects. The authors hypothesized that morphine might produce analgesia without sedation at lower doses while requiring more frequent administration due to its shorter elimination half-life. However, further studies are warranted.

Hydromorphone

Hydromorphone is a μ-opioid receptor agonist with a potency of approximately five to seven times that of morphine in humans.[28] Hydromorphone is administered by the parenteral, transmucosal, and epidural routes for the management of both acute and chronic pain.[28] A recent study evaluated the thermal antinociceptive effects of hydromorphone hydrochloride following IM administration to orange-winged Amazon parrots *(Amazona amazonica)*.[5] Hydromorphone at 1 and 2 mg/kg significantly increased the thermal foot withdrawal response at 0.5, 1.5, and 3 hours, and 1.5 and 6 hours, respectively, compared with the response after saline administration. In a follow-up study to evaluate the PKs of hydromorphone hydrochloride following intravenous and intramuscular administration of 1 mg/kg, plasma hydromorphone concentrations in orange-winged Amazon parrots were maintained above 1 ng/mL for 6 hours in 6/7 and 8/8 for the IV and IM routes, respectively.[6] The IM mean bioavailability was 97.6%. The mean maximum concentration (C_{max}) was 179.1 ng/mL at 17 minutes after IM administration. The mean terminal half-lives were 1.45 and 1.74 hours after IV and IM administration. This study indicates that hydromorphone hydrochloride has a positive PK profile in Amazon parrots, with a large volume of distribution and high bioavailability after IM administration. However, clearance from the plasma is rapid, resulting in a short terminal half-life, which may require frequent dosing to

TABLE 35.1

Opioid and Opioid-Like Analgesics Evaluated in Avian Species by Either Pharmacokinetic or Pharmacodynamic Studies

Drug	Dosage (mg/kg)	Route	Frequency (q/h)	Species	Comments	Type of Study	Reference Number
Morphine	2	IV	Single dose	Chicken *(Gallus gallus domesticus)*	Decreased time to finish the obstacle course and sedation, which confounded assessment of its analgesic effects	PD	4
Hydromorphone	0.1, 1, 2	IM	Single dose	Orange-winged Amazon parrot *(Amazona amazonica)*	Increased thermal nociceptive thresholds at 1 and 2 mg/kg	PD	5
	1	IM, IV	Single dose	Orange-winged Amazon parrot *(A. amazonica)*	Maintained above 1 ng/mL plasma concentrations for 6 hours following IM administration, with a terminal half-life of 1.74 hours	PK	6
	0.3, 0.6	IM	Single dose	Great horned owl *(Bubo virginianus)*	Increased thermal nociceptive thresholds at 0.3 and 0.6 mg/kg	PD	7
	0.6	IM, IV	Single dose	Great horned owl *(B. virginianus)*	Maintained above 1 ng/mL plasma concentrations for 9 hours following IM administration, with a terminal half-life of 1.62 hours	PK	8
Methadone	1, 3, 6	IM	Single dose	Orange-winged Amazon parrot *(A. amazonica)*	Increased thermal nociceptive thresholds at 1 and 2 mg/kg	PD	9
	6	IM, IV	Single dose	Orange-winged Amazon parrot *(A. amazonica)*	Elimination half-life of 2.29 hours	PK	10
	6	IM	Single dose	Chicken *(Gallus gallus domesticus)*	Decreased MAC of isoflurane by 30% at 15 minutes after administration	PD	11
	6	IM	Single dose	Chicken *(Gallus gallus domesticus)*	Elimination half-life of 2.95 hours	PK	12
Fentanyl	25 μg/hour	TD patch	Single dose	Chicken *(Gallus gallus domesticus)*	Large interindividual differences. Maintained plasma concentrations above 0.2–1.2 ng/mL for 72 hours	PK	13
	5	TD solution	Single dose	Helmeted guineafowl *(Numida meleagris)*	Maintained plasma concentrations above 0.6 ng/mL for 7 days	PK	14
Buprenorphine sustained-release	1.8	SC, IM	Single dose	American kestrel *(Falco sparverius)*	Maintained plasma concentrations above 1 ng/mL for 48 hours and elimination half-life of 11.1 and 13.5 hours after SC and IM administration	PK	15
	1.8	IM	Single dose	American kestrel *(Falco sparverius)*	Increased thermal nociceptive thresholds for at least 24 hours	PD	16
Buprenorphine high-concentration	0.3, 1.8	SC	Single dose	Red-tailed hawk *(Buteo jamaicensis)*	Plasma concentrations were maintained above 1 ng/mL for at least 24 and 48–72 hours, with an elimination half-life of elimination half-life was 6.23 and 7.84 hours for the low and high dose, respectively	PK	17
	1.8	SC	Single dose	American flamingo *(Phoenicopterus ruber)*	Plasma concentrations were maintained above 1 ng/mL for at least 48–72 hours, with an elimination half-life of 12.6 hours	PK	18
	0.1, 1, 2	SC	Single dose	Orange-winged Amazon parrot *(A. amazonica)*	Increased thermal nociceptive threshold at 2 mg/kg	PD	Unpublished

provide adequate analgesia. In addition, during the study into the antinociceptive effects, significant agitation, nausea-like behavior (including vomiting in one bird), ataxia, and pupillary constriction were observed following administration of the 1 and 2 mg/kg hydromorphone doses. Thus, while hydromorphone at 1 and 2 mg/kg IM appears to have desired analgesic effects, especially for severe pain management, the presence of adverse side effects warrants consideration of lower doses for clinical use in orange-winged Amazon parrots. In great horned owls *(Bubo virginianus)*, the PKs following IM administration of 0.6 mg/kg showed high bioavailability and rapid elimination.[8] Mean C_{max} was 225.46 ± 0.2 ng/mL at 13 minutes after IM injection. The mean terminal half-lives were 1.35 and 1.62 hours after IV and IM administration, respectively. The metabolite H3G was readily measured shortly after administration by both routes. This study was the first to document the presence of the metabolite H3G in avian species, which suggests similar hydromorphone metabolism as in mammals. In a follow-up study in the same species, hydromorphone at 0.3 and 0.6 mg/kg resulted in significant thermal antinociceptive effects for up to 3 and 1.5 hours, respectively, and mild to moderate sedation.[7] Two owls were observed tremoring after administration of the 0.6 mg/kg dose, which was not noted after the 0.5-hour timepoint; no other adverse effects were identified. These studies offer scientific evidence to support the use of hydromorphone in great horned owls for pain management.

Methadone

Methadone is a μ-opioid receptor agonist that acts similarly to morphine with regard to its degree of analgesia and duration of action in small animals.[29] However, it is also a noncompetitive inhibitor of *N*-methyl-D-aspartate (NMDA) receptors and can reduce reuptake of norepinephrine and serotonin, which may contribute to its analgesic effects. Due to these additional mechanisms of action, it is potentially more efficacious than

other μ-agonists (e.g., morphine), particularly for neuropathic or chronic pain.[29] Methadone is more lipid-soluble than morphine and approximately 1 to 1.5 times as potent. It does not cause significant histamine release when administered intravenously and has been shown to cause less excitation or vomiting than some other μ-receptor agonists.[29]

In hens, methadone at the dose of 6 mg/kg IM decreased the isoflurane minimum anesthetic concentrations by 30% at 15 minutes after administration. At this dose, in spontaneous ventilated hens, methadone produced mild respiratory acidosis, decreased heart rate, and increased systemic blood pressure, with occasional cardiac arrhythmias.[11] In the same study, hens under isoflurane anesthesia and using the same 6 mg/kg dose, the PK parameters were determined with an elimination half-life of 177 minutes and a C_{max} of 950 ng/mL at 18.3 minutes after IM administration. The bioavailability was estimated to be 79% for IM administration.[12]

In orange-winged Amazon parrots, methadone demonstrated comparable PKs, with a mean bioavailability of 85.7% and mean C_{max} of 515 ng/mL at 25 minutes after IM administration.[10] Mean plasma methadone concentrations were 393 ± 135 ng/mL at 0.5 hours and 242 ± 73 ng/mL at 1.5 hours. Mean terminal half-life was short (2.35 and 2.29 hours for IV and IM administration, respectively), indicating frequent dosing may be needed to maintain plasma concentrations above the analgesic threshold. A follow-up study, evaluating the thermal antinociceptive effects,[9] showed that methadone, administered at 6 mg/kg IM, resulted in a significant increase in thermal threshold in orange-winged Amazon parrots when compared to saline administration, while lower doses of 1 and 3 mg/kg did not yield a significant effect. In the same study, methadone caused significant agitation, ataxia, and nausea-like behavior when compared to saline administration. Hence, while methadone at 6 mg/kg IM appears to have the desired analgesic effects, the presence of these adverse effects warrants consideration of lower doses for clinical use in orange-winged Amazon parrots. In addition, while the PK properties appeared comparable between chickens and orange-winged Amazon parrots, the potential for species differences in drug metabolism and response warrants further studies to evaluate the analgesic and adverse effects of methadone in avian species.

Fentanyl

Fentanyl is a short-acting μ-opioid receptor agonist often administered as a continuous rate infusion or as a transdermal patch for severe pain. The patch delivery theoretically achieves and maintains steady-state therapeutic plasma levels more readily than bolus administration, being less stressful than continuous rate infusion, which requires IV access. In a study including chickens of Brahma, Delaware Redstar, and Wyandotte breeds, the plasma concentrations of fentanyl were evaluated following the application of 25 μg/hour transdermal fentanyl patches (TFP).[13] The TFPs were in place for 72 hours over the left iliopsoas muscle after plucking the feathers. There was a significant degree of interindividual difference in maximum plasma fentanyl concentrations that was attributed to absorption variability, but all chickens reached the human target plasma concentrations of 0.2 to 1.2 ng/mL within 2 to 4 hours and had a rapid decrease following the removal of the patch. Based on data from this PK study, fentanyl transdermal application of patches for chickens targeted to provide 8 to 10 μg/kg per hour of fentanyl resulted in fentanyl plasma concentration within the range considered therapeutic in people for 72 hours.[13] However, because of substantial individual variation in absorption, results from longer applications would likely be inconsistent among patients, hence warranting further studies to determine effective and safe plasma concentrations of fentanyl in this and other bird species.

Another study evaluated the effects of a transdermal fentanyl solution in helmeted guineafowl *(Numida meleagris)*.[14] The solution was placed on the skin in the interscapular region at 5 mg/kg, which resulted in mean plasma concentrations above those considered analgesic for dogs (0.6 ng/mL) from 4 hours through at least 7 days with no evidence of adverse effects or change in behavior. Unfortunately, this commercial formulation had been discontinued at the time of writing this chapter.

Buprenorphine

Buprenorphine hydrochloride has a slow onset of action with a longer duration than other opioid drugs and a unique and complex pharmacological profile. Buprenorphine is thought to act as a μ-receptor agonist, but its κ-receptor activities are less well defined. In a PK study in American kestrels *(Falco sparverius)*, subcutaneous (SC) and IM administration of 1.8 mg/kg of Buprenorphine SR-LAB (Wildlife Pharmaceuticals, Windsor, CO, USA) were both characterized by rapid absorption.[15] Forty-eight hours after both IM and SC administration, mean plasma concentrations remained above target concentrations of >1 ng/mL. The elimination half-life was 13.5 and 11.1 hours, respectively, which is nine times longer than the half-life of 1.5 hours reported in a similar study in American kestrels that received 0.6 mg/kg IM of buprenorphine HCl.[30] This difference was expected due to the sustained-release properties of this formulation and the higher dose administered than in the prior study. Subcutaneous hematomas in three of the birds that received Buprenorphine SR-LAB SC were attributed to traumatic administration but resolved without intervention. A follow-up study evaluating the thermal antinociceptive effects of this formulation in the same species concluded that 1.8 mg/kg IM could require administration for at least every 24 hours to manage pain, although the duration of action could be longer depending on the severity and type of pain, adjunctive therapy, and the individual response.[16]

In red-tailed hawks *(Buteo jamaicensis)*, the PKs of two doses of a concentrated formulation of buprenorphine (Simbadol; Zoetis, Kalamazoo, MI, USA) were evaluated after SC administration.[17] Maximum buprenorphine concentration was achieved at approximately 5 and 15 minutes for the 0.3 and 1.8 mg/kg doses, and plasma concentrations were maintained above 1 ng/mL for at least 24 and 48 to 72 hours, respectively. The mean elimination half-life was 6.23 and 7.84 hours for the low and high doses, respectively. Baseline sedation scores were significantly lower than all other time points for each individual, with return to near baseline by 24 to 48 hours, consistent with mild to moderate sedation. No adverse effects were noted in any birds. The use of this concentrated buprenorphine formulation might help mitigate stress related to repeated handling and administration of treatments in raptors while providing consistent pain management. An

additional benefit is that, for the same dose, this formulation is more cost-effective than the standard buprenorphine formulation which is a very important factor for wildlife rehabilitation. A similar PK study in American flamingos *(Phoenicopterus ruber)* following administration of 1.8 mg/kg SC of the same concentrated formulation showed a longer terminal half-life of 12.6 hours, maintaining above target plasma concentrations in other species for 48 to 72 hours.[18] Additional studies are needed to evaluate the efficacy of this opioid in flamingos.

In orange-winged Amazon parrots, the thermal antinociceptive effects of a concentrated formulation of buprenorphine (Simbadol) after SC administration were evaluated.[31] Buprenorphine at 2 mg/kg resulted in a small but significant increase in thermal threshold when compared to saline, while lower doses of 0.1 and 1 mg/kg did not result in a significant effect. No significant effect of buprenorphine on the agitation-sedation score was observed at any of the doses evaluated. These results provide evidence of weak efficacy at lower doses for pain management in this species, like previous findings in the cockatiels, and highlight the differences in efficacy with the raptor species evaluated, which is an efficacious opioid drug. Further studies are needed to fully determine the analgesic and adverse effects of buprenorphine in psittacine birds and warrant its evaluation in other species.

Butorphanol

Butorphanol is a mixed κ-opioid receptor agonist and μ-opioid receptor antagonist opioid drug. This opioid has historically been one of the most commonly used opioid analgesics in birds for moderate and severe pain, despite many studies suggesting that it requires very frequent dosing.[19] In a recent study evaluating the analgesic efficacy of butorphanol, lame broiler chickens underwent an OC and LTL test before injection at 30 minutes and 2 hours after injection to assess their walking ability and their standing ability.[4] Following the injection of 2 mg/kg IV butorphanol, chickens finished the OC faster, and the authors concluded that it may be analgesic in chickens for up to 2 hours.

In Hispaniolan Amazon parrots *(Amazona ventralis)*, the thermal antinociceptive effects of a formulation containing butorphanol in a 25% poloxamer 407 base (But-P407 25%; Sigma-Aldrich, Oakville, ON, Canada) were evaluated following SC administration.[21] P407 (Sigma-Aldrich) is a thermosensitive hydrogel, a compound that exhibits a property known as reverse gelation. P407 is liquid at room temperature, allowing easy mixing with therapeutic agents and routine handling for injection. Once injected into homeothermic animals, micellar packing forms at the warmer temperature of the body and the compound becomes a gel. This micellar packing is responsible for the high viscosity, partial rigidity, and slow dissolution of the gel, which makes it a highly effective sustained-release system for both hydrophilic and hydrophobic drugs. Butorphanol was well absorbed from the But-P407 25% with a maximal plasma butorphanol concentration reached at 90 minutes. Plasma concentrations of butorphanol remained above 100 ng/mL for 3 and up to 8 hours with no noted adverse effects. The mean elimination half-life was 3.41 hours, with a very high interindividual variability, which is almost five times longer than the half-life reported in the same species for the standard butorphanol tartrate formulation.[32] A dosage of 12.5 mg/kg SC would theoretically provide analgesia for 3 to 8 hours. Unfortunately, those theoretical analgesic effects could not be confirmed in a later thermal antinociceptive study in orange-winged Amazon parrots as no significant difference was identified between the results for But-P407 and those for either the control treatment (saline solution or P407).[20] Only some mild sedation was noted following But-P407 administration. In the same study, the thermal antinociceptive effects of the standard butorphanol tartrate formulation were also evaluated following the administration of 5 mg/kg. At this time, a significant but short-lived increase in thermal threshold was noted, but only at the 30-minute timepoint after butorphanol tartrate (vs saline solution) administration and not at 1.5, 3, or 6 hours. These results with the standard butorphanol tartrate formulation confirm the previous findings evidencing the very short duration of action of this drug in psittacine birds and together with the other recent findings with hydromorphone in orange-winged Amazon parrots, the historical paradigm that κ-opioid receptor agonists–μ-opioid receptor antagonists are the opioids of choice for management of acute pain in psittacines, warrants reevaluation.

In common peafowl *(Pavo cristatus)*, the PKs of butorphanol administered via an osmotic pump, a novel delivery method, were assessed.[22] Two osmotic pumps containing 2 mL butorphanol at a concentration depending on body weight of the bird and administering the drug at a rate of 247 μg/kg/hour each were surgically implanted in 12 birds (two pumps per bird) and removed 7 days later. The osmotic pumps used in the study were 5.1 cm in length and weighed 5.1 g. Plasma butorphanol concentration was measured before implantation SC in the left inguinal region, for several hours to days after implantation, and 3 and 6 hours after the implant removal. In most birds, the plasma concentration reached 60 ng/mL after 24 hours, stayed above this threshold for 7 days, and then decreased rapidly after implant removal. There was no evidence of sedation or adverse effect. These results indicate that osmotic pumps may provide a promising new technique for pain management in large birds, although it should be noted that deep sedation or general anesthesia will likely be required for implantation and removal.

Tramadol

Tramadol hydrochloride is an analgesic drug often used in avian medicine. It is a synthetic μ-opioid receptor agonist that appears to have variable efficacy depending on the species. The efficacy is thought to be primarily related to the production of the *O*-desmethyltramadol metabolite (M1). This metabolite acts centrally over the opioid receptor and is thought to have almost 200 times higher affinity for this receptor than the parent drug. Tramadol also has effects on the κ- and δ-opioid receptors, as well as inhibiting reuptake of norepinephrine and serotonin, and is used for moderate pain. In Muscovy ducks *(Cairina moschata domestica)*, tramadol at 30 mg/kg PO was effective in improving a number of variables in a temporary arthritis model induced by an injection of 3% monosodium urate solution into the intertarsal joint and assessed by ground-reactive forces measured by a pressure-sensitive walkway (PSW) system.[23] A PK study of the same investigators in the same species following administration of tramadol at 30 mg/kg PO showed that it has an elimination half-life of 3.95 hours with a C_{max} of 780 ng/mL at 1.16 hours.[24]

In this study, it was also demonstrated that Muscovy ducks readily produce the M1 metabolite and maintain it well above the concentrations that are known to be therapeutic for humans and other avian species.

In African penguins *(Spheniscus demersus)*, the PK parameters were determined following 10 mg/kg PO administration.[25] The elimination half-life for tramadol was 7.3 hours, which is significantly longer than other species reported, with a C_{max} of 815 ng/mL at 4.6 hours. Tramadol and M1 concentrations were determined and were consistent with therapeutic concentrations in humans through 12 hours in 9/15 birds for tramadol and 36 hours in 14/15 birds for M1. Based on plasma concentrations alone, the authors concluded that an oral dose of 10 mg/kg of tramadol once daily could be used.

In Harris' hawks *(Parabuteo unicinctus)*, the electrical antinociceptive effects of tramadol were evaluated.[26] No effects were noted following 5 mg/kg IM, but 15 and 30 mg/kg IM resulted in electrical nociceptive effects and mild to moderate sedation.

Tapentadol

Tapentadol is an analgesic agent that acts as both a μ-opioid receptor agonist and a norepinephrine reuptake inhibitor. It is a common therapeutic agent in human medicine for managing acute and chronic pain, and it is now being investigated for use in veterinary medicine. The PKs of tapentadol were evaluated in Hispaniolan Amazon parrots following a single 30 mg/kg PO of compounded 5 mg/mL tapentadol suspension.[27] Detectable plasma concentrations were identified in only 2/7 birds, and the bird with the highest plasma levels had a maximum concentration of 143 ng/mL and a half-life of 24.8 minutes. The low oral bioavailability and short half-life of this drug in Hispaniolan Amazon parrots suggest that this drug would be of limited clinical use in this species, but further studies are recommended in other avian species to evaluate its analgesic potential.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Nonsteroidal antiinflammatory drugs (NSAIDs) have different mechanisms of action. The cyclooxygenase (COX) inhibitors act through enzyme cyclooxygenase 1 and/or 2 inhibition, helping to relieve mild to moderate pain as a result of inflammation. Newer COX inhibitors focus their action on COX-2 inhibition while sparing COX-1 inhibition to limit the inhibition of physiologically important prostaglandins. A new class of NSAIDs has recently appeared on the market and has a different mechanism of action through prostaglandin E_2 (PGE_2) receptor antagonism. NSAIDs are often used in the postoperative period and in patients suffering from trauma or inflammation of musculoskeletal tissues. Aside from their effects in patients with acute pain, NSAIDs are helpful in alleviating chronic pain such as that experienced by patients with osteoarthritis. Commonly used NSAIDs in birds include meloxicam, carprofen, ketoprofen, celecoxib, and piroxicam (Table 35.2), which each have a distinct COX-1/COX-2 ratio resulting in differences in efficacy and toxicity.

Meloxicam

Meloxicam is the most widely used antiinflammatory medication today in avian practice. Meloxicam is a COX-2-selective NSAID that may demonstrate more COX-1 selectivity at higher dosages.[47,48] Meloxicam is currently available as an oral tablet, oral suspension, and injectable formulation. Single-dose PK studies of meloxicam in several breeds of chickens,[39,40,47] ostriches *(Struthio camelus)*, emus *(Dromaius novaehollandiae)*,[47,49] mallard ducks *(Anas platyrhynchos)*,[48] Pekin ducks *(Anas platyrhynchos)*,[50] Bilgorajska geese *(Anser anser)*,[51] brown pelicans *(Pelecanus occidentalis)*,[36] turkeys (*Meleagris* spp.),[48] pigeons,[48,52] zebra finches *(Taeniopygia guttata)*,[53] ring-necked parakeets *(Psittacula krameri)*,[54] Hispaniolan Amazon parrots,[55] Grey parrots *(Psittacus erithacus)*,[56] cockatiels,[34,57] flamingos *(Phoeniconaias minor, P. ruber, Phoenicopterus ruber ruber)*,[58–60] African penguins,[37] red-tailed hawks, great horned owls,[61] and multiple vulture species *(Gyps africanus, Gyps coprotheres, Torgos tracheliotos*, and *Neophron percnopterus)*[62] have been published.

Differences in dosage, bioavailability, and elimination half-lives most likely contribute to the significant clinical differences seen with the use of this NSAID. For example, the elimination half-life of meloxicam in chickens and pigeons is three times as long as that of mallard ducks, ostriches, and turkeys.[48] There are even differences between breeds of chickens. Jing Hong layers can be dosed at 1 mg/kg every 16.9 hours.[63] Recently, it was found that white leghorn chickens have a shorter terminal half-life of meloxicam compared to Bantam Cochin and Wyandotte breeds including a shorter residue time in eggs.[40,41] Hence, it has been recommended to reduce the dosing frequency of meloxicam of 1 mg/kg orally to once daily in Bantam Cochin and Wyandotte chickens, compared with the twice daily dosing frequency in leghorn chickens. The authors of a study evaluating the PK of 1 mg/kg PO meloxicam in Pekin ducks were surprised as to how different PK values were between Pekin and mallard ducks, finding that the $t_{1/2el}$ of meloxicam in Pekin ducks was 20 times longer than in mallard ducks.[48,50] Following 1 mg/kg PO administration of meloxicam, the elimination half-life and bioavailability of meloxicam in Hispaniolan Amazon parrots were 15.8 ± 8.6 hours and 49% to 75%, respectively.[55] However, in Grey parrots following 1 mg/kg PO meloxicam, the elimination half-life was twice as long as that of the Hispaniolan Amazon parrots with significantly lower oral bioavailability (38.1% ± 3.6%).[56] In cockatiels following 1 mg/kg PO meloxicam of the commercial formulation, it was found to have only 11% oral bioavailability and an elimination half-life of less than 1 hour.[34] The highly variable bioavailability in avian species[55,56,61] is quite different than that in mammals, in which it usually exceeds 85%.[34] A possible explanation could be variability in proventricular pH among species.[56] In a multiple-dose PK study performed in Grey parrots, three different dosages of meloxicam (1 mg/kg IM q24h, 1 mg/kg PO q24h, and 1.6 mg/kg PO q24h) were evaluated. For all routes and dosages, plasma concentrations were maintained at values greater than the effective analgesic concentrations described for other avian species. In addition, evidence of moderate drug accumulation was found with both IM and PO routes of administration.[38] The more PK studies of meloxicam in different avian species, the more it shows the importance of evaluating PKs for each target species.

TABLE 35.2

NSAIDs Evaluated in Avian Species by Pharmacokinetic, Pharmacodynamic Studies, Toxicologic, or Clinical Studies

Drug	Dosage (mg/kg)	Route	Frequency (q/h)	Species	Comments	Type of Study	Reference Number
Carprofen	5	IV, IM, PO	Single dose	White-backed vulture *(Gyps africanus)*		PK, PD	33
Celecoxib	10	IV, PO	Single dose	Cockatiel *(Nymphicus hollandicus)*		PK	34
Mavacoxib	4	IV, PO	Single dose	Cockatiel *(Nymphicus hollandicus)*	Very long half-life	PK	34
	6	PO	Single dose	Caribbean flamingo *(Phoenicopterus ruber)*	Very high interindividual variability	PK	35
Meloxicam	0.2	PO	Single dose	Brown pelican *(Pelecanus occidentalis)*	Longest half-life of any avian species to date	PK	36
	0.5, 1	IM and PO, respectively	Single dose	African penguin *(Spheniscus demersus)*	0.5 mg/kg IM and 1 mg/kg PO results in concentrations above the target for approximately 24 and 60 hours, respectively	PK	37
	1	IM, PO	Multiple dose, q24h for 12 and 7 days, respectively	Grey parrot *(Psittacus erithacus)*	Moderate bioaccumulation following IM administration	PK	38
	1	IV, PO	Single dose	Cockatiel *(Nymphicus hollandicus)*	Very low (11%) oral bioavailability and shorter half-life than other psittacines	PK	34
	1	PO	Multiple dose q12h for 5 days	White Leghorn chicken *(Gallus gallus domesticus)*	Twice daily dosing needed; 2-week withdrawal time should be adequate to avoid drug residues in eggs	PD	39
	1	PO	Single dose	Wyandotte chicken; Bantam Cochin chicken *(Gallus gallus domesticus)*	Once daily dosing only	PK	40, 41
Sustained-release meloxicam	3	SC	Single dose	Hispaniolan Amazon parrot *(Amazona ventralis)*	Very high interindividual variability. Remained above target plasma concentrations for 12–96 hours	PK	42
	3	SC	Single dose	American flamingo *(Phoenicopterus ruber)*	Remained above target plasma concentrations for 0.5–4 hours	PK	43
Piroxicam	0.5, 1	PO	Single dose	Brolga crane *(Antigone rubicunda)*		PK	44
	1–2	IM	Multiple dose 1 q12h for 4 days	Chicken *(Gallus gallus domesticus)*		PD	45
Robenacoxib	4	PO	Single dose	Domestic goose *(Anser anser domesticus)*	Very short elimination half-life; not recommended for use in this species	PK	46

IV, Intravenous; *PD,* pharmacodynamic; *PK,* pharmacokinetic; *PO,* orally; *q/h,* every hour.

In chickens, dosing of meloxicam 1 mg/kg PO q12h for 5 days resulted in meloxicam residues in eggs in the yolks and whites after 8 and 3 days, respectively.[39] Similarly, a web-based interactive physiologically based pharmacokinetic (iPBPK) model for meloxicam laying hens determined that 22 and 4 days were necessary to clear meloxicam from yolks and whites, respectively.[64] Meloxicam was also identified in 2/3 unfertilized eggs of captive bearded vultures *(Gypaetus barbatus)* after breeding failure, but its implication is unclear.[65] A very recent study evaluating the PK of meloxicam in ovarian follicles and eggs showed much higher concentrations of meloxicam in the ovarian follicles than in the yolk and whites. On the basis of these results, a 2-week withdrawal time should be adequate to avoid drug residues in eggs meant for consumption.[39,66]

A sustained-release formulation of meloxicam (Meloxicam SR; Wildlife Pharmaceuticals, Windsor, CO, USA) has been evaluated in Hispaniolan Amazon parrots[42] and American flamingos *(P. ruber)*.[43] In Hispaniolan Amazon parrots, this formulation results in a rapid rise to peak concentrations and maintains above target plasma concentrations for 12 to 96 hours after a single dose of 3 mg/kg SC, likely due to interindividual variability. Because of these highly variable results, the use of this formulation in this species cannot be recommended until further PK, safety, and pharmacogenomic evaluations are performed to establish accurate dosing recommendations and to understand the high PK variability. In American flamingos, the sustained-release meloxicam formulation also had a rapid rise to peak plasma concentration, but it remained above target plasma concentrations for only 0.5 to 4 hours after a single subcutaneous dose of 3 mg/kg. Based on these results, the formulation would not extend the interval between treatments as compared to the regular formulation of meloxicam in this species.

Since higher doses of meloxicam can induce COX-1 enzyme activity, this drug has the potential to induce the adverse effects of gastrointestinal, renal, and cardiac toxicity seen in mammals, but reports of intoxication at doses used in avian practice are minimal. In a number of studies evaluating the adverse effects of meloxicam in budgerigars *(Melopsittacus undulatus)*; 0.1 mg/kg IM),[67] Grey parrots (0.5 mg/kg IM),[68] zebra finches (1–2 mg/kg PO),[53] domestic pigeons (2 mg/kg IM),[69] Japanese quail *(Coturnix japonica*; 2 mg/kg IM),[70] American kestrels (2–20 mg/kg PO),[71] and Hispaniolan Amazon parrots (1.6 mg/kg PO),[72] no significant renal, gastrointestinal, or hemostatic adverse effects were reported at the dosages evaluated. In contrast, 2/9 American kestrels had gastric ulceration after a dose of 20 mg/kg.[71] Plasma and urine *N*-acetyl-β-D-glucosaminidase activities were significantly increased in Grey parrots at the end of meloxicam treatment at 1.6 mg/kg PO every 24 hours for 7 days.[38]

Elimination half-lives of meloxicam are highly variable with some species such as the cockatiel being quite rapid,[34] which likely explains the lack of adverse effects seen in many avian species with this drug. However, the elimination half-lives in Grey parrots and African penguins are comparably very much longer, at 31.4 ± 4.6 and 25.8 hours, respectively, for oral dosing.[37,56] Anecdotal reports of visceral gout and gastrointestinal ulceration in brown pelicans using dosages commonly used in other species prompted a PK study using a single dose of 0.2 mg/kg PO, where the elimination half-life was 36 hours, the highest reported to date in any species heightening suspicion that adverse effects including renal toxicity may be attributed to this.[36]

The renal effects of NSAIDs have been of particular concern in the Asian vultures *(Gyps bengalensis*, *G. indicus*, and *G. tenuirostris)*.[73,74] These species are more sensitive to the adverse renal effects of several NSAIDs, with the exception of meloxicam where the elimination half-life is <1 hour.[75] However, recently, meloxicam was detected in eggs of captive bearded vultures.[65] Despite meloxicam's large therapeutic range and relative safety compared with other NSAIDs, these new data demonstrate that dose extrapolation is not a suitable method for meloxicam dose determination in avian species. Species-specific PK, efficacy, and toxicity studies are necessary to determine the appropriate dosage.

Celecoxib, Mavacoxib, and Robenacoxib

Celecoxib, mavacoxib, and robenacoxib are COX-2 selective as opposed to meloxicam which is COX-2 preferential, inhibiting both COX-1 and COX-2. Celecoxib in humans is used for acute pain, osteoarthritis, rheumatoid arthritis, and spondylitis. Its use in veterinary medicine is off-label in the United States and many other countries; it is not approved for use in any veterinary species. Nevertheless, celecoxib has been used for years in dosages of 10 mg/kg PO every 24 hours to reduce inflammation associated with avian ganglioneuritis.[76] A recent study in cockatiels using this dose showed no alterations in clinical presentation, viral shedding, gross lesions, histopathology, or viral distribution following experimental inoculation with parrot bornavirus 2 (PaBV-2) (see Chapter 14).[77] However, birds were infected with a large viral load, which induced severe disease, thereby making it difficult to determine whether the drug has any efficacy against the natural inflammation induced by this disease. Anecdotally, suggestions have been made to use even higher doses of 30 to 40 mg/kg divided PO every 12 hours, then long term 15 to 20 mg/kg PO every 12 hours for gastrointestinal signs, and up to 60 to 80 mg/kg divided PO every 12 hours for CNS involvement with ABV-associated ganglioneuritis.[78]

Mavacoxib administered orally has a long mean half-life of 15.5 days in dogs, allowing for monthly dosing after two loading doses administered apart.[79] Plasma concentrations of 0.4 μg/mL mavacoxib were associated with efficacy in reducing osteoarthritis in dogs.[80]

The single-dose PKs and oral bioavailability of celecoxib 10 mg/kg PO and mavacoxib 4 mg/kg PO were evaluated in the cockatiel.[34] Mavacoxib was completely absorbed (bioavailability = 111%), but celecoxib only had a mean oral bioavailability of 56%.[34] Bioavailability of the coxibs is often directly associated with feeding status; the presence of food has been shown to increase absorption of both of these NSAIDs.[81] The cockatiels in this study were fed ad libitum. A further study in cockatiels with ad libitum feeding and additional gavage feedings during the study showed that changes in body temperature, mentation, and posture were less pronounced with a single dose of mavacoxib 4 mg/kg PO compared to celecoxib 10 mg/kg at the tested dosages.[57] This is likely associated with the higher oral bioavailability of mavacoxib in cockatiels compared to celecoxib and meloxicam. Plasma concentrations of 0.4 μg/mL mavacoxib, found to be effective in osteoarthritic dogs,[82] were maintained for 1000 hours in the cockatiels in the aforementioned

studies,[34,57] whereas Caribbean flamingos *(Phoenicopterus ruber ruber)* maintained plasma concentrations of >0.4 μg/mL for 120 hours after a single dose of 6 mg/kg[35] Elimination half-lives in cockatiels (135 hours)[34] and Caribbean flamingos (74.5 hours)[35] were not as long as in dogs but are still much longer than most NSAID elimination half-lives in birds, therefore warranting additional studies to determine dosing frequencies, efficacy, and safety of these drugs in birds.[35]

Robenacoxib is also a long-acting NSAID that has been used anecdotally IM at 2 to 10 mg/kg once weekly, then monthly[83] in birds with clinical avian ganglioneuritis[84] and West Nile virus–induced CNS disease (B. Speer, personal communication, March 2, 2021). Robenacoxib is available as tablets and in an injectable formulation currently in the United States. There is only a single PK study of robenacoxib in birds to date. Based on the results from the PK study in domestic geese *(Anser anser domesticus)* at 4 mg/kg PO, it is suggested not to use this drug in this species due to a very short elimination half-life.[46]

Carprofen

Carprofen is considered a weak COX inhibitor at therapeutic doses, which may explain its apparent wide margin of safety. However, despite its weak COX inhibition, carprofen does exhibit good antiinflammatory activity, which may in part be achieved through other pathways. Even though it is believed that carprofen ingested by *Gyps* vultures does not pose a toxic risk like diclofenac, there are still concerns about its safety in these birds. In a recent PK and toxicokinetic study in white-backed vultures *(G. africanus)*, 5 mg/kg was administered IV, IM, and PO for the PK study, and a subset of birds were administered the dosage found at injection sites in cattle (64 mg/kg) for the toxicology study. Carprofen was well tolerated at 5 mg/kg via all routes of administration, but oral bioavailability was only 42%.[33] One vulture died in the toxicology study with elevations of uric acid and potassium identified, similar to the toxicity found with diclofenac and ketoprofen in *Gyps* vultures. The authors suggest that carprofen should not be used in domesticated ungulates in areas where carcasses are accessible or provided to vultures at supplementary feeding sites.[33]

Ketoprofen and Piroxicam

Ketoprofen is a potent nonselective COX-1 inhibitor that has been used extensively in small animal medicine, in particular because of its excellent oral availability. Very little new data exist on the use of this COX-1 preferential NSAID. Ketoprofen and meloxicam were detected in the eggs of captive-reared bearded vultures.[65] Two studies evaluated the effects of an extraordinarily high single-dose (50 mg/kg IM) ketoprofen as a premedication to ketamine and midazolam in pigeons and found no significant differences in clinical findings, biochemistry analytes, or histopathology between the groups.[85,86] Regardless of their findings, the extremely high dosing of this drug should be reviewed in multidose studies with the utmost caution before considering it for use.

Piroxicam is a nonselective NSAID used for its antiinflammatory properties and its value as a chemopreventative and antitumor agent. It has a much higher potency against COX-1 than COX-2. Similar to ketoprofen, little new studies have been published on its use in birds. In chickens, intramuscular administration of 1 to 2 mg/kg of piroxicam twice daily for 4 days failed to result in gastrointestinal lesions consistent with toxicity.[45] Piroxicam has been used in cranes for more than 20 years to treat a variety of conditions including trauma, inflammation, and postoperative pain with minimal observed side effects.[44] A PK study in brolga cranes *(Grus rubicunda)* evaluated two single doses of 0.5 and 1 mg/kg PO, finding that daily administration might be appropriate for this species based on plasma concentrations.[44]

Grapiprant

Grapiprant is a PGE_2 receptor antagonist NSAID approved for use in dogs in the United States. Grapiprant binds to the EP4 receptor, blocking the sensitization of sensory neurons and stimulation of inflammation, mediated by the PGE_2 receptor. It does not rely on the inhibition of COX enzymes and preserves functions associated with COX enzyme pathways. Oral administration of grapiprant at 30 mg/kg to fasted red-tailed hawks achieved plasma concentrations approximately 100 times the canine therapeutic concentrations, but it is still unknown whether these concentrations are analgesic or could be toxic in hawks.[87] While adverse effects were not identified in the main study, two birds did regurgitate at 45 mg/kg in the pilot study.[87] Grapiprant administered at the same dose to nonfasted red-tailed hawks had delayed and decreased absorption with only 50% of birds reaching the targeted canine concentrations for a much shorter time, significantly lower compared to the fasted PK study (M.G. Hawkins, personal communication, December 9, 2024). Further studies to evaluate the PKs of grapiprant at either higher doses or increased frequency with food and multidose administration are underway.

LOCAL ANESTHETICS

Local anesthetics reversibly bind to Na^+ channels and block impulse conduction, thereby making them favorable for use during surgical procedures to prevent pain conduction and sensitization of the CNS. The duration of action depends on the molecular properties and lipid solubility of the drug. Following local application, the anesthetic will be quickly absorbed into the blood stream, increasing the potential for toxic reactions. Typically, local anesthetics are administered via local line or splash blocks (Table 35.3).

Lidocaine

Lidocaine is an amide local anesthetic that decreases neuronal excitability by blocking voltage-dependent sodium channels, thus preventing the conduction of action potentials that mediate nociception. Empirically, dosages of 2 to 3 mg/kg have been recommended, although previous studies in chickens and mallard ducks showed no toxic effects following intravenous administration of 6 or 15 mg/kg for brachial plexus block, respectively. In more recent studies, the effects of lidocaine were evaluated in 2-kg broiler chickens during spinal anesthesia (also called subarachnoid or intrathecal block). During this study, lidocaine was administered in doses of 0.5, 1, and 2 mg/kg (2% preservative-free lidocaine, made up to 0.2 mL in saline) between the intervertebral space between synsacrum and first free coccygeal vertebra (synsacrococcygeal space).[88] Analgesia was tested by pinching the skin of the pericloacal area with thumb forceps to determine the onset and duration of analgesia. The interval

TABLE 35.3

Local Anesthetics Evaluated in Avian Species by Either Pharmacokinetic or Pharmacodynamic Studies

Drug	Dosage (mg/kg)	Route	Frequency (q/h)	Species	Comments	Type of Study	Reference Number
Lidocaine	0.5, 1, 2	IT	Single administration	Chicken *(Gallus gallus domesticus)*	Onset of pericloacal anesthesia 1–2 minutes, and duration of effect 4.5, 11.3, and 21.3 minutes, respectively	PD	88
Bupivacaine	1.33, 1.96	IV	Single administration	Chicken *(Gallus gallus domesticus)*	1.96 mg/kg IV bupivacaine associated with a 50% probability of a clinically relevant change in MAP and HR, whereas 1.33 mg/kg IV bupivacaine is associated with a 1% probability of causing the same effect	PD	89
Bupivacaine	0.1, 0.25, 0.5	IT	Single administration	Chicken *(Gallus gallus domesticus)*	Onset of pericloacal anesthesia 9, 4.33, and 3.33 minutes, respectively and duration of effect was 11.18 and 54 minutes, respectively	PD	90

HR, Heart rate; *IT,* intrathecal; *IV,* intravenous; *MAP,* mean arterial pressure; *PD,* pharmacodynamic.

to onset of analgesia was not significantly different for all doses of lidocaine (1.5, 2, and 1.3 minutes for 0.5, 1, and 2 mg/kg). Duration of analgesia was significantly longer following injection with 2 mg/kg than 0.5 or 1 mg/kg lidocaine (21.3, 4.5, and 11.3 minutes). In a follow-up study, using the same spinal anesthesia technique in broiler chickens of the same size, spinal anesthesia was evaluated following administration of 2 mg/kg lidocaine.[90] The onset to effect and the duration of action were calculated based on the pinch test at 1.3 and 17.8 minutes, respectively. Considering the results of the studies evaluating spinal anesthesia in chickens and the disorders that affect the cloaca, this technique would be indicated to provide local anesthesia in this species. However, caution should be exercised in other species, especially the smaller ones in which this technique has yet to be evaluated.

Bupivacaine

Bupivacaine is an amide local anesthetic that decreases neuronal excitability by blocking voltage-dependent sodium channels, thus preventing the conduction of action potentials that mediate nociception. Because it is a long-acting local anesthetic, bupivacaine can be useful for perioperative purposes. In recent studies, the cardiovascular tolerance of bupivacaine was evaluated in chickens anesthetized with isoflurane.[89] In this study, it was determined that 1.96 mg/kg IV bupivacaine is associated with a 50% probability of a clinically relevant change in MAP and HR, whereas 1.33 mg/kg IV bupivacaine is associated with a 1% probability of causing the same effect. The effects of bupivacaine have also been evaluated in spinal anesthesia following administration of 0.1, 0.25, and 0.5 mg/kg (0.5% bupivacaine hydrochloride, made up 0.2 mL in saline) in 2-kg broiler chickens.[90] The onset to effect calculated based on the pinch test was 9, 4.33, and 3.33 minutes for the 0.1, 0.25, and 0.5 mg/kg, respectively. The duration of action of the 0.5 mg/kg dose (54 minutes) was significantly longer than that of any other groups (11 and 18 minutes for the 0.1 and 0.25 mg/kg, respectively). Based on these results and comparing them with those of lidocaine use, bupivacaine would be preferred to lidocaine when using this technique in chickens.

OTHER DRUGS (TABLE 35.4)

Gabapentin

Gabapentin is an analog of the neurotransmitter gamma-aminobutyric acid (GABA) that binds to voltage-gated calcium channels acting presynaptically to decrease the release of excitatory neurotransmitters, thereby being helpful to treat neuropathic pain. Until recently, few studies had evaluated its use in avian species, but in the last years, several PK studies have been published. In these studies, a compounded formulation was used to avoid potential risks associated with xylitol in the commercially available oral suspension of gabapentin for humans. In great horned owls following administration of an oral dose of 11 mg/kg PO, the C_{max}, T_{max} (time to maximum concentration), and elimination half-life were 6.17 μg/mL, 51.43 minutes, and 4.4 hours, respectively. In this study, plasma gabapentin concentrations were maintained above 2 μg/mL for 9.6 hours, suggesting that gabapentin administered orally every 8 hours may be appropriate in great horned owls.[91] In Hispaniolan Amazon parrots, oral bioavailability was estimated to be 80% to 89%.[92] Two and three birds, respectively, received 10 and 30 mg/kg PO, with a C_{max}, T_{max}, and elimination half-life of 7.29 and 16.08 μg/dL, 2 and 2.5 hours, and 5.41 and 3.74, respectively. Mild transient sedation was noted after intravenous injection of gabapentin that resolved after 20 to 30 minutes. From that study the authors concluded that 15 mg/kg every 8 hours would be a starting point for oral dosing in Hispaniolan Amazon parrots based on effective plasma concentrations reported for human patients. However, additional studies were considered necessary

TABLE 35.4

Other Drugs Evaluated in Avian Species by Either Pharmacokinetic or Pharmacodynamic Studies

Drug	Dosage (mg/kg)	Route	Frequency (q/h)	Species	Comments	Type of Study	Reference Number
Gabapentin	11	PO	Single dose	Great horned owl *(Bubo virginianus)*	Plasma concentrations maintained above 2 μg/mL for 9.6 hours. Suggests q8h administration	PK	91
	10, 30	PO	Single dose	Hispaniolan Amazon parrot *(Amazona ventralis)*	Elimination half-life was 5.41 and 3.74 hours, respectively. Suggests 15 mg/kg q8h	PK	92
	15, 25	PO	Single dose	Caribbean flamingo *(Phoenicopterus ruber ruber)*	Elimination half-life of 3.39 and 4.46 hours, respectively. Suggests administration of 25 mg/kg q12h, but some individuals could need higher doses	PK	93
Amantadine	10	PO	Single dose	Orange-winged Amazon parrot *(Amazona amazonica)*	Elimination half-life of 23.2 hours. Reaches plasma concentrations associated with toxicity in humans	PK	94
	5	PO	Multiple dose, q24h for 7 days	Orange-winged Amazon parrot *(A. amazonica)*	Elimination half-life of 21.5 hours. Suggests q24h administration	PK	94
Cannabidiol	60, 120	PO	Single dose	Hispaniolan Amazon parrot *(A. ventralis)*	Very high interindividual variability. Elimination half-life of 1.28 hours at the higher dose evaluated	PK	95
CBD, CBDA, THC, THCA, CBG, CBGA, and cannabichromene	Dosing based on CBD/CBDA 30/32.5 mg/kg	PO	Single and multiple dose q12h for 7 days	Orange-winged Amazon parrot *(Amazona amazonica)*	In the multiple-dose study, elimination half-life of 8.6 and 6.3 hours for CBD and CBDA, respectively. Suggests q12h administration		96

CBD, Cannabidiol; *CBDA,* cannabidiolic acid; *CBG,* cannabigerol; *CBGA,* cannabigerolic acid; *IV,* intravenous; *PD,* pharmacodynamic; *PK,* pharmacokinetic; *PO,* orally; *THC,* Δ-tetrahydrocannabinol 9; *THCA,* tetrahydrocannabinolic acid.

to demonstrate that these suggested dosages would be effective. In a more recent study in Caribbean flamingoes, following administration of a 15 and 25 mg/kg dose, the C_{max}, T_{max}, and elimination half-life were 13.23 and 24.48 μg/mL, 0.50 and 0.56 hours, and 3.39 and 4.46 hours, respectively.[93] Based on the results of this study, gabapentin dosed at 25 mg/kg orally in most Caribbean flamingos was considered likely to maintain plasma concentrations above the therapeutic range established for humans for approximately 12 hours; however, dosages as high as 37 mg/kg orally every 12 hours may be needed in some individuals.

Amantadine

Amantadine is an antiviral medication that increases dopamine in the CNS and weakly inhibits the NMDA receptors that contribute to chronic pain.[97] Amantadine is synergistic with NSAIDs, opioids, and gabapentin/pregabalin. In humans, amantadine has been shown to decrease opioid use in postoperative patients, decrease pain in postherpetic neuralgia, and aid in neuropathic analgesia.[98,99] Amantadine orally administered to dogs at 3 to 5 mg/kg every 24 hours in conjunction with meloxicam showed significant improvement in the management of osteoarthritis pain refractory to meloxicam alone in dogs.[100] In orange-winged Amazon parrots, the single- and multiple-dose PK profiles were evaluated following 10 mg/kg PO once and 5 mg/kg PO q24h for 7 days.[94] The heart rate, respiratory rate, behavior, and urofeces were monitored. Mean ± SD maximum plasma concentration, time to maximum plasma concentration, half-life, and area under the curve from the last dose to infinity were 1174 ± 186 ng/mL, 3.75 hours, 23.2 hours, and 38.6 hours/μg/mL, respectively, for the single-dose study and 1185 ± 270 ng/mL, 3.0 hours, 21.5 hours, and 26.3 hours/μg/mL, respectively, for the multiple-dose study at steady-state. No obvious adverse effects were observed. Based on these results, once daily administration of amantadine at 5 mg/kg orally in orange-winged Amazon parrots is able to maintain above target plasma concentration with weak accumulation. For long-term administration, especially for other species, it is recommended to check plasma concentrations over time. Further studies evaluating the safety and efficacy of amantadine in orange-winged Amazon parrots and other avian species are warranted. It is also important to remember that the use of amantadine in chickens, ducks, and turkeys is prohibited in the United States by the Federal Drug Administration.

Cannabidiol and Other Cannabinoids

Cannabidiol (CBD) oil, derived from hemp, is the primary nonpsychoactive cannabinoid derived from the cannabis plant *(Cannabis sativa)* that can interact with the endocannabinoid system. Cannabinoids have been evaluated in other species for their multiple effects including pain relief and antiinflammatory properties, making them an attractive therapeutic option in birds with chronic pain. The PKs of a CBD oral formulation (50 mg/mL; Canna Companion, Mill Creek, WA, USA) have been evaluated in Hispaniolan Amazon parrots.[95] The C_{max} were 213 and 562 ng/mL at 0.5 and 4 hours with an elimination half-life elimination of 1.28 hours for the 60 and 120 mg/kg doses evaluated. The highly variable results and short half-life of the drug in Hispaniolan Amazon parrots, even at high doses, suggest that this formulation would have to be administered at least three to four times daily. More recently, a commercial hemp *(Cannabis sativa)* extract (100 mg/mL; Ellevet, South Portland, ME, USA) that contained CBD, cannabidiolic acid (CBDA), Δ-tetrahydrocannabinol 9 (THC), tetrahydrocannabinolic acid (THCA), cannabigerol (CBG), cannabigerolic acid (CBGA), and cannabichromene (45.2, 49, 1.86, 0.56, 0.69. 1.21, and 1.53 mg/mL, respectively) was evaluated in orange-winged Amazon parrots in a single- and multiple-dose PK and safety study at a dose of 30/32.5 mg/kg PO of CBD/CBDA.[96] The half-life in the multiple-dose study was 8.6 and 6.3 hours for CBD and CBDA, respectively. Interesting differences in the metabolism of some of the cannabinoids when compared to other species studied were found. The results from that study were encouraging for a q12h administration, based on plasma concentrations and limited safety data in the 7-day multiple-dose study. Evaluation of other formulations and in other species is recommended to further characterize the analgesic potential of CBD, CBDA, and other cannabinoids in birds.

CHAPTER 36

Wound Management

Kelly V. Rockwell • Thomas N. Tully Jr.

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Avian patients are frequently presented with skin wounds and injury to the underlying tissue. These injuries may be the most common problem affecting birds treated by veterinarians. Wounds affecting the skin and/or underlying tissue may present or be classified as abrasions, lacerations, crushing trauma, self-trauma, infections, thermal injuries, or limb amputations. Initial therapeutic efforts should address blood loss, shock, and pain in addition to rapid treatment of the affected area(s). These treatments increase probability of patient stabilization, timely injury care, and appropriate wound management, hence increasing the chance for a complete recovery based on the initial prognosis.

An important component to obtain the most expeditious resolution for dermal wounds in birds is understanding the pathophysiology of wound healing and determining which treatment options are best for each case. New treatment options and products are routinely being introduced, often providing improved healing modalities but making a clinician's decision for treatment difficult. Knowledge of wound healing principles will help the veterinarian determine an appropriate treatment regimen for the patient. The information presented here should aid clinicians in understanding these principles and common products used when treating avian skin wounds to have the greatest chance for successful resolution of these cases.

AVIAN SKIN

The anatomical structure of avian skin is like that of mammals, in that there is an outer epidermis and inner dermis; however, a bird's skin is generally much thinner and more delicate. The epidermis varies in thickness throughout the body and is avascular. It is routinely three to five cells thick, but in certain areas, such as the legs and face, will be much thicker.[1] The epidermis is composed of two layers: the stratum germinativum (also referred to as stratum basale) and stratum corneum.[2] The stratum germinativum is the site of cellular growth where keratinocytes change in form and function then migrate upwards to the outer cornified layer, or stratum corneum.[1] The dermis contains connective tissue with blood vessels, nerves, tendons, muscles, and feather follicles. It consists of two layers, the superficial and deep. The deep dermal layer is further divided into compact and loose layers, with the loose layer sitting at the base of the dermis, and attaches to the subdermis where it is infiltrated with fat and apterial muscles.[2]

STAGES OF HEALING

Wound healing is an organized process that generally has three to four phases, including the hemostasis (coagulation), inflammatory and debridement, proliferation, and maturation (remodeling) phases (Figure 36.1).[3] These phases often overlap, creating variable distinction between the categories. While hemostasis is often separate, it can also be considered part of the inflammatory phase. These stages are similar between mammals and birds. Hemostasis occurs immediately after the injury, causing vasoconstriction and activation of the clotting cascade in order to form a fibrin clot. This is followed by vasodilation within 30 minutes. The release of proinflammatory cytokines causes recruitment of neutrophils, endothelial cells, and fibroblasts to the wound. After 24 to 48 hours, the inflammatory phase causes increased capillary permeability to allow for neutrophils, macrophages, and lymphocytes to infiltrate the wound. This can last for up to 2 weeks and often overlaps with the debridement phase. Once debridement is accomplished, the proliferative phase begins, usually 3 to 4 days following the original injury. A granulation bed develops through the combination of fibroblasts, new blood vessels, and fibrous tissue. Keratinocytes proliferate and mature to form a new epidermal layer. The final phase, maturation (remodeling), typically occurs 1 week after the original injury and can continue for weeks to months. The newly formed collagen fibers remodel and strengthen the newly formed tissue.[3]

Several factors dictate wound healing, including level of bacterial contamination, extent of tissue damage or necrosis, and patient's healing ability.[4] Traumatic wounds that require initial and/or repeated cleaning and debridement take longer to heal compared to aseptic, surgically repaired wounds. In avian patients, wounds of distal extremities with a reduced vascular supply and wounds located over joints, the axilla, and the patagium tend to heal more slowly. Other systemic factors can also impair healing and should be addressed. As wounds exude large amounts of protein daily, if a patient is already hypoproteinemic or has inadequate nutrition, they may break down protein for energy and further deplete their body's ability to heal. Additionally, patients recovering from soft tissue

Phase	Time frame	Cells involved	Function of activity	Cellular and bio-physiologic events
Hemostasis (coagulation)	Immediate	Platelets	Clotting	Vascular constriction Platelet aggregation, degranulation, and fibrin formation (thrombus)
Inflammatory/ debridement	Days 1–4	Neutrophils Macrophages	Phagocytosis	Neutrophil infiltration Monocyte infiltration, and differentiation to macrophages Lymphocyte infiltration
Proliferation	Days 4–21	Macrophages Lymphocytes Angiocytes Neurocytes Fibroblasts	Fill defect Reestablish skin function Closure	Reepithelialization Angiogenesis Collagen synthesis
Maturation (remodeling)	Day 21–2 years	Fibrocysts	Develop tensile strength	Collagen remodeling Vascular maturation and regression

FIGURE 36.1 The stages of wound healing are similar between birds and mammals and are an organized process that involves three to four phases. (Modified from Stacey M: Why don't wounds heal? *Wounds Int* 7:16–21, 2016.)

wounds will have higher daily water intake requirements in order to provide moisture at the surface of the wound and help white blood cell migration to the injury site. It is important to address hypoproteinemia, poor nutrition, and dehydration in any avian patient presenting with injuries as these conditions may delay healing. Other conflicting factors include systemic or chronic disease, especially chronic anemia or cardiovascular disease. Patients suffering from these conditions may have compromised blood flow to or decreased oxygenation of the wound, which both can delay the healing process.

WOUND EVALUATION

Obtaining a thorough history when patients present with a soft tissue injury is critical for appropriate treatment of the wounds and should include the cause and period of time that has expired since the initial injury. This information will help dictate treatment, including decontamination and closure, if necessary, in addition to patient stabilization.

When a patient is presented with a skin wound that may have underlying soft tissue involvement, it is important to determine the overall condition of the avian patient. The bird should be stabilized prior to any prolonged and/or stressful treatment efforts, which may include direct treatment of the wounds. During initial stabilization, the wound should be examined for hemorrhage, which should be immediately addressed, in addition to providing therapeutics, including pain medications (see Chapters 34 and 35). Temporary dressings can be placed over the affected area until further treatment can be performed (Figure 36.2). Once the patient is able to withstand prolonged handling, the wound can be appropriately treated. Major considerations when evaluating wounds include wound type, vascular supply, contamination, possible infection, presence of exudate (type, volume, and consistency), condition of the surrounding/underlying tissues, dimensions (length, width, and depth), location, and, if known, cause of injury. Fractures and luxations can be a common result of traumatic injuries and should also be addressed (Figure 36.3). For more information on managing fractures, see Chapter 37. Aseptic technique should always be practiced when treating these wounds. To determine the extent of injury, removal via plucking or cutting of overlying feathers to produce 2 to 3 cm of exposed, healthy skin, surrounding the affected area should be performed. Pulling feathers from torn or lacerated skin should be done cautiously as it easily results in tearing of the

FIGURE 36.2 Temporary bandage placed over a wound on the dorsal aspect of the left carpal joint in a Quaker parrot *(Myiopsitta monachus)*.

FIGURE 36.3 Traumatic wound of the right elbow joint of a domestic cockatiel *(Nymphicus hollandicus)*. The right radius and ulna were also fractured.

skin, particularly in species and regions where it is particularly thin, thereby increasing the extent of the injury, especially in waterfowl. Cutting feathers with sharp scissors, in contrast, is generally less traumatic and stressful.

Therapeutic tools and agents used to stabilize critical patient are generally available in most hospitals and include catheters (22- to 26-gauge intravenous catheters, 1.5-inch 22-gauge spinal needles for intraosseous catheters), crystalloid and colloidal fluids, iron dextran (Watson Laboratories Inc., Corona, CA, USA), and a nutritional critical care formula (Emeraid; Lafeber Co., Cornell, IL, USA; see also Chapter 34 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 17, Critical Care). Analgesic compounds are a beneficial addition for most veterinary patients, and for the avian patient this has been no exception (see Chapter 35 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 20, Recognition, Assessment, and Management of Pain in Birds). Meloxicam (Metacam; Boehringer Ingelheim, St. Joseph, MO, USA), a nonsteroidal antiinflammatory, and butorphanol tartrate (Torbugesic; Zoetis, Parsippany, NJ, USA), a mixed agonist-antagonist, are two of the most commonly used analgesic compounds for avian patients. Meloxicam is available in both oral suspensions and a 5-mg/mL injectable form. For many hospitalized patients and common companion species, injectable 10 mg/mL butorphanol is the pain medication of choice due to its agonist activity at kappa opioid receptor, which is more prominent in the avian forebrain and midbrain.[5] Based on pharmacokinetic studies, frequent (every 2–3 hours) intramuscular or intravenous administration at 5 mg/kg is recommended. Oral administration was found to be an ineffective route, as <10% of the drug was available in Hispaniolan Amazon parrots *(Amazona ventralis)*.[6] Topical analgesia can also be beneficial when managing pain associated with wounds, especially when given prior to debridement. Lidocaine is a common local anesthetic that can be injected subcutaneously or applied topically. It comes in both a 5% jelly and ointment preparation, which can be applied directly to a wound for analgesia within 3 to 5 minutes of contact. Injectable lidocaine can also be administered subcutaneously surrounding a wound in a ring block fashion. The high acidity of lidocaine will often cause a burning or stinging sensation when administered in this route, so it is often recommended to buffer the solution with sodium bicarbonate to decrease the irritating side effects. Analgesic effects of lidocaine can last as long as 2 hours. Bupivacaine, another local anesthetic, can provide analgesic for up to 8 hours; however, its onset of action is much longer (5–10 minutes) compared to lidocaine. For more information on analgesia in birds, see Chapter 35 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 20, Recognition, Assessment, and Management of Pain in Birds.

Like mammals, avian patients may succumb to bacterial sepsis from wounds without antibiotic treatment, depending on the source of the wound. Common aerobic bacterial isolates in avian wounds include *Pasteurella multocida*, *Streptococcus* spp., *Staphylococcus* spp., *Moraxella* spp., and *Neisseria* spp. Common anaerobes include *Fusobacterium* spp., *Bacteroides* spp., *Porphyromonas* spp., and *Prevotella* spp. Antibiotic treatment choice should ideally be based on culture and sensitivity testing, but preemptive treatment considering these agents and the type of wound present is critical. More information on the use of antimicrobials in birds can be found in Section 3: Therapeutic Intervention. The antibacterial, antifungal, and antiparasitic drugs used to treat both systemic and topical wounds are like those found in most veterinary hospitals. Avian patients often tolerate oral fluid medications better than pill or tablet forms. Exceptions to this include medications that carry a bitter or poor taste, such as metronidazole hydrochloride compared to the more palatable metronidazole benzoate. If a veterinary hospital does not have common antibiotic agents formulated in an oral suspension form or if a clinician desires added flavoring to help with palatability, a compounding pharmacy, such as Kingswood Compounding Pharmacy in Australia, Diamondback Drugs or Roadrunner Pharmacy in the United States, or Pharmacy Lab in the UK, should be contacted. More information on compounding can be found in Chapter 5.

LAVAGE

Depending on the wound, cleansing and decontamination can be achieved with a moistened gauze sponge and/or rigorous lavage with sterile isotonic fluids (e.g., saline, Plasma-Lyte, lactated Ringer's solution). This not only removes debris from the tissue but also helps to rehydrate the exposed dermis and underlying tissue. It is important to note that heat support may be necessary while lavaging wounds to prevent hypothermia in avian patients, especially smaller species, which can be prone to rapid heat loss when wet.

In contaminated wounds, either 0.05% chlorhexidine or 0.05% povidone-iodine antiseptic solution may be used for

lavage. In a study assessing the healing times of induced open wounds in blue-fronted Amazon parrots *(Amazona aestiva)* with varying treatments applied every other day,[7] saline and chlorhexidine solution were found to have significantly shorter healing time compared to vitamin B_5 ointment, castor oil, and a control group. The chlorhexidine group also showed the highest neovascularization production and fibroplasia compared to the other study groups. Similar results were seen in an earlier study in the same species where application of chlorhexidine every other day showed more efficient wound healing compared to vitamin B_5 ointment, castor oil, saline, and laser therapy.[8] It is important to note that both studies used noncontaminated induced wounds. Similarly, a review of clinical trials assessing the effectiveness of povidone-iodine in the treatment of wounds in humans found that it does not prolong or interfere with healing.[9]

Advancements in products for wound management include the advent of Tricide (Molecular Therapeutics, LLC, Athens, GA, USA). This product is a chelating agent that acts as an antimicrobial potentiator and is used to flush the wound bed and control infection. Tricide creates holes in the bacterial cell wall, which allows the introduction of antibacterial drugs into the organism. Tricide can be prepared with normal saline or distilled water, has a shelf life based on the package instructions, and mixes well with multiple antibiotic and antifungal drugs. Solutions containing this product have been shown to be effective against multidrug-resistant bacteria cultured from human burn patients and from companion animals and help to reduce the concentration of antimicrobials necessary to achieve the minimum inhibitory concentration (MIC).[10] As it causes direct physical damage to the bacteria, there is decreased likelihood of resistance to the added antimicrobial agent. To date, however, no studies have assessed its efficacy in avian wounds. See Table 36.1 for a list of lavage products and their properties.

DEBRIDEMENT

To stimulate and encourage healing, removal of nonviable and necrotic tissue and/or foreign debris is the next step in wound treatment after cleansing has been performed. This can be accomplished through either surgical or mechanical means and should typically be done only during the inflammatory phase of wound healing.[3] Surgical debridement includes targeted removal of nonviable tissue and solidified exudative material with instrumentation (e.g., scissors, forceps). Ideally, the tissue debridement is performed under general anesthesia or sedation and local anesthesia, but this decision should be based on clinical assessment of the wound and the stability of the patient. Exposed tissue, including tendons, ligaments, blood vessels, and nerves, should be grossly examined to determine viability, but debrided as minimally as possible to maintain function (Figure 36.4). This process is often staged, debriding obvious nonviable tissue while leaving questionable tissue, and bandaging the area. This process is repeated daily until any and all tissues that have been determined to be avascular or obviously nonviable are removed.

Mechanical debridement is accomplished through gentle rubbing of a healing wound with a saline or antiseptic soaked gauze sponge or by placing a wet-to-dry or dry-to-dry bandage over the affected area. With this process, debridement

FIGURE 36.4 Surgical debridement of a leg wound exposes vital connective tissue, vessels, and nerves that supply the distal limb. Structures should be grossly examined to determine viability and debrided as minimally as possible at the onset of treatment.

TABLE 36.1

Lavage Agents Used to Treat Contaminated Wounds in Avian Patients

Product	Properties	Toxicity
0.05% povidone-iodine	Broad-spectrum antimicrobial, penetrates biofilms, anti-inflammatory, nonirritating.[11]	Low cytotoxicity, but may cause mild irritation if exposed to eyes.
0.05% chlorhexidine	Broad-spectrum antimicrobial, expedited healing time.	Associated with corneal damage and severe pain if exposed to eyes. Higher concentrations can cause tissue toxicity,[12] inhibition of granulation tissue,[13] and temporary decreased tensile strength.[14]
Isotonic fluid (saline, Plasma-Lyte, lactated Ringer's solution)	Rehydrates exposed dermis and underlying tissue. Little to no antimicrobial properties.	Tolerated well in most tissues.
Tricide	Antimicrobial potentiator that is mixed with saline or distilled water for topical application or bathing. May also be mixed with multiple antibiotics or antifungals and results in decreased development resistance.	Serious ocular irritation can occur. Proper protective equipment should be worn with use.

is nonselective and removes debris in addition to the superficial layer of the wound bed. Removal of dressings may be painful and typically requires changing multiple times daily for the first few days.[3] Other forms of debridement include enzymatic or autolytic processes, but these are rarely used. Commercial enzymatic debridement products often contain collagenase or papain-urea.[3] These products selectively reduce necrotic tissue and liquefy coagulum and bacterial biofilm.[15] Enzymatic ointments and gels are often expensive, have to be used judiciously due to possible damage to viable tissue, and are not recommended for large wounds or long-term management.[3] Collagenase-based preparations are the most common type of enzymatic debriding agent. Collagenase is water-soluble proteinase derived from bacteria such as *Clostridium histolyticum* and *Vibrio* spp. that has a specific activity against collagen in nonviable cells, meaning that it does not break down healthy tissue. In several canine and feline case studies with nonhealing wounds, granulation tissue was observed within 2 days of beginning treatment with the collagenase preparation Iruxol Mono (Smith & Nephew Ltd., London, UK), and all successfully healed. However, further research is required to compare the efficacy of this treatment with other wound management techniques as well as determine the efficacy and safety in avian patients.[16]

Maggot infestation (myiasis) can be a problem in wounds, especially during the summer months or in regions where it is commonly warm and humid.[17] Removal of the fly larvae is necessary to prevent further contamination and provide a healthy environment for wound healing. Maggots may be removed manually, but in large wounds the time to do this should be weighed against patient stability. Nitenpyram, the active ingredient of Capstar (Elanco Animal Health, Greenfield, IN, USA), is an effective treatment for myiasis. No pharmacokinetic studies have yet been performed on birds, but the authors have used it successfully in avian patients. It may be used topically or orally at 1 mg/kg and usually kills larvae within 1 to 2 days. Ivermectin at 0.2 to 0.4 mg/kg may also be used orally or subcutaneously, but no studies evaluating the efficacy of treating myiasis in birds are available at this time.

CLOSURE

Depending on the degree of wound contamination, patient status, and amount of soft tissue loss surrounding the wound, wounds may be treated with primary, secondary, or tertiary intention closure. Primary closure of the wound is the apposition of skin edges using suture or an adhesive (e.g., tissue glue) at or close to the time of presentation. There has been a general belief in an "8-hour golden period" where primary closure can be performed following injury.[18] Degree of contamination should be considered a larger factor to determine management of wounds, with delayed primary closure (tertiary intention) being preferred in soiled or heavily contaminated wounds, such as cat bites. This treatment has been found to reduce wound infection rates and hospital stays in human patients with contaminated wounds[19] and should be implemented in avian patients with similar history. Secondary intention closure allows the wound to heal through development of a granulation bed at the wound site. As previously mentioned, tertiary intention healing, or delayed primary intention closure, is when a wound is purposefully left open to allow for treatment and cleaning over an extended period (usually between 3 and 5 days) as well as to allow demarcation between viable and nonviable tissue, then closed using primary intention techniques (Figure 36.5). Closure with

FIGURE 36.5 Tertiary closure of a neck wound in a wild lesser scaup *(Aythya affinis)*. The patient was presented to the Wildlife Hospital of Louisiana with a traumatic neck wound of unknown origin that had developed a large eschar (A). After several days of topical treatment, the wound was surgically debrided, cleaned, and closed under general anesthesia (B).

absorbable suture (2-0 to 5-0) with an atraumatic tapered needle can be used to close muscle and subcutaneous tissue.[17] In the case of crop wounds, tertiary wound closure can be beneficial in reducing the risk of infection at the wound bed and stricture as the area heals. It is important to provide systemic support, such as gavage feeding through a pharyngostomy feeding tube.

SKIN GRAFTS AND FLAPS

In larger birds, such as raptors, the use of skin flaps or grafts can be considered to close large wounds. Advancement, or pedicle, flaps involve sliding or rotating skin over an adjacent defect (Figures 36.6 and 36.7). The area is elevated and moved, keeping a portion attached to the donor site in order to

FIGURE 36.6 Serial images of cervical advancement flap procedure in a 46-year-old green-winged macaw *(Ara chloropterus)* with a chronic, nonhealing 9-month-old wound at the occipital region. (A) Anesthetized bird in ventral recumbency and the firmly adhered dry eschar is visible. Blood pressure cuff is visible over the right humerus as a part of anesthetic monitoring setup. (B) Using iris scissors and jeweler's forceps, the eschar is progressively elevated and removed. (C) Following removal of the eschar, the exposed caudal portion of the skull is visible, covered by the remaining periosteum; granulation tissue is present peripherally. (D) Using jeweler's forceps to minimize iatrogenic damage to the skin, construction of the advancement flap is commenced, and Metzenbaum scissors are used for progressive blunt-blunt dissection. Linear incisions are advanced caudally down the dorsal cervical region, in slightly diverging angles, bilaterally. (E) A small rent was inadvertently created in the left cervicocephalic air sac and sutured closed prior to continuing with dissection. If possible, care should be taken to minimize opening this air sac and leading to leakage and subcutaneous emphysema as a postoperative complication. Good intraoperative magnification, appropriate surgical instruments, and delicate tissue handling skills are helpful. (F) The advancement flap is initially tacked in its designated position. It is important to assure that there is minimal tissue tension to minimize risks of dehiscence, particularly at the cranial-most attachment sites.

Continued

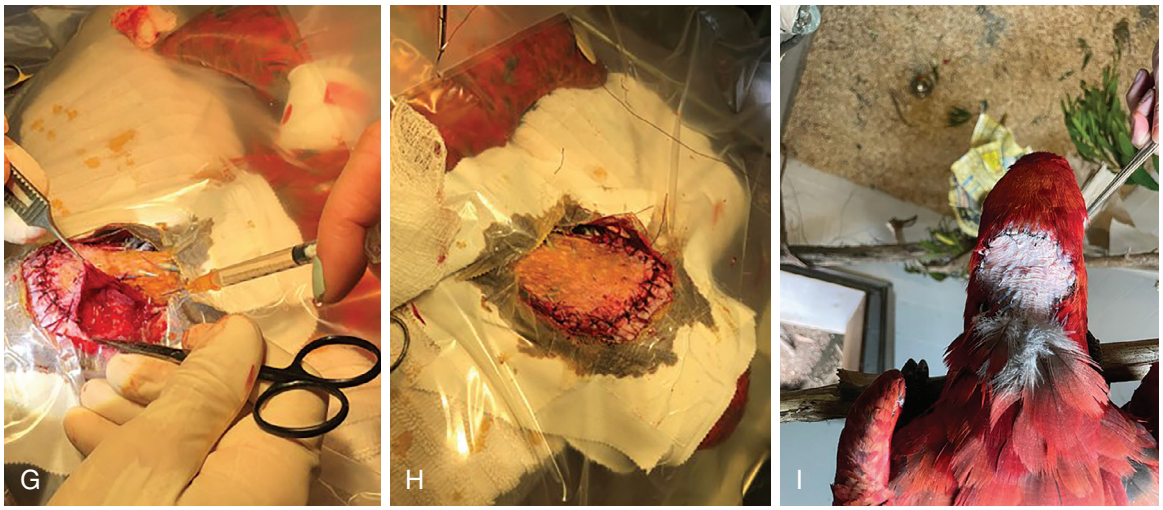

FIGURE 36.6, cont'd (G) A series of simple interrupted sutures are visible, as intraoperative bupivacaine is applied during closure. (H) The completed, closed wound. (I) The healed wound 3 weeks following surgery. (Images courtesy Brian Speer.)

FIGURE 36.7 Images of preoperative and two postoperative repairs of a large irregular occipital wound in a domestic chicken *(Gallus gallus domesticus)*. (A) The anesthetized patient is positioned in ventral recumbency. A caudal aspect of the comb is visibly missing, because of the predator attack that caused the injury. (B) Left lateral view of the patient immediately postoperatively. Care was needed to keep the ear openings patent and effectively restored and to not provide excessive dorsal tension that would cause elevation of the eyelids. (C) Right lateral view of the same patient, immediately postoperatively. (Images courtesy Brian Speer.)

maintain blood supply to the subdermal plexus. With this intact intrinsic blood supply, properly designed flaps have a greater chance of viability compared to grafts. Skin flaps also provide immediate coverage and as a result, contraction and epithelialization of the wound do not affect healing, as they would with open wounds. They also decrease the possibility of excessive scarring, contracture, poor or prolonged healing, or nonhealing, which could occur if left to heal via second intention closure.[20] However, rotation of feather growth is a consideration with flaps as the direction of the pterylae may change with placement. Using these in areas of high tension is cautioned as it carries a high risk of failure. Flaps that incorporate a direct cutaneous artery are known as axial pattern flaps. These can be used to cover a larger area of tissue and ensure flap survival via the flap's own blood supply. Skin flaps also provide immediate coverage and as a result, contraction and epithelialization of the wound do not affect healing, as it would with open wounds. They also decrease the possibility of excessive scarring, contracture, poor or prolonged healing, or nonhealing, which could occur if left to heal via second intention closure.[20] The published use of skin flaps have been used in closure of wounds in a great horned owl *(Bubo virginianus)* with a large open wound on the distal antebrachium,[21] to cover degloving wounds on the head of northern goshawks[11] *(Accipiter gentilis)* and a red-tailed hawk[22] *(Buteo jamaicensis)*.

Free skin grafts are used in cases with significant tissue loss such as burns or degloving injuries. They can be full- or partial-thickness segments of skin removed from one area and placed over the wound. Grafts can be harvested from the same individual (autogenic graft), from another animal of the same species (allogenic graft), or from a different species (xenogenic graft). Once placed, they must develop a new blood supply in order to survive. Eventually, new vessels grow into the graft and from the skin along the margins of the wound. As avian skin is thin, revascularization is easily facilitated.[23] Since grafts often contain full-thickness skin and subcutaneous tissue, they can also provide normal feather coverage if they contain pterylae.[22] The provided graft is often fashioned in a split mesh pattern to allow drainage, which prevents seroma formation as well as to provide greater coverage for larger or uneven wounds.[20] Skin grafts are only practical in larger avian patients as grafts with smaller surface area are at greater risk of failure. Successful use of full-thickness skin grafts has been reported in great horned owls,[24] an ostrich[12] *(Struthio camelus)*, and a wild bald eagle[13] *(Haliaeetus leucocephalus)*. The bald eagle presented with large eschar formations on the dorsal head and right stifle likely caused by electrical injury. A full-thickness skin graft was harvested from the bird's medial inguinal skin fold of the left pelvic limb. Ten days following the procedure, approximately 90% of the graft had been accepted and remained healthy (Figure 36.8).

PRODUCTS AVAILABLE FOR TOPICAL WOUND MANAGEMENT

Topical therapeutic products, including antimicrobial ointments/creams, may be applied, depending on the nature of the injury and advantages of using the product for that

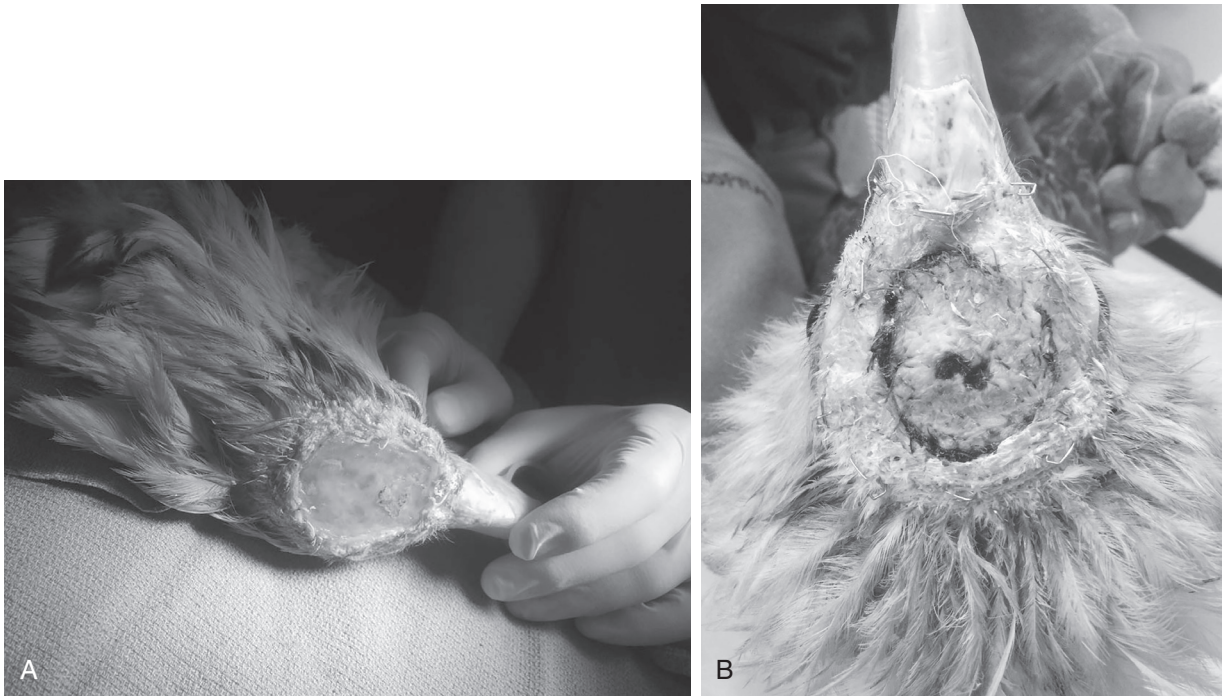

FIGURE 36.8 Use of a skin graft in a bald eagle *(Haliaeetus leucocephalus)*. The animal presented with eschar formation on the head (A). The area was debrided and a full-thickness skin graft from the medial left leg was used to cover the defect. Ten days following the procedure, there was approximately 90% acceptance of the graft (B).[23] (From Kane LP, Shrader TC, Stice RC: Successful, full-thickness skin graft in a bald eagle (*Haliaeetus leucocephalus*), *J Avian Med Surg* 33(2):184–188, 2019.)

particular case. When prescribing a topical ointment/cream for avian use, caution must always be applied. Owners need to be educated on the application process, using only a small amount to treat the lesion to reduce the possibility of feather matting. Topical ointments containing corticosteroids are not recommended due the high potential for severe adverse side effects. In addition to having glucocorticoid activity, corticosterone also has significant mineralocorticoid activity, causing increased potassium retention and glomerular filtration.[14] Documented side effects of corticosteroids in birds include suppression of cell-mediated and humoral immunity,[25] lymphopenia and granulocytosis,[26] rendering birds more susceptible to aspergillosis. In addition to immune suppression, birds given corticosteroids may also develop polyuria, polydipsia, decreased growth, hyperphagia, increased gluconeogenesis and protein catabolism causing lipemia, hypercholesterolemia, excess hepatic glucose deposition, steroid-induced diabetes mellitus, and glucosuria. As systemic absorption is facilitated through the thin avian skin, topical treatment with corticosteroid-containing products can readily lead to increased blood levels and associated side effects. A study evaluating the suppressive effects of glucocorticoids on the pituitary-adrenocortical system in pigeons found that topical glucocorticoid containing dimethyl sulfoxide resulted in systemic effects, though less pronounced than oral or ophthalmic application. However, when glucocorticoid-containing cream without dimethyl sulfoxide was used, there was no suppression of the pituitary-adrenocortical system, suggesting that local effects on the skin may be maintained.[27] Regardless, these products should be used judiciously. If topical corticosteroids are considered necessary in the treatment, every other day application is recommended to prevent secondary infections. Commonly used topical products are listed in Table 36.2 and discussed below.

Acemannan Freeze-Dried Gel (Carravet)

Acemannan Hydrogel, or Carravet (Carravet, Palmetto, FL, USA), is found in wound dressings, which can be applied directly to low-to-medium exudative wounds in birds. Acemannan is a bioactive polysaccharide that promotes tissue repair. It has

TABLE 36.2

Topical Products Used to Treat Dermal Wounds in Avian Patients

Product	Properties	Toxicity
Acemannan freeze-dried gel	Antimicrobial, promotes tissue repair, can be used on low-medium exudating wounds. Must be maintained with a bandage.	Nontoxic, nonirritating.
Borate-based biological glass	Promotes angiogenesis and healing. Must be maintained with a bandage.	Nontoxic, nonirritating.
Chlorhexidine 0.05%	Broad-spectrum antimicrobial, expedited healing time.	Associated with corneal damage and severe pain if exposed to eyes. Higher concentrations can cause tissue toxicity,[12] inhibition of granulation tissue,[13] and temporary decreased tensile strength.[14]
Hydrogel wound dressings	Maintains a moist environment, promotes autolytic debridement, and may improve healing time.	Nontoxic, nonirritating.
Hydrogel silver antimicrobial wound gel	Broad-spectrum antimicrobial, absorbs and retains wound exudate, prevents penetration of environmental bacterial, provides cooling and soothing benefits, prevents dressings from adhering to wound.	Nonirritating, nonharmful to granulation tissue.
Hydrolysate of type I collagen	Provides a matrix for tissue regeneration and moist environment, promotes autolysis.	Nontoxic, nonirritating.
Hypochlorous acid	Antimicrobial, provides moisture to wound.	Nontoxic, nonirritating.
	Slow-release antimicrobial properties for up to 7 days,[28] maintains moisture in wound, promotes cell growth and neovascularization.[29]	Nontoxic, nonirritating, low risk for toxicity to healthy tissue
Manuka honey	Broad-spectrum antimicrobial, can be used in high-exudate wounds, may stimulate the immune response, suppress inflammation, and promote debridement of the wound.	In vitro studies have shown cytotoxicity to human cells with prolonged use.[30]
Povidone-iodine cream 5%	Broad-spectrum antimicrobial, penetrates biofilms, low bacterial resistance, antiinflammatory.[11]	Low cytotoxicity, but may cause mild irritation if exposed to eyes.
Sea salt and lysozyme spray/foam	All-natural, antimicrobial, provides minerals to enhance cell growth and tissue repair.	Nontoxic.
Silver sulfadiazine cream 1%	Bactericidal and bacteriostatic properties.	Does not appear irritating, but may cause impaired reepithelialization, hypertrophic scar formation and cytotoxic effects on fibroblast cells with prolonged use, especially at higher concentrations (2%).
Triple antibiotic ointment	Antibacterial (neomycin, bacitracin, and polymyxin), but overuse may cause resistance.	May cause local irritation.

been shown to significantly accelerate skin wound closure and cell proliferation in experimentally induced skin wounds in mice.[31] This product should be applied to an aseptically cleansed wound and covered with a bandage.

Borate-Based Biological Glass (RediHeal)

RediHeal (Avalon Medical, Stillwater, MN, USA), a borate-based biological glass, is placed directly on a wound to quickly react with tissue fluids. Upon reacting with moist tissue, trace elements are released that promote a strong angiogenic response. By improving the blood flow to damaged tissue, oxygenation is increased, thereby promoting the healing process. This product must be maintained in place with a semiocclusive bandage and can be changed daily.

Chlorhexidine 0.05%

Due to its high bactericidal properties, chlorhexidine is a commonly used disinfectant and antiseptic solution. When used in wound treatments, stock solution should be diluted to a much weaker concentration. Chlorhexidine has been found to accelerate wound healing in full-thickness wounds in beagles[32] and has been found to be relatively safe at lower concentrations (0.02%) for use as a surgical wound irrigation solution. Only the higher concentration (0.05%) has been shown to cause slight tissue toxicity in rats.[30] Other studies have found chlorhexidine to cause inhibition of granulation tissue in guinea pigs[33] and decreased tensile strength of wounds in rats.[34] In rats, however, this appeared to be temporary as strength improved over time and chlorhexidine-treated wounds had decreased healing time.[28] Chlorhexidine-treated open wounds in blue-fronted Amazon parrots had significantly shorter healing time as well as increased neovascularization and fibroplasia.[8] It should be avoided on facial wounds, though, as contact with the eyes can cause corneal damage and severe pain.[35] Otherwise, chlorhexidine appears to be relatively safe with little effect on the wound healing process.

Hydrogel Wound Dressings (Intrasite, Purilon Gel, Nu-Gel, Granugel, Derma GeL)

Intrasite (Smith & Nephew, London, England, UK), Purilon gel (Coloplast, Minneapolis, MN, USA), Nu-Gel (Systagenix, Skipton, England, UK), Granugel (Convatec, West Yorkshire, England, UK), and Veterinus Derma GeL (Maximilian Zenho & Co, Brussels, Belgium) are topical amorphous hydrogel products. Hydrogel is able to maintain a moist environment in the wound by providing moisture to dehydrated tissue. It can also rehydrate necrotic tissue, which facilitates autolytic debridement and loosen tissue. The hydrophilic residue is then able to absorb moisture, slough, and exudate by swelling extensively without changing its gelatinous structure.[36] As it absorbs fluid, it becomes less viscous but remains nonadherent, therefore not harming viable tissue or skin surrounding the wound. These properties make it an acceptable topical dressing for wounds during every stage of the management process. Both Derma GeL and Intrasite have shown bacteriostatic and fungistatic activity in vitro against *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Candida albicans*.[37] Improved healing time has been documented with many of these products when compared to traditional saline dressings.[36] Each product comes with a provided application system, which is typically available in a range of sizes to help with application in awkward wound sites.

Hydrogel Silver Antimicrobial Wound Gel (SilvaSorb, Gemcore360°, Normlgel Ag)

Hydrogel silver antimicrobial wound gels, such as SilvaSorb (Medline, Northfield, IL, USA), Gemcore360° (Gemco Medical, Hudson, OH, USA), and Normlgel Ag (Molnlycke Health Care, Brooklyn, NY, USA), are wound dressings that utilizes ionic silver and is indicated for moist wounds that will respond to an antimicrobial barrier. This product is nonirritating, not harmful to granulation tissue, and absorbs and retains wound exudate, which in turn promotes fibroblast proliferation and keratinocyte migration.[38] The tight mesh of hydrogels prevents environmental bacteria from reaching the wound, while the broad-spectrum antimicrobial hydrogel product releases ionic silver contained within a controlled manner for up to 3 days. High water content of the hydrogel not only provides a cooling and soothing benefit but also prevents the dressing from sticking to the wound, causing less pain and discomfort with removal.[38]

Hydrolysate of Type 1 Collagen (Collasate, Collasate Silver Topical Dressings)

Collasate and Collasate silver topical dressings (PRN Pharmacal, Pensacola, FL, USA) are products that provide the healing benefits of collagen for wounds, including providing a matrix for cellular colonization and tissue regeneration,[39] reduction in bleeding, protecting the wound bed, providing a moist healing environment, and promoting natural autolysis. In a group of humans with diabetic foot ulcers that were treated with collagen-containing wound products, patients had faster healing time compared to those given hyaluronic acid-medicated gauze. They also complained less about pain and itch.[40] This product is available in both a spray and gel preparation, with an additional gel formula that contains silver oxide. The added silver oxide provides antibacterial properties and helps maintain a moist wound environment.

Hypochlorous Acid (Vetericyn)

Hypochlorous acid is the active ingredient in many wound care products made by Vetericyn (Rialto, CA, USA) which are promoted as a next generation line of animal health care that offers an advanced alternative to saline solutions. Hypochlorous acid is an antimicrobial agent that is safe on all tissues. Many veterinarians appear to be very happy with the clinical results of this product when treating avian wounds. Hypochlorous acid is nontoxic, nonirritating, and safe to use on birds and around the face. These products come in spray form that can be used by the owner to treat a bird through the cage.

Ionic and Metallic Silver Absorbable Wound Matrix (Microlyte Ag)

Microlyte Matrix (Imbed Bioscience, Madison, WI, USA) is a thin, transparent, dissolvable gel fiber wound dressing, which provides a slow-release antimicrobial barrier for up to 7 days. The thin dressing allows it to conform to the wound bed while the silver-containing gel provides antimicrobial activity. A micrometer-thick-soluble film of polyvinylalcohol that laminates the fiber dissolves when placed on a moist wound, leaving the silver-loaded film immobilized on the wound bed and maintaining a moist environment.[41] This conformational contact with the wound bed enables localized delivery of silver. In vivo studies using mice models have shown significant decrease

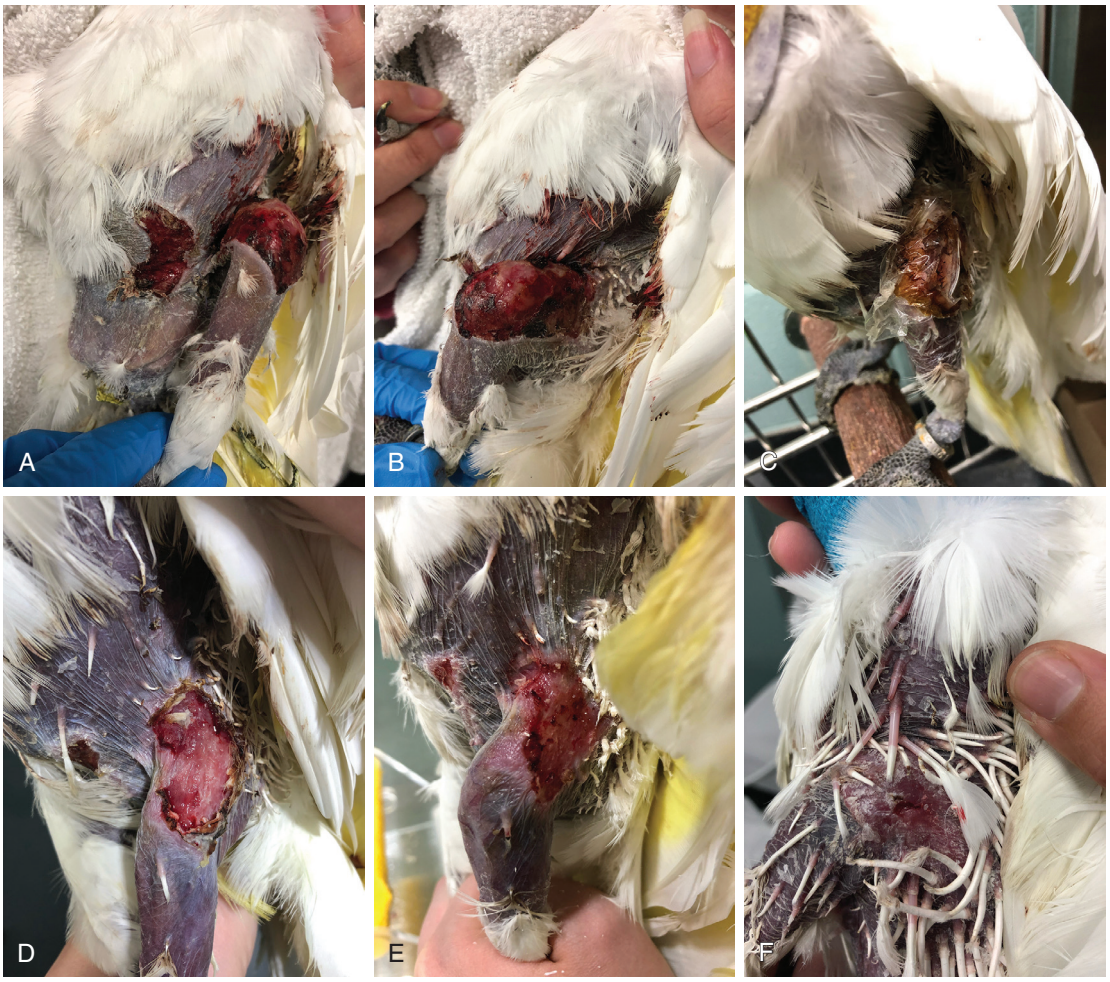

FIGURE 36.9 Severe degloving wound from self-trauma of a surgical incision in an umbrella cockatoo *(Cacatua alba)* (A and B). After 3 weeks of delayed healing with other topical products, an ionic and metallic silver absorbable wound matrix (Microlyte Ag) was applied (C) which after one application showed improved granulation (D) and more rapid healing after only 2 weeks of treatment (E). After 7 weeks following initial presentation, the wound had completely healed (F).

in bacterial burden beneath the applied dressing at 72 hours after application to contaminated wounds.[42] Studies also indicate that the matrix allows for cell growth and neovascularization, promoting faster healing time.[43] This product should be applied to a moistened wound bed. As the product is dissolvable, it does not need to be removed prior to reapplication. The authors have used this product with success in slow-healing wounds (Figure 36.9).

Manuka Honey (Medihoney, Vetramil, Dermiel)

Manuka honey and honey-containing ointments, such as Medihoney (Derma Sciences, Princeton, NJ, USA), Vetramil (Bfactory Health Products B.V. Mooresvilled, NC, USA), and Dermiel (AST Farma, Oudewater, Netherlands) have gained popularity in veterinary medicine. Although honey has been promoted as having broad-spectrum antimicrobial activity, there are considerable differences in this benefit between honey products. Manuka honey nectar contains dihydroxyacetone, which converts into methylglyoxal in the honey product. This compound prevents the inactivation of hydrogen peroxide that is produced at the wound site by enzymes present in blood.[39] Even when used in a wound environment of substantial exudate, manuka honey appears to still inhibit the growth of bacteria.[44] The high osmolarity of honey also helps to draw out fluid from bacteria and the wound bed to create an outflow of lymph. There is also strong evidence that manuka honey has bioactivities that stimulate an immune response, suppress inflammation, and promote rapid autolytic debridement at the injury site. Results of studies comparing treatment of burn wounds in humans show that honey dressings promote better wound healing than silver sulfadiazine (SSD) products.[45] The results of in vitro studies have indicated that, when combined with certain antibiotics, manuka honey may provide synergistic effects against the growth of methicillin-resistant *Staphylococcus aureus*.[46] Using the Unique Manuka Factor (UMF) rating system implemented by the manuka honey producers, the product should have a minimum rating of >10 UMF to be considered potent enough to be therapeutic. Normal, table honey has a UMF of 0–5. While difficulty in obtaining manuka honey products may lead some practitioners to consider commercially produced table honey, it is important to know why this is not

an appropriate substitute. Table honey is heated to eradicate *Clostridium botulinum* spores, which exist in the environment. However, this process also alters the peroxide activity, removing most of the medically beneficial properties. Medical-grade honey, instead, is treated with gamma irradiation, which destroys spores but also has no adverse impact on its beneficial properties. More so, when compared to medical-grade honey, a variety of table honeys were shown to have lower antibacterial activity and contain a wide range of microbial species.[47] Locally made and unprocessed honey may exhibit antibacterial effects as they still contain hydrogen peroxide, though these properties may vary with geographical location and floral source.[48]

Manuka honey should be used judiciously, as in vitro studies with human cells have shown time-dependent cytotoxicity. This may be due to the osmotic effect of honey, which also provides its antibacterial property.[49]

Povidone-Iodine 5%

Povidone-iodine is an antimicrobial agent that has long been used as an antiseptic and wound healing treatment. Povidone-iodine has many properties that make it a favorable topical treatment for wounds, including broad spectrum of activity, ability to penetrate biofilms, lack of associated bacterial resistance, antiinflammatory properties, low cytotoxicity, and good tolerability.[34] In a human comparison study with a triple antibiotic cream and 5% povidone-iodine cream, both were nonirritating to human skin while reducing bacterial counts and had significantly faster healing times than if no treatment was utilized.[50] In a study evaluating treatment options for *S. aureus* infections in rat models with prosthetic grafts, povidone-iodine use resulted in a 90.73% decrease in *S. aureus* colonies in wounds after 4 days of treatment.[51] In human studies, povidone-iodine has been shown to have low cytotoxicity to the skin. These studies also suggest that it may counteract inflammation elicited by both pathogens and the host response.[52]

Povidone-iodine comes in a liquid, spray, cream, and ointment. According to Betadine (iNova Pharmaceuticals, Chatswood, NSW, Australia), povidone-iodine ointment is more concentrated than the cream and does not spread as easily, suiting smaller skin wounds or infections that concentrate in one area.[53] Although this is not a novel product and may not often be considered for wound treatment, it remains an effective topical option.

Sea Salt and Lysozyme Spray/Foam (Vet-Aid)

These wound care products by Vet-Aid (Vet Aid, Stuart, FL, USA) are promoted as an all-natural sprays and foams that can be used to clean and heal wounds without tissue or cellular toxicity. The goal of the product is to provide antimicrobial activity while providing essential minerals to enhance cell growth and tissue repair resulting in a faster healing time as well as reducing inflammation in and around the affected healing site.

Silver Sulfadiazine Cream 1% (Silvadene, Flammazine)

SSD cream 1%, such as Silvadene (Pfizer, Kalamazoo, MI, USA) or Flammazine (A. Menarini, Florence, Tuscany, Italy) is a white, water-miscible cream containing the antimicrobial agent SSD in micronized form, providing both bactericidal and bacteriostatic properties. Clinically this product appears to aid in rapid wound healing without being irritating; however, based on clinical research studies, SSD should be used with care due to the potential for impaired reepithelialization, greater hypertrophic scar formation, and cytotoxic effect on dermal fibroblast. In a single study,[29] 24 rabbits were placed in four groups and subsequently treated with a base cream, 0.01% SSD, 0.1% SSD, and 1% SSD on similarly produced wounds. At day 7 following creation of the wounds and succeeding treatment, half the rabbits were euthanized with the remainder being sacrificed on day 28 to evaluate the epithelial gap and granulation area of the affected areas.[29] At day 28, the 0.1% and 1% SSD groups both had significantly larger hypertrophic epithelial gaps and hypertrophic scar formation than the base cream group. No difference in granulation tissue development was noted between treatment groups. A study[54] focusing on a reptilian species, the green iguana *(Iguana iguana)*, showed that SSD does provide beneficial antimicrobial and healing properties with no delay in healing time; however, this treatment may not be any more advantageous compared to other wound treatments. A 14-day course of 1% SSD on induced wounds showed no significant histological differences in ulceration, bacterial infection, reepithelialization, necrosis, inflammation, fibrosis, and collagen maturity when compared to laser treatment, a topical antimicrobial product, or no treatment.[54] A study that investigated the effect of 2% SSD on the wound healing process and dermal mechanical strength of a 15-day treated lesion in rabbit ear skin found that there was impaired dermal regeneration and decreased mechanical strength of the repaired tissue.[55] It was suggested that the impaired healing was due to the cytotoxic effect of the SSD cream on dermal cells.[55] The belief that SSD cream is cytotoxic to dermal cells was substantiated through the fact that the investigators determined SSD to be highly cytotoxic to cultured human dermal fibroblast cells.[55] As stated previously, low-concentrated SSD creams (1%) do not appear to adversely affect the formation of granulation tissue and can aid in the control and prevention of infection.[54,55] Nevertheless, there are potential adverse side effects with this product, especially at higher concentrations (2%), which demands judicious use by the medical professionals that are treating avian patients with SSD cream.

Triple Antibiotic Ointment (Neosporin, Perrigo Triple Antibiotic Cream)

Triple antibiotic ointment, like Neosporin (Johnson & Johnson, New Brunswick, NJ, USA) or Perrigo triple antibiotic cream (Perrigo, Allegan, MI, USA), is recommended for use in minor skin wounds and contains three antibiotic agents: neomycin, bacitracin, and polymyxin. The ointment should be applied two to three times a day, ensuring to use only small amounts of the product at any one time. When applied properly, only the surface of the wound surrounding the skin should glisten. If any ointment can be visualized, then the excess should be removed or gently massaged into the wound. A primary bandage can be applied over the wound, if necessary, following application of the triple antibiotic ointment.

BANDAGING

There are many reasons to apply a bandage to wounds. These range from protection of the wound site to maintaining a wound treatment in place. For whatever reasons a veterinarian feels a bandage is necessary, careful thought should occur regarding necessity and benefit prior to application. Birds present a unique anatomical challenge for clinicians regarding bandaging and maintaining dressings. Unlike the forelimb of

a mammal, wings can be difficult to bandage with their folding capability. Unique techniques have been developed to keep bandages on wings, such as figure-of-eight and body wraps. For more information on these types of bandages, see Chapter 37. Birds also have strong beaks capable of tearing through strong adhesives and bandaging material. "Distractor tabs" are often placed, which are benign pieces of tape or other material coming off a bandage to create a distraction from patients chewing off their bandage.

Wound dressings are categorized into three layers, with one or all of the layers being applied over the wound. The first, or primary, layer is the product that contacts the wound surface, which may be either an adherent or nonadherent dressing. Nonadherent dressings (such as Adaptic; Ethicon Inc., Somerville, NJ, USA) prevent tissue desiccation and cause minimal trauma. Adherent dressings use wide mesh material to allow fluid and debris to become incorporated into the bandage, which is then removed at bandage changes. However, this is a nonselective process and may damage healthy tissue if inappropriately used. Adherent dressings are classified as dry-to-dry, wet-to-dry, or wet-to-wet based on composition. Dry-to-dry consist of dry gauze applied to the wound. If placed on wounds with exudate, these may be painful to remove but enable significant tissue debridement. Wet-to-dry bandages are made with saline-moistened gauze placed directly on the wound. These can also be painful to remove but result in less tissue desiccation than dry-to-dry bandages.[23] Wet-to-wet bandages tend to damage tissue beds by keeping the healing tissue too moist. Occlusive primary bandages that are impermeable to body fluid and air have been reported to have a decreased healing time and better cosmetic result,[56] likely because they allow vital proteins and cytokines to be retained in the wound bed. This facilitates autolytic debridement within the wound and promotes healing.

The secondary layer provides support to the limb, pads the wound, holds the primary contact layer in place, and may also absorb fluid.[23] This layer is typically composed of cast padding, roll cotton, or gauze sponges. In avian species, secondary bandages are often minimized to reduce bulk and weight in relation to the patient's size.

The tertiary layer holds the primary and secondary layers in place, protects them from environmental contamination, and provides pressure.[23,56] There are a number of bandage materials available for use on an avian patient and most are commonly used for dogs and cats. These include Vetrap (3M, Saint Paul, MN, USA), Elastikon (Johnson & Johnson Medical Inc., New Brunswick, NJ, USA), and white cloth tape (waterproof and nonwaterproof). The more common bandaging products used on avian patients are listed in Table 36.3 and described below.

Cellulose Acetate Fabric With Petrolatum Emulsion or Paraffin-Impregnated Gauze (Adaptic, Jelonet, Respectively)

Adaptic (Johnson & Johnson, New Brunswick, NJ, USA) and Jelonet (Smith & Nephew, London, England, UK) are types of nonadherent dressings made of tight mesh, which allows for the dressing to be cut to size, though they also come in a variety of sizes. The mesh allows exudate from the wound to be absorbed by secondary dressing placed over the mesh.

Cyanoacrylate Tissue Adhesive (Vetbond)

Cyanoacrylate tissue adhesive like Vetbond (3M, St. Paul, MN, USA) bonds tissues together to form a flexible barrier and also acts as a hemostatic agent. Once contacting the body,

TABLE 36.3

Bandaging Materials Used to Dress Wounds in Avian Patients

Type	Properties	Type of Wound Best for
Dry-to-dry	Adherent, significant tissue debridement.	Heavily necrotic wounds, may be painful to remove.
Wet-to-dry	Adherent, significant tissue debridement with less tissue desiccation.	Heavily necrotic wounds, may be painful to remove.
Wet-to-wet	Adherent, may damage tissue beds by keeping it too moist.	Not recommended.
Cellulose acetate fabric with petrolatum emulsion or paraffin-impregnated gauze	Nonadherent, nonabsorptive, protects wound.	Nonexudative wounds during the proliferative phase; may be used as a primary layer with absorptive secondary layer in low to high exudative wounds.
Cyanoacrylate tissue adhesive	Forms long-lasting transparent bandage, protects wound, semiocclusive.	Noncontaminated wounds, wounds of small size or in areas difficult to bandage.
Hydrocolloid dressings	Adhesive, occlusive, impermeable to moisture and oxygen, maintains a moist environment, absorbs fluid and exudate.	Noncontaminated wounds, dry wounds, low to moderate exudative wounds.
Semiocclusive polyurethane membrane coated with acrylic adhesive	Adherent, semiocclusive, nonabsorptive, prevents external contamination, maintains moist environment.	Noncontaminated wounds, no to low exudative wounds. May be used as secondary layer with absorptive primary layer in high-exudate wounds.
Specialized nonadherent gauze pads	Nonadherent, absorptive.	Dry to lightly draining wounds.
Tilapia skin	Nonadherent, nonabsorptive, prevents loss of moisture, contains collagen that accelerates healing process.	Sterile burns or degloving injuries.

the liquid transforms into a solid in order to seal wounds within seconds of application and prevent external contamination. The blue dye contained in the product increases visibility during application. It will naturally slough off over the course of 5 to 7 days. This helps eliminate the need for overbearing bandages that may stress out the animal. It is especially effective for areas that are difficult to bandage, noninfected wounds, and surgical incision sites. Care should be used when applying, as the adhesive should only be applied to the dermal surface and not directly to exposed subcutaneous tissue. The quick drying time can also cause external objects, including surgical instruments, gloves, feathers, drapes, and so on, to easily stick to the product and the patient. The area should be completely clean prior to application. Skin edges should be appropriately apposed and using a new applicator tip, the tissue adhesive is applied in single drops along the apposed margins.

Hydrocolloid Dressings (Allevyn, DuoDERM, Medihoney)

Allevyn (Smith & Nephew, London, England, UK), DuoDERM (Convatec, West Yorkshire, England, UK) and Medihoney (Derma Sciences, Princeton, NJ, USA) are adhesive, opaque, and impermeable hydrocolloid dressings. These occlusive dressings provide a moist and insulating healing environment for uncontaminated wounds which allows the body's own enzymes to heal the area. The hydrophilic dressings absorb fluid and exudate from the wound surface to produce a gelatinous, moist cover for the healing surface. They may require additional bandaging material to hold in place despite their adhesive covering.

Semiocclusive Polyurethane Membrane Coated With Acrylic Adhesive (Tegaderm)

Tegaderm (3M Medical Solutions, St. Paul, MN, USA) is a thin semiocclusive polyurethane membrane coated with a layer of acrylic adhesive. The polyurethane membrane protects the wound from external contamination while reducing moisture loss from the exposed tissue. The wound environment promoted by this dressing prevents eschar formation, thereby increasing epidermal regeneration. Due to its adhesive nature, the product can be applied as a primary contact layer bandage alone, which provides good visualization of the wound. The thin material allows it to be contoured to fit small patients and wounds in difficult locations. Its beneficial adherent properties can also cause difficulty when applying, as the product may adhere to itself. This can cause frustration for the attending clinician or personnel who is applying the product. Based on the author's experience, once the wound is prepared, it is easiest to remove the paper lining and then apply the adherent side to the area to be covered prior. Once applied, the paper tabs can be removed, ensuring to apply pressure to the bandage margins as they are removed. This product may be used at home by clients for long-term wound management, but proper instructions on application should be provided. There are many products available that can be used as primary contact layer bandages including high-performance foam, Ag mesh dressing with silver, hydrocolloid adhesive dressings, alginate dressing, alginate Ag silver dressing, hydrogel wound filler, and nonadherent contact layer.

Specialized Nonadherent Gauze Pads (Telfa, Melolin)

Telfa (Covidien, Dublin, Ireland) and Melolin (Smith & Nephew, London, England, UK) are types of specialized nonadherent gauze pads that can be used as primary or secondary dressings. A polymer coating on both sides of the dressing prevents the product from adhering to the wound bed if placed directly on it, unlike gauze. These come in a variety of sizes and variations.

TILAPIA SKIN

Application of Nile tilapia skin *(Oreochromis niloticus)* is an emerging advancement in wound management. Previously seen as a fish-processing byproduct, tilapia skin has been found to greatly improve healing time in cases of skin burns or degloving injuries. Tilapia skin has low toxicity and is well tolerated in mammalian patients. The collagen nanofibers contained in the skin promote skin regeneration by inducing keratinocyte differentiation and collagen synthesis by dermal fibroblasts.[57] Additionally, it acts as a barrier from excessive exudate and fluid loss, prevents bacterial invasion, and is easily removed for changing purposes. The tilapia skin is prepared with sterilization and irradiation, so it can last up to 2 years. It is applied as an occlusive dressing, often sutured in place, and left for up to 10 days. Its application may be limited to larger avian patients with large enough surface area to accept. Though reported use of this dressing is limited in avian patients, clinicians should consider this product for large sterile skin wounds. For more information on the use of tilapia skin, see Chapter 53.

THERAPEUTIC MODALITIES FOR WOUND TREATMENT

Laser Therapy and Photobiomodulation

Red and near-infrared light wavelengths are directed over the wound area for increased therapeutic effect. The light interacts with chromophores in cells, causing upregulation or downregulation of some biochemical processes. Wavelengths in the range of 400 nm (violet) to 1100 nm (near infrared) can result in photobiomodulation.[58] The mechanism of action of photobiomodulation is not yet completely understood but has been shown to promote improved healing time, provide analgesia at the wound site, increase circulation, and decrease edema. Low-level laser therapy has been shown to reduce inflammation and significantly increase collagen deposition in open wounds in rats, with the best results seen with daily application of 16 J/cm^2.[59] It has even resulted in superior wound contraction in full-thickness burns in rats compared to topical treatment of 2% SSD.[60] Pododermatitis in Magellanic penguins *(Spheniscus magellanicus)* showed better healing rates and times after surgical debridement with laser therapy than in a group treated with antiinflammatories and antibiotics.[61] Multiple treatments are usually required to achieve the most beneficial effect of increasing the metabolic activity of cells surrounding the wound to stimulate healing. For smaller avian patients, lower therapeutic doses are recommended compared to larger species and are listed in Table 36.4.

TABLE 36.4

Suggested Doses for Laser Therapy in the Treatment of Avian Wounds[58]

Dose	Usage
1 J/cm^2	Surgical wound healing and postoperative pain Dermal burns
2 J/cm^2	Lacerations
2–4 J/cm^2	Trauma site inflammation and pain Minimize scar formation and increase healing from self-mutilation
3–4 J/cm^2	Pododermatitis
4 J/cm^2	Deep wounds
4–6 J/cm^2	Reduce patagial extension restriction following trauma

Due to the risk of retinal damage, operators and patients should have their eyes protected. Caution should be used to prevent tissue overheating and overuse in pigmented areas, which will absorb more light. Neoplastic or infected tissue may become overstimulated with laser therapy and should also be avoided. Treatment is also not recommended over open fontanels, hemorrhagic tissue, or in pregnant patients.[58]

Ultrasonography

The delivery of ultrasonic waves to tissue provokes thermal and nonthermal effects that may stimulate soft tissue healing. The sound waves interact with large protein molecules (such as collagen), causing increased skin temperature, which results in increased extensibility and flexibility of collagen-rich scar tissues and blood flow.[58] This may be beneficial in cases of chronic inflammation. Appropriate selection of frequency, intensity, duty cycle, and duration of ultrasonic waves delivered are important considerations. With conventional therapy, high frequency (1.1–3.3 MHz) and intensity (0.1–3.0 W/cm^2) ultrasonic waves are delivered to the target area in a continuous or pulsed mode.[58] Pulsed mode may be more advantageous in providing mechanical effects over thermal ones. Therapeutic ultrasonography, when used in rat models, decreased necrosis of skin flaps and increased levels of endothelial growth factor in skin margins compared to nontreated animals.[62] Similar results have also been reported in rabbits with skin grafts.[63]

Negative Pressure Wound Therapy

Negative pressure wound therapy (NPWT) is promoted to improve wound perfusion, reduce interstitial edema, promote the formation of granulation tissue, decrease the formation of substances that inhibit wound healing, and diminish bacterial contamination of the injury site. Studies evaluating their use in wound treatment in rabbits[64,65] and chelonians[66–68] have shown that NPWT can be effective at reducing edema and promoting a healthier wound environment causing expedited healing. No reports of their use in an avian species have been published at this time. Small portable units including the vacuum-assisted closure (VAC) device (KCI, San Antonio, TX, USA) can be used for larger birds. NPWT is not practicable for small avian patients because their body surface area is not often large enough to achieve a negative pressure wound environment over the affected area; however, NPWT remains a therapeutic option to treat avian wounds and it is up to the attending veterinarian to determine if the patient in question would benefit from this treatment and if it would be possible to use.

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy (HBOT), up to this time, appears to be a rarely used modality to treat avian wounds due to availability and cost. Recently there has been an increase in HBOT chambers manufactured specifically for the pet market, and this treatment option may become increasingly popular for avian wound care soon. The patient's natural healing process is enhanced by inhaling 100% oxygen in a chamber where atmospheric pressure is increased and controlled. Through HBOT supplemental oxygen infiltrates injured areas of the body, improving the antimicrobial activity of the white blood cells, reducing swelling, and promoting angiogenesis. It may also have some bactericidal activity. HBOT has shown improved healing times in full- and partial-thickness wounds in rats,[69] full-thickness wounds in mice,[70] and second-degree burns in guinea pigs.[71] Preliminary results evaluating the effects of HBOT on healthy domestic chickens by the author showed no adverse effects on the chicken's overall health.

Regional Limb Perfusion

Regional limb perfusion is a technique where antibiotics are administered intravenously to a selected region of a limb through the venous system. A tourniquet is placed, often for no more than 15 minutes, to diminish systemic absorption of the medication. Concentrations of ceftiofur sodium in synovial fluids exceeded therapeutic thresholds when administered via intravenous regional limb perfusion in an avian model,[72] indicating that this technique allows for a high local concentration within deep tissue. This technique has been routinely used in veterinary medicine in a variety of species, including horses, rabbits, and elephants. The first reported use in an avian species showed improvement in lameness and size of lesions associated with pododermatitis in a chicken with intravenous amikacin.[73] Intravenous regional limb perfusion should be considered an effective technique for treatment of contaminated wounds and other infections of the distal aspect of limbs in birds. For more information, see Chapters 6 and 33.

Hydrosurgery

Hydrosurgery uses a device that forces saline solution through a narrow window at high velocity, creating a localized vacuum. This allows for dead tissue to be removed while also diluting the local bacterial load. The suction permits targeted tissue to be cut while aspirating debris from the site. It has been described as a debridement technique for burns, venous leg ulcers, and pressure ulcers in human medicine. Studies in human trials found no significant shortening of wound healing time with hydrosurgery compared to traditional techniques and no difference in quantitative bacterial load.[74] It also does not allow for hemostasis, limiting its use for large and hemorrhagic wounds. It may be effective on dry fibrin and necrotic tissue though. In vitro studies using equine muscle showed that hydrosurgery reduced the load of *S. aureus* by 99.7%, which was higher than saline irrigation with sharp debridement (87.4%), sharp debridement (82.2%), and saline irrigation (46.0%).[75] At the time of publication, the only reported clinical case of hydrosurgery in veterinary medicine was the use in a beluga whale.[76] Its application may be considered in the future for the contamination of necrotic wounds in avian patients.

Coblation

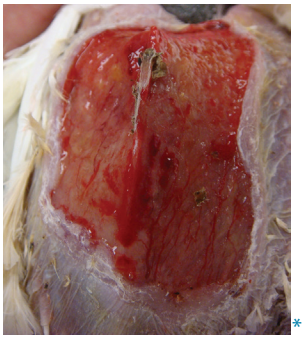
Coblation uses bipolar radiofrequency to energize molecules via a conductive solution surrounding an active electrode,

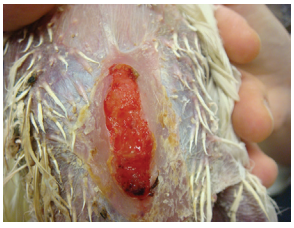
which creates a precisely focused plasma field. The glow discharge plasma produces chemically active radical species from the dissociation of water, breaking molecular bonds and causing tissue dissolution. Unlike hydrotherapy, there is no risk of spreading aerosolized bacteria. It also provides a hemostatic effect, which may be beneficial for chronic inflammatory wounds.[74] There have been no human-controlled trials assessing its effectiveness in wound healing in humans published to date, but in vitro studies have shown significant microbicidal effects. Its application in veterinary medicine has also not been reported for the purpose of wound management, as this remains an emerging new technology for clinicians.

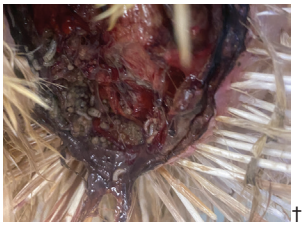
SUMMARY

Wound management is an important part of avian veterinary practice. Birds are often presented with skin injuries that are the result of many causes. The presented wounds need to be assessed and treated in a proper manner in order to promote a rapid healing process (see Table 36.5 for examples of common avian wounds and their recommended treatment). It is important to remember that upon initial presentation, the bird must be stabilized before extensive wound treatment can take place. A temporary bandage can be applied to protect and reduce further trauma to the affected area as the patient gains strength prior to properly managing the injury. There are many treatment products available to the veterinarian for wound management and to ensure optimum healing outcome, knowledge of both wound healing and the products used is essential. A flow chart to facilitate decision-making when managing wounds in the avian patient can be seen in Figure 36.10.

TABLE 36.5

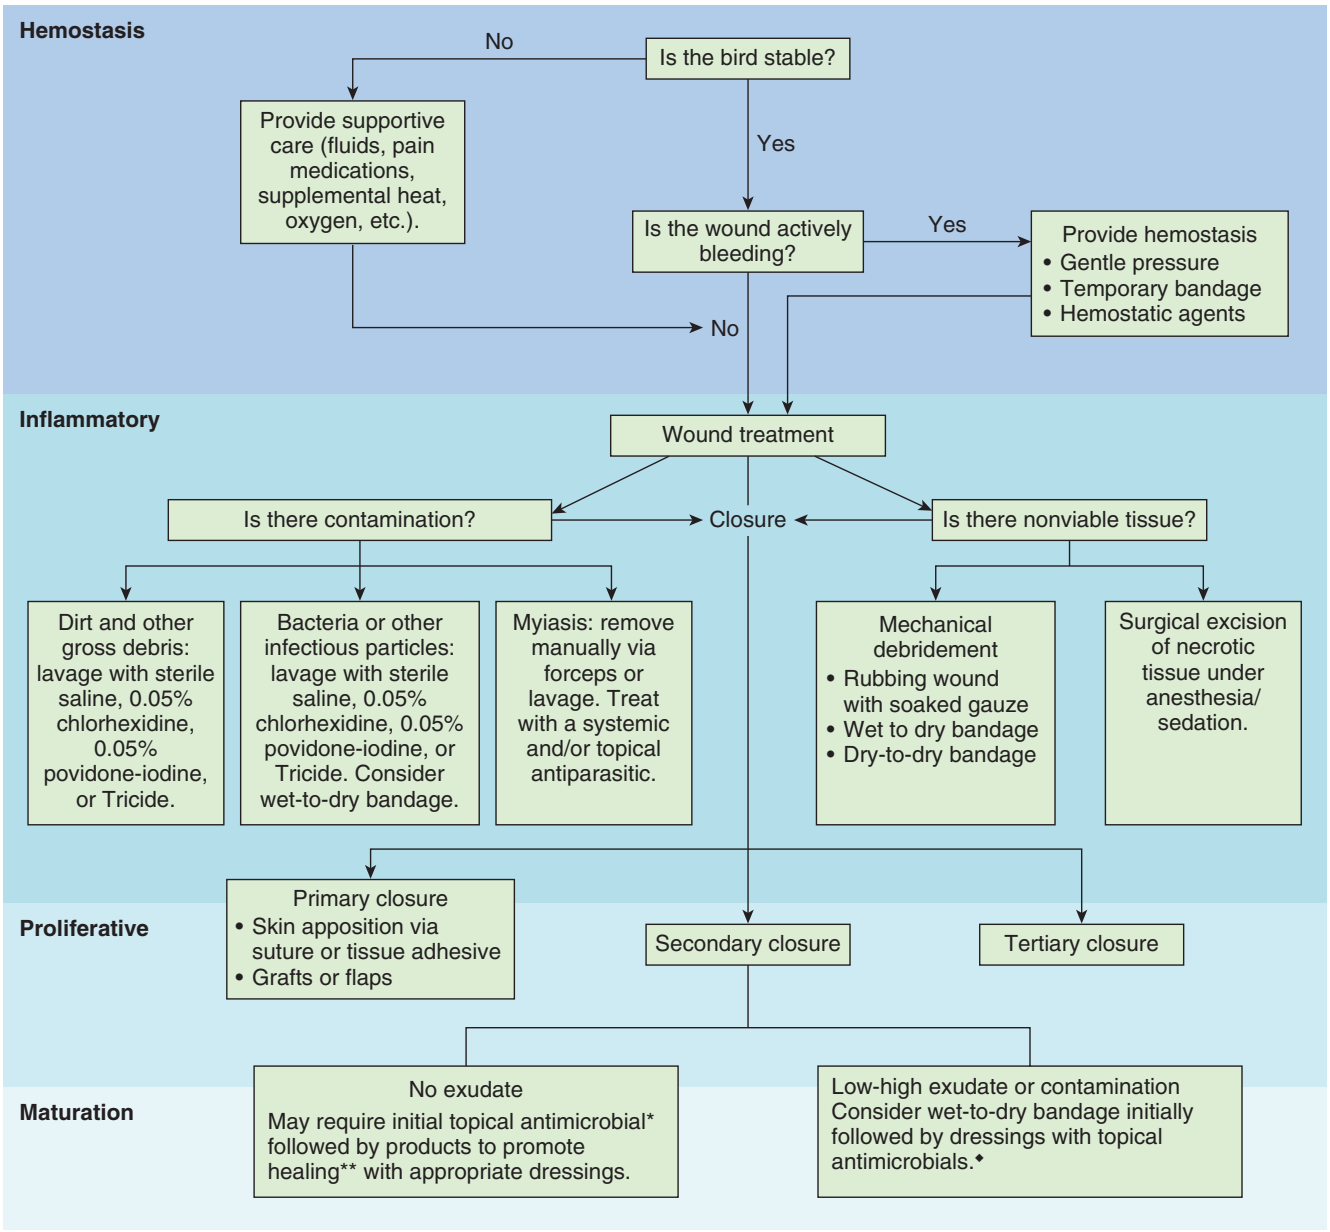






Examples of Common Avian Wounds and Recommended Treatment

Example	Type of Wound	Recommended Treatment
 *	No exudate, poor granulation or agranular tissue (pale, gray/brown)	Primary or secondary closure Dressings that provide antimicrobial and exudate-management Focus on nutrition to help grow stronger tissue
 **	Low exudate	Topical lavage Primary or secondary closure Dressings that provide moisture to prevent desiccation
 *	High exudate (soft, gelatinous)	Topical lavage to reduce bacterial load ± wound debridement Secondary or tertiary closure Dressings should provide direct pressure and manage moisture and pathogens



Continued

TABLE 36.5

Examples of Common Avian Wounds and Recommended Treatment—cont'd

Example	Type of Wound	Recommended Treatment
*	Necrotic (black, nonlistening) with or without plaque formation	Wound debridement (surgical or mechanical) Secondary or tertiary closure Consider dressings that aid in autolytic debridement
*	Granulation tissue (firm and pink-to-beef-reddish color)	Debridement and management of exudate product Dressings that ensure minimally moist and protective environment
	Epithelialized tissue (pale, pink/mauve tissue usually found at the edge of wounds)	Secondary closure Dressings that provide from exposure and excessive moisture
†	Myiasis	Manual removal followed by topical lavage Systemic or topical antiparasitics Secondary or tertiary closure Dressings that provide continued antimicrobial treatment

*Topical products for no exudate wounds:
Chlorhexidine 0.05%
Hypochlorous acid
Povidone-iodine 5%
Silver sulfadiazine cream 1% (judiciously)
Sea salt and lysozyme spray/foam
Triple antibiotic ointment (judiciously)

◆Topical products for low-high exudate wounds:
Acemannan gel
Chlorhexidine 0.05%
Hydrogel silver wound gel
Hydrogel
Hydrolysate of type I collagen
Hypochlorous acid
Manuka honey
Povidone-iodine 5%
Silver sulfadiazine cream 1% (judiciously)
Sea salt and lysozyme spray/foam
Triple antibiotic ointment (judiciously)

**Topical products that promote healing:
Borate-based biological class
Ionic and metallic silver absorbable wound matrix
Hydrogel
Hydrolysate of type I collagen

FIGURE 36.10 Decision-making schematic for wound management.

CHAPTER 37

Management of Fractures and Luxations

Julia B. Ponder • Michelle Willette • Dana Franzen-Klein

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Successful management of fractures and luxations in the avian patient requires an understanding of orthopedic principles, an appreciation of the unique anatomy of birds, a comprehensive evaluation of the presenting patient, and clear outcome objectives. Musculoskeletal injuries are common in avian medicine and while the proximate cause of most fractures and luxations is traumatic, there are many potential underlying contributing factors that are reflected in the diversity of avian species and their reasons for being in captivity. Wild birds being treated in rehabilitation centers present with different comorbidities and overall health status than caged birds living as companion animals. Exotic and domestic bird species held for display or education in zoos and nature centers represent a third type of avian patient with a wide variety of health histories, ranging from a captive-bred exhibition bird to an ambassador animal that is permanently injured and nonreleasable. Nutritional status will vary based on their life history as will overall health and exercise levels. Each of these groups has a different role to fill and those histories influence treatment, prognosis, and acceptable outcomes. Successful outcomes are defined by the requirements the bird needs for survival or its purpose in its specific setting (e.g., free-flight program) as well as the bar set for acceptable long-term welfare.

Many of the most common orthopedic conditions, including fractures, luxations, and degenerative joint disease, are secondary to trauma with or without an underlying pathological disorder such as metabolic bone disease, neoplasia, or malnutrition.[1] Because avian long bones have brittle cortices and minimal soft tissue covering, birds present with a higher level of comminution than humans, dogs, or cats.[1] Fractures often occur in pet birds as a result of trauma from falling, impacting a window or ceiling fan, being stepped on, or being the victims of an encounter with a dog, cat, or other predator.[2] Trauma can also be seen secondary to weakness, ataxia, or seizures in companion birds with other health issues such as atherosclerosis, bornavirus infection, and disease or lead toxicosis. In addition, malnutrition and poor bone quality often contribute to companion bird fractures, especially in laying hens on poor diets. Poor bone density may also contribute to wing fractures that occur secondary to restraint in psittacines. These fractures are likely to be lower energy (lower impact) than those suffered by wild birds, with less soft tissue damage and less comminution. Free-living wild birds, however, are more likely to suffer high-energy fractures with significant soft tissue damage and highly fragmented bones. In addition, they are more likely to have concurrent traumatic issues such as eye damage, head trauma, and multiple limb fractures.

In general, companion and aviary birds are more likely to present with pelvic limb fractures than wing fractures.[1,3] Small caged birds such as canaries have been reported to have a very high prevalence of tibiotarsal fractures.[4] Wild raptors, however, have a higher incidence of pectoral limb breaks with approximately 80% of their reported fractures involving the wing (The Raptor Center [University of Minnesota] unpublished data).[5] Reports of commonly seen luxations are correlated with fracture locations: pet and aviary birds are more susceptible to femorotibial and coxofemoral luxations while wild birds have a higher incidence of elbow and shoulder girdle luxations (The Raptor Center, unpublished data).[6] Understanding the differences between avian populations related to the most likely cause of injury, underlying health conditions, and potential concurrent injuries will influence the clinician's diagnostic and treatment plan for the avian trauma patient.

Different populations of birds also have different desired final outcomes. For wild birds, the goal is full restoration of flight and function so that the bird can be returned to its natural existence. For a companion bird, full restoration is still the ideal goal, although it may be less critical. When full restoration of function is not possible for whatever reason, it may be appropriate to set a goal of returning a patient to a comfortable and pain-free life. With food supplied daily by a provider and often no requirement for flight, captive birds may have acceptable welfare despite less-than-perfect restoration of function. Ultimately, the decisions made, and actions taken on presentation of a fracture case will impact the long-term outcome and set the stage for the quality of the bird's welfare.

Management of orthopedic conditions encompasses the care that is provided from initial presentation through active fracture treatment and extends after fracture healing with physical therapy and management changes. The likelihood of a successful outcome is increased when the clinician has an appreciation of the unique characteristics of birds, a strong understanding and appropriate application of orthopedic principles, and clear, appropriate objectives for patient outcomes.

ANATOMICAL CONSIDERATIONS

The evolution of flight has resulted in a skeleton that is very lightweight while at the same time strong enough to withstand the stresses of flight, including takeoff and landing. Many of the bones in the skeleton of birds are fused, resulting in a smaller total number of bones than other vertebrates and providing extra stability for flight.[7] This increased rigidity to the skeletal system also predisposes to traumatic fractures. Although the avian skeletal system is quite strong, the cortices of the long bones are substantially thinner relative to bone diameter than in similarly sized mammals. Because of these thin and brittle cortices, bones often shatter on impact and fractures are frequently comminuted. Another complication of the thin cortices of bird bones is they have less holding capacity for fixation than mammalian bones.[2]

Other structural characteristics of note in avian patients are the presence of pneumatized bones in many bird species and the bipedal nature of movement. Most, but not all, birds have pneumatized bones, which communicate with the respiratory system. This communication is recognized as a potential pathway for the movement of pathogens between a traumatized limb and the respiratory system and must be considered during treatment. Diving birds have less pneumatization of bones than birds that spend more time flying. In general, pneumatic bones do not secure fixation as well as solid bones, another consideration that the clinician should take into account when preparing a treatment plan. The bipedal nature of birds means that wings do not need to be weight-bearing during recovery/fracture healing, an advantage when determining the optimal treatment plan for a wing fracture. With pelvic limb fractures, however, the clinician has to take into account the requirement for almost immediate weight-bearing or use of the injured leg when developing a plan.[8]

In addition to unique bone structure relative to most mammals, birds have a minimal amount of soft tissue covering their long bones. With very thin skin, minimal subdermal tissue, and centralized musculature, many long-bone fractures are open, potentially resulting in contamination, devascularization, and loss of bone viability. This paucity of soft tissue protection can have a substantial impact on both treatment approach and prognosis. It is critical to lubricate, protect, and support/stabilize exposed bone fragments during triage to avoid devitalization and bone loss. If soft tissue connections are preserved, birds have a strong ability to incorporate their bone fragments into a healing fracture. Although the need to preserve long-bone length makes it intriguing, successful bone grafts have not been commonly used in birds as they have very little cancellous bone and there are few other options.[2]

The propatagium is a soft tissue structure critical for flight that may be damaged during traumatic events. Severe contraction of the propatagium occurs when the elastic fibers forming it are replaced by fibrous scar tissue after a traumatic event. This type of scarring can also be seen when wing fractures are treated with figure-of-eight bandages and/or not provided adequate physical therapy.[8] As the loss of patagial elasticity and function can prevent return to full flight capacity despite adequate fracture healing, particular attention needs to be paid to conserving and protecting this structure in birds for which restoration of wing function is critical to their survival.

In hens, derangements of calcium metabolism associated with egg laying can present unique challenges. The primary function of medullary bone in avian long bones is to serve as a calcium reservoir for the rapid movement of calcium required by hens. As an eggshell represents up to 10% of the total body calcium, the demand of egg laying can complicate bone healing by redirecting the calcium needed for bone healing to egg formation, especially in a malnourished hen.[9] During the hyperostotic bone phase of calcium mobilization the radiographic appearance of the bone changes, and the placement of an intramedullary (IM) pin may not be possible.

FRACTURE HEALING

Relative to mammals, avian bone healing can be quite rapid.[10] Uncomplicated humeral and femoral fractures can heal in 3 to 4 weeks in adults and even more quickly in juvenile birds (Table 37.1). As a rule of thumb, the more distal long bones have slower healing. Overall outcomes will be improved if normal joint movement, range of motion, and bird mobility can be maintained during the healing process, goals most easily achieved with surgical fixation. In an experimental setting, it took 5 weeks for a radius/ulna fracture to heal with a surgical approach while similar fractures took 8 weeks when treated with coaptation.[11] More recently, a retrospective study in raptors showed that conservatively managed cases healed more quickly than surgically managed ones, although this may have been biased by case selection (i.e., more complicated cases were more likely to be surgically managed).[12] Complicating conditions such as open fractures, severely comminuted fractures, infection, patient comorbidities, and very distal limb fractures will all contribute to delayed healing times.

Because the predominant source of hematogenous nutrition is associated with the periosteal blood supply, disruption of this system may result in delayed healing or a nonunion.[2] While free bone fragments without a blood supply have a high risk of necrosis and sequestrum formation, the presence of soft tissue attachments indicates that fragments may be incorporated into the healing process.[13] For these reasons,

TABLE 37.1

General Healing Times for Uncomplicated (e.g., Simple Transverse, Closed) Versus Complicated (e.g., Comminuted, Open) Fractures

Fracture	Uncomplicated (in Weeks)	Complicated (in Weeks)
Coracoid, clavicle, scapula	3–4	4–6
Humerus	3–4	4–6
Radius and ulna	4–5	6–8
Metacarpal and phalanges	5–6	7–10
Femur	3–4	4–6
Tibiotarsus	4–5	6–8
Tarsometatarsus and digits	6–8	10–12

Note these are general guidelines, and each fracture will heal at a different pace depending on the fracture itself, the complication, how quickly and effectively the complication is addressed, and the overall health status of the individual patient.

minimization of tissue handling and avoiding disruption of fragments are key concepts.

How bone healing progresses is a function of adequate nutrition (blood supply) and the amount of (or lack of) motion between fragments. The concept of interfragmentary strain has been used to explain direct and indirect bone healing.[14] When fixation is complete and there is no movement or gap between fragments, direct or primary healing occurs and there is minimal callus formation. This requires a minimum of 50% alignment and contact between the fragments as osteoclasts, osteoblasts, and osteoid production cannot cross any gaps. Healing is hard to assess radiographically as there is only a gradual loss of detail to fracture lines. With primary healing, it can take many months for sufficient remodeling to return bone to its original, functional strength. In contrast, if there is any gap present between fragments at the fracture site, bone healing occurs indirectly, starting with the formation of a hematoma and progressing through inflammation, soft callus formation, deposition of osteoid, and mineralization. Eventually, with the formation of woven bone, a stiff callus is formed. Successful healing is based on the amount of interfragmentary gap strain. While this results in a strong and successful union, without adequate rigidity in the early phases, there may be too much gap strain, which can result in a fibrous union rather than a bony callus.[15]

Over time, the approach to surgical fixation of mammalian fractures has progressed from open reduction and rigid fixation through mechanical stabilization to a biologically friendlier approach stressing preservation of blood supply and gentle tissue handling (OBDNT—"Open But Do Not Touch"). This progression has continued in recent years to a new philosophical approach known as minimally invasive osteosynthesis (MIO), in which the fracture site is not opened, preserving the initial hematoma, and promoting earlier healing. MIO preserves the biological environment and emphasizes longitudinal and axial alignment of bones rather than perfect structural anatomy, as well as focuses on optimal construct stability and integrity rather than rigid interfragmentary stability.[16] This philosophy is well aligned with the experiences and teachings of Dr. Patrick Redig of the University of Minnesota's Raptor Center, a pioneer in avian orthopedics who has stressed soft tissue–preserving approaches to avian orthopedics for decades. Redig's development and use of the tie-in fixator (TIF), also known as an external skeletal fixator-intramedullary tie-in (ESF-IM tie-in) followed the OBDNT approach and recommended a closed (minimally invasive) approach whenever possible. Although supported by clinical outcome and evidence-based medicine, this minimally invasive fracture repair method does have some downsides, including the need for excellent knowledge of anatomy and early intervention to align fragments and maintain limb length, an option that is not always available with avian patients.[17]

DECISION-MAKING PROCESS FOR FRACTURE TREATMENT

Timely and appropriate decision-making on fracture treatment is fundamental to consistently getting to the best possible outcomes. The earliest choices made are often the most influential on outcome and need to take into consideration the treatment goals, the overall patient, and the specifics of the fracture presentation. The clinician should have clear objectives based on the "role" of the patient. Is it a wild bird that absolutely needs full function before release? Is it a companion bird who has a caregiver to provide for it and ensure good welfare? Or is it a bird that is on display or used for educational purposes? Depending on the environment that the bird must function in posthealing, acceptable outcome goals may vary. Ideally, the goal for all cases would be a return to full function, which often dictates whether a surgical or nonsurgical treatment approach is utilized. In situations where full function is not a feasible outcome and the bird's long-term care can be provided for, it is important to take prognosis for long-term comfort (lack of pain) and the ability to ensure good welfare into consideration when determining a treatment approach. All potential outcomes are enhanced by choosing an approach that maximizes healing while minimizing secondary morbidity.

EVALUATING THE PATIENT: A HOLISTIC APPROACH FROM INITIAL ASSESSMENT THROUGH TO FINAL OUTCOME

Given the wide diversity of birds, the signalment of the presenting case is important. Species variations can have an extremely significant impact on decision-making. Psittacine species are more resilient than raptors and will adapt to life with a limb amputation in ways that raptors rarely do. The number of pneumatized bones is correlated with size and ecological behavior and varies by species. In general, the number of pneumatic bones is increased in species such as albatross, condors, and vultures that soar while diving birds have a reduction in number. Hawks and falcons typically have pneumatized humeri and femurs while the monk parakeet and cockatiel have only pneumatized humeri. Loons, penguins, and cormorants are considered to have apneumatic bones.[18] These anatomical variations may restrict the choices on surgical fixation devices. In addition, patient size also matters. Many of the orthopedic techniques used in birds were developed for raptors weighing a kilogram or more. The TIF, a very versatile device, can be easily adapted to birds under 100 g but is not realistic for a 20-g passerine.[2] Age and sex also influence outcomes with the bones of juvenile birds healing much more quickly than adults and calcium metabolism affecting the bones of laying hens.

The clinician often has more treatment options with captive birds than with wild birds, where a successful outcome is defined by the ability to survive in the wild, and some decisions, such as conditions necessitating euthanasia, are defined by regulatory agencies such as the United States Fish and Wildlife Service (FWS), Migratory Bird Treaty Act (MBTA) and Code of Federal Regulations (CFR). Among captive birds, living environments also vary tremendously. Typically maintained in some type of enclosure, these can be anything from individual cages to large, free-flight aviaries. These long-term husbandry and housing conditions influence choices on acceptable outcome compromises. Diet and nutrition, on the other hand, are important considerations for treatment and prognosis. While wild birds often have far more complex fractures and a higher bar for acceptable outcomes, they almost always have better bone integrity and nutrition levels than companion birds, providing more options on fixation devices and better prognosis for healing.

In addition to the husbandry issues mentioned earlier and the outcome considerations dictated by the bird's activities

and living circumstances, the patient's overall health status influences treatment decisions. Comorbidities may be the result of lifestyle (poor nutrition, limited exercise) over the years, secondary injuries associated with trauma, or simply related to aging and geriatrics. Of note for wild birds is the high incidence of ocular impairment associated with trauma. Studies have shown that 14% to 28% of raptors admitted to wildlife rehabilitation centers have ocular damage, which may affect decisions regarding releasability.[19] A complete ophthalmological examination and visual assessment should be done as part of the admission process as visual compromise may impact survival odds. In the authors' experience, ipsilateral trauma is common in birds admitted with chronic ocular lesions, possibly indicating a compromised ability to avoid injury. Additionally, wild birds may also have significant internal traumatic injuries that may delay their stability for a prolonged anesthetic event associated with surgical fixation.

ORTHOPEDIC EVALUATION AND PLANNING THE REPAIR

When evaluating a fracture patient's treatment options and prognosis, it is essential to understand the characteristics of a fracture and its anatomical location in order to achieve successful outcomes.[20] The type of fracture, bone integrity, and degree of fracture displacement should be assessed with a minimum of two orthogonal radiographic views; additional views such as the H-view for shoulder girdle fractures and oblique views for femoral head fractures can be very helpful (Figures 37.1 and 37.2).[21,22]

The common classification systems for fractures, which often include causal factors, location, morphology, and severity, are helpful tools in characterizing fractures as the nature of the fracture has direct implications for the choice of treatment (Table 37.2; Figure 37.3).[20,23] When planning the construction of a fixation device, the type of fracture is a key consideration. Transverse fractures often can load share with a fixation device while oblique, segmental, and comminuted fractures are unlikely to have an initial capacity for load sharing and require a much stronger construct for fixation. The clinician must also consider the location of the fracture, nearby structures, and the ability to place fixation without damaging joints or other structures. Mid-diaphyseal long-bone fractures are less likely than periarticular fractures to be associated with joint damage, which often leads to chronic degenerative joint disease, a complication that may prevent a wild bird from being successfully released or require long-term pain management for a permanently captive bird. Loss of joint function is likely

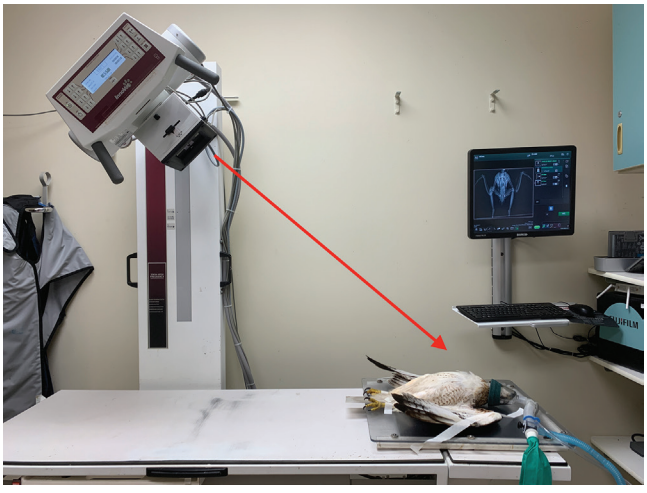

FIGURE 37.1 Setting the radiographic machine with the beam centered on the thoracic inlet at a 45-degree angle to the patient in dorsal recumbency (H-view) avoids superimposition of shoulder girdle bones and may allow clearer visualization of fractures.

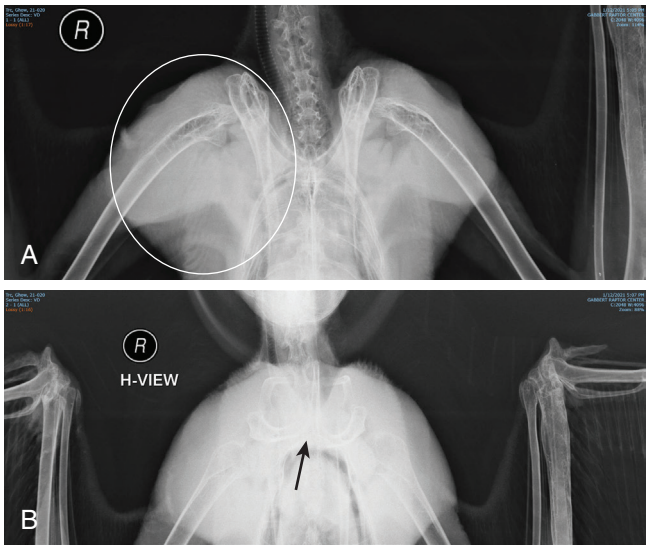

FIGURE 37.2 Radiographic images of an adult female great horned owl *(Bubo virginianus)* admitted to The Raptor Center at the University of Minnesota after being observed on the side of the road unable to fly. Image (A) is a ventral-dorsal radiograph taken on admit showing an apparently normal shoulder girdle. There is mild to moderate soft tissue swelling of the right shoulder *(white circle)*. Image (B) is an H-view taken on admit showing the right proximal coracoid luxation. Note the asymmetry where the coracoid bones meet the keel along the midline *(black arrow)*.

Fracture classification based on bone (2: radius/ulna), location (2: mid-diaphyseal), and complexity (C: comminuted): 22C.

to occur if a fracture is closer to the joint than 1.5 times the diameter of the bone.[24] The location of the fracture relative to muscle/tendon attachment/insertion sites will change the types and degree of forces applied to that fracture site and may change treatment decisions. Additionally, it may be hard to build adequate fixation in situations with small fragments and strong muscle attachments, requiring creative construct development to meet the goal of early and complete rigidity.

While there is a minimal force required to break a bone, the avian patient may experience much greater forces than this during a traumatic event. Fractures resulting from high-energy impacts are more likely to be highly comminuted with more devastating soft tissue compromise than those associated with low-energy events as energy is transferred to and absorbed by the patient's tissues. The forces experienced when a free-flying raptor is hit by a moving car are likely much greater than a companion bird flying into a stationary object (although malnutrition and poor bone integrity may complicate that latter situation). These high-energy fractures are more difficult to treat, slower to heal, and carry a poorer prognosis for complete recovery. Once again, successful outcomes are more likely to be achieved with strong adherence to the fundamental goals of early and adequate rigidity while minimizing additional soft tissue damage.

Tools in the Toolbox

A major goal in fracture treatment is to capitalize on the body's ability to heal the bone while minimizing complications. In planning the clinician's approach to fracture management, decision-making should be based on the ability to meet the following objectives, which inform best practices[2,7,23]:

- Establish early and effective rigidity
- Maintain anatomical alignment longitudinally and axially, as well as bone length
- Return limb to normal function and range of motion as quickly as possible
- Preserve and protect soft tissues
- Where possible, provide load sharing between the fixation device and the bone
- Reduce morbidity and prevent iatrogenic damage
- Promote patient mobility and comfort

After initial patient stabilization, the clinician should make an early decision whether the definitive treatment will be surgical intervention or conservative management. A fracture is considered stabilized when the forces of bending, rotation, shear, tension, and axial compression are neutralized. The ability to achieve most of the orthopedic objectives listed earlier in any fracture case positively correlates with the robustness of the treatment approach. The level of robustness required for maximum healing potential is dependent on the load sharing capacity of the bone, the construction of the stabilization device, and the integrity of the materials; the fixation must have the strength, duration, and capacity to counteract the forces of bending, rotation, and compression. A highly comminuted fracture in a weight-bearing limb of a large-bodied bird requires a fixation device with much more integrity and stability than a simple transverse fracture in a small bird. While this concept may seem intuitively obvious, it is fundamental to achieving a successful outcome. Failure to establish early, rigid stabilization with adequate fixation leads to a host of complications including delayed healing, nonunions, and fracture disease (compromised limb function).

Treatment options for fracture management vary in their ability to resist these forces. In order of increasing robustness, treatment options include cage rest, external coaptation, tape splint, IM pin, type I ESF, type II ESF, and the TIF (Table 37.3).

Cage rest

Very few avian fractures have satisfactory outcomes with just cage rest, which is mostly used as a supplement to coaptation or surgical fixation. Pelvic, spinal, and shoulder girdle fractures on small birds may do well with just cage rest. Management tools to enhance cage rest include reduced lighting to decrease activity and smooth-sided enclosures with removal of perches to prevent climbing.

TABLE 37.3

Tools for Managing Fractures

Cage rest/ confinement	◆ Very small birds ◆ Injuries not amenable to bandaging/ surgery (pelvic fractures)
Body wrap	◆ Initial or temporary fracture immobilization of wing fractures ◆ Coracoid/shoulder girdle fractures/ luxations ◆ Supplementary to wing wrap, figure-of-eight, or curved-edge splint
Wing wrap	◆ Initial or temporary fracture immobilization of wing fractures ◆ Nondisplaced wing fractures
Figure-of-eight	◆ Initial or temporary fracture immobilization of antebrachial fractures ◆ Immobilization of elbow and distal wing
Curved-edge splint	◆ Initial or temporary fracture immobilization ◆ Metacarpal fractures
Tape splints (Altman)	◆ Initial or temporary fracture immobilization ◆ Tibiotarsal fractures (birds <300 g) ◆ Metatarsal fractures (birds <300 g) ◆ Digit fractures (birds <300 g) ◆ Intertarsal joint luxations (birds <300 g)
Metatarsal and ball bandages	◆ Initial or temporary fracture immobilization ◆ Metatarsal fractures (birds <300 g) ◆ Digit fractures (birds <300 g)
Intramedullary pin	◆ Radius fracture ◆ Small bird long bones ◆ Immature birds
Type I ESF	◆ Ulna fractures ◆ Metacarpal fractures
Type II ESF	◆ Distal tibiotarsal fractures ◆ Tarsometatarsal fractures
TIF	◆ Humerus ◆ Ulna ◆ Femur ◆ Tibiotarsus
FESSA system	◆ Used as external bar for type I ESF, TIF ◆ Requires excellent alignment
Circular fixators	◆ Tibiotarsal ◆ Tarsometatarsal ◆ Distraction osteogenesis to increase bone length
Bone plates[a]	◆ Humerus ◆ Femoral ◆ Tibiotarsal ◆ Coracoid

Coaptation

Bandaging techniques are very useful for temporary fixation to prevent additional trauma and pain prior to definitive treatment. They often result in poorer outcomes and complications when used alone as bandaging is often bulky and requires prolonged immobilization of joints. As a definitive fixation tool, coaptation is best suited for very small birds, nondisplaced fractures, shoulder girdle fractures, phalangeal fractures, and single bone fractures of the antebrachium. Coaptation may be a good option in situations where full return to function is not required, when surgical risk is too great, or when there is minimal displacement, and owners are not willing to spend the money for surgery. Commonly used bandaging techniques include body wrap (Figure 37.4), wing wrap, figure-of-eight, modified figure-of-eight (Figure 37.5), tibiotarsal tape splints (Figure 37.6), and foot wraps/ball bandages.[20,25] Curved-edge splints are a good choice for many metacarpal fractures and tape splints may be used for definitive fixation for lower-leg fractures of smaller birds (Figure 37.7).

Surgical fracture management

A variety of devices and approaches can be applied surgically and used to provide definitive fixation. An IM pin is relatively easy to insert into a long bone and provides excellent opposition to bending forces. Because of its inability to resist torsional, compressive, and tensile forces, the IM pin is typically combined with coaptation for increased stability. On the other hand, type I, II, and III ESF devices are very good at resisting rotational, compressive, and tensile forces, while having moderate capacity to oppose bending forces (Figure 37.8). The TIF combines these two approaches to create a very versatile and effective system for long-bone fixation (Figure 37.9). The TIF construct consists of an IM pin, two or more ESF pins, and an external connecting bar that integrates these components into one unit, resulting in a robust device that resists all relevant forces. The external connecting bar can be created from acrylic (Technovit; Jorvet, Loveland, CO; Acrylix; IMEX, Dallas, TX, USA) using a Penrose drain or small plastic tubing as a mold or epoxy putty (Epoxy ESF Putty; Jorvet, Loveland, CO, USA).[7,20] In addition, the Fixateur Externe du Service de Santé des Armées (FESSA) system is commercially available and has been used successfully in both ESF and TIF styles.[26,27] Plates and nails have been used with varying degrees of success in repairing avian fractures with available information deriving primarily from individual case reports, including one in which a locking compression plate was applied externally and used as an ESF connector bar.[28] Limitations include lack of suitably sized plates and nails to accommodate the wide range of bone sizes in avian patients, lack of strength of the small plates to accommodate applied forces, morbidity associated with their placement, and expense.[20] More recently, adaptations of circular fixators have been used for definitive fixation as well as scaffolding for distraction osteogenesis to reestablish long-bone length.[29–31]

The robustness of each of these methods can be enhanced by clinical choices in application. For instance, while the materials and design used in a bandage or a splint will determine its ability to resist movement at the fracture site, these tools inherently reduce the patient's ability to use the limb during fracture healing. The surgically applied constructs are significantly stronger when applied correctly and meet the goal of allowing a quicker return to function. These devices can be reinforced by adding additional components. While an appropriately applied ESF requires a minimum of two pins in each fragment for stabilization of the fracture, adding additional ESF pins will increase the strength and rigidity of

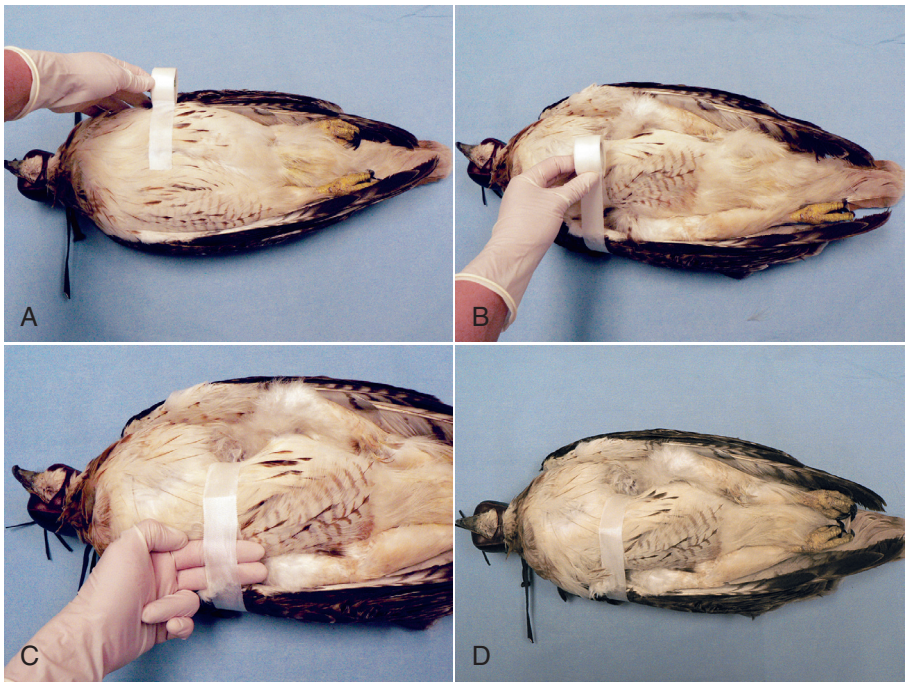

FIGURE 37.4 Application of a body wrap. Beginning mid-keel (A), the tape is passed away from the injured wing (B) and wrapped once around the body with the second wrap incorporating the injured wing (C). Final wrap should be snug, but not tight (D).

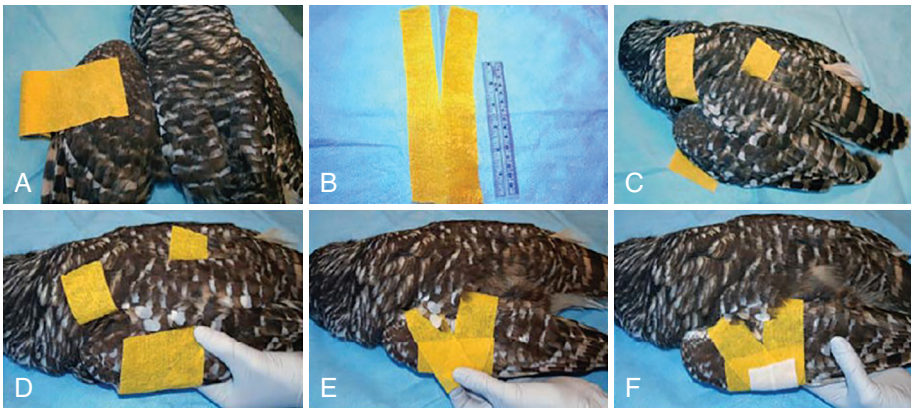

FIGURE 37.5 A modified figure-of-eight wrap. (A) Use a piece of self-adhesive bandage material wide enough to cover approximately two-thirds of the dorsal surface of the wing between the elbow and the wrist and long enough to overlap by 4–6 inches (10–15 cm) when wrapped around tucked wing. (B) Cut a slit in the self-adhesive bandage material that is parallel to the longest length of the bandage material. The slit should extend approximately half of the length of the bandage material. A ruler can be used to gauge the length of the slit if desired. The length of the slit should be approximately equal to the width of the wing from humerus to major metacarpal bone as measured on the dorsal surface of the wing when folded in a normal perching position. (C) Position the self-adhesive bandage material on the affected wing. One length of the cut bandage material is positioned in the axillary region proximal to the elbow joint and passing from the ventral to dorsal surface of the wing. The second length of cut bandage material is passed from the ventral surface of the wing, cranial/anterior to the humerus and over the patagium to rest on the dorsal surface of the wing. The uncut piece of self-adhesive bandage material is placed on the ventral surface of the antebrachium in the region of the radius/ulna, and is passed around the distal aspect of the wing over the major metacarpal bone onto the dorsal surface of the wing. (D) As the bandage is placed, tuck the wing into a normal perching position. (E) The bandage is secured in place by bringing the cut pieces of the bandage material together to join the single intact piece of self-adhesive bandage material on the dorsal surface of the wing and the bandage material is adhered together to secure the wing in place. (F) A piece of tape can be used to help secure the bandage. When appropriately placed, this modified figure of 8 bandage is able to immobilize both the elbow and the wrist joint, and is conceptually easier for some practitioners to place.

FIGURE 37.6 Application of a tape splint to a tibiotarsus/tarsometatarsus. After preparing the leg (A), place a light gauze wrap around the leg (B) and sandwich between two pieces of tape, ensuring no loose gauze strands are exposed (C, D). Using a hemostat, crimp the tape snug to the leg (E) and trim the excess tape (F). Final splint may be hardened with a coating of cyanoacrylate. (Images courtesy Y.R.A. van Zeeland.)

the device. Similarly, although a TIF requires only two ESF pins in its construction, additional ESF pins will add to its robustness, as will using a larger external bar for the tie-in.[32] The limitation to these choices is the ability of the bird to handle the size and weight of the fixation construct. Meeting both the objectives related to robust fixation and the goal of permitting patient mobility, comfort, and maximum range of motion for joints during healing often requires a clinical decision of surgical fixation (Figures 37.10 and 37.11).

While conservative management is best practice for some fractures such as shoulder girdle or pelvic fractures, for others (e.g., humeral fractures) a requirement for normal flight necessitates surgical fixation. In many situations, however, either coaptation or surgical fixation may be a practical option, a decision that requires thoughtful consideration. What are the goals for the patient? Is its long-term living environment (release to the wild, exhibit, or pet) determinant in the decision? Does the patient require return to full function? Are there future concerns for additional problems or

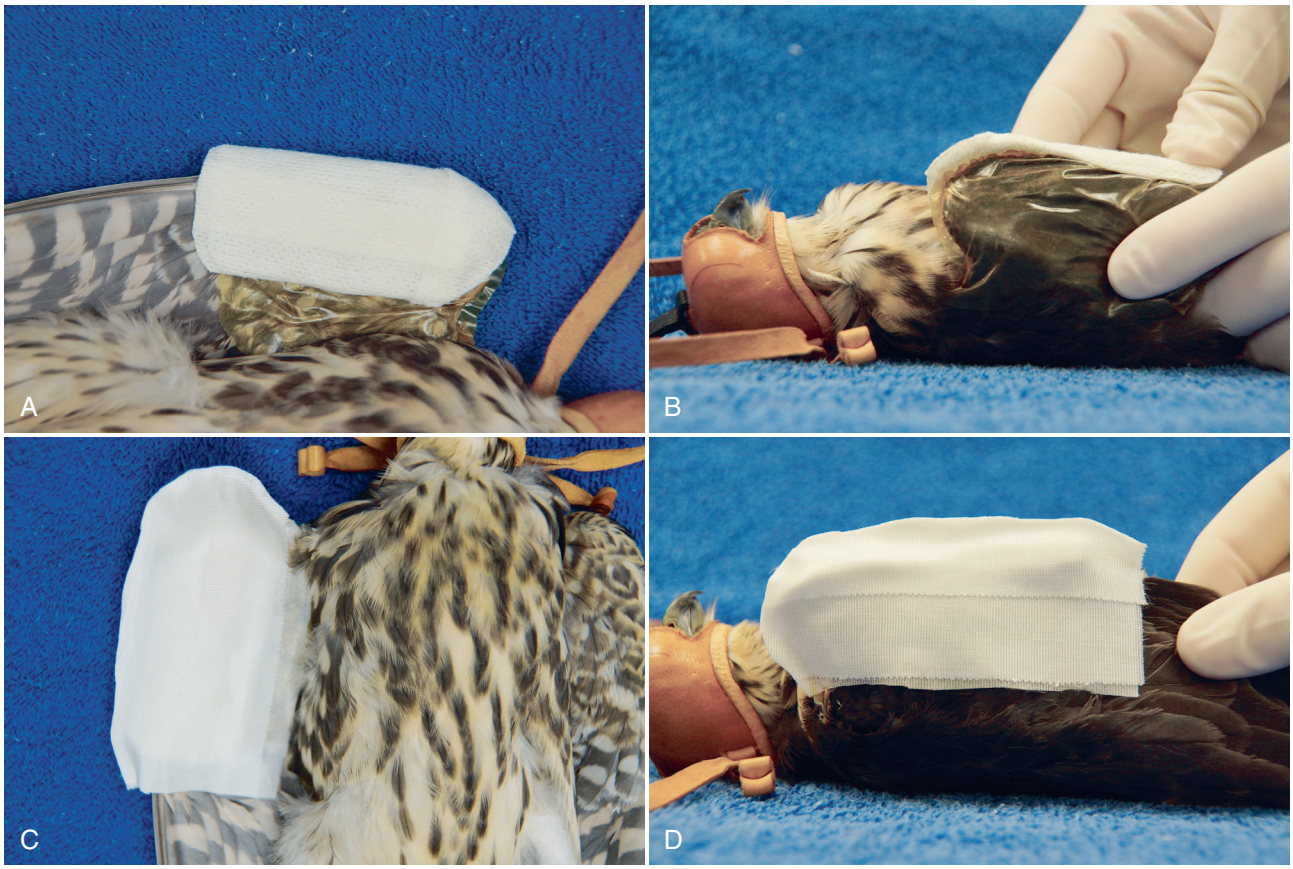

FIGURE 37.7 Curved-edge splint made from moldable thermoplastic. A piece of thermoplastic is cut to the length of the metacarpus and molded to the ventral aspect of the bone (A) with a right-angle bend covering the leading edge of the bone (B). The splint is sandwiched in place using overlapping pieces of adhesive tape applied ventrally (C) and dorsally (D).

complications? What are the resources available for treatment, including financial and equipment resources, clinical knowledge and experience, and surgical skills in avian fracture management?[20] For many patients, the question of whether there are adequate postoperative nursing care and rehabilitation facilities is important to consider.

The question of limb amputation as a salvage procedure and the ramifications of that decision can be complex. As previously noted, some avian groups such as psittacine species adapt far better to limb amputations than others. Characteristics such as species, biology, husbandry, and behavior all influence this decision. With wild birds, the options for amputation are limited in the United States; the Code of Federal Regulations proscribes euthanasia for any wild bird requiring an amputation of wing above the elbow or any part of a leg or foot other than a toe. A waiver can be requested by a veterinarian for wild birds being maintained in permanent captivity, although prior to requesting this waiver, it is critical that the veterinarian understands the ramifications of the decision in that species and the implications to the specific patient's welfare and is not basing the decision on whether or not the surgery can technically be done.

Triage and Treatment

Upon presentation for traumatic injury, the patient should be evaluated completely, including signalment, history, physical

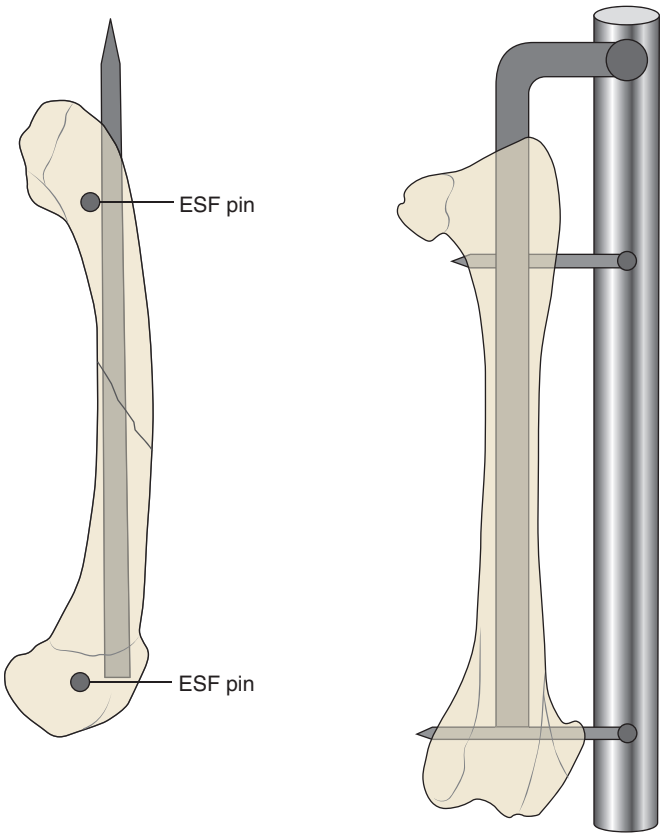

FIGURE 37.9 Diagram of a tie-in fixator (TIF), which uses an acrylic bar to connect an intramedullary (IM) pin with a type I external skeletal fixator (ESF), applied to a femur.

examination, orthopedic assessment, and radiography with stabilization of the patient and its immediate critical care concerns being prioritized, including supportive care and initiation of medications for antibiosis and analgesia (see also Chapters 34 and 35). In the earliest stages of diagnosis and treatment, the long-term prognosis for wild birds should be evaluated as quickly as possible to avoid unnecessary suffering when the prognosis is poor. As most avian fracture presentations are emergency situations or acute traumas, these patients must first and foremost be considered critical care patients. While fracture stabilization and soft tissue care are essential to minimize morbidity, careful consideration must be given to what the patient can withstand upon initial presentation. Preserving the patient's life is the principal consideration. A holistic approach should be used, addressing immediate critical care concerns, assessing the overall health status of the patient, and constantly evaluating the patient's condition and ability to withstand additional handling.

There are some actions, however, that—if taken early—will set the stage for successful outcomes. Attention to the preservation of soft tissue and bone during preliminary treatment of the avian patient is a key component of optimizing healing potential. Many avian long-bone fractures are open due to the paucity of soft tissues. Debridement of wounds should be performed without excessive manipulation to preserve soft tissues and avoid compromising circulation to bone fragments. Protection of the bone ends protruding through the skin should be done as quickly as possible through coverage with a water-based, water-soluble lubricant (K-Y Jelly; Reckitt Benckiser, NJ) or saline-moistened gauze as the first bandage layer (no direct contact between dry gauze and bone;

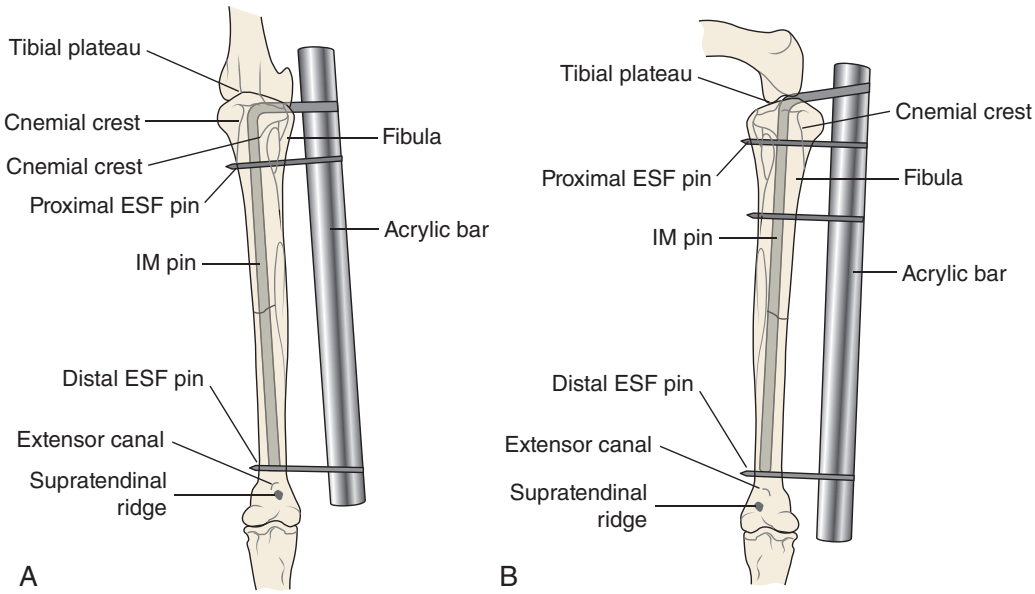

FIGURE 37.10 The robustness of an external skeletal fixator (ESF) or a tie-in fixator (TIF) can be increased by the addition of ESF pins. A standard TIF with one ESF pin in each fragment (A) is strengthened by adding additional ESF pins in one or more fragments. (B) Note, the IM inserts through the tibial plateau with the stifle in normal standing flexion and does not enter the femur.

FIGURE 37.11 Radiographic example of adding additional robustness with extra external skeletal fixator (ESF) pins on bilateral bald eagle *(Haliaeetus leucocephalus)* tibiotarsal fractures.

FIGURE 37.12 An open fracture with exposed bone showing loss of soft tissue attachments, darkened bone color, and a demarcation line reflecting loss of viability.

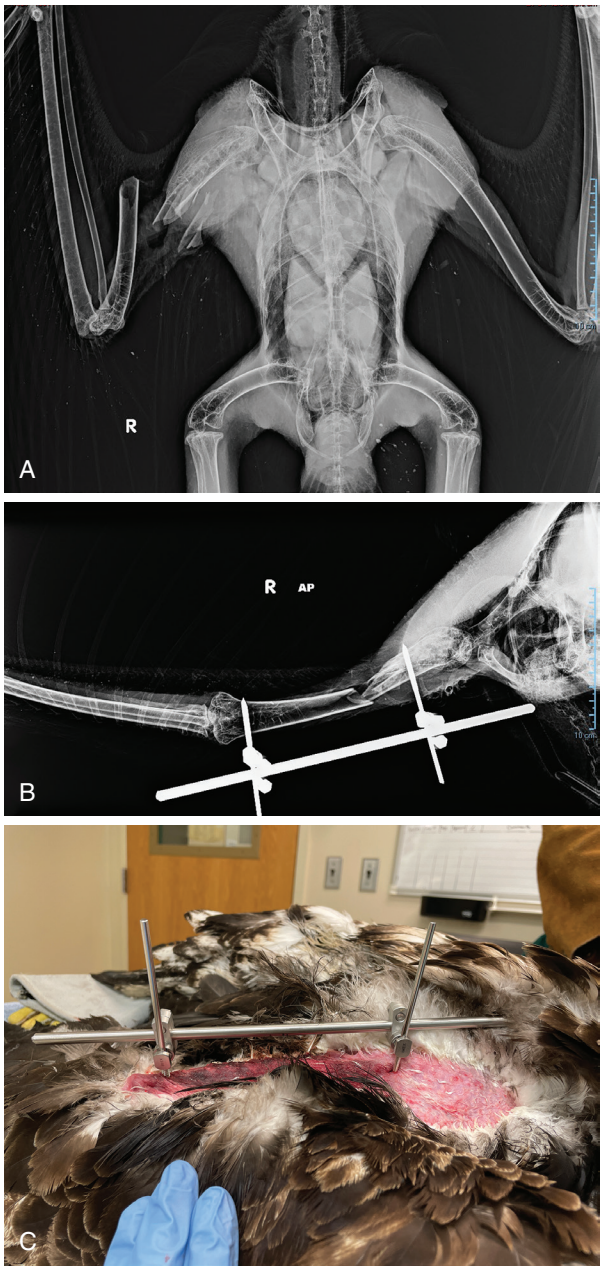

FIGURE 37.13 Use of a type I external skeletal fixator (ESF) as a temporary fixator on a bald eagle *(Haliaeetus leucocephalus).* (A) Intake radiograph showing a comminuted, mid-diaphyseal humeral fracture. (B) Caudal-cranial radiograph taken after placement of the temporary type I ESF and (C) image of fixation in place on the patient.

see Chapter 36). The treatment of the exposed bone ends will prevent this tissue from becoming devitalized and preserve bone integrity. Especially in wild birds, exposed bone is often already nonviable (Figure 37.12) and this should be taken into triage consideration as loss of long-bone length can impair flight mechanics, preventing full restoration of flight and releasability.

Stabilizing the fracture often occurs in two stages—temporary stabilization upon presentation of the patient with definitive repair after stabilization and full assessment of the patient has occurred. Preliminary treatment of orthopedic trauma should include reduction and stabilization of fractures and luxation. Coaptation methods such as body wraps, wing wraps, and leg splints are important presurgically to stabilize the fracture site and minimize additional soft tissue damage. Temporary stabilization with a type I ESF (Figure 37.13) is another option that can be applied relatively quickly in the unstable traumatized patient to protect the fracture site until the patient is stable enough for surgery. The two-pin, type I ESF helps prevent muscle contracture that can be challenging to overcome when

surgery is delayed and can help prevent the fracture from reopening in the presurgical period. If the ESF pins are well placed and still well seated at the time of surgery, they can be incorporated into the final fixation when using a TIF or ESF.

APPROACHES TO FRACTURE MANAGEMENT WITH SPECIES CONSIDERATIONS (TABLE 37.4)

Pectoral Limb

Shoulder girdle (Figure 37.14)

The coracoid, a key structural element in the avian shoulder girdle, is often fractured or luxated because of a frontal collision with an object. The force required to break this bone is significant, so the clinician should look carefully for concurrent trauma elsewhere. A key component in determining prognosis is the integrity of the shoulder joint. Despite sometimes dramatic displacement of the shoulder joint secondary to trauma, most birds will have a good prognosis if the actual joint is intact. If the fracture (or luxation) involves the joint, the prognosis for return to flight is poor (Figure 37.15).

TABLE 37.4

Management Techniques by Bone in Order of Decreasing Strength and Robustness

Bone	Temporary Stabilization	Definitive Fixation
Coracoid	Body wrap Cage rest	Body wrap Cage rest
Humerus	Type I ESF (two ESF pins) Body wrap	Tie-in fixator IM pin Coaptation[a]
Ulna	Figure-of-eight bandage Modified figure-of-eight wrap Body wrap	Tie-in fixator Type I ESF (four or more ESF pins) IM pin Coaptation (if radius intact)
Radius	Figure-of-eight bandage Modified figure-of-eight wrap Body wrap	IM pin Coaptation (if ulna intact)
Metacarpus	Splint Figure-of-eight wrap with body wrap	Curved-edge splint Type I fixator (four or more ESF pins)
Femur	Cage rest (well-padded)	Tie-in fixator IM pin Splint/cage rest
Tibiotarsus	ESF-IM tie-in, type II fixator	Tie-in fixator Type II fixator Tape splint
Metatarsus	Padded Splint	Type II ESF Tape splint
Phalanges	Coaptation Splint Ball bandage	Splint Ball bandage Thermoplastic/Styrofoam shoe

[a]Not generally recommended by authors for definitive fixation.
ESF, External skeletal fixators; *IM*, intramedullary.

While there are reports of successful surgical fixation of the coracoid in larger birds such as eagles, conservative management has been associated with an excellent prognosis for successful outcome in all sized birds and is the recommended approach.[7,33,34] Conservative management consists of cage rest combined with limiting wing motion on the affected side when possible. In raptors, successful outcomes are consistently achieved using a body wrap for 2 to 3 weeks with twice weekly physical therapy, and antiinflammatory and joint support medications.

Humerus (Figure 37.16)

Humeral fractures most often occur in the middle third of the diaphysis, frequently in the area where the muscle mass tapers off into more tendinous structures. A key characteristic influencing the approach to treatment is that the powerful flight muscles that attach to the proximal end of the humerus provide a formidable distraction force, resulting in fractures that are rarely even remotely aligned (unless partial or greenstick). Most commonly oblique, these fractures are frequently open with the sharp end of the proximal fragment projecting through the skin on the dorsal surface of the wing and the distal fragment exposed on the ventral surface. The radial nerve, which crosses from caudal to cranial in the midshaft portion of the bone, is often close to the fracture site and must be preserved during treatment. Because of the marked fragment distraction associated with humeral fractures, they almost invariably require a surgical approach and internal fixation if the bird is to return to normal function and flight. If treated with conservative management (coaptation), the outcome is, at best, a misaligned fracture and often a nonunion due to the inability to adequately stabilize the fracture with coaptation alone due to the strong forces applied by the proximal flight musculature.

Coaptation is important in the presurgical period. While the recommendation to use a figure-of-eight bandage on humeral fractures can be found in the literature, this technique is inadequate alone as it increases the distractive forces at the fracture site. A body wrap is simpler to apply, adequately stabilizes the joints above and below the fracture, and can be effective for short-term stabilization prior to surgical fixation. A TIF is well suited for definitive fixation of most humeral fractures. While it is an advantage that the pectoral limb does not need to be weight-bearing during healing, there are times when extra ESF pins are recommended to strengthen the construct (e.g., large birds, highly comminuted fractures). In smaller birds with uncomplicated fractures, a simple IM pin combined with external coaptation may be adequate. With extremely proximal or distal (within two to three bone diameters of condyles) humeral fractures, the short fragment may not provide enough purchase for an IM pin, necessitating that the surgeon employ a more involved construct such as a cross-pin technique or a tension band approach.[7]

Antebrachium (Figure 37.17)

The approach to treating fractures of either the radius or the ulna depends on the integrity of the other bone as well as the long-term objectives. External coaptation may provide satisfactory results, especially in small birds, if only one antebrachial bone is fractured. While a figure-of-eight bandage

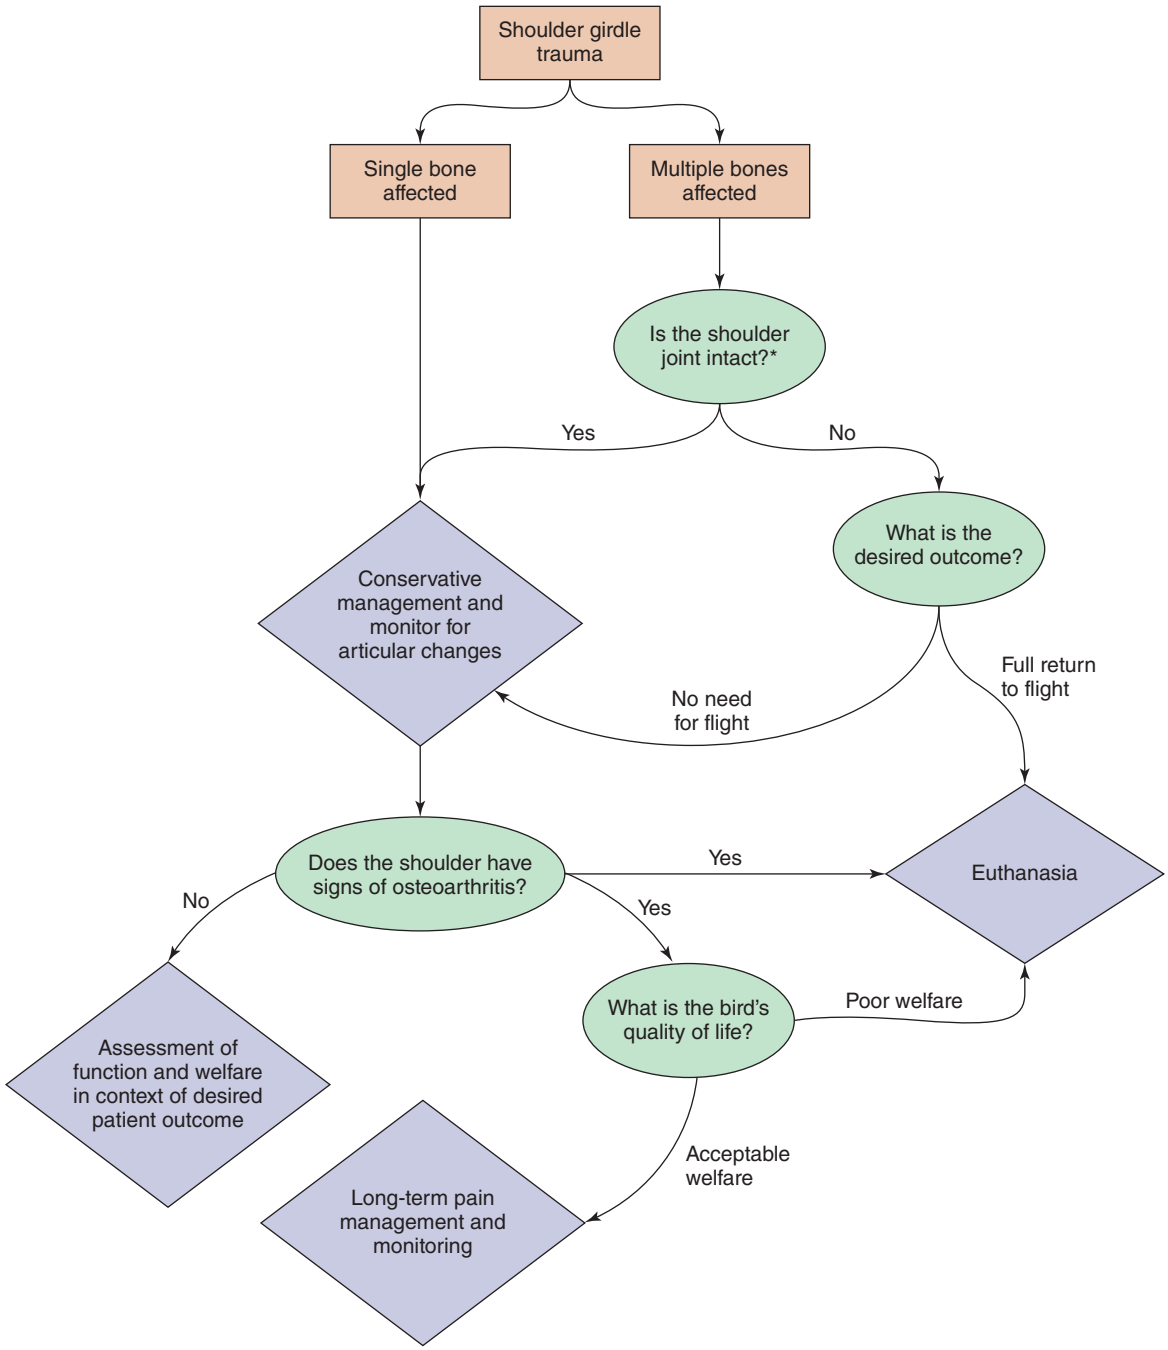

FIGURE 37.14 Decision tree to help guide the avian practitioner through the clinical decision-making process when presented with a bird with shoulder girdle trauma.

provides relatively good stabilization in this situation, its use carries a risk of complications such as reduced range of motion or patagial contracture.[2,20] These risks have been reduced by the use of a modified figure-of-eight bandage. In fractures involving one bone in the distal third of the antebrachium, the risk of synostosis developing can be reduced with a surgical approach utilizing internal fixation (IM pin in radius, TIF on ulna). In raptors, with an ulna fracture and intact radius, both conservative and surgical treatment approaches have been shown to be effective, with conservative management being used for chronic fractures with good alignment.[12]

When both antebrachial bones are fractured, some amount of internal fixation is typically required for return to normal function. Inserting an IM pin into the radius may be adequate with coaptation if the ulna is minimally displaced. However, the relatively small diameter of the radius necessitates a small diameter IM pin, which is often not rigid enough to provide adequate support even with additional coaptation when both the radius and ulna are fractured. Surgical fixation of the ulna in these situations, using a TIF, is still recommended if possible as it will result in greater integrity of the fixation and shorter healing times.[7]

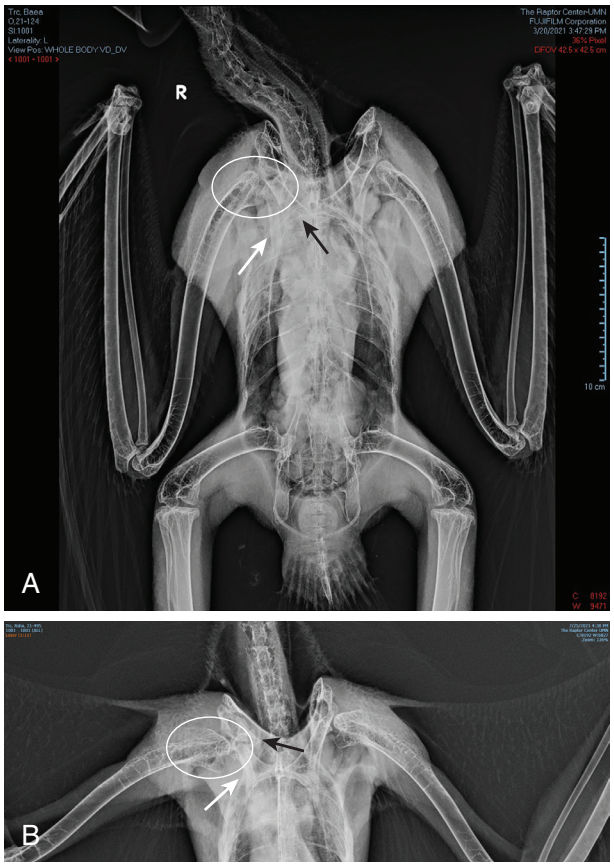

FIGURE 37.15 Radiographic image of a bald eagle (*Haliaeetus leucocephalus*) with a proximal right coracoid luxation (*black arrow*), a right scapula luxation (*white arrow*)—the scapula is displaced caudally relative to the normal right side, and a right clavicular fracture. (A) Note that the orientation of the articular surfaces of the humeral head relative to the scapular head has been preserved *(white circle)*. (B) Radiograph of a red-shouldered hawk *(Buteo lineatus)* with a transverse mid-diaphyseal right coracoid fracture *(black arrow)*, and a right scapula luxation *(white arrow)*. Note that the orientation of the articular surfaces of the humeral head relative to the scapular head has changed *(white circle)*.

Carpus/metacarpus (Figure 37.18)

Especially in wild birds, carpal trauma is often high energy with fractures of the major metacarpal having significant comminution. With even less soft tissue than other areas, open fractures and luxations in the carpal/metacarpal area can be challenging. In one study on metacarpal fractures in raptors, management with a moldable (curved-edge) splint supplemented with coaptation was shown to have good outcomes with relatively quick healing (21 days).[35] The authors have had good success with both curved-edge splints and type I ESF fixation. Carpal luxation has the best prognosis when stabilized after reduction with a type I ESF.[7] Chronic luxations are very difficult to reduce and often lead to reduced range of motion or ankylosis.[36] Whether stabilizing with a curved-edge splint or a fixation device, it is important to provide additional support with a body wrap when applying any weight to the distal wing.

Pelvic Limb (Figure 37.19)

Pelvis

Fractures of the pelvic girdle are most common in wild birds and often associated with car strikes or other major trauma. Frequently, there are multiple bones involved due to the high level of trauma. Treatment is cage rest with close attention to neurological integrity for prognosis. Involvement of the caudal synsacrum may result in abnormal tail position. In gulls (Laridae), fractures of the vertebral column caudal to the acetabulum carry a poor prognosis for return to flight. The successful use of a tail splint has been reported by taping the primary and secondary flight feathers of one or both wings together, then taping the tail to the wing tips.[37]

Femur

The avian femur is closely associated with the body wall, which provides substantial support. Because of this, femur fractures are less common than other leg fractures in birds. Stabilization with coaptation can be difficult, although the use of a spica splint has been recommended.[7] In almost all species, a TIF can be used with materials scaled as needed for the size of the bird. Smaller birds may do well with a simple IM pin for fixation, while in very small birds, a K-wire can be used as an IM pin. While malalignments are common, small birds may have successful outcomes with simple cage rest. In small-bodied altricial chicks, the femur may achieve adult length within the first week of life. In these birds, the incorporation of ESF pins to secure rotational stability may not interfere with growth. Chick bones may be amenable to piercing by hypodermic needles to use as ESF pins. Passerine femurs will typically accept a 25- or 27-gauge (0.020 inches, 0.5 mm or 0.0164 inches, 0.42 mm) 1.5 inches (3.8 cm) needle as an IM pin with the same size needles as ESF pins. A small amount of epoxy putty on a thin piece of wooden coffee stir stick works well as an ESF. Pinning these tiny fractures prevents the chick from growing up with a permanent disability.

Tibiotarsus

The tibiotarsus is among the most fractured bones in birds, being especially common in both pet birds and falconry birds. In psittacine species, tibiotarsal fractures occur most frequently in the mid to distal portions of the diaphysis while in raptors, they are mostly found in the proximal third of the bone. These fractures are generally closed and carry a relatively good prognosis. External coaptation is recommended for smaller birds weighing less than 300 g and tape splints were shown to have good outcomes in 92% of cases in one study (86 total cases).[2,20,38] For larger birds, surgical fixation is recommended, with Bueno and Redig reporting success outcomes in 84% of 37 cases following surgical reduction and the application of a TIF.[39]

Tarsometatarsus

There is tremendous variability in the confirmation of the tarsometatarsus among species, which is reflected in treatment approaches. For example, psittacine birds have a rounded tarsometatarsus, while raptors have a C-shaped bone with the powerful flexor tendons traveling in the plantar concavity. As with the tibiotarsus, tape splint fixation of tarsometatarsal fractures in smaller psittacines is generally associated with good outcomes. Larger psittacines and most raptors will benefit from

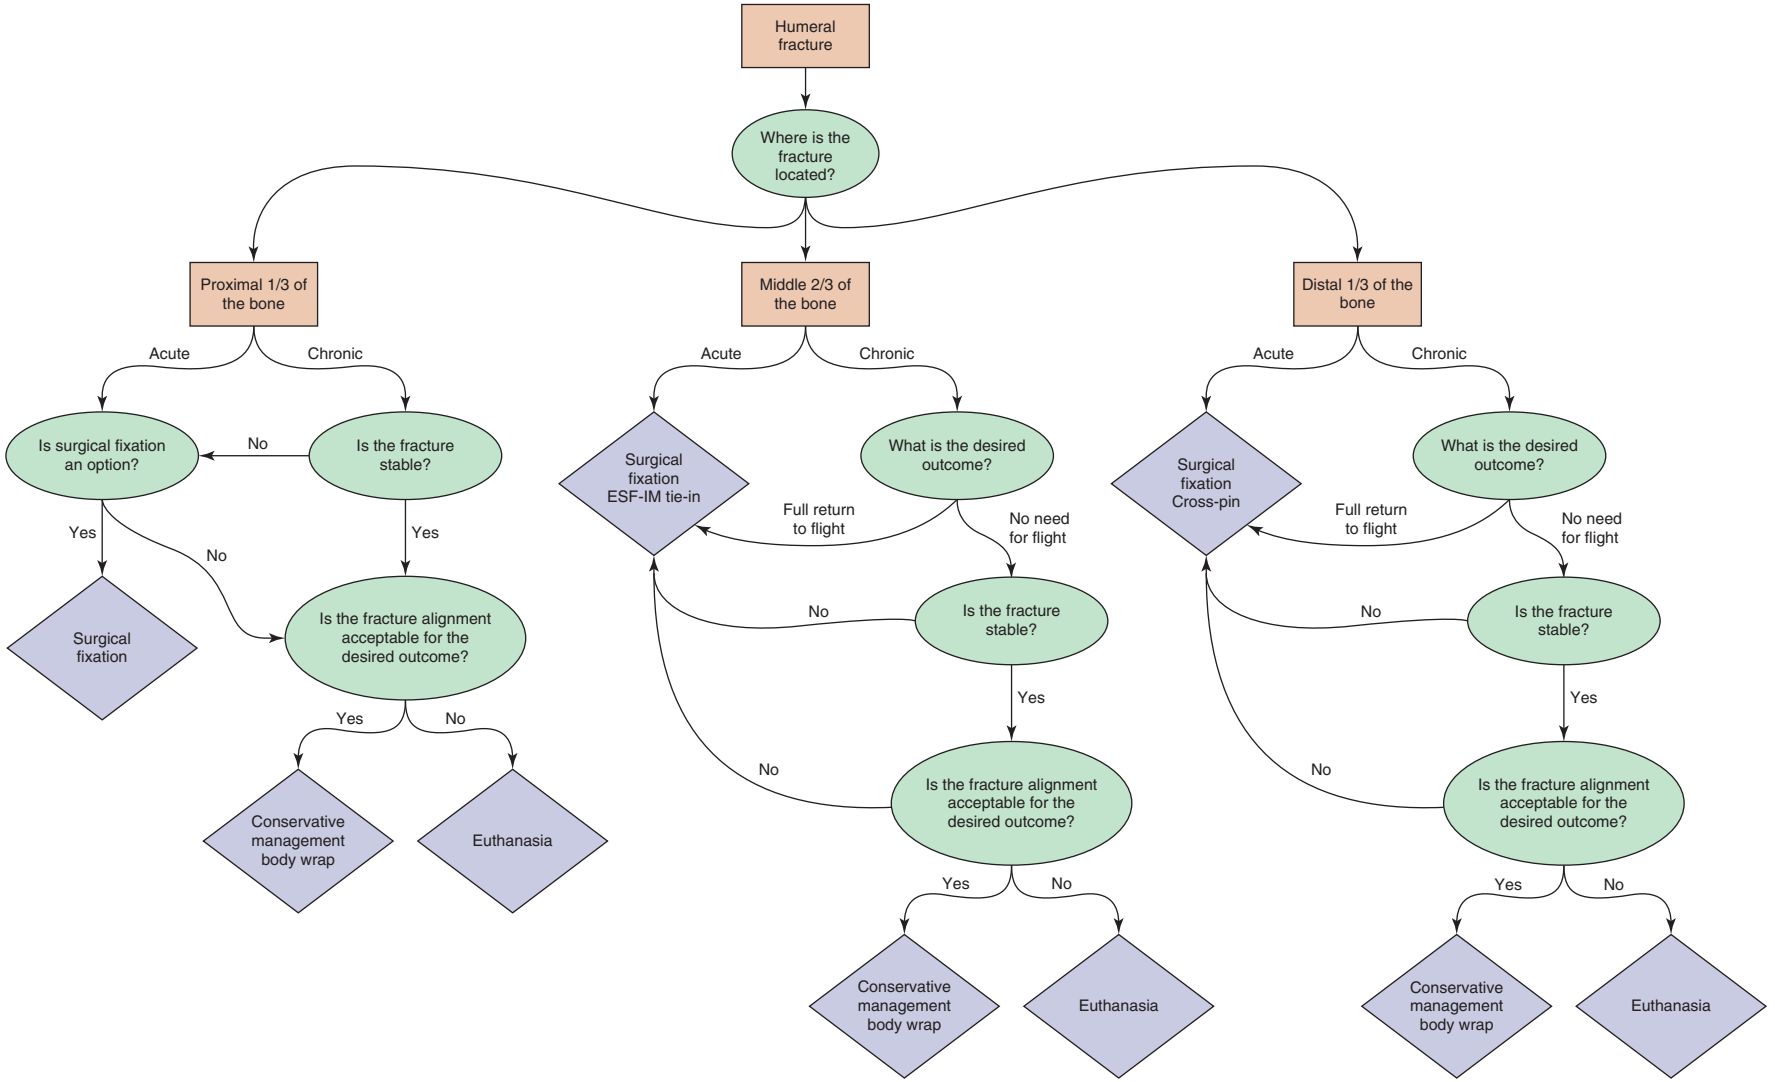

FIGURE 37.16 Decision tree to help guide the avian practitioner through the clinical decision-making process when presented with a bird with humeral trauma. When assessing if the fracture alignment is acceptable for the desired outcome, longitudinal and rotational alignment should be considered, as well as if there is a significant loss of bone length. *ESF*, External skeletal fixator; *IM*, intramedullary.

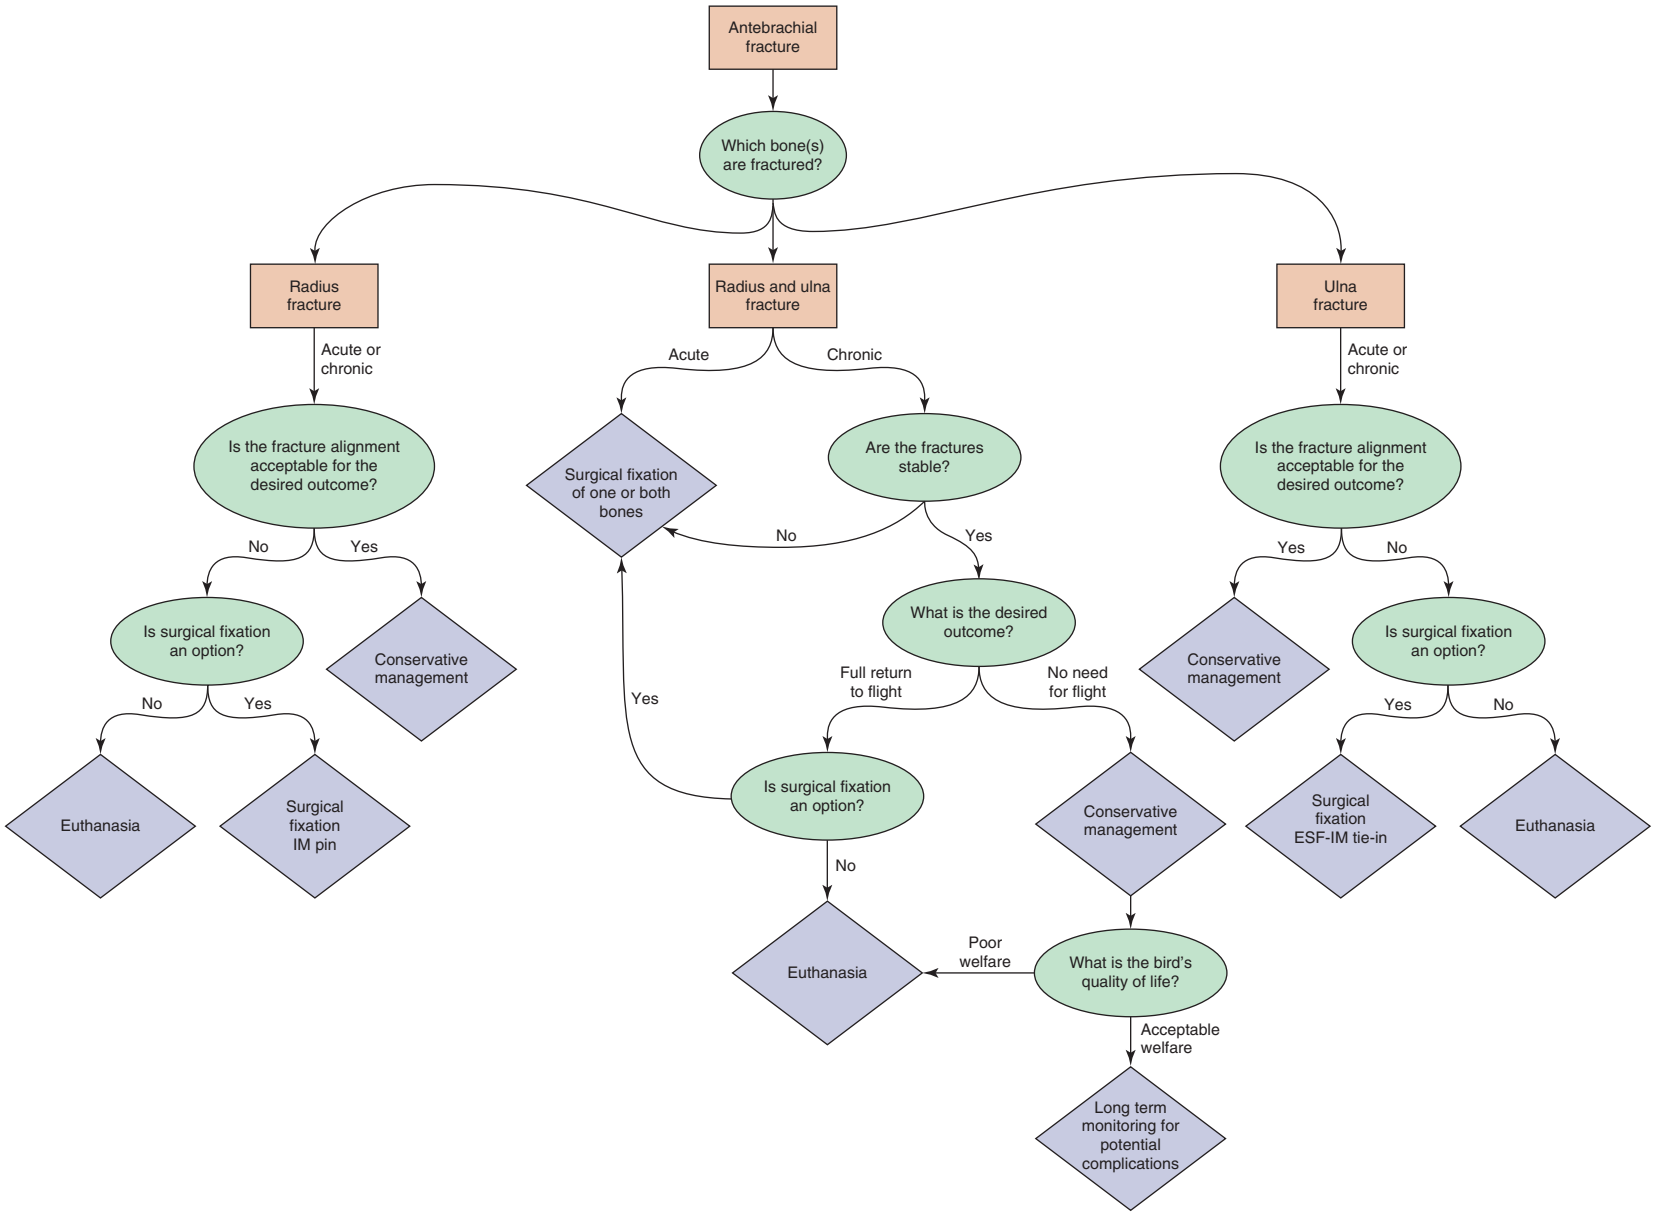

FIGURE 37.17 Decision tree to help guide the avian practitioner through the clinical decision-making process when presented with a bird with an antebrachial fracture. For a radius or ulna fracture where the other bone is intact, the fracture fragments need at least 50% alignment for the fracture to heal successfully with conservative management. *ESF*, External skeletal fixator; *IM*, intramedullary.

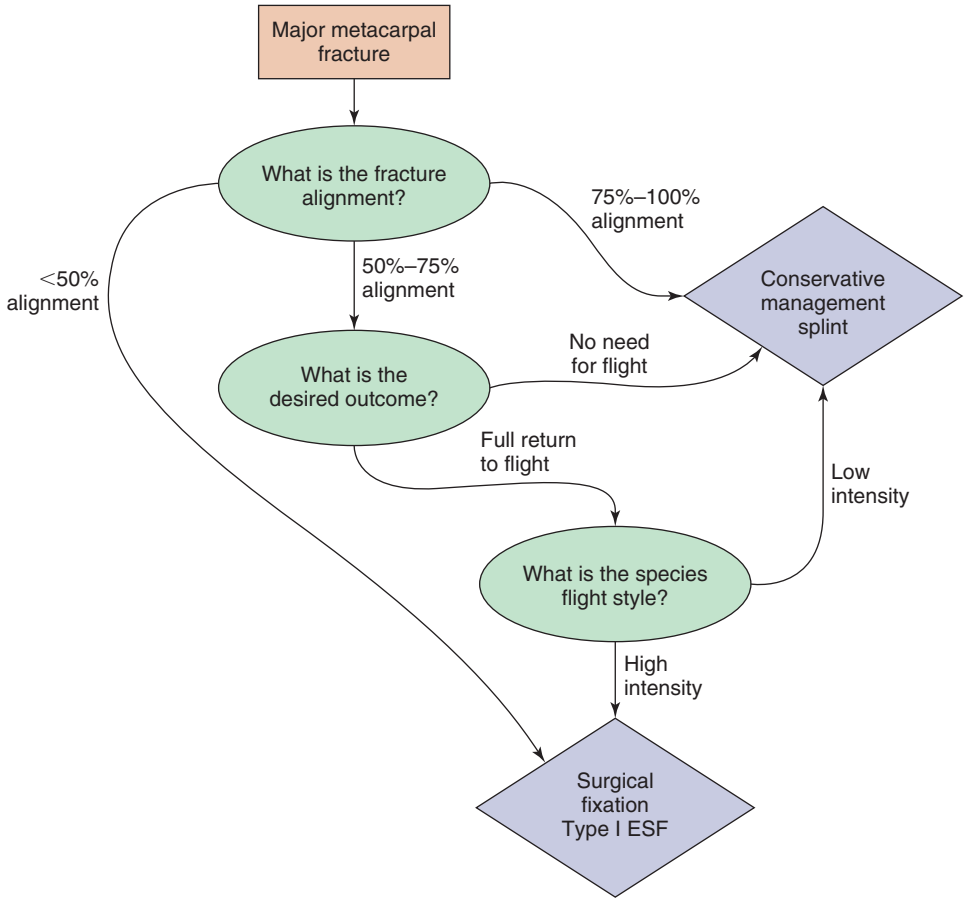

FIGURE 37.18 Decision tree to help guide the avian practitioner through the clinical decision-making process when presented with a bird with a major metacarpal fracture. *ESF,* External skeletal fixator.

surgical fixation utilizing a type II ESF as the placement of an IM pin is difficult in both groups. Another option is the placement of an L-shaped splint along the plantar side of the foot, leaving the toes to function freely and thus preventing immobilization of the flexor tendons during callous formation.

Galliformes, passerines, and rails have a tarsometatarsus that is amenable to stiff splints that provide rigid immobilization to fracture fragments without restraining adjacent joints; these splints can often be quite snug without risk of a tourniquet effect as the tarsometatarsus does not include much soft tissue in these species. Pelicans (Pelicanidae) and herons (Ardeidae), however, have enough muscle on this section of the leg that it does not allow for stiff coaptation to be applied due to risks of marked edema.[37] While raptors have primarily tendons in this area, the power of their flexor tendons limits the use of splints or coaptation for tarsometatarsal fractures.

Waterfowl are amenable to an external coaptation "boot" for tarsometatarsus fractures and have an excellent prognosis for rapid healing and release or full return to function even when the metatarsals have fractured free of each other or the tarsometatarsus (Figure 37.20).[40] Oblique metatarsal fractures may pierce the skin to become an open fracture underneath splints, but the simple application of a hydrocolloid bandage over the area prior to splinting often mitigates this concern. These boots allow the bird to walk, run, and swim while the fracture is healing. Restricting movement of the hock is not necessary if the fracture fragments are well restrained by the boot and external coaptation of the tarsometatarsus fragments. While oftentimes these splints will violate the principle of stabilizing joints above and below the fracture, evidence-based medicine demonstrates they often work.[40] The boot assists the bird in maintaining the foot in a normal walking position. Never splint a mallard *(Anas platyrhynchos)* or domestic goose *(Anser anser domesticus)* foot in a nonergonomic position as recovery to full function is much less likely; if the foot joint results in poor range of motion after external coaptation in a standing position, the bird will still be able to comfortably stand and walk.

Phalanges

Fractures of the digits usually respond well to conservative management in most species. In parrots, where trauma is often a result of inadequate grooming and long nails getting tangled in cage furnishings or other objects, cage rest is recommended if the fracture is closed. Immobilization of toes through splinting may result in formation of adhesions and reduced range of motion. If the fracture is open, as is often the case with bites from cage mates, there is a risk of osteomyelitis, and amputation has been recommended as a consideration. In other species, natural history and management should be considered prior to amputation. For instance, amputation of the hallux in

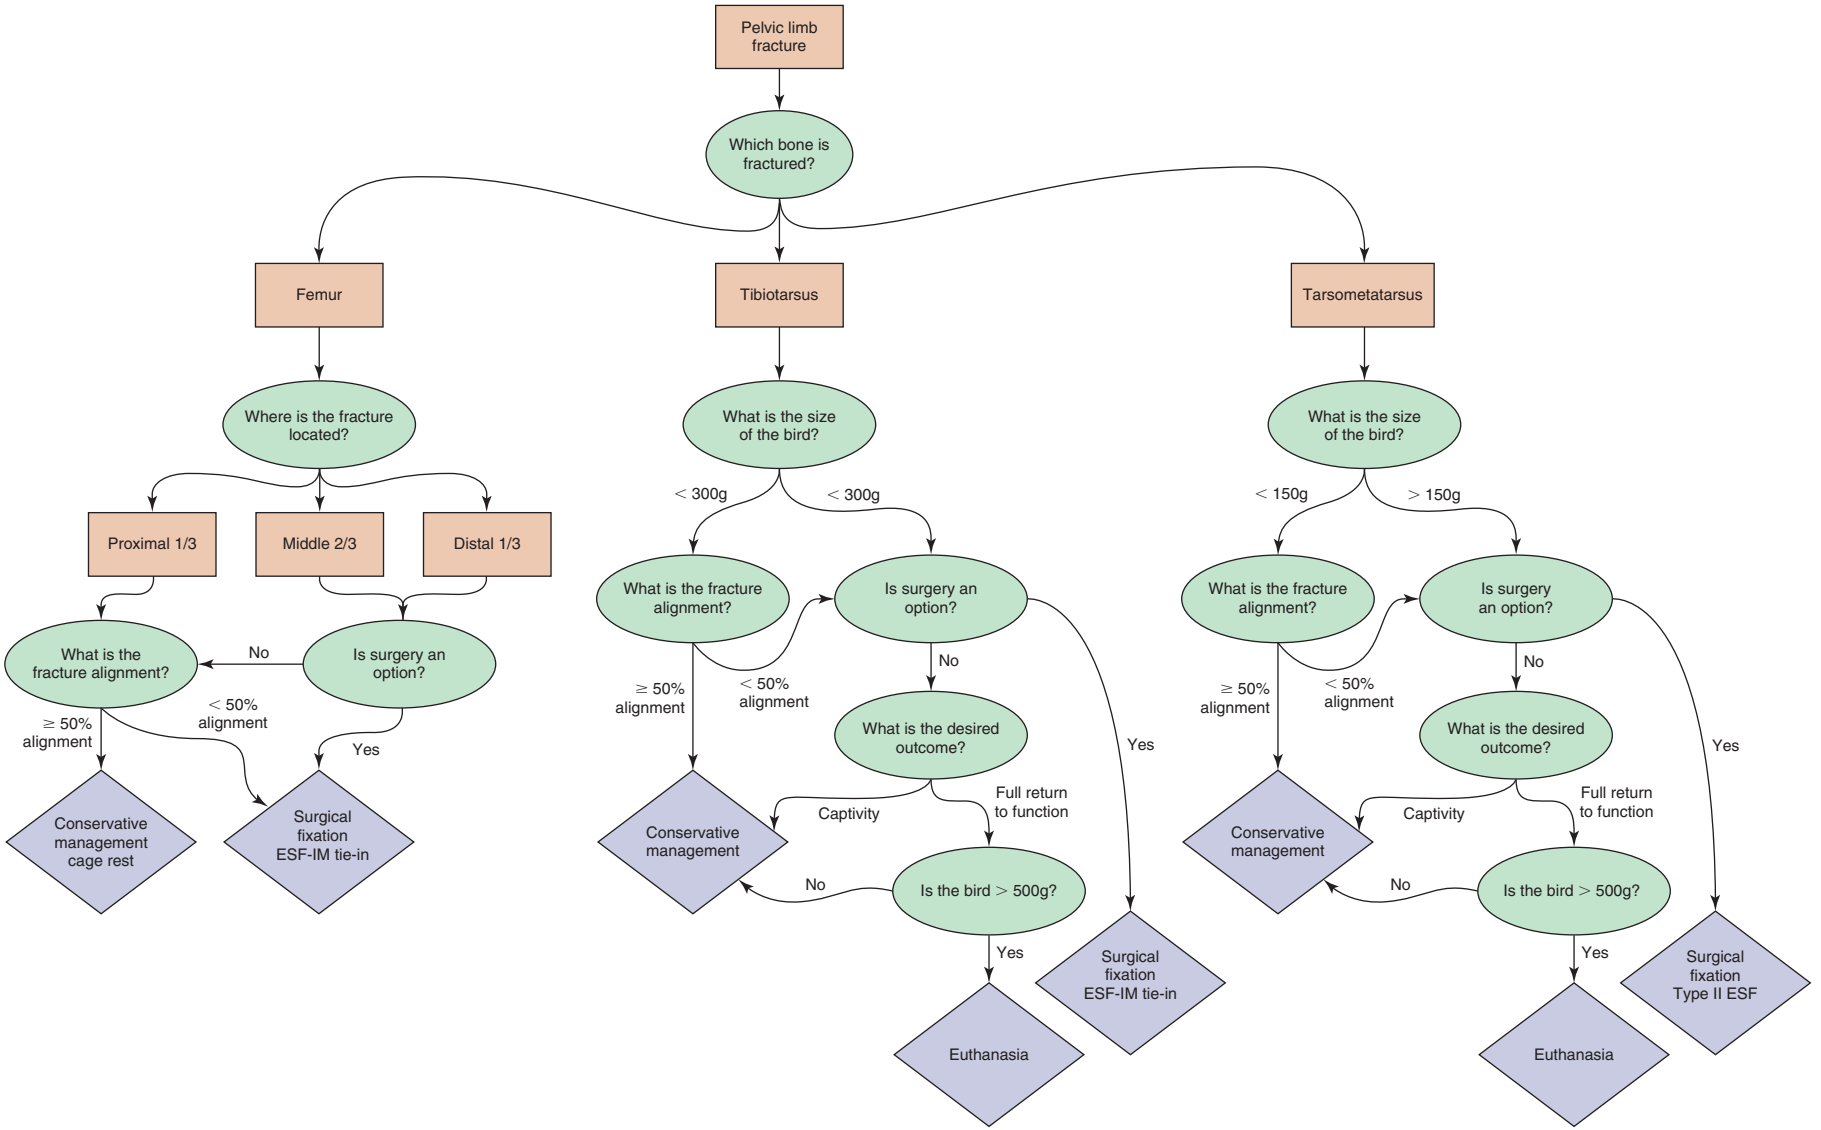

FIGURE 37.19 Decision tree to help guide the avian practitioner through the clinical decision-making process when presented with a bird with a pelvic limb fracture. *ESF*, External skeletal fixator; *IM*, intramedullary.

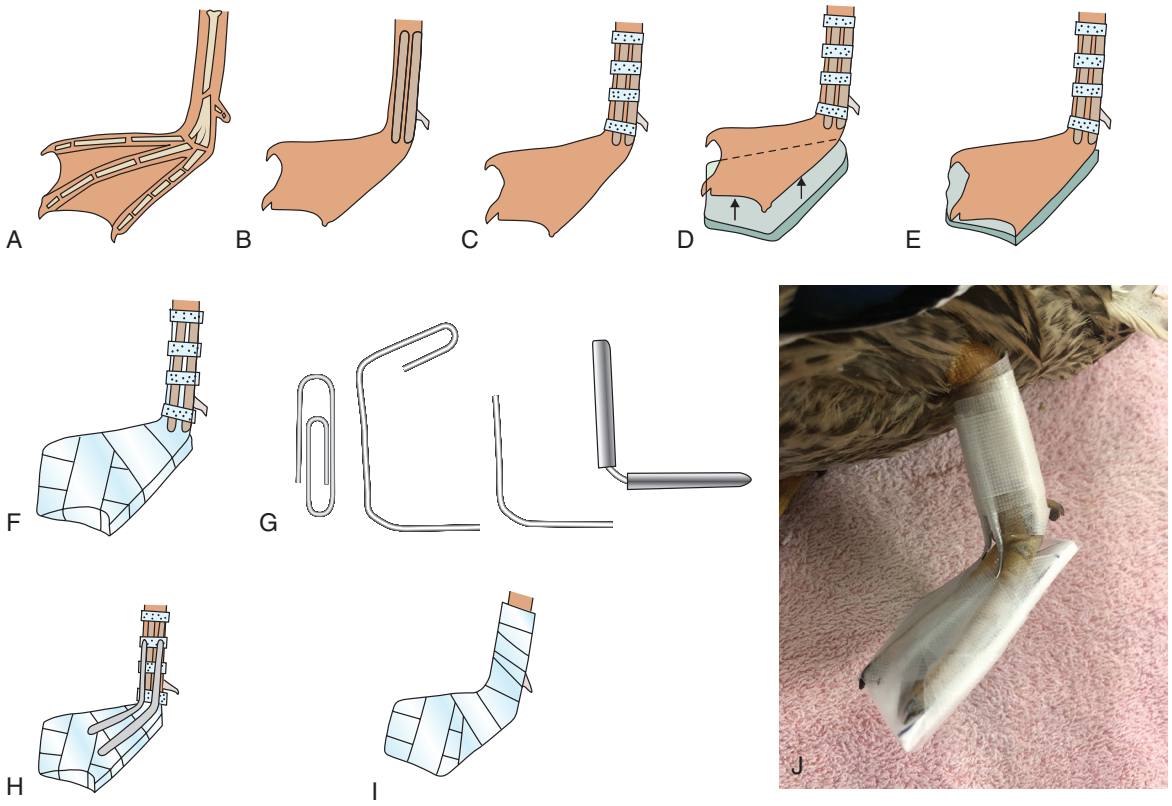

FIGURE 37.20 Application of a waterfowl tarsometatarsal "walking boot" for a closed, distal tarsometatarsal fracture (A). Swimming is also potentially allowable with this boot. Splint the fractured tarsometatarsus in a standing position. If fracture is oblique with sharp ends, or extra padding is indicated, apply a layer of hydrocolloid dressing to leg before applying splints. The fracture is stabilized with two narrow wooden splints covered with layers of plastic tape (Transpore, 3M, St. Paul MN). This clear tape allows observation of the foot during healing and stays on well in water. (B) Tape splints to lateral and front sides of the leg, avoiding medial metatarsus and associated vasculature and snugly fitting one piece of tape distal to digit I (C). Trace foot to create shoe from packaging foam (D, E) and secure to bottom of foot by taping toes in place (F). Create L-shaped braces from metal paperclips (G), cover with layers of tape and secure one between digits II and III, and the other between digits III and IV (H). Adjust the angles for comfortable standing posture. Tape snugly to front of tarsometatarsus and between toes (I). Wrap foot with yet more Transpore tape, leaving toe tips exposed to monitor swelling as possible (J). Inspect for tape loosening daily, replace as needed. Remove boot weekly to monitor progress. The shoe may not need to be replaced at 1 week, and the fracture should be stable to palpation in 2 to 3 weeks. (Images courtesy Rebecca Duerr.)

a raptor is never recommended due to its importance in hunting strategies and concerns with subsequent pododermatitis and/or balance concerns. Acceptability of amputation of other toes on raptors depends on their hunting style. For example, digit II is critical in buteos and owls (Strigiformes), while digit III is more important in accipiters. Gulls can handle amputation of digit II or IV (not both) while the webbed feet of waterfowl are often evaluated on ability to maintain surface area.

Splinting is the recommended method for treatment of most phalangeal fractures.[7] A basic ball bandage can be used to immobilize digits and remove weight-bearing in raptors or psittacines (Figure 37.21). Other methods used include incorporating a fitted "shoe" made from thermoplastic, hexalite, or open-cell foam into the splint (Figure 37.22). Shoes can be donut shaped (Figure 37.23). Once healing is well underway, the splint can be replaced with a thick interdigitating bandage extending the length of the involved digit.

Splinting is also recommended for most other avian species although the diversity of birds creates slightly different considerations for different taxa. Splints can be made from a variety of materials, including rigid plastic, Styrofoam, or padded aluminum; cardboard is typically not recommended as it holds water.[41] The splint is shaped so that it can be applied to the plantar surface of the foot and the toes taped in place to immobilize and secure the shoe to the foot. Routine rechecks (one to two times per week) are recommended with the splint being removed to allow examination of the plantar foot surface of the foot for development of pododermatitis. Waterfowl provide some additional challenges with their webbed feet and their predisposition to pododermatitis and keel lesions when maintained on land. In addition to the application of a splint to the foot, housing and management are particularly important.

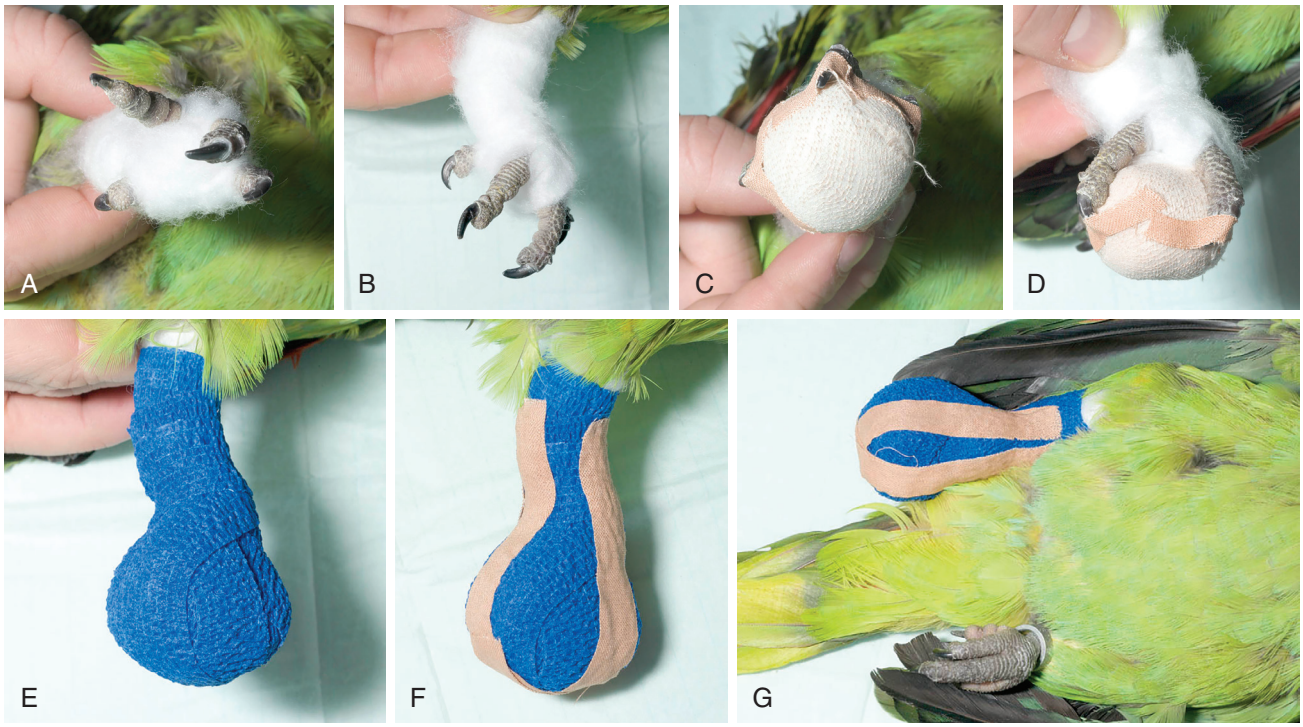

FIGURE 37.21 A ball bandage on a parrot foot. Apply a layer of padding to foot and leg (A, B) and then place a ball of cotton wrapped in gauze on the plantar aspect of the foot and tape the toes to the ball (C, D). Wrap the foot in self-adherent wrap, extending up tarsometatarsus to provide support (E) and apply tape strips to hold in place (F). Finished ball bandage on a parrot (G). Facial Fractures/Skull

The diverse taxa of birds differ markedly in facial structure, form, and function. The diversity of morphology of bills has a profound bearing on both the types of injuries sustained and treatments. The beak shows wide variation in the number and location of hinges in both upper and lower bills (see Chapter 31). Lifestyle also has a large impact on feasibility of treatment for many fractures, and housing needs must be kept in mind during care lest the treatment predisposes to further problems. External fixators modified to adapt to beak confirmation are the most common form of surgical fixation. These fixators and other hardware can easily become entrapped in netting or other aspects of housing or handling equipment.

Birds that have heavily keratinized bills, especially those with heavily keratinized gnathotheca (lower bill) such as gulls, many passerines, and parrots are prone to problems with keratin overgrowth of the opposite bill when a malocclusion is present. In the wild, these birds are likely to develop progressive rhamphothecal overgrowth abnormalities that will ultimately cause the bird to starve to death. In captivity, these species often require rhamphothecal shaping procedures as part of ongoing routine care, or corrective surgical procedures of the primary malocclusion problem, if possible (see Chapter 31). Consequently, if portions of the bill are missing in these species, the bird is not a candidate for wild release. These cases are also often not suitable for placement; as per USFWS regulations, wild birds must be able to apprehend food to be a candidate for placement. When the tip of the upper bill is missing, species vary in how much can be missing and retain the potential for regrowth of adjacent keratin to fill in a gap to achieve normal occlusion; several months may be needed to ascertain whether regrowth will result in a bird potentially suitable for release. Species with fleshy bills such as ducks, pelicans, cormorants (*Phalacrocorax* spp.), and others often adapt well to bill defects as long the defect does not impair food apprehension. Prostheses are not appropriate for birds intended for wild release due to their need for regular maintenance and adjustments.

Spinal Fractures

In most birds, there is an evolutionary fusion of thoracic vertebrae into the notarium and thoracic, lumbar, sacral, and caudal vertebrae into the synsacrum, which provides a rigid and lightweight structure for flight. In many species, there is a free thoracic vertebra located between the notarium and synsacrum. Because this intervertebral joint is more vulnerable than the rest of the rigid spinal column, it is often the site of severe trauma. When nondisplaced, visualization of these lesions on survey radiographs can be very difficult. If neurological deficits are severe, the prognosis for full recovery is poor and wild birds are often humanely euthanized. For wild birds with mild deficits or captive birds that do not require full return to function, conservative management consists of maintaining in an enclosure with thick padding and monitoring for cloacal output (gentle flushing or evacuation as needed). If the trauma occurred within 8 hours of admission, administration of high-dose methylprednisolone sodium succinate (Solu-Medrol; Pfizer Inc, NY) may be helpful.

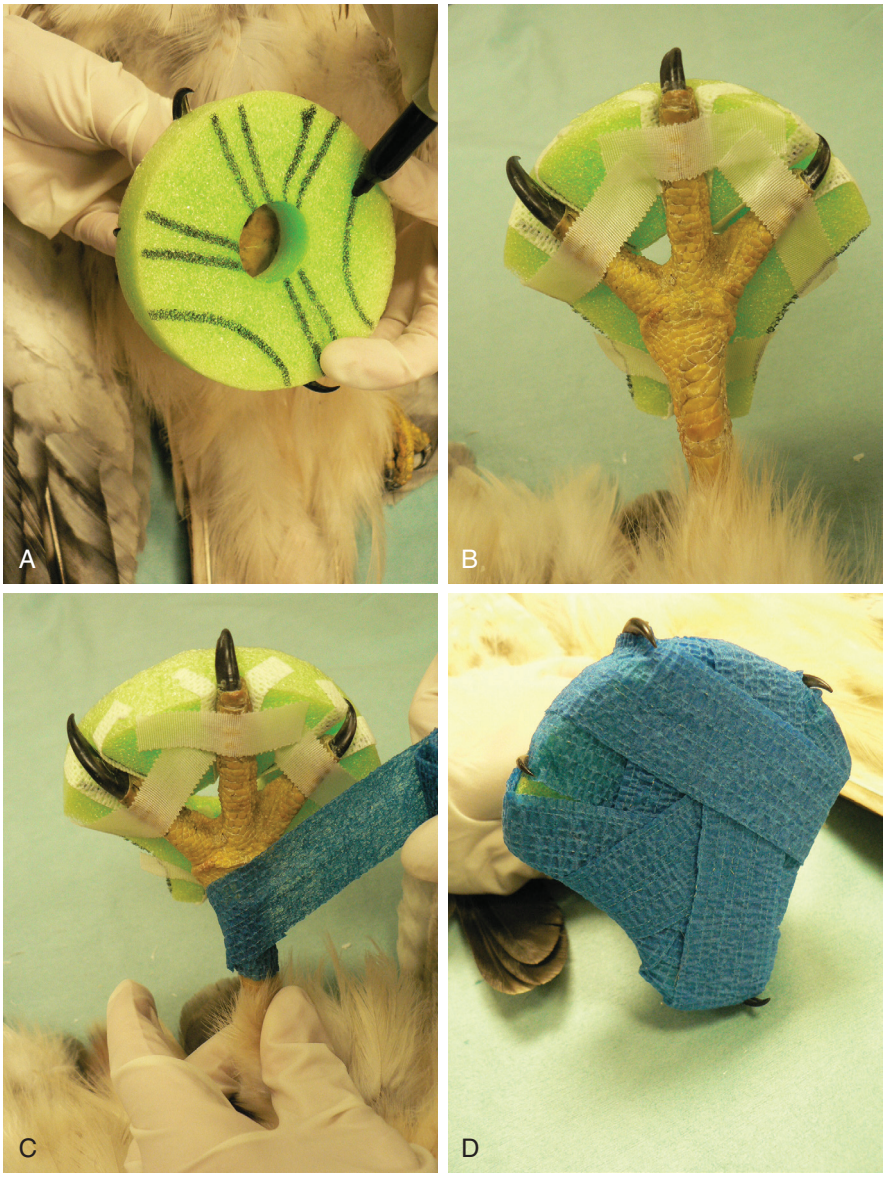

FIGURE 37.22 Creating a raptor "shoe" from a foam disk. Normal toe position is sketched on disk (A) and channels cut out for positioning toes, which are taped in place (B). The foot is then wrapped in self-adherent wrap, extending up the metatarsus for support (C) and covering the whole shoe (D). Optional materials include making shoes from thermoplastic or hexalite (see Chapter 33).

Luxations

Shoulder girdle

Coracoid luxations are treated similarly to coracoid fractures, with conservative management focusing on cage rest, coaptation, and physical therapy. Proximal coracoid fractures at the sternal juncture carry a better prognosis than distal luxations where the coracoid articulates with the scapula, clavicle, and humerus in the authors' experience. If the integrity of the shoulder joint is altered, the bird has a poorer prognosis for full restoration of flight.

Elbow

While some success has been reported with caudodorsal luxations on the elbow, the prognosis for these cases is usually poor either because of the inability to maintain reduction, loss of range of motion, or because of the development of significant long-term degenerative joint disease. Successful outcomes are most likely to be achieved with early intervention with quick reduction of the luxation. Once reduced, the joint needs to be protected from reluxation either with coaptation or with a transarticular ESF fixator while it heals. Regular physical therapy using passive range of motion exercises (anesthesia recommended) is also needed. Lateral imbrication of the joint done after the initial swelling has resolved will help to stabilize the joint.[42]

Metacarpal-phalangeal

While there are few reported treatments for luxation of this joint, joint arthrodesis had a successful outcome with full restoration of flight in a prairie falcon. A type I ESF was used to stabilize the joint during healing.[43]

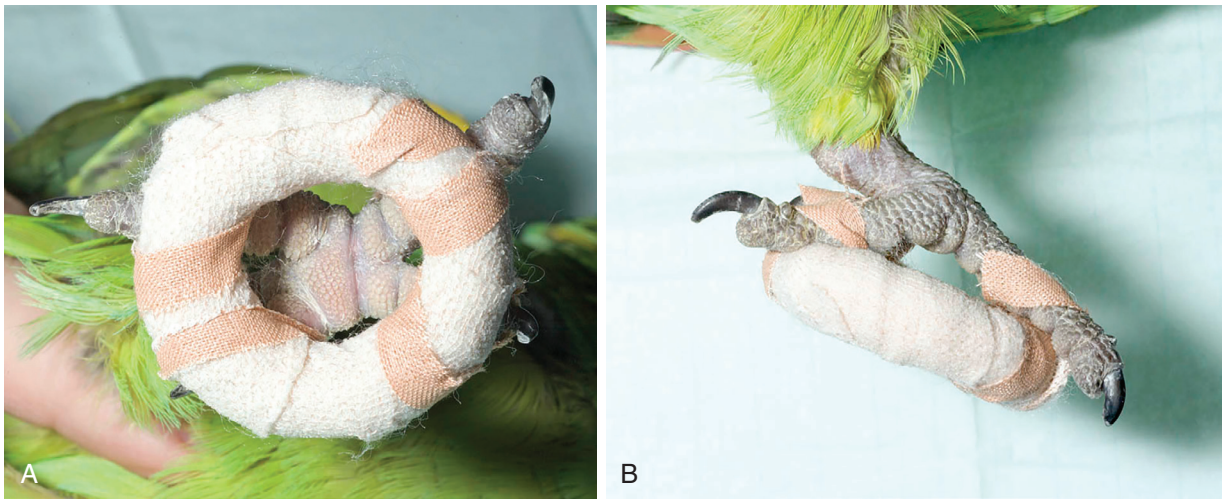

FIGURE 37.23 (A) A donut shoe on the plantar aspect of a parrot foot and (B) lateral view showing toes taped in place. (Images courtesy Y.R.A. van Zeeland.)

Hip

Femoral head luxations occur with the capital physeal ligament between the femoral head and the acetabulum being ruptured. Small birds may do well with closed reduction and cage rest while a femoral head and neck ostectomy has been used successfully with larger birds.[2,22]

Stifle

Treatment of stifle luxations involves reduction and stabilization while the traumatized tissues heal. A transarticular ESF with an acrylic bar connection can be used to stabilize the stifle and hold it in a flexed perching position.[44] Another reported method involves the placement of IM pins in both the femur and tibiotarsus with both pins projecting at the stifle. These pins were bent where they protruded and connected with acrylic to maintain alignment of the joint during healing.[45]

SUMMARY

The broad diversity in patients and injuries seen in avian practice requires that the clinicians have a strong understanding of the guiding principles of orthopedics and the unique challenges presented by birds. Getting to successful outcomes requires a variety of tools, as well as creativity and adaptability in using them. Given the limited number of controlled studies and emphasis on case studies in the literature, the value of evidence-based medicine cannot be overstated. Choosing the right approach in any specific case requires a systematic approach to decision-making that is based on the patient and its circumstances, the resources available, and the ability to apply those resources to construct adequate stabilization for fracture healing.

CHAPTER 38

From Fertilization to Hatch: Egg and Embryonic Development

Lorenzo Crosta

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

The most striking difference between mammalian and avian reproductive strategy is that of oviposition: birds lay eggs, mammals do not. It has long been a puzzle why "birds constitute the only vertebrate class that is both rich in species number and exclusively oviparous."[1] The absence of avian viviparity has frequently been explained by citing morphological or physiological factors that presumably are incompatible with live birth.[2] Whatever the reasons for maintenance of oviparity, their success is obvious, judging from the large number of species of birds that have evolved and their colonization of all parts of the world. The number of known bird species is more than double the number of mammals. One can also look at birds as successful competitors with mammals by adapting incubation behavior, shell structure, and shell porosity to varied environmental conditions to deliver hatchlings that are behaviorally, functionally, and in gross composition like mammalian neonates. Some of the key differences between the reproductive systems of birds and mammals are displayed in Table 38.1. Common differences in physiologic features are displayed in Box 38.1.

There are also many differences between avian and mammalian reproduction. For example, mammals exhibit physiological monospermy, in that only a single sperm enters the ovum. Monospermy is ensured by a variety of mechanisms, which are collectively known as the block to polyspermy. However, in birds, many fish, amphibians, and reptiles, the principal feature of fertilization is physiological polyspermy, which involves penetration of the ovum by many sperm.[4] Following ovulation, the ovum is transported to the infundibulum of the female reproductive tract where multiple spermatozoa then encounter the inner vitelline layer. Soon after contact with this layer, an outer vitelline layer is quickly assembled, trapping many spermatozoa, and preventing additional spermatozoa from entering. Once a single sperm enters the germinal disk (GD) and fuses with the female oocyte, the other supernumerary sperm degenerates.

PHYSIOLOGY OF EGG LAYING

The major hormones involved in the ovulation are gonadotropin-releasing hormone-1 (GnRH-1) and luteinizing hormone (LH).[5] Follicle-stimulating hormone (FSH), which is an important hormone in the ovulation in mammals, is involved in the differentiation of granulosa cells and induction of steroidogenesis in the prehierarchical follicles. However, in contrast to mammals, it is not directly involved in ovulation. Estrogens and testosterone need to be present to allow ovulation to occur, but neither of these hormones can induce ovulation on their own. The role of corticosteroids during ovulation is unclear, but their presence is required in order for ovulation to occur. Progesterone is present during ovulation with an increase 4 to 6 hours prior to ovulation, produced by the granulosa layer of the largest preovulatory follicle F1, and during the egg development. Progesterone receptors in the oviduct stimulate the hyperplasia of the epithelial cells and the tubular gland cells. Progesterone plays a role in the production of avidin, a protein that is involved in the defense mechanism of the uterus and egg, the contraction of the myometrium, and the shell formation. Estrogen during egg development is involved in the synthesis of ovalbumin, ovotransferrin, ovomucoid, and lysozyme in the magnum. During oviposition, the smooth muscle of the oviduct needs to be relaxed, which occurs under the influence of several hormones including prostaglandins, acetylcholine, galanin, oxytocin, arginine vasotocin (AVT), and angiotensin II. In laying hens, the administration of oxytocin and AVT induces premature oviposition.

ANATOMY OF THE FEMALE REPRODUCTIVE TRACT AND FORMATION OF THE EGG

In contrast to mammals, the reproductive tract in birds allows internal fertilization, while further development of the ovum

TABLE 38.1

Key Differences Between the Avian and Mammalian Reproductive Systems

	Avian	Mammalian
Definition	Permits internal fertilization Allows the development of the embryo in the external environment	Permits internal fertilization Development of the embryo inside the body Produces offspring directly
Male organs	Testes and epididymis, ductus deferens, seminal glomera, phallus (in some species)	Scrotum, testes, epididymis, vas deferens, ejaculatory duct, penis, seminal vesicles, prostate gland, Cowper's gland
Female organs	Ovary and oviduct	Ovaries, oviducts, uterus, vagina
Nourishment of the embryo	By the ovum itself	Through the placenta
Birth of offspring	Oviposition and egg hatch in the external environment	Delivery of fully developed offspring

BOX 38.1 SOME DISTINGUISHING FEATURES OF BIRD EMBRYOS AND NEONATES IN COMPARISON WITH MAMMALS

1. Avian embryos are maintained at temperature of about 36°C (96.8°F) and mammalian embryos at 37°C (98.6°F).
2. During the late stages of development, the O_2 and CO_2 tensions of the embryonic and extraembryonic blood vessels in avian embryos attain values like those in the mammalian fetus. In both, the acid-base status is essentially that of the adult, characterized by a plasma PCO_2 of 30–40 torr and a pH of 7.4–7.5, the hallmark of warm-blooded vertebrates.
3. Both birds and mammals deliver equivalent neonates, which range from altricial species, born naked and blind, to precocial species, born furred or feathered, and able to walk and thermoregulate.
4. The relative water content of neonatal birds is inversely proportional to their state of maturity and, in birds, varies from approximately 85% in altricial species to approximately 65% in the most precocial species.[2] The percentage of the body composed of water in a term human neonate is 75% (40% extracellular fluid, 35% intracellular fluid). Term newborns usually lose 5% to 10% of their weight in the first week of life, almost all of which is water loss.[3]

occurs outside of the body. This requires that all the nutrients that are needed for the embryo to develop to be included in the egg before it is laid. As a result, egg formation is a complex process that is highly dependent on the functionality of the ovary and oviduct. While two bilaterally symmetrical ovaries and oviducts develop in the avian embryo, in nearly all species, the right ovary and oviduct regress leaving only the left side functional in adult life. Exceptions include the kiwi (Apterygiformes) and some birds of prey from the families Cathartidae, Accipitridae, and Falconidae, in which the right oviduct is commonly vestigial or nonfunctional, but two functional ovaries are present.[6]

The left ovary is located in the intestinal peritoneal cavity, cranial to the left kidney and adjacent to the adrenal gland.[6] The ovary, which is attached to the left kidney and body wall by the mesovarian ligament, is less compact compared to mammals, with a poorly defined medulla and cortex. In young hens, the ovary is barely visible, but as the hen matures, follicles start to develop within the ovary giving it the appearance of a small bunch of grapes. Primary oocytes visible on the surface of the ovary are termed follicles, which pertain to the primary oocyte and its membranous covering. The age at which this functional development occurs depends on the life span of the species. For example, many of the larger psittacine birds become reproductively active between 4 and 7 years of age, whereas smaller species often become sexually mature well before 3 years of age. During the breeding season, the follicles undergo rapid growth, during which yolk and protein produced by the liver accumulate in the oocyte or ovum, giving it its characteristic yellow color. Yolk is made in the liver and is hematogenously delivered to the developing follicle. After completion of the rapid growth period, the primary oocyte undergoes two maturation divisions. The mature follicle consists of white yolk, yellow yolk, and the GD. These are surrounded by the vitelline membrane. As in most other vertebrates, the ovum is ovulated with its nucleus at metaphase of the second meiotic division. In the chicken the voluminous 3- to 4-cm-diameter ovum is primarily comprised of yellow yolk. On its surface is a 3- to 5-mm-diameter GD, composed of white yolk that forms the animal pole. The GD contains the female complement of genetic material as well as most cytoplasmic organelles.[7,8]

Following ovulation, the ovum passes through the entire length of the oviduct, where the components of the egg are secreted and deposited from respective parts of the oviduct. The contributions of the respective segmental portions of the oviduct in the ovulatory cycle are highlighted in Box 38.2 and Figure 38.1.

The left oviduct is attached to the dorsal body wall by the dorsal ligament and has three general primary functions: egg formation; sperm selection, storage, and transport; and it is the site of fertilization and early embryonic development. Glandular development within the oviduct results in a thickening of its walls that differentiate it into five functional regions associated with egg formation. These portions are termed the infundibulum, magnum, isthmus, uterus, and vagina.[6]

The infundibulum is the funnel-shaped structure at the proximal end of the oviduct along with a very small portion of

BOX 38.2 CONTRIBUTIONS OF OVIDUCTAL SEGMENTS IN EGG FORMATION

1. **Infundibulum.** Following ovulation, the ovum is engulfed by the infundibulum where it resides for approximately 18 minutes (range, 15–30 minutes in the domestic fowl). Fertilization and formation of the chalaziferous membranes occur in the infundibulum.
2. **Magnum.** The ovum next passes to the largest portion of the oviduct, the magnum (a length of 33 cm in the chicken), where most of the albumen is formed. Movement of the ovum through the magnum is primarily via peristaltic action of longitudinal circular layers of muscle. The ovum remains in the magnum approximately 2–3 hours in the domestic fowl.
3. **Isthmus.** The isthmus is clearly demarcated from the magnum. Both inner and outer shell membranes are formed during the 1- to 2-hour (mean time, 1 hour and 14 minutes in the domestic fowl) passage through the isthmus.
4. **Shell gland (uterus).** The shell gland (uterus) is characterized by a prominent longitudinal muscle layer lined medially with both tubular and unicellular goblet cells. Prior to calcification, the egg takes up salts and water into the albumen from the tubular glands, a process termed "plumping." The ovum remains in the shell gland for 20–26 hours. Calcification of the egg occurs over a period of 15 hours, while the pigment of the shell is formed during the last 5 hours in the domestic fowl.
5. **Vagina.** The vagina is separated from the shell gland by the uterovaginal sphincter muscle and terminates at the cloaca. The vagina has no role in the formation of the egg, but, in coordination with the shell gland, participates in the expulsion of the egg.

Modified from Johnson AL: Reproduction in the female. In: Sturkie PD, editor: *Avian physiology*, ed 4, New York, Springer-Verlag, 1986, pp 403–431.

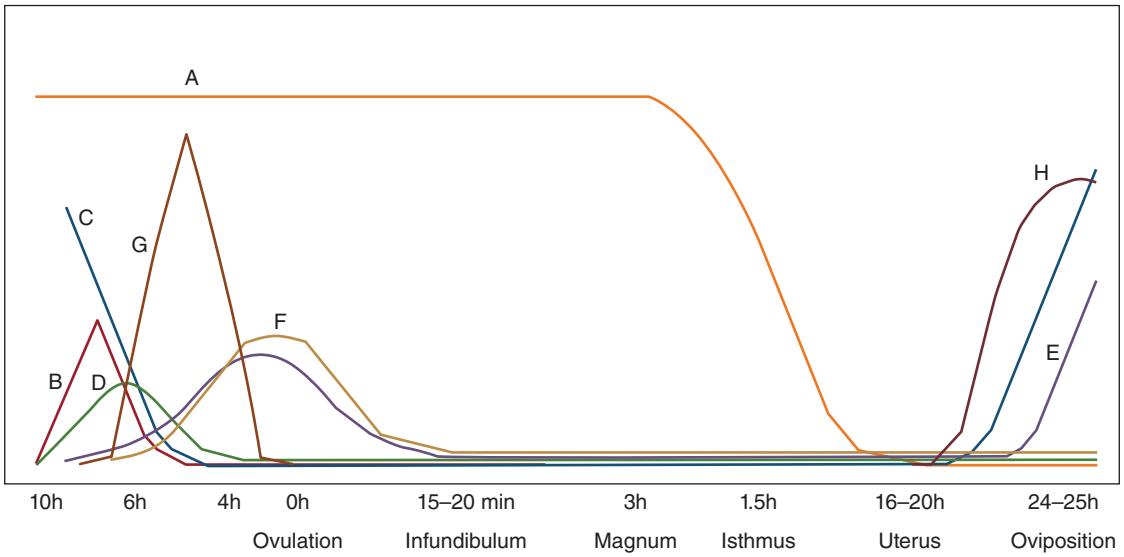

FIGURE 38.1 P. Schnitzer: Scheme of hormone involvement during oviposition: *A*, medullary bone formation with osteoblast activity; *B*, testosterone; *C*, prolactin; *D*, progesterone; *E*, estradiol; *F*, corticosterone; *G*, LH peak; *H*, prostaglandins (PGF2α, PGE1, PGE2), angiotensin II, galanin, acetylcholine, arginine, vasotocin, and oxytocin. *LH,* Luteinizing hormone; *PG*, prostaglandin.

the tubular-shaped proximal oviduct. The funnel-shaped portion of the infundibulum forms an elongated slit that faces the ovary. The ovulated secondary oocyte is literally swallowed or "caught" by the funnel portion of the infundibulum, regardless of the presence or absence of spermatozoa for the purpose of fertilization. This "catching" process is facilitated by the adjacent air sac that tightly encloses the ovary and forms the "ovarian pocket," leaving only the direction of the infundibulum for easy movement of the secondary oocyte. Fertilization of the ovum occurs within 15 minutes of ovulation and presumably occurs in the infundibular oviduct. Formation of the outer layers of the yolk membrane probably begins in the tubular portion of the infundibulum. These outer layers of yolk membrane are termed the chalaziferous layer of albumen and the chalazae. The chalazae are spiral shaped and made of albumen-like proteins that form the attenuated continuous layer and the more extensive outer perivitelline layer (OPVL). This fibrous investment strengthens the perivitelline layer (PVL) complex supporting the megalecithal ovum in its transit through the oviduct.

The magnum is the longest and most coiled portion of the oviduct. It is distinguished by its greater external diameter and markedly thicker wall caused by the presence of numerous secretory glands that account for the prominent mucosal folds of the magnum. These glands *(glandulae magni)* secrete the thick albumen protein (ovalbumin, ovotransferrin, ovomucoid, ovoglobulins, and lysozymes) around the ovum. The stimulus to secrete albumen may be mechanical, arising from passage of the ovum along the magnum. Smooth muscle contractions peristaltically move the ovum along the oviduct. In a reproductively

active bird, the magnum undergoes tremendous enlargement. The added length of the enlarged magnum causes a folding of the oviduct upon itself. The division between the magnum and the isthmus is marked by a thin, translucent line that can be seen on the mucosal surface with the unaided eye in domestic fowl. This region of the oviduct is short and has less prominent mucosal folds than the magnum.

The isthmus consists of two sections. The more proximal section is nonglandular with no folds, while the distal part, also termed red isthmus, is glandular with sulfur-containing keratin-type protein–producing glands *(glandulae isthmi)*. These proteins form the outer and inner membranes, are composed of 10% collagens (types I, V, and X) and 70% to 75% proteins and glycoproteins, and are semipermeable allowing exchange of gases and water while retaining the albumen loosely around the ovum and albumen.

The uterus (shell gland) is initially a similar diameter as the isthmus, but rapidly expands to form a pouch that retains the egg during the entire portion of egg formation. The density in the lamina propria of glands is higher in the uterus or shell gland. The egg remains for up to 20 hours in the uterus or shell gland in the domestic fowl. The glands *(glandulae uterinae)* add water to the albumen and the different layers of the eggshell. Calcium secretion starts approximately 7 hours after ovulation. Microcrystals of calcite and calcium carbonate are added to form the inner mammillary cone layer and the palisades.

The short terminal portion of the oviduct immediately proximal to its junction with the urodeum is the vagina. The strong muscle of the vaginal wall and a well-developed muscular sphincter *(m. sphincter vaginae)* at the uterovaginal junction (UVJ) serve to expel the egg during oviposition. The vaginal glands store sperm in the tubular utero-vaginal sperm host glands *(fossulae spermaticae)*.

The cuticle is the outer layer of the eggshell and is composed of an inner mineralized layer (inorganic phosphorus, hydroxyapatite crystals) and an outer layer of organic matrix (glycoproteins, polysaccharides, lipids). It plays a role in controlling water exchange by repelling water and limiting microbial colonization of the eggshell surface; it is likely the last portion of the egg to be formed. It covers the pores of the egg but is still able to allow gas and water exchange. Despite the knowledge of its existence and its function for at least 130 years, there remains confusion about its formation, its relationship with protoporphyrin pigmentation of eggs, and where it is formed. According to Wilson et al., the cuticle is deposited in the uterus instead of the vagina.[9] Its deposition is susceptible to environmental stressors and is specifically linked to steps of the normal endocrine cascade that occur immediately prior to oviposition. However, premature oviposition induced by AVT, one of the final endocrine events prior to oviposition, will not result in the deposition of cuticle, even if AVT is administered close to the expected time of oviposition. This indicates that deposition of the cuticle is a specific event that is distinct from other events in eggshell formation and is neither directly related to the organic matrix of the eggshell nor to pigment deposition (although these processes may partially overlap).

The cuticle can be found on eggs from many avian species, with its thickness greater on eggs laid in nests with a greater microbial challenge, particularly those of aquatic birds. The presence of cuticular mineralized nanospheres has been suggested to be correlated with the wetness and warmness of the nest for the species, and the reports of eggs with no cuticle are from species such as the budgerigar (*Melopsittacus undulatus*), which are from drier environments. Thus there is an apparent relationship between damp environments and presence of a cuticle.[9] Following oviposition, the two layers of the shell membrane separate to form the air cell near the blunt end of the egg.

The "ovulatory cycle," encompassing ovulation, egg formation, and finally oviposition, in the domestic fowl is about 24 to 25 hours in duration and is repeated with each egg in a clutch. If the ovum was fertilized in the infundibulum, which generally occurs within 15 minutes of ovulation, the initial cleavage furrows would appear in about 5 to 7 hours after sperm penetrates the ovum, around the time that the egg resides in the isthmus or uterus. During this time, the blastoderm undergoes further cleavage divisions and consists of 30,000 to 60,000 cells at the time of oviposition, depending on the species.[4,10]

ANATOMY AND COMPOSITION OF THE EGG

The egg is composed of five fundamental parts: yolk, white, chalazae, shell membranes, and shell (Figure 38.2).[6] At the time of oviposition, the egg must contain all the needed nutrients to support the health and development of the embryo. The breeding pair, and especially the female, needs adequate nutrition to be able to put all nutrients in the egg. An important saying of the aviculturist is: "The egg is what the hen eats!" The whole egg consists of 9% to 11% eggshell, 60% to 63% albumen, and 28% to 29% yolk. The composition of the yolk is approximately 33% lipids, 17% proteins, and 48% water. Albumen is composed of 88% water and 10% protein, 54% of which is ovalbumin, 13% ovotransferrin, 11% ovomucoid, 8% ovoglobulins, 3.5% lysozyme, 3% beta-ovomucin, and 1.5% alpha-ovomucin.[5]

Different supplements and drugs have been shown in chickens to cause alterations in the content of their eggs. Their effects on the hatchling are not fully understood and remain unclear at the present time (Box 38.3).

Aside from supporting the development of the embryo, the egg serves an important role in the protection of the embryo, acting as a barrier against physical, chemical, and biological threats. The different components of the eggshell, membranes, and egg white create a physical and chemical barrier, which protect the embryo from pressure, heat, osmotic stressors, and microbial colonization and infection. Ovotransferrin, lysozyme, and P-NAGase are the primary components acting as a chemical barrier within the egg white.[5]

SPERM SELECTION, STORAGE, AND TRANSPORT

In hens that have mated naturally or have been subjected to artificial insemination (AI), a relatively small number of spermatozoa are transported to storage sites at the proximal end of the vagina, a region referred to as the UVJ. In the surface epithelium of this UVJ, discrete tubular structures, known as sperm storage tubules (SSTs), can be found, which are populated

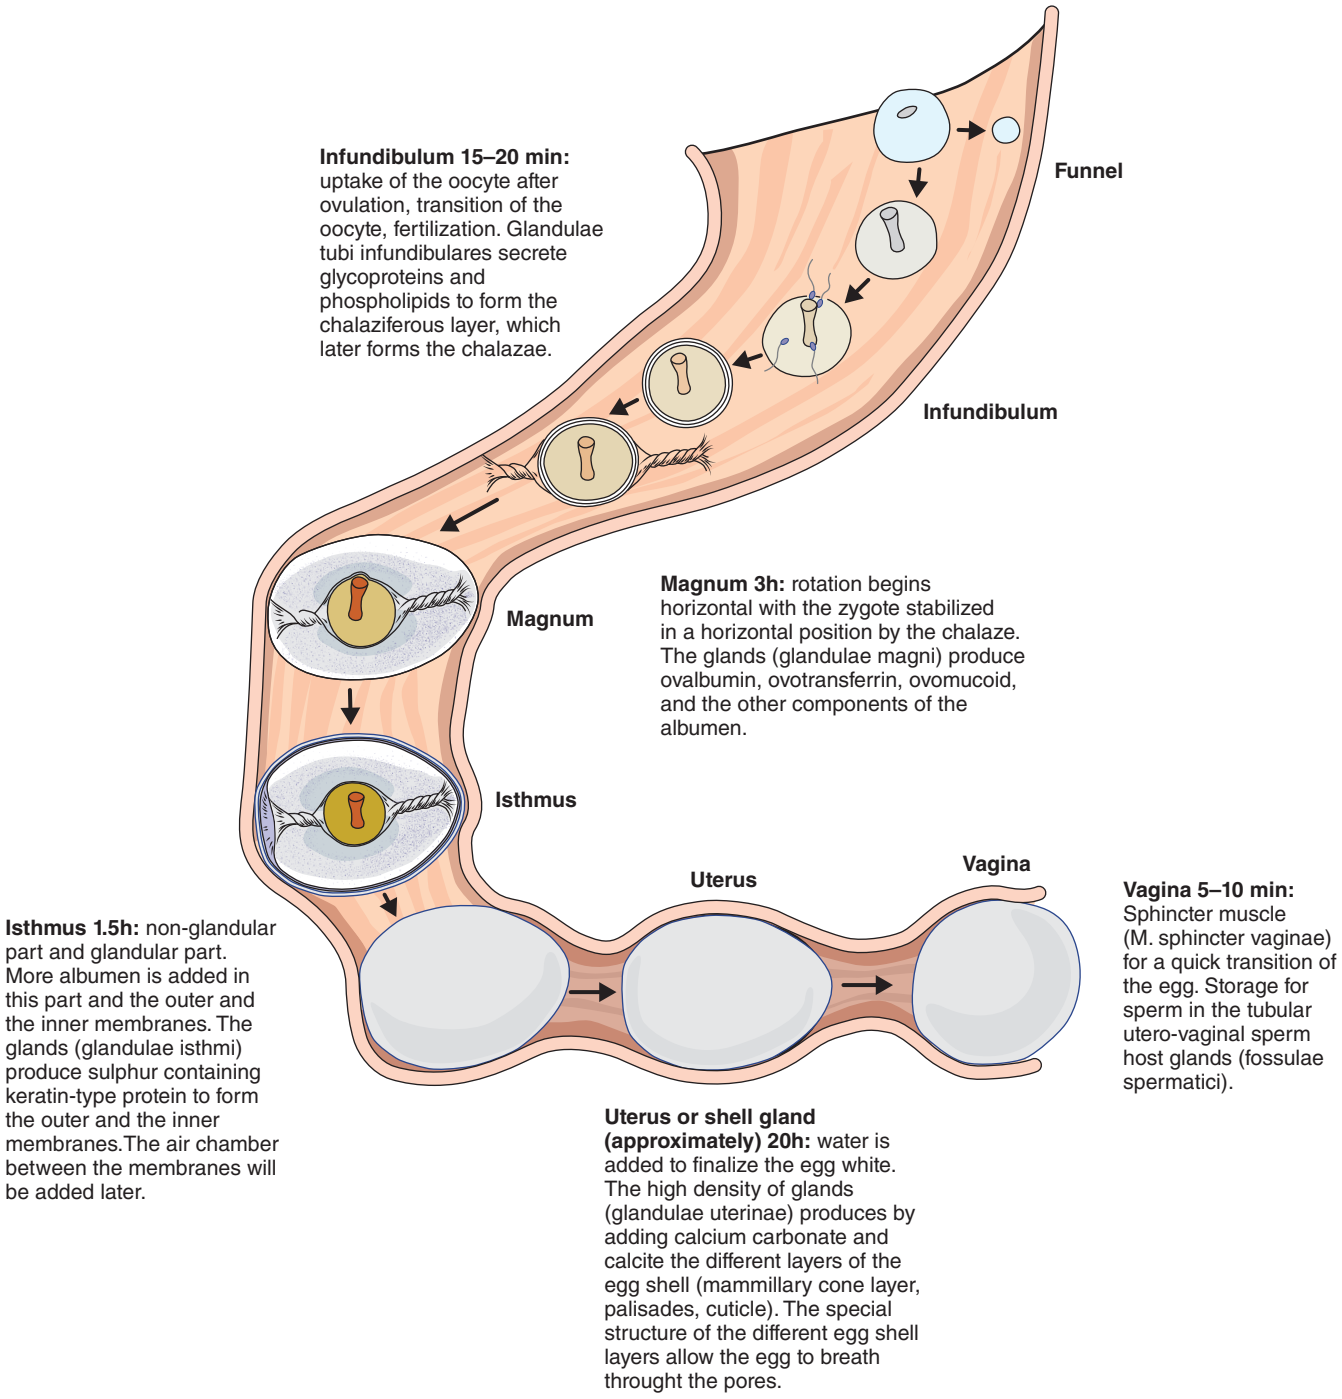

FIGURE 38.2 Diagrammatic representation of the formation of the egg.

by the spermatozoa that successfully traverse the vagina. Generally, these spermatozoa are distinct in both mobility characteristics and surface membrane composition compared to those that are unsuccessful in entering the SST. Depending on the bird species, spermatozoa are stored for variable lengths of time in the SST before their release and ascension into the infundibulum (Box 38.4, Figure 38.2), which is the site of fertilization and presumably also a secondary sperm storage site. Sperm transport is probably a combination of spermatozoal mobility and activity of the ciliated epithelium lining the oviductal mucosa. Most spermatozoa that are transferred into the vagina at copulation or AI fail to populate the SST. As a result, the maximum number of sperm cells in the SST remains below 10 million, even if hens are inseminated with higher numbers of up to 150 to 350 million spermatozoa. Obviously, the vagina orchestrates an intense sperm selection process. The mechanisms behind such selection remain to be elucidated.[4]

The spermatozoa that reach the UVJ and enter the SST can be viewed as "selected" sperm. It appears that acceptance

BOX 38.3 SUPPLEMENTS AND TREATMENTS AND THEIR KNOWN EFFECTS ON EGG COMPOSITION

Supplements/Treatments Prior to Oviposition	Alterations in Egg Composition
Garlic powder at 10 g/kg	Increase of egg weight, decrease in egg yolk cholesterol concentration
Flaxseed supplementation	Increase in albumen and decrease in yolk content of the egg
Soy oil supplementation	Increase of egg weight, increase in albumen, and decrease in yolk content of the egg, reduced shell thickness
Enrofloxacin treatment	Reduced IgY concentration in the egg
Choline and methionine supplementation	Increase of egg weight, increase in phospholipid content of the egg yolk
Grape seed extract	Increase in egg size and shell elasticity, decreased steroid production without affecting fertility
Vitamin E, carotenoids, selenium	Decreased susceptibility to lipid peroxidation, improved antioxidant system of hatchlings

BOX 38.4 SPERM STORAGE DURATION IN SELECTED BIRD SPECIES

Common Name	Scientific Name	Sperm Storage Duration (Days)
Ring-necked pheasant	*Phasianus colchicus*	21
Japanese quail	*Coturnix japonica*	6.3
Domestic chicken	*Gallus gallus domesticus*	12
Turkey	*Meleagris gallopavo*	42
Willow ptarmigan	*Lagopus lagopus*	7.8
Northern bobwhite	*Colinus virginianus*	8.3
Helmeted guineafowl	*Numida meleagris*	7
Graylag goose	*Anser anser*	9.7
Mallard	*Anas platyrhynchos* (wild)	9.9
Domestic duck	*Anas platyrhynchos* (var. domestica)	10.3
Pigeon	*Columba livia*	8
African collared dove	*Streptopelia roseogrisea*	8
Budgerigar	*Melopsittacus undulatus*	11
Zebra finch	*Taeniopygia guttata*	10
White-rumped munia	*Lonchura striata*	8
American kestrel	*Falco sparverius*	8.1

Modified from Birkhead TR, Moller AT: Numbers and size of sperm storage tubules and the duration of sperm storage in birds: a comparative study, *Biol J Linn Soc* 45:363–372, 1992.

of spermatozoa in the SST and interaction with the ovum is in part controlled by the hen,[11] but the underlying mechanisms as well as factors that favor transport of some of these spermatozoa over others currently remain unknown.[12]

In mammals, ejaculated spermatozoa are progressively motile yet do not have an immediate capacity for fertilization. In the case of in vivo fertilization, this ability is gained after residing in the female reproductive tract, whereas it can also develop following incubation in an appropriate medium in case of in vitro fertilization (IVF). The physiological changes that render the spermatozoa competent to fertilize are referred to as capacitation.[13,14] It is generally believed that capacitation of sperm is not essential for fertilization in birds.[15] This was primarily based on observations that avian ova could be fertilized in vitro by freshly ejaculated sperm that had not been previously treated with a special capacitation medium.[16–18] Moreover, it was shown in vivo that avian spermatozoa do not need to reside long in the female reproductive tract to be competent for fertilization since fertilized eggs could be observed within 15 minutes after AI into the vagina[19] or infundibulum.[10] However, while freshly ejaculated sperm can fertilize an ovum in vitro, the spermatozoa that fertilize a daily succession of ova have often resided for days or weeks in the oviductal SST. Bakst et al. suggested that sperm residing within the SST are quiescent, with motility, metabolism, and enzyme systems reversibly suppressed ("decapacitated" in the mammalian sense).[12] Upon release from the SST and prior to their ascension to the fertilization site, the oviductal environment was suggested to reactivate or recapacitate the spermatozoa. However, more recently, Nixon et al. demonstrated in Japanese quail *(Coturnix japonica)* that spermatozoa did not need a real capacitation to fertilize the ovum.[20] However, their research did suggest that hemoglobin is secreted into the quail epididymis to support sperm metabolism, aid in motility, and/or act as an antioxidant.

FORMATION AND DEVELOPMENT OF THE EMBRYO

The avian embryo has a long history as a subject of embryological study. The egg is universally available, and the embryo is readily accessible because it is a self-supplying system and does not depend on the mother for its nutrition, unlike the embryo of placental mammals. The first clear-cut account of chick embryology was given by Hippocrates (460–377 BCE). He is quoted by Needham[21] as follows: "Take 20 eggs or more and give them to 2 or 3 hens to incubate, then each day from the second onwards till the time of hatching take an egg, break it, and examine it ...." This orderly and systematic approach is meaningful even today. Aristotle (382–322 BCE), who also followed this system, appears to have been the first to dissect the chick embryo.[22]

According to Moran[23] and De Oliveira et al.,[24] embryonic development can be divided into three major phases as follows:

1. **Establishment of germ.** This phase includes the first week of incubation, which is characterized by the formation of egg compartments (amnion, chorion, allantois, and yolk sac) that support the survival of the growing embryo. Oxygen supply may be limited due to immature blood cells and an underdeveloped chorionic vascular system, so metabolic energy is provided by anaerobic glycolysis of the limited amounts of glucose present in the egg.[23,25]

2. **Embryo completion.** This phase of embryonic development is characterized by a fully developed chorioallantois, which assures adequate oxygen-carbon dioxide exchange and supports rapid embryonic growth.[23] Establishment of chorioallantoic respiration occurs around day 8 of embryonic development in the domestic chicken *(Gallus gallus domesticus)*.[26] Chick embryos are structurally completed around 14 days of incubation, whereas 22 days of incubation are needed to complete embryo development in the turkey *(Meleagris gallopavo)*. As the embryo approaches full body mass, maximum chorioallantoic respiration capacity is reached in what is called the plateau stage of oxygen consumption.[27]
3. **Emergence.** This last phase is characterized by oral consumption of the amnion by the embryo, accumulation of glycogen reserves in muscle and liver tissues and glycogenolysis, initiation of pulmonary respiration, abdominal internalization of remaining yolk, shell pipping, and emergence.[23,28–33] During this period, dramatic physiological and metabolic changes occur, and any disturbances during this period may markedly affect embryonic survival and later performance.[32,34,35]

The normal stages of morphological development in the domestic fowl embryo have been described in detail by Hamburger and Hamilton,[36] Hamilton,[37] and Romanoff.[38] A good description of the chicken embryo development is reported online by Hill in 2020,[39] and the Hamburger and Hamilton (HH) development stages are reported in Box 38.5. Figure 38.3 demonstrates the embryonic development of a cockatiel.

BOX 38.5 HAMBURGER AND HAMILTON DEVELOPMENTAL STAGES IN CHICKEN BY DAY OF INCUBATION

Hamburger and Hamilton Stages	Age	Identification of Stages
Before Laying		
Early cleavage	3.5–4.5 hours	Shell membrane of egg formed in isthmus of oviduct
During cleavage		Germ wall formed from marginal periblast
Late cleavage	4.5–24.0 hours	Shell of egg formed in uterus
After Laying		
1		Preprimitive streak (embryonic shield)
2	6–7 hours	Initial primitive streak, 0.3- to 0.5-mm long
3	12–13 hours	Intermediate primitive streak
4	18–19 hours	Definitive primitive streak, 1.88-mm long
5	19–22 hours	Head process (notochord)
6	23–25 hours	Head fold
7	23–26 hours	1 somite; neural folds
7–8	ca. 23–26 hours	1–3 somites; coelom
8	26–29 hours	4 somites; blood islands
9	29–33 hours	7 somites; primary optic vesicles
9+ to 10–	ca. 33 hours	8–9 somites; anterior amniotic fold
10	33–38 hours	10 somites; 3 primary brain vesicles
11	40–45 hours	13 somites; 5 neuromeres of hindbrain
12	45–49 hours	16 somites; telencephalon
13	48–52 hours	19 somites; atrioventricular canal
13+ to 14–	ca. 50–52 hours	20–21 somites; tail bud
14	50–53 hours	22 somites; trunk flexure; visceral arches I and II, clefts 1 and 2
14+ to 15–	ca. 50–54 hours	23 somites; premandibular head cavities
15	50–55 hours	24–27 somites; visceral arch III, cleft 3
16	51–56 hours	26–28 somites; wing bud; posterior amniotic fold; trigeminal ganglion (CN V) close lateral head ectoderm
17	52–64 hours	29–32 somites; leg bud; epiphysis
18	3 days	30–36 somites extending beyond the level of leg bud; allantois
19	3.0–3.5 days	37–40 somites extending into tail; maxillary process
20	3.0–3.5 days	40–43 somites; rotation completed; eye pigment
21	3.5 days	43–44 somites; visceral arch IV, cleft 4
22	3.5–4.0 days	Somites extend to tip of tail
23	4 days	Dorsal contour from hindbrain to tail is a curved line
24	4.5 days	Toe plate, eye primordium reaches optic cup stage
25	4.5–5.0 days	Elbow and knee joints
26	5 days	First 3 toes
27	5.0–5.5 days	Beak
28	5.5–6.0 days	3 digits, 4 toes
29	6.0–6.5 days	Rudiment of fifth toe
30	6.5–7.0 days	Feather germs; scleral papillae; egg tooth

Continued

BOX 38.5 HAMBURGER AND HAMILTON DEVELOPMENTAL STAGES IN CHICKEN BY DAY OF INCUBATION—cont'd

Hamburger and Hamilton Stages	Age	Identification of Stages
31	7.0–7.5 days	Web between first and second digits
32	7.5 days	Anterior tip of mandible has reached beak
33	7.5–8.0 days	Web on radial margin of wing and first digit
34	8 days	Nictitating membrane
35	8.5–9.0 days	Phalanges in toes
36	10 days	Length of third toe from tip to middle of metatarsal joint = 5.4 ± 0.3 mm; length of beak from anterior angle of nostril to tip of bill = 2.5 mm; primordium of comb; labial groove; uropygial gland
37	11 days	Length of third toe = 7.4 ± 0.3 mm; length of beak = 3.0 mm
38	12 days	Length of third toe = 8.4 ± 0.3 mm; length of beak = 3.1 mm
39	13 days	Length of third toe = 9.8 ± 0.3 mm; length of beak = 3.5 mm
40	14 days	Length of beak = 4.0 mm; length of third toe = 12.7 ± 0.5 mm
41	15 days	Length of beak from anterior angle of nostril to tip of upper bill = 4.5 mm; length of third toe = 14.9 ± 0.8 mm
42	16 days	Length of beak = 4.8 mm; length of third toe = 16.7 ± 0.8 mm
43	17 days	Length of beak = 5.0 mm; length of third toe = 18.6 ± 0.8 mm
44	18 days	Length of beak = 5.7 mm; length of third toe = 20.4 ± 0.8 mm
45	19–20 days	Yolk sac half enclosed in body cavity; chorioallantoic membrane contains less blood and is "sticky" in living embryo
46	20–21 days	Newly hatched chick

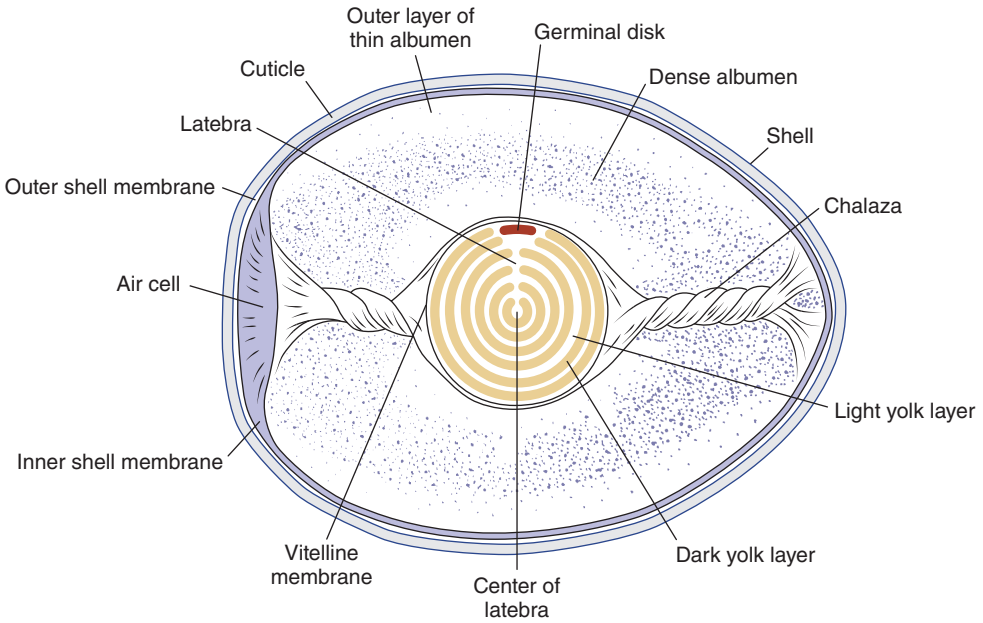

FIGURE 38.3 Diagram of the anatomy of the egg.

HATCHING

Many significant changes in metabolism occur during the last days of incubation as the embryo prepares for and ultimately hatches successfully. Hatching is a complex process, and not surprisingly, there can be a peak of embryonic mortality seen during the hatch. Unlike what is seen in mammals, essentially all the stimuli are generated by the embryo itself, though it can respond to stimuli from both the parents and the other members of the clutch.[40] However, which of these signals trigger shifts in metabolism and hormone release during this critical process has not been completely elucidated. Nevertheless, it has been suggested that thyroid hormones together with glucocorticoids play an important role.[41] Uncovering these mechanisms may yield creative ways to manipulate physiological or nutritional conditions to improve hatchability, survival, and vigor of hatchlings.[24]

There are three major events in the sequence of hatching: 1) the onset of pulmonary respiration; 2) pipping (i.e., the creation of a single point of fracture in the shell, usually in that overlying the air space), and 3) the emergence of the hatchling from the egg. However, underlying these more obvious events are many others, such as maturation of muscles, changes in the circulation, and withdrawal of the yolk sac, which all occur in a particular sequence to help ensure a successful outcome of incubation.

The egg, with its hard shell, does not enable embryonic ventilatory movements, and thus there is no convective gas exchange until the embryo's lungs begin to function. Early in incubation, prior to the formation of the heart and even initially after the detection of embryonic heartbeats, oxygen can be adequately supplied from the environment to the embryo through diffusion. However, when gas transport by diffusion alone becomes inadequate, blood convection begins to meet oxygen demand during development, with three different gas exchangers sequentially functioning in the egg: the area vasculosa, the chorioallantois, and the lungs.

The area vasculosa is a well-vascularized region of the yolk sac that fans out from the embryo and rapidly expands around the yolk during the third to fifth days of incubation (Figure 38.4).[42] Starting at day 2, the blood vessels of the yolk sac connect with the dorsal aorta of the chick embryo, following which blood begins to circulate through the embryo and area vasculosa. The fine reticulation of the vitelline vessels serves as the main source of gas exchange during this first period until the time that the chorioallantois connects with the inner shell membrane at approximately day 6. At that time, the respiratory function is taken over by the outer surface of the chorioallantois, the chorioallantoic membrane (CAM).[43] At this point in time, gas exchange takes place by diffusion across the porous shell, the shell membranes, and capillary blood of the CAM. The CAM continues to function as the main gas exchanger during the prenatal development until the embryo pips it and the inner shell membrane (internal pipping) and it degenerates.[43] Once the shell is broken by the chick (external pipping), the lung ventilation gradually takes over and the chick starts breathing in environmental air. Unique to birds and reptiles is the passing through a period where both the embryonic and adult respiratory surfaces, the chorioallantois and the lungs, function side by side. This period is conveniently described as the parafetal period, whereas the chick at this stage of development is referred to as the parafetus.[44]

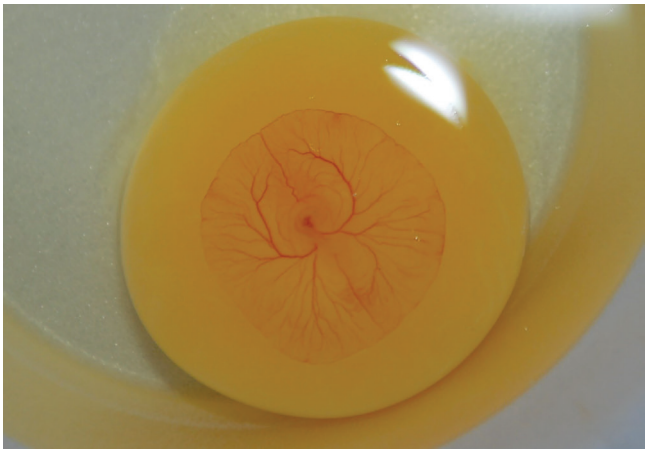

FIGURE 38.4 In this fertile egg, the area vasculosa is visible, as it rapidly expands out and over the yolk. (Photo courtesy Steve Duncan http://www.avianresources.com/.)

A prerequisite for breathing is the removal of the fluid present within the respiratory tract. This fluid primarily comprises amniotic fluid, but within the lungs an ultrafiltrate of the embryo's blood may also be present. The uptake of amniotic fluid, by active imbibition, generally starts when 70% of the incubation period has elapsed and is completed just prior to the initiation of breathing (i.e., approximately 1 day before hatching in domestic fowl).[40]

Early attempts to identify the pulmonary stimulus for respiratory movement indicated that it is probably gaseous and that possibly a high partial pressure of carbon dioxide in the arterial blood ($PaCO_2$) is the responsible trigger. This was primarily based on the observation that respiratory movements could be initiated by a 12-mm Hg PCO_2 rise in the atmosphere surrounding the egg whereas a reduction of 68 mm Hg in PO_2 was required to produce the same effect.[45] However, other authors have argued that either enhanced PCO_2 or reduced PO_2 in the space surrounding the egg, or the combination of both, can be responsible for stimulating breathing.[46] However, perforating or ventilating the air space fails to delay the onset of embryonic breathing, which renders this an unlikely possibility. Later work has shown that, toward the end of the embryonic period, the $PaCO_2$ may reach a very high level (~60 mm Hg),[47,48] while PaO_2 is relatively low (~20 mm Hg).

Sound stimuli also have a role in the initiation of breathing and hatching. For example, the hatching process can be substantially advanced by a "clicking" sound. This suggests that under certain circumstances the gaseous stimulus for breathing can either be initiated earlier or overridden by the sound stimuli. Similarly, an earlier initiation of pulmonary respiration by sound stimulation has been observed in the fowl, duck *(Anas platyrhynchos)*, goose *(Anser anser)*, and Japanese quail, but not in the bobwhite quail *(Colinus virginianus)*.[49,50] However, despite sound stimulation leading to an earlier initiation of breathing, no clear differences in $PaCO_2$ or PaO_2 could be identified.[51] In the end, it is now a common opinion that although a high $PaCO_2$ is one of the strongest stimuli to start the pulmonary activity, there are other triggers to respiration that play an important role in the onset of active breathing.

EGG WEIGHT LOSS

Throughout the development of the embryo, the egg steadily loses water by transpiration through the CAM. This water loss is a linear and consistent event throughout the entire incubation process. Because of this loss of water and the loss of yolk fats metabolized during development, the egg is much lighter at hatching than when it was laid. In most avian species, the weight loss is approximately 15% of the original weight of the egg (Figure 38.5). The eggshell, too, is thinner than when it was laid because the chick has absorbed much of the calcium from the inner shell lining. In the imminent hatching period, the chick absorbs the remainder of the yolk sac into the abdominal cavity and begins to swallow any amniotic fluid that remains.[24] During this period, there is an escalated rate of weight loss, as shown in the weight loss graph

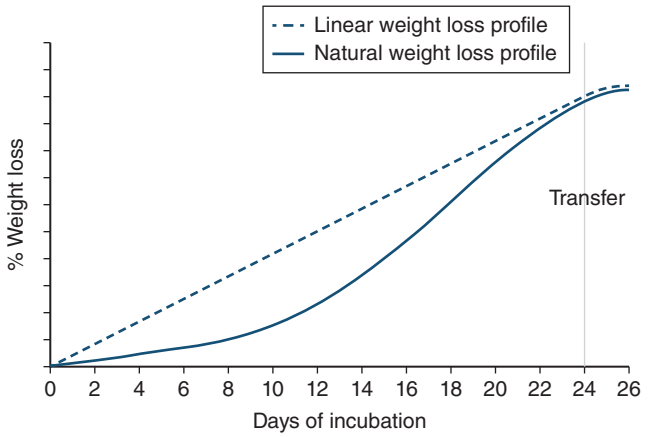

FIGURE 38.5 Natural weight loss of an egg as compared to direct linear weight loss over the incubation period. Weight loss of an egg during a 26-day incubation period, showing a completely linear weight loss of 15% *(dashed line)*, as compared to actual egg weight loss *(solid line)*. Although weight loss ultimately is the same, it is not a completely linear process over the entire course of incubation.

in Figure 38.5. Both excessive and inadequate weight loss can lead to embryonic morbidity and mortality (see Chapter 40).

PIPPING AND THE HATCHING PROCESS

In birds, pipping involves the process of breaking open the eggshell. Two specialized structures that are only found in hatchlings aid the chick in its struggle to break open the shell. The first is a small, sharp "egg tooth" that develops on the dorsal tip of the rhinotheca and is used to "pip" and "cut" out of the shell. The second is a substantial enlargement of the complexus muscle (pipping muscle) that is in the proximal dorsal cervical region and helps to brace the neck and cushion the head as the chick forces the egg tooth through the shell (Figure 38.6).[52] After hatching, most of the fluid within the

FIGURE 38.6 One-day-old hyacinth macaw chick *(Anodorhynchus hyacinthinus)*. The complexus muscle is identified *(black arrow)*, and the egg tooth is marked with the *red arrow*. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

complexus muscle is reabsorbed, and this muscle continues to function as an extender of the head in most adult birds. The egg tooth is also lost in the first few weeks following hatching.[24]

Immediately prior to the start of the hatching process, the air cell expands to encompass approximately 20% to 30% of the total internal egg volume. This change can be noted by candling and is referred to as the "draw down." At the start of hatching, the beak of the embryo penetrates the inner shell membrane to gain access to the air cell (i.e., the internal pip), and the lungs become functional by inspiring air from the air cell.

The external pip occurs when the chick cracks or cuts the outer shell membrane and shell. In fowl, this occurs approximately 8 or 9 hours after breathing is established. At this point in the hatching process, the lungs are meeting about 40% of the total oxygen requirements of the parafetus, and the parafetus might be expected to face increasingly hypoxic conditions. Just prior to pipping, the PO_2 in the air space may fall to as low as 60 mm Hg, while the PCO_2 may reach 60 mm Hg.[53] Pipping, like breathing, seems to result from rising PCO_2 in the air cell. Nevertheless, stimuli other than oxygen and carbon dioxide also seem to play a role in the external pipping process, and at current there is consensus that the hatching stimulus is not gaseous alone. The suggestion for hormonal involvement was strengthened by the observation that thyroid hormones accelerate the hatching process and specifically stimulate active hatching.[54–56] It has also been suggested that progesterone is the hormone responsible,[57] though Oppenheim has been unable to repeat the experiments to support this claim.[56] The musculus complexus has also been ascribed an important role in the hatching processes.[58–60] This muscle shows marked development just before hatching begins and acts to raise the head of the parafetus, presumably providing most of the force necessary for breaking down the shell. The timing of its maturation seems to be unique but attempts to explain this timing have thus far largely failed.[58–60]

At the onset of breathing, the oxygen requirements of the parafetus are met by the combined activities of the chorioallantois and lungs. During hatching, the oxygen requirements of the parafetus further rise. Typically, a domestic fowl parafetus consumes 25 mL/hour prior to breathing, 35 mL/hour 1 prior to active hatching, and approximately 40 mL/hour at the time of emergence from the shell. After this, a further substantial rise occurs.

The parafetus's requirement for carbohydrates also increases markedly during the hatching process, and a dramatic mobilization of glycogen stores has been recorded shortly before breathing commences. It is likely that the glucose that is made available through mobilization of these glycogen stores is necessary for the proper functioning of the central nervous system. A marked rise in the glycogen stores of the brain has been noted to occur at this time.[61] During this period, the overall respiratory quotient does not show any increase, however, remaining at about 0.7, consistent with an absence of hypoxia during the bulk of the hatching process.[40] A transient period of mild hypoxia is indicated by the fall in cardiac glycogen stores at the time of pipping.[62]

General activity, including that of the "hatching" muscle *(musculus complexus)*, increases as the parafetus moves further into the air space. Eventually, the beak contacts the calcareous

shell, and the enhanced muscular activity leads the egg tooth—the reinforced tip of the upper beak (see Thiebold and Bucher)[52]—to penetrate it. Once the shell is pipped, the parafetus enters a more quiescent period, at least in terms of physical activity, which persists until 3 or 4 hours before the chick emerges from the shell. The final activity of the parafetus is directed toward cutting round the shell and the emergence of the chick.

In domestic fowl, a period of about 20 hours elapses between pipping and hatching. In nondomestic bird species, this time frame from internal pipping to hatch can normally range from 6 to up to 48 hours. Most parrot species normally hatch within a 24-hour period from internal pip to completed hatch (see Chapter 40, Table 40.2). The hatching process is discussed in Chapter 40.

TRANSMISSION OF DISEASE THROUGH THE EGG

Infectious agents can be transmitted to the embryo vertically, or horizontally through the eggshell barrier at some point following oviposition or during incubation. Transmission of an infectious agent from a parent to an egg during fertilization, during development in the oviduct, or immediately after laying is termed vertical transmission. Once the egg is in the nest, some agents can pass through the eggshell upon contact with contaminated feces, urates, or bedding, termed horizontal transmission.[63]

Most of the information about transmission of avian pathogens we know or speculate from the data available about the infectious diseases of poultry. In poultry, vertically transmitted viral agents include chicken anemia virus, egg drop syndrome 1976 virus, fowl adenovirus, avian encephalomyelitis virus, avian leukosis viruses (genetically transmitted retroviruses), and potentially avian influenza and Newcastle disease viruses (but these usually kill the embryo and do not make it to the next generation) (P. Groves, personal communication, 2020).[64] Bacterial agents capable of vertical transmission include *Mycoplasma* (*Mycoplasma gallisepticum*, *M. synoviae*, and *M. meleagridis*), *Salmonella* (*Salmonella pullorum* and *S. gallinarum* classically, but also *S. enteritidis* and *S. typhimurium*), and *Ornithobacterium rhinotracheale*.

In other avian species, we have a lesser understanding of how and when infectious agents are transmitted to the embryo or to the chick. Apart from the assumption that some pathogens behave in the same way in nonpoultry species as they do in poultry, there are some specific infectious agents that have been reported to be transmitted vertically.

Avian Bornavirus

The first evidence to support the presence of vertical transmission was found in 2011 when the embryos of avian bornavirus (ABV)-positive psittacine parents were tested positive for ABV-RNA in the brain (see Chapter 14 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Similarly, 10 eggs out of 61 eggs obtained from a psittacine flock with proventricular dilatation disease (PDD)-affected birds within it contained ABV-RNA either in the yolk or in the brain of two embryos. However, all embryos developed uneventfully, and no inflammation typical for PDD was seen, demonstrating that vertical transmission of the virus will not automatically lead to development of disease, and may—if at all—only occur when certain, currently unknown cofactors are present. Therefore, from clinical observation, the route of transmission, at least the circumstances of a successful transmission, is currently not fully understood, though vertical transmission has recently been suggested to play a role in development of carriers (see Chapter 14 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Nevertheless, many factors still remain poorly understood, including the abilities and means by which ABV can overcome skin or mucosal barriers, as well as the influence of viral factors (e.g., pathogenicity of different genotypes) and host factors (e.g., immunosuppression, incompetency in juvenile birds, or other immunologic variables) in the development of disease. However, both the irregular horizontal transmission and the vertical transmission of ABV open large potential opportunities in preventing further spread of the virus and clearing flocks of ABV.[65–67]

Chlamydiosis

Vertical transmission through the egg has been demonstrated in the domestic duck, in the black-headed gull *(Chroicocephalus (Larus) ridibundus)*, in the budgerigar *(Melopsittacus undulatus)*, and is suspected to occur in the turkey.[68]

Psittacine Circovirus (Psittacine Beak and Feather Disease Virus [PBFDV])

There is no experimental evidence that has conclusively confirmed vertical transmission rather than horizontal transmission to the embryo via cloacal secretions and nesting material. If vertical transmission occurs, it is unlikely to be a significant mechanism for circovirus maintenance in populations. Vertical transmission is less likely as its presence would be more likely to be a deep force for virus-host coevolution.[69]

Avian/Psittacine Polyomavirus

Experimental data and observations with the natural disease suggest that polyomavirus transmission in budgerigars may occur by both horizontal and vertical routes (both among members of a flock and between generations from parent to offspring). Vertical transmission of polyomavirus has been confirmed in budgerigars but has not been confirmed to occur in other psittacine birds.[70]

CHAPTER 39

Natural Incubation

Alessandro Melillo

INTRODUCTION

Oviparity or egg laying is the most common reproductive strategy in animals: invertebrates, fish, amphibians, and reptiles, like birds, produce eggs in which the embryo develops. Unlike other zoological groups such as crocodiles, lizards and tortoises, birds generally do not abandon their eggs with trust that the physical and chemical parameters provided by their resting environment will enable the development environment. Instead, birds actively create the correct conditions for the growth of the embryo around their eggs. This process is defined as *incubation* and corresponds to the gestation of mammals. Unlike mammals, the developing embryos are exposed to additional risks outside of the female's body, but at the same time, this allows for joint efforts to be made by both sexes in the care for their offspring (in addition to the obvious advantage of not burdening the female with pregnancy).[1]

INCUBATION AND BROODING

Incubation is the process by which oviparous animals hatch their eggs. For most species, either or both parents typically sit on the eggs, heating and moving them: this action is defined as *brooding*.[1] Exceptions to this type of incubation are the Australian megapodes (order Galliformes, family Megapodidae), which build a kind of incubator from rotting plant material which in turn allows for fermentation to produce the heat necessary for the development of the embryo.[1] Crab plovers *(Dromas ardeola)*, on the other hand, make partial use of heat from the sun to cut down on parental care.[2] Brooding duties vary among species. As examples, in emu *(Dromaius novaehollandiae)* only the male is responsible for brooding, whereas for the orders Galliformes, Anseriformes, and several Passeriformes, hens are primarily responsible for brooding, and both genders are involved in brooding for almost all Psittaciformes and Columbiformes.[1,3] In the parasitic bird species (e.g., common cuckoo, *Cuculus canorus*), instead of the biological parents sitting on the eggs, brooding is conducted by other species.[1]

Brooding behavior is mainly signaled by prolactin. Changes in this hormone will result in behavior changes, with most birds becoming more shy or secretive.[4] However, certain individuals or species are known to become more aggressive and fiercely defensive of their nesting site (Figure 39.1).[4] Aside from prolactin, visualization of the clutch of eggs in the nest serves as another antecedent to brooding behavior. Birds in general show a strong attraction for their eggs and egg-shaped objects, although species differences exist. Sphenisciformes (penguins), for example, attend their eggs, but in the absence of them, may also incubate stones. Passeriformes, on the other hand, are usually more bonded to the nest and remain indifferent to the eggs when they are outside of the nest itself.[1]

Certain species begin to brood as soon as the first egg is laid, to protect it from environmental factors. This occurs in birds of the orders Falconiformes, Strigiformes, Psittaciformes, and Pelicaniformes (family Ardeidae: herons; family Pelicanidae: pelicans).[1] A consequence of this is that chicks will hatch at different ages, and hence will have different strengths. Particularly in birds of prey (e.g., eagles), this results in the older and more vigorous chicks being better positioned to successfully compete for food brought by the parents, while their younger siblings starve or are even eaten by them. Conversely, should something unexpected happen to the eggs or the older chick(s), the younger chick(s) will be capable of functioning as a reserve, preventing a total failure of the brood. In other bird groups, the ability to respectively focus on more sophisticated parenteral care for all hatchlings of the clutch (Psittaciformes) or produce different densities of crop milk (Columbiformes) is usually beneficial to allow all chicks to grow.[1,3,5] In contrast to the aforementioned bird orders, Galliformes, Anseriformes, and most Passeriformes start brooding after deposition of the last egg, so that all chicks hatch at a similar time.[1] This is particularly useful for species with precocial offspring (Galliformes, Anseriformes) because the chicks can all start to follow the parents simultaneously (see Chapter 45).

Brooding not merely involves "sitting on eggs" but is an active process designed to transfer heat to the eggs. This is accomplished through "incubation plaques" or "brooding patches," which are areas of thickened and highly vascularized featherless skin on the ventral body surface that are in direct contact with the eggs.[1,5] Down feathers fall from pterylous tracts or are selectively plucked before laying the first egg; then capillary blood flow to the dermis is selectively increased leading to local edema under the influence of estradiol (which induces molting of feathers) and prolactin (which modifies vascularization of the area).[1,4,5] After brooding is completed, the patches will regress. Brooding patches have different distributions among species. In Columbiformes, Falconiformes, and many songbirds there is only one (median) incubation patch which corresponds to the central apterium.[1] Conversely, there are two incubation patches in auks (Charadriiformes; Alcidae), and Galliformes; and gulls (Charadriiformes, Laridae) have three patches in total. Other groups of birds, including ducks and geese

FIGURE 39.1 A blue-and-gold macaw *(Ara ararauna)* broods and protects her clutch of three eggs in her artificial nest box. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

(Anseriformes), do not possess incubation patches.[1] Instead, these species actively pull feathers from their chest region to allow the exposed skin to be placed in contact with the eggs. Gannets (Pelicaniformes, Sulidae) wrap their webbed feet, which are richly vascularized, around the egg, and the emperor penguin *(Aptenodytes forsteri)* places a single egg on its feet and then covers it with a special skin fold.[1]

The temperature at the level of the brooding patch is close to 40°C (104°F) and induces a temperature of 34°C (93.2°F) on the egg. However, as only part of the egg is in direct contact with the brood patch, a temperature gradient develops between the parts that are in direct contact with the body and the part that rests in the nest. In addition, temperature differences can be seen between the eggs that occupy a central position in the nest versus those that are positioned more to the periphery. To facilitate uniform distribution of heat and gas exchange through the pores of the shell, the eggs are therefore also periodically turned by the brooding parent. In addition, the eggs' position within the nest is also varied and rotated. The frequency with which these activities are performed is highly dependent on the species. Combined, these parental actions all are designed to have direct benefit in aiding optimal embryo development.

Birds that nest outdoors may also need to protect their eggs from overheating by the sun. This may be accomplished by standing over the nest and opening wings as an umbrella, as is seen in sandgrouse (*Pterocles* spp.).[1] The humidity that the eggs are being brooded at can be adjusted through the addition of green leaves to the nest, bathing, and moistening plumage before returning to the nest, or regurgitating water directly on the eggs. Some species cover the nest with leaves when they leave, either for the purpose of camouflage or to reduce fluctuation of incubation parameters.[1] Those species that nest in cavities can rely on the benefits of a more stable microenvironment provided by the nesting cavity.

Eggs are known to withstand drops in temperature, particularly at the beginning of incubation.[6] This durability is often necessary to allow the brooding parent to get away in case of danger or to search for food. In species where both parents share the brooding duties, eggs are rarely, if ever, left alone. However, in species where a single parent broods, the eggs must endure periodic temperature changes, directly proportional to the resistance to fasting and continual brooding demands. For example, hummingbirds (Apodiformes) leave the nest every few minutes, while the albatross (Procellariiformes, Diomedeidae) can brood continually for weeks before being replaced by its mate. The emperor penguin can brood for up to 2 months. Brooding birds are aware of the environmental temperature fluctuations and will leave the nest less often in cold weather.[1]

For species in which both parents brood, the division of incubation duties across the parents can vary. In these species, individuals will take turns at intervals measured in hours or days. The exchange of duties is often associated with characteristic innate behavioral displays of the species.[1] Among Columbiformes, the male broods during the day and the female at night, while the opposite occurs in ostriches *(Struthio camelus)*. In Passeriformes, generally the female has a predominant role in brooding, while the male feeds her and guards the nest. However, in some passeriform species, the male also actively participates in incubation. In other taxonomic groups, for example in Galliformes, incubation and brooding activities are almost entirely left up to the female. These hens typically fast for the entire incubation period or leave the nest minimally to feed. In the rhea (Rheiformes, Rheidae), the male is exclusively responsible for incubation and brooding. Exclusive male incubation and brooding responsibilities are also noted in the little spotted kiwi *(Apteryx owenii)* and brown kiwi *(Apteryx mantelli)*, the emperor penguin, jacanas (*Jacana* spp.), and polyandric species ((e.g., Charadriiformes).[7] The red-legged partridge *(Alectoris rufa)* shows a quite peculiar behavior: the female lays two consecutive broods, leaving the male in charge of one and herself of the second. In hoatzin *(Opisthocomus hoazin)*, other individuals (mainly males) help their parents with the brooding of later clutches. Incubation periods vary from 12 days in many small passerine species to 65 days in the emperor penguin, and up to 80 days in the brown kiwi and some great albatross species (*Diomedia* spp.).[1]

THE NEST

A fundamental condition for the reproductive success in birds is a nest: this is the location where the eggs are laid and incubated and where altricial chicks dwell until they are fully developed. The nests of birds can in essence be very simple—a few twigs piled up like those built by most Columbiformes, or a hole in the gravel as created by different wader birds. Some birds, such as tropical terns *(Gygis alba)*, do not even use a nest but instead deposit their single egg balanced on a branch. Alternatively, nests can be wonderfully complex, such as those of the penduline tit (*Remiz* spp., *Anthoscopus* spp.) or the African weavers (*Ploceus* spp.).[1] Most parrot species nest in cavities, usually in tree trunks but also in clay walls, termite mounds, or cactus drums. An exception is the monk parakeets *(Myiopsitta monachus)*, which breed in colonies and build large complex spherical nests of branches, hanging from trees or artificial structures.[3,6]

In captive breeding conditions, the provision of a nesting site that is appropriate and acceptable to the species and concurrently allows for individual preferences is often key to success.[3,5] Geese (*Anser* and *Branta* spp.) and several ducks

(*Anas* spp.), for example, build a rudimentary nest of grasses under a shelter (e.g., barrel, dog house, or simple wooden plank) but may also do so in the grass or the bushes. Many other ducks, such as the wood and mandarin ducks (*Aix* spp.), require real nest boxes raised at least 0.5 m (~1.64 feet) from the ground. In Anseriformes, incubation is reserved exclusively for females, but males of different species remain near the nest and protect it.[5]

Parrots are generally cavity nesters and in captivity typically require different types of nest boxes.[3,6] As is seen in most of the cavity-nesting species, parrots lay white eggs, often two to four in number. Smaller parrot species such as lovebirds (*Agapornis* sp.) or budgerigars *(Melopsittacus undulatus)* commonly lay even more eggs per clutch. As the larger parrot species can be very destructive toward wooden nests, many breeders use metal containers or metal-lined nest boxes. This solution is not ideal, as those chewing and destructive behaviors are a component of the adaptive reproductive strategy for many species. The pair's demonstrated desire to change the environment to make it suitable for breeding is important for many to effectively synchronize reproductive endocrine biology. For many psittacine species, including members of the Cacatuidae family and the *Pionus* and *Eclectus* genera, the process of enlarging and modifying the entry of the nest is an important component of nest site preparation to help achieve and synchronize reproductive status of the breeding pair. For this reason, aviculturists often apply slats of wood or bark to partially occlude the entrance to the nest to meet this need while preventing excessive damage to the nest box. Perhaps even more appropriate is the provision of multiple nests in different shapes, sizes, and locations, and made of different materials, to allow the pair to choose a preferred nesting site. The main styles of nest boxes are vertical, horizontal, and L-shaped (both vertical and horizontal; Figures 39.2–39.5). Vertical nests should have an internal ladder made from wire mesh under the entrance hole to prevent birds from jumping inside and breaking the eggs. Alternatively, nests can be hung

FIGURE 39.2 A vertical nest box design. This red-headed Amazon hen *(Amazona viridigenalis)* looks in on her chicks from the wire provided as a ladder below her entry hole in a vertically designed nest entrance approximately 1 m (3 feet) higher up. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

FIGURE 39.3 Vertical nest box design with demonstration of the vertical wire ladder extending from the nest entrance to the actual nesting site for the eggs and chicks. This nest design can be placed vertically as depicted, horizontally, or even diagonally. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

FIGURE 39.4 Diagonal placement of the vertical nest box design for a breeding pair of red-and-green macaws *(Ara chloropterus)*. The nest site entrance is on the elevated end to the right, and the selected nesting site is typically in the lower corner on the left. An access to the nest site for inspection can be seen on the lower outer wall. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

on the diagonal, but those in vertical L-shapes are more often preferred by most pairs, and equally effective. Horizontal nests are often preferred by smaller-sized species.

Few species, including the budgerigar, lay on the bare wood; however, many others will require some kind of padding. This padding can be transported by the birds from external sources. Lovebirds, as an example, transport willow bark, dry grass, palm leaves, and other frayed plant materials. Padding for the nesting site can be produced within the nesting site itself or by allowing the birds to chew on the inside

FIGURE 39.5 Construction of a vertical L-shaped nest box. The entrance is elevated at the top, with a wire ladder provided to allow the birds to access the lower nesting chamber at the bottom. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

walls of the nest or other provided wood items (Figure 39.6). To avoid damage to the nest box, softwood shingles can be screwed to the inner walls for the birds to chew. The floor of the nest box can also be covered with wood chips, crumbled bark, or coconut fiber.[3,5]

Some psittacine species have special nesting needs. The palm cockatoo *(Probosciger aterrimus)* nests in old hollow trees

FIGURE 39.7 A view down into a natural, vertically positioned log nesting site, as may be utilized for breeding the palm cockatoo *(Probosciger aterrimus)* and some other species. Eggs and chicks are visible at the bottom. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

that are open at the top and will rarely accept the more common or traditional parrot nesting boxes. There are testimonials of pairs that have nested in bins or barrels, but in general they require natural nests made of hewn logs (Figure 39.7). Other unique reproductive strategies of species include those that lay a single egg and build a nest of branches within the cavity. In the wild, keas *(Nestor notabilis)* nest in cavities of rocks. In captivity, they usually prefer to lay their eggs on the ground rather than using regular nest boxes. A simple compromise may be to place a nest box at about 0.9 m (3 feet) to the side on the ground and cover it with stones or build the structure with cement blocks. A fundamental element for the

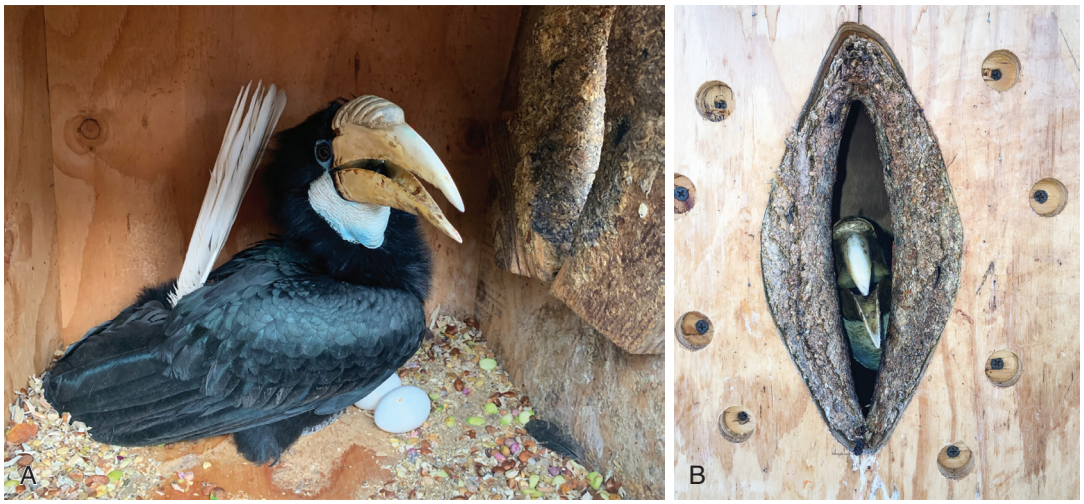

FIGURE 39.6 (A) Papuan or Blyth's hornbill *(Rhyticeros plicatus)* hen in an artificially constructed nesting site. The wood around the entrance was added to give a larger surface for the bird to pack additional material onto. The material packed inside and outside of the entrance is mostly feces, fruit pulp, and some fibrous material such as wood shavings. The nest entrance is low enough for the female, and later the babies, to back up to and squirt droppings out so that they do not accumulate in the nest. The fruit pits seen on the floor of the nest are mostly loquat pits *(Eriobotrya japonica)*, which are often fruiting while the species generally go to nest. (B) An exterior view of the same hen in the nesting site. (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

nest of the kea is a tunnel for access, which may be simulated by placing a concrete or wooden pipe of about 50 cm (20 inches) in diameter and 50 to 100 cm (20–40 inches) in length in front of the nest opening. The tunnel allows the female to prevent the male from getting into the nest. The red-headed lovebird *(Agapornis pullarius)* also has special nesting needs that involve nesting in termite mounds. To induce nesting for this species in captivity, nest boxes should be filled with sheets of cork through which the female can dig a tunnel to access the nest chamber.[3]

Columbiformes build very rudimentary nests and are often content to accumulate a few sprigs over an intersection of branches or in a basket. The domestic pigeon *(Columba livia)*, which nests in cavities, will take advantage of almost any hollow structure including holes in the wall, mezzanines, balconies, or cassettes. More exotic species of doves and pigeons generally nest in bushes and trees and will assemble collected twigs on intersections of branches or in baskets. Several species are slow and reluctant to start nesting and breeding, but once the right conditions are identified, most will reproduce well in captivity. Male and female Columbiformes share brooding responsibilities, with the male usually brooding during the day and the female at night. The incubation period is often short in Columbiformes, lasting only around 2 weeks, and begins immediately after the deposition of the first egg, so that chicks hatch at different ages.[5]

Among Passeriformes, there are vastly different incubation strategies. In the commonly bred finch species, which includes the canary *(Serinus canaria)*, the female builds a cupped nest using plant material, which she lines with (horse) hair, and other soft materials. Estrildidae, which includes the Australian finches and the small African waxbills, build nests in cavities. These differences in nesting strategy are reflected in the appearance of the eggs: whereas finch eggs are colored gray and pale blue streaked with red brown, the eggs of cavity-nest builders are white in color, and chicks typically have luminescent growths around and inside their beak that serve as helpful cues for their parents to feed them. Crows (Corvidae) build bulky nests together in trees, but only the female will incubate the speckled, green-to-brown eggs. Titmice (Paridae) and nuthatches (*Sitta* sp.) are cavity nesters but often build an elaborate and padded nest. Similarly, mousebirds (*Colius* and *Urocolius* spp.), belonging to the ancient order of Coliiformes, build a cup shaped twig nest in thick bushes and trees, and will accept proper sized baskets in captivity (Figure 39.8). Among Leiothrichidae, the Pekin robin *(Leiothrix lutea)* is quite commonly bred. In this species, the male is typically responsible for building the nest, which is suspended from a horizontal branch and created from dried herbs and lined with herbs and animal hair. In captivity, these birds will accept baskets or net hammocks but are not interested in nest boxes of any kind. The female incubates the lightly spotted, pale greenish to bluish eggs during the night, whereas male and female frequently take turns during the day. Among Sturnidae, the hill mynah *(Gracula religiosa)* will use either vertical or horizontal boxes, building a messy nest from leaves, dry grasses, or other materials. Incubation of the pale blue, dark spotted eggs is carried out by both pair members and lasts 14 days. The Bali mynah *(Leucopsar rothschildi)* is bred in a similar manner.[5]

FIGURE 39.8 This white-backed mousebird *(Colius colius)* is shown nesting in an open basket. The nest is typically hidden in a thicket. Nestlings are fed by both parents as well as helpers, which are usually young birds from previous clutches. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

REPRODUCTIVE PARASITISM

Some bird species rely on pairs of an entirely different species to incubate their eggs and raise the young, referred to as brood parasitism.[1] Often the parasitic species destroys the eggs of the host so that their young are the only ones being cared for, but occasionally the eggs of the host are left alone to allow the foster parents to brood both egg types and raise the chicks together in the same nest. Nest parasitism is reported in Cuculiformes (Cuculidae), Piciformes (Indicatoridae), Passeriformes (Icteridae, Ploceidae), and Anseriformes (Anatidae). Within the order Anseriformes, only the South American black-headed duck *(Heteronetta atricapilla) shows nest parasitism, whereby the female* lays eggs in the nests of other ducks (especially the rosy-billed pochard, *Netta peposaca*), swans, coots, gulls, ibis, and other species. The ducklings, which are already independent a few hours after birth, move away from the host's nest once hatched and continue to live by themselves. Among Cuculidae, European species are highly specialized in brood parasitism, while almost all the American species reproduce normally. After mating, the female of the common cuckoo searches for nests under construction by songbirds; identification of an available nest site subsequently triggers ovulation. A single female can produce a dozen eggs at intervals of 48 hours and deposits one egg per parasitized nest at a time that foster parents leave their nest unattended. The egg is either laid directly in the nest or laid onto the ground and then transported to the targeted nest by the female using her beak. Once the egg is in the nest, the female cuckoo continues observing the nest to ensure that her eggs are incubated by the foster parents. If this does not occur

(e.g., the nest is abandoned, which can happen if the cuckoo is spotted by the nesting pair), the female may move them to another nest. Following incubation of the egg, the cuckoo chick develops more rapidly than the other eggs, and will hatch approximately 1 day before the other chicks. A few hours after hatching, the cuckoo chick develops an intense cutaneous reflex because of contact with the skin of the back, following which everything that meets its back is raised and expelled from the nest, including the eggs and other chicks. In other parasitic species this does not occur, but the host's chicks are still doomed to starvation, given the rapid development of the parasite that monopolizes the parent's attention for food. Small passerines are extremely diligent in their efforts to feed the rapidly growing cuckoo, most likely due to the super-stimulus provided by its giant red beak. Commonly, parasitic species lay their eggs in the nests of species that produce eggs very similar to theirs. As a result, distinctly defined populations exist that parasitize different species and allow them to coexist in the same territory. African parasitic species include members from the order Piciformes, which parasitize other woodpeckers, but also starlings (Sturnidae), bee-eaters (Coraciiformes, Meropidae), and hoopoes (*Upupa* spp.). Chicks have a sharp beak and, by the second day of life, use this to kill the adoptive siblings to remain the only chick in the nest. Among Ploceidae, the African widows (*Vidua* spp.) have developed a less bloody, parasitic behavior on several species of waxbills. Widows have many similarities with the species that they parasitize, up to incorporation of part of their song in their own singing. In this group, the eggs are always white, but the interspecific mimicry is perfectly expressed by the luminescent wattles in the chick's oral cavity, which perfectly alings with the chosen waxbill's pattern. This is essential because, unlike cuckoo chicks, the small widow chicks do not kill the waxbill offsprong but are rather raised together by the host species' parents.[1]

The captive breeding strategy and modified version of reproductive parasitism is the use of foster parents to support reproduction in species that are not yet well adapted to captivity. The best-known example, which is linked to the case of widows, is that of the society finch *(Lonchura striata* var. *domestica)*, which is used as a foster parent for many species of Australian, Asian, and even African finches and waxbills. The society finch is not a true, naturally occurring species but rather a domestic bird with selected genetic contributions from several species of the genus *Lonchura*. This hybrid nature was responsible for the loss of conditioning of the bird to a precise oral cavity color pattern to cue feeding behaviors, so the society finches willingly feed chicks of different species, even mixed in the same nest. However, some African finch species remain too different, and may therefore not be willingly fed by society finch foster parents. Other finch species that may be used as foster parents include the canary and the Mexican finch *(Carpodacus mexicanus)*. Small poultry breeds, often Silkie or bantams, have been used to brood and raise pheasant chicks. While the use of foster parents improves the production of species that are more difficult to breed successfully in captivity, concerns are raised regarding the risk of inadvertently selecting for genetic variants that lack reproductive instinct. This has been noted in many gallinaceous species. In addition, fostering by other species may increase the risk for transmission of infectious agents from foster parents to the chicks. An example of concern is the transmission of *Cochlosoma* from society finches to fostered Gouldian finch chicks (*Chloebia gouldiae*; see also Chapter 24).[5] Because of this risk of exposure from an asymptomatic species to a fostered but vulnerable species, caution is advised prior to instituting this practice.

CHAPTER 40

Artificial Incubation

Petra Schnitzer

Aristotle reports first on artificial incubation dating back to 400 BCE, where the Egyptians created the first incubator to hatch the eggs of birds. The use of these ancient methods remained present until the use of electricity and the invention of the thermometer around 1881, when incubators could be designed and produced commercially.[1] Hatching and rearing birds without their parents has turned out to be a highly successful and potentially lucrative procedure, for the simple reason that removal of eggs from the nest for artificial incubation and hand-rearing the chicks leads to more clutches and eggs being produced each year by the breeding pair, hence increasing the number of offspring. The second advantage of artificial incubation is associated with the opportunity for improved infectious disease control. With the help of artificial incubation, it is feasible to eradicate horizontally transmitted diseases from a bird collection. Other benefits to aviculture include the higher profit for breeders that are producing birds for the commercial or pet industry such as chickens or parrots and the positive effects on programs working toward conservation of endangered species.[2,3] Common reasons for artificial incubation are listed in Box 40.1.

Although artificial incubation and hand-rearing techniques may have beneficial effects, potential adverse consequences should also be considered. For example, the breeding pair may be more easily exploited and suffer from compromised welfare because of overproduction and a potential resultant loss of breeding lifespan or through learned aversive responses to perceived loss of eggs or chicks over time. Similarly, hand-rearing may have deleterious consequences for the chicks. Current information pertinent to optimal welfare and breeding indicates that, compared to hand-rearing, leaving the chick with its natural parents, or foster parents, may be beneficial—if not optimal—for young birds. Several studies have shown that hand-reared birds are more prone to developing behavior problems such as feather-damaging behavior and may no longer mate with conspecifics, build nests, or incubate the eggs (see also *Current Therapy in Avian Medicine and Therapy*, Vol 1, Chapter 5, Behavior).[4,5] Hence, parent rearing is important to develop normal (reproductive) behavior, which is especially important for conservation programs and for the purpose of replacing aging breeding birds in a breeding facility. While hand-rearing traditionally has been performed to produce tame birds that are well socialized to humans, parent-raised birds can make good yet presumably behaviorally better-balanced pets, especially if co-parenting strategies have been applied.[4–7] Depending on the species (altricial or precocial), the chick either needs to be hand-reared after hatching or introduced to a bird pair for parent rearing.

ARTIFICIAL INCUBATION—PLANNING AND EQUIPMENT

When implementing artificial incubation in practice, a mid- to long-term breeding plan including a properly laid-out nursery and adequately functioning incubators is required. The layout, traffic flow pattern, and design, as well as the numbers of incubators to be utilized will vary immensely, depending on the species, the numbers of eggs anticipated to be incubated, and the anticipated variation in temperature/humidity gradients that will be required.[2] In some select situations, like the fostering of chicks under a different hen, eggs can be incubated under a different hen. As an example, brooding chickens have been used to incubate the eggs of several other species.

The ideal incubator serves as a "room within a room" and should be able to provide the desired incubation parameters necessary for the species (Figure 40.1). The room in which the incubator is placed should be thermostatically and humidity-controlled so that the climate can be kept constant, independent of daily climactic conditions. Without this type of control, fluctuations should be expected within the incubator unit.[8] The unit should be constructed with nonporous materials for two reasons: optimal temperature and humidity control, and opportunity to effectively clean and sterilize the unit.

In those facilities that maintain separate incubation and nursery areas, a general floor plan should be established for the incubation area. This floor plan should allow a specific traffic pattern to promote the efficient use of time and materials while also ensuring a passive barrier against waste and contamination. The so-called "spaghetti test" is a helpful aid toward establishing a fluid floor plan. By tracing the daily activity that will occur within a building for normal work tasks on a schematic map of the facility, the amount of overlap and inefficiency of motion will become evident in a floor plan/entire facility analysis. If the projected foot traffic begins to resemble a "spaghetti ball," the relative risk of cross-contamination and motion/time inefficiency should dictate a change in the blueprint (see Chapter 11).[9]

Before one can commence artificial incubation, they must understand and acknowledge that this may be a full-time job that can be extremely demanding. Box 40.2 highlights important considerations prior to initiating an artificial incubation effort. As a part of the plan for artificial incubation, additional factors should be considered and included during the planning phase (Box 40.3).

While there is no "gold standard" for a good incubation plan, there are basic principles and goals of incubation, and if

BOX 40.1 REASONS TO IMPLEMENT ARTIFICIAL BREEDING IN A BREEDING FACILITY OR ZOO

- To increase the production of eggs and chicks.
- Species conservation, particularly of species that have high biological value. Many zoos and breeding facilities participate in reintroduction and recovery programs for endangered species (e.g., California condor [*Gymnogyps californianus*], whooping crane [*Grus americana*], Spix's macaw [*Cyanopsitta spixii*]; see also *Current Therapy in Avian Medicine and Therapy*, Vol 1, Chapter 23, Conservation of Avian Species), which often requires a high number of offspring to be produced for release into the wild.
- High financial value associated with increased production. This can either be related to a high volume of chicks produced (e.g., commercial poultry industry) or related to a high financial value of the individual chicks produced. For example, chicks of certain species that are harder to breed in captivity, such as the hyacinth macaw *(Anodorhynchus hyacinthinus)*, or gyrfalcons *(Falco rusticolus)*, fetch a high price and breeders may want to increase the number of offspring to generate more income.
- Impaired ability or inability of a given pair to rear chicks successfully. Some breeding pairs may have a history of breaking the eggs, abandoning the nest, or not caring for or showing aggression toward their chicks after hatch. Additionally, death or illness of one or both parents may warrant artificial incubation and hand-rearing to save the chicks or eggs.
- Inexperience of a breeding pair. A first-time breeding pair of a particularly important or valuable species may not yet have the skills to incubate and rear chicks. To guarantee that at least some chicks survive, the breeder may choose to collect some eggs from the first clutch for artificial incubation.

FIGURE 40.1 Two incubators being used in a separate temperature- and humidity-controlled room. The central incubator is currently in use for psittacine species, and its bottom tray is being concurrently used as a hatcher. The incubator on the right is being maintained as a backup for cracked and repaired eggs or in the case of a functional problem with the central one currently in use. Other incubators are being used for other species groups with different incubation requirements.

the aviculturist does not follow the rules, the obtained results could be disappointing. A reasonable goal for a successful artificial incubation in psittacine species is that 90% of the fertile eggs should hatch, and 90% of the hatchlings should reach the weaning age (L. Crosta/P. Schnitzer, personal communication, 2024).

RECORD-KEEPING

Accurate data collection is essential for the aviculturist or veterinarian to enable objective and rational evaluation of the incubation results and allow for appropriate and correct management decisions to be made. Especially when artificial incubation is unsuccessful or achieved results are below the target goals, record review and analysis are of the greatest importance.

BOX 40.2 IMPORTANT CONSIDERATIONS PRIOR TO ARTIFICIAL INCUBATION

1. Financial investment: incubators, hatchers, brooders, furniture, and special rooms need to be purchased, constructed, and installed.
2. Time is required to monitor incubator performance and to assess and record egg and embryo/hatchling data.
3. Time is required to maintain and improve knowledge and skills related to the latest information, concepts, and discoveries.
4. Time is needed for record-keeping of the climatic conditions (room temperature, humidity), hygiene and disinfection, and observations related to the immediate environment.
5. Considerable time and facility investment are required for the care of the chicks, particularly when incubating altricial species (though to a lesser degree also a prerequisite for the precocial species). Chick care largely includes hand-rearing and socialization, as well as introduction to foster parents (in rare exceptions).

BOX 40.3 ADDITIONAL VARIABLES TO DISCUSS AND INCORPORATE INTO AN ARTIFICIAL INCUBATION PLAN

- What is the main role of the aviculturist?
- What level of experience with artificial incubation and hand-rearing do they have?
- How much time do they have to spend on both activities?
- How many breeding pairs are in the facility? How many of these will be used for artificial incubation?
- What species are present in the collection? Will incubation requirements for their eggs necessitate different incubators and settings?
- Are the breeding birds experienced in rearing chicks, or are they first-time breeders?
- Are there any specific disease concerns present that might lead to different breeding techniques in the breeding facility (e.g., diseases that are not transmitted vertically, hence increasing suitability of artificial incubation to eliminate disease from the flock)? (See also Chapters 11 and 12)

Note screens for breeder activities, clutch activities, and nursery inventory displayed; each has several subset tabs for the information categories available. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

Records to be maintained in avicultural settings can be divided into four main areas, including general information, adults, hatchlings, and incubation. Factors including the aviculturist's mission statement, record-taking abilities, and attention to detail determine the desired and required information to be collected and recorded in the system. Excessive record-keeping can potentially be as detrimental as incomplete record-keeping, as excessive efforts to record data that have no practical or applicable value can amount to wasted time and additional fatigue and frustration on the aviculturist's part.[2]

Incubation records maintained may include identification of the specific incubator used, incubation temperature and humidity parameters, turning rate and degree, date on which the egg was laid, date on which the egg was set and incubation commenced, egg weight at setting and at hatch, expected and actual hatch dates, hatch intervals within the clutch, hatching observations, chick weight at hatch, egg candling observations such as fertility, vascularity, dead-in-shell (early, mid, and late embryonic mortality), and any and all diagnostics performed, including the results. The data obtained from these incubation records relate to both parental reproductive and systemic health, as well as incubation management by the aviculturist. The egg identification (ID) can be written on the eggshell with a blunt soft pencil (Figure 40.2). The advantage of using a pencil is that no toxic substances will be released inside the egg, and most egg disinfectants do not wash the notes away. Generally, data recorded on the eggshell will include date of lay, species, and ID (number of the pair, the female, or aviary). Elsewhere, other data are recorded, either in a notebook or computer-based record-keeping system (Figure 40.3). A Windows-based avicultural record-keeping program that is commercially available and can be easily downloaded is AviMate.

EGG STORAGE

Storing the eggs is common practice in the poultry industry, but it is also applied in breeding facilities for psittacine and other avian species. Most aviculturists will set eggs into the incubator on the same day that the egg is harvested from the nest. In part, this decision results from lack of knowledge regarding the specific date of lay. If the eggs are not yet set by the parents, and incubation has not started embryogenesis significantly, storage can be utilized to synchronize hatch groups. Allowing the eggs to rest prior to incubation, if possible, can also increase hatchability of fertile eggs. However, once incubation has started (either naturally or artificially), the eggs should not be cooled, as the risk of embryonic mortality increases significantly upon warming, cooling, and then warming the egg again. Storage between 2 and 5 days seems to yield optimal results, whereas short or excessively long storage times tend to reduce hatchability.[10]

Freshly laid eggs should be examined for dirt, abnormal shape, or cracks in the shell. If the eggs are dirty, the dirt can be gently brushed off using a fine bristle brush, but only when the eggs are dry. Routine use of water for cleaning psittacine eggs is generally discouraged (unlike in poultry species), as it can damage the cuticle, which functions as the outermost protective layer of the eggshell, thereby increasing the risk of microbial contamination. In case of a cracked shell, the egg should preferably be discarded, but in case of valuable eggs (e.g., vulnerable species), repair of the egg can be considered (Figure 40.4). Several techniques for eggshell repair have been utilized, with variable results. Glue, candle wax, and even cling wrap can be used. It is important to remember that by sealing the crack, the egg pores will also be closed, hence altering the egg's respiration and metabolism of the embryo. For this reason, focal application of repair patches is advised, as opposed to coverage of a larger surface area of the egg. A cracked egg that has been repaired needs to be handled as if it is an infected egg and should ideally be kept in a separate incubator.

Psittacine eggs are placed horizontally in a clean container and laid on a soft, clean substrate (e.g., millet seeds, dry sand, trays specifically designed for egg storing). The eggs can then

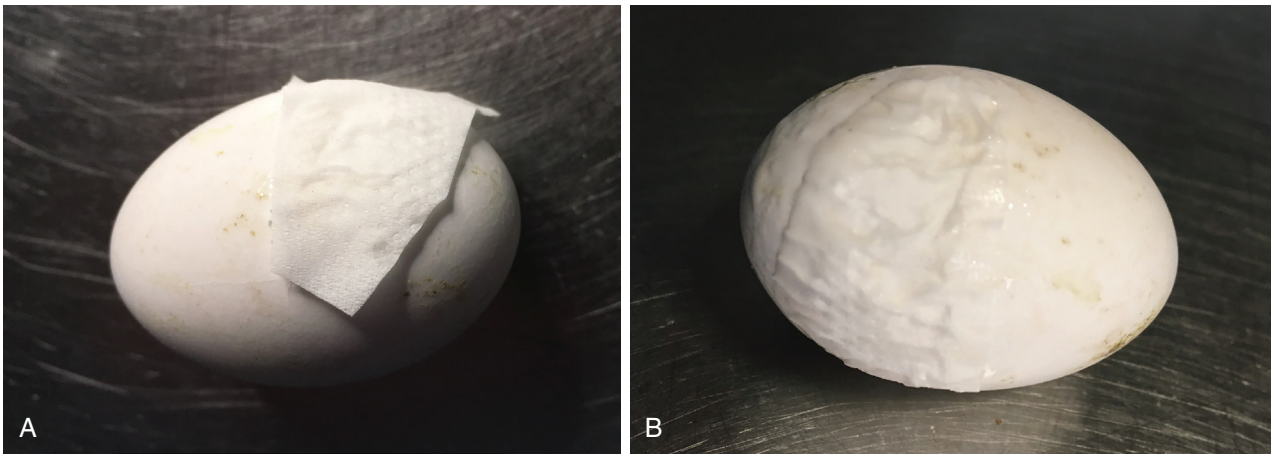

FIGURE 40.4 Egg shell crack repair. Prior to repair, the shell is lightly cleaned (A). Tissue paper is then applied to the specific area of the cracked shell and then sealed with white glue (B). Repaired eggs should be housed in a separate incubator, and regarded as if they are contaminated, to reduce risk of contamination of the primary incubator and eggs within it. (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

be stored at 13°C to 16°C (55.4–60.8°F). During the initial period of egg cooling in the nest or storage site, the air cell develops following separation of the inner and outer shell membranes. Minimal handling, movement, or vibrations of the eggs during both storage and incubation are important, as any disturbance during these early phases of incubation and embryo development can predispose to early embryonic death and malposition.

INCUBATORS

Commercial incubators are available in varying brands, models, and prices. Independent of the chosen model, the incubator needs to be stable, capable of incubating eggs of different sizes, and capable of monitoring the inner temperature and maintaining it constant (Box 40.4). For these machines to operate optimally, it is recommended to keep them in an air-conditioned room with constant temperature and humidity—the so-called "room within a room" concept (Figure 40.1). In addition, it is recommended to place additional thermometers and hygrometers in the center of the incubator for close monitoring, even if a built-in unit is present. Heat and humidity are circulated by fans, which provide proper air circulation and ensure a more even temperature throughout the incubator. Generally, a common goal in artificial incubation is to provide a more uniform and even distribution of heat and humidity, as opposed to the variations that may be seen with natural incubation. Studies performed in broilers report a discrepancy from 0.4°C to 3.0°C in fan-heated incubators.[11] Depending on the egg size, how full the incubator is or is not, and the distance from the fan, late embryonic mortality can increase because of inadequate air circulation and uneven distribution of temperature and humidity.[11] Units with low air turnover should be expected to vary in their ability to distribute temperature evenly throughout the unit, particularly when the unit becomes progressively filled with eggs. Alternatively, incubators that have been altered to improve ventilation may have a higher temperature variability because of increased heat loss.[11]

New ideas and concepts are constantly developing on artificial incubation and one of these concepts includes imitation of the natural incubation process. The "brood patch" that is present in hens ensures transfer of heat to the egg once the hen is sitting on the nest, following which a thermal gradient is generated between the lower and upper parts of the egg. Additionally, when the hen leaves the nest, the eggs will cool down and be susceptible to environmental temperatures. This causes a contraction and expansion of the egg content, or "egg breathing," which seemingly improves the metabolism of the egg and the embryo. To mimic this natural process and physiologic temperature fluctuations, incubators were designed with a broad heater on the ceiling of the unit (representing the brood patch) to improve the metabolism and development of the embryo. Whether or not these types of incubators indeed improve the hatchability of the eggs currently is unknown due to the lack of published evidence comparing the older and newer methods. However, it is likely that these newer incubator designs are at least equally good as the traditional ones, and the concept of using these is nowadays widely popular and supported in avicultural circles.

BOX 40.4 IMPORTANT PARAMETERS WHEN SELECTING AND EVALUATING AN INCUBATOR FOR ITS SUITABILITY

- Amount of useable inner space
- Types of egg trays, including their versatility for the anticipated sizes of eggs to be hatched
- Ease of cleaning and maintenance
- The ease and practicality of use
- Degree of incubator mass: the bigger the mass of the incubator, the greater the degree of stability of temperature and humidity inside it
- Availability of technical assistance

BOX 40.5 COMMON REASONS FOR EMPLOYING MULTIPLE INCUBATORS

- Eggs of different sizes may need different trays for optimal air and heat circulation around them.
- Broken but repaired eggs should be considered contaminated and should be incubated separately. These eggs can "sweat" or produce foam, or even explode during incubation.
- Eggs from different species can have different incubation parameter requirements for relative humidity and temperature.
- Eggs may require different numbers of turnings per day. Small eggs generally require a higher number of turnings per day compared to larger eggs.
- A controlled number of eggs may be needed per machine to facilitate optimal incubation.
- An incubator may break down, requiring the availability of a backup device.

Regardless of the type or model that is used, there are several reasons why it is recommended to have more than one incubator available and running at the same time (Box 40.5).

It is important to verify proper functioning of the incubator(s) at least 1 month prior to the onset of the breeding season to provide adequate time to address any issues in case problems are encountered. Incubators should be capable of running and reaching the desired humidity and temperatures consistently at least 2 weeks prior to placing the eggs in the device. Regular maintenance is advised and should include checking whether the different components are functioning adequately, including the wet bulb, thermometer, hygrometer, timers, and turning mechanisms. Incubators (and brooders) should also be carefully cleaned and disinfected using nontoxic substances (available as a liquid solution or fog/mist), at least once at the end of the breeding season (see Chapter 12). The fan of the incubator should receive extra attention as it can easily harbor and distribute pathogens the following season unless cleaned well.

INCUBATION

Successful artificial incubation is highly dependent on the skills of the aviculturist and the attention paid by them to detailed record-keeping, care, and monitoring of the equipment; precision of the egg handling technique; and perseverance. For many aviculturists, it can be very satisfying to have control over the development and hatching of the chicks. However, it can also be very frustrating and emotionally challenging if embryonic mortality is high.[12]

The incubation period for the eggs depends on the species involved and is like the incubation time by the parents. For example, incubation times vary from 12 to 15 days for the zebra finch *(Taeniopygia guttata)* and from 28 to 30 days for blue-fronted Amazon parrot *(Amazona aestiva)*, and are around 35 days for the gyrfalcon *(Falco rusticolus)* and around 42 days for the ostrich *(Struthio camelus)*.[2,8]

Three key factors that are essential for successful artificial incubation include temperature, humidity, and turning frequency of the eggs. It is important that all these factors approach natural circumstances and are maintained constant in the incubator through careful monitoring by the operator.

TEMPERATURE

The incubator's temperature settings are paramount for proper embryonic development and control the speed of embryonic development. Generally, the higher the temperature, the faster the rate of embryonic development. From this perspective, incubation times will be shorter with higher temperatures and longer with lower temperatures. However, temperature extremes in both directions can result in higher rates of embryonic mortality. A balance to ensure optimal embryonic development is the goal. For most avian species, the optimal temperature ranges between 36.9°C (98.42°F) and 37.5°C (99.5°F). In most parrots and some birds of prey, the optimal temperature is 37.2°C (98.96°F) ± 0.1°C (0.2°F). Individual testimonials of temperatures ranging from 37.2°C to 37.4°C (99.0–99.3°F) have proven successful for psittacine egg incubation. While incubating the eggs it is important that the heat produced is consistent and uniformly distributed within the unit.

HUMIDITY

The humidity in the incubator regulates the transpiration of the egg. As a result of water evaporation from the egg, weight loss will normally occur during the incubation process. This process is critical for normal growth and hatching of the embryo. Humidity is traditionally measured with the use of both wet bulb and dry bulb thermometer in the incubator. The wet bulb temperature is the lowest temperature to which air can be cooled by the evaporation of water into the air at a constant pressure. The dry bulb temperature is the ambient temperature. The difference between these two temperatures is a measure of the humidity of the air. Alternatively, humidity can be measured in the incubator with the use of hygrometers that are strategically placed within. Excessively high humidity during incubation will lead to inadequate weight loss and to weak and edematous embryos, commonly called "wet chicks." These "wet chicks" are predisposed to have more difficulty hatching and a higher rate of mortality at or immediately following hatch. Generally, chicks from precocial species will show the classic signs of edema, whereas chicks from altricial species will more commonly show a weaker than normal hatch, increased tendency to develop splay leg, and possibly develop immunosuppression-linked problems. Conversely, an excessively low humidity may result in excessive weight loss, and a dehydrated and weak embryo, referred to as "dry" or "sticky chick" (Figure 40.5). Like wet chicks, these embryos are weakened and predisposed to difficulties at hatch and increased rates of mortality.

As humidity is critical to ensure normal embryonic development and hatch, this parameter should be carefully monitored throughout the incubation process. Humidity is generally expressed as relative humidity (RH) and expressed as a percentage. In addition to evaluating the RH in the room and incubator, the weight loss of the eggs can be calculated. This can have value in the diagnosis and management of suspected humidity issues in the psittacine hatchery. Should deviations from the desired RH or weight loss curve be observed, immediate action can be taken to adjust and reach the desired

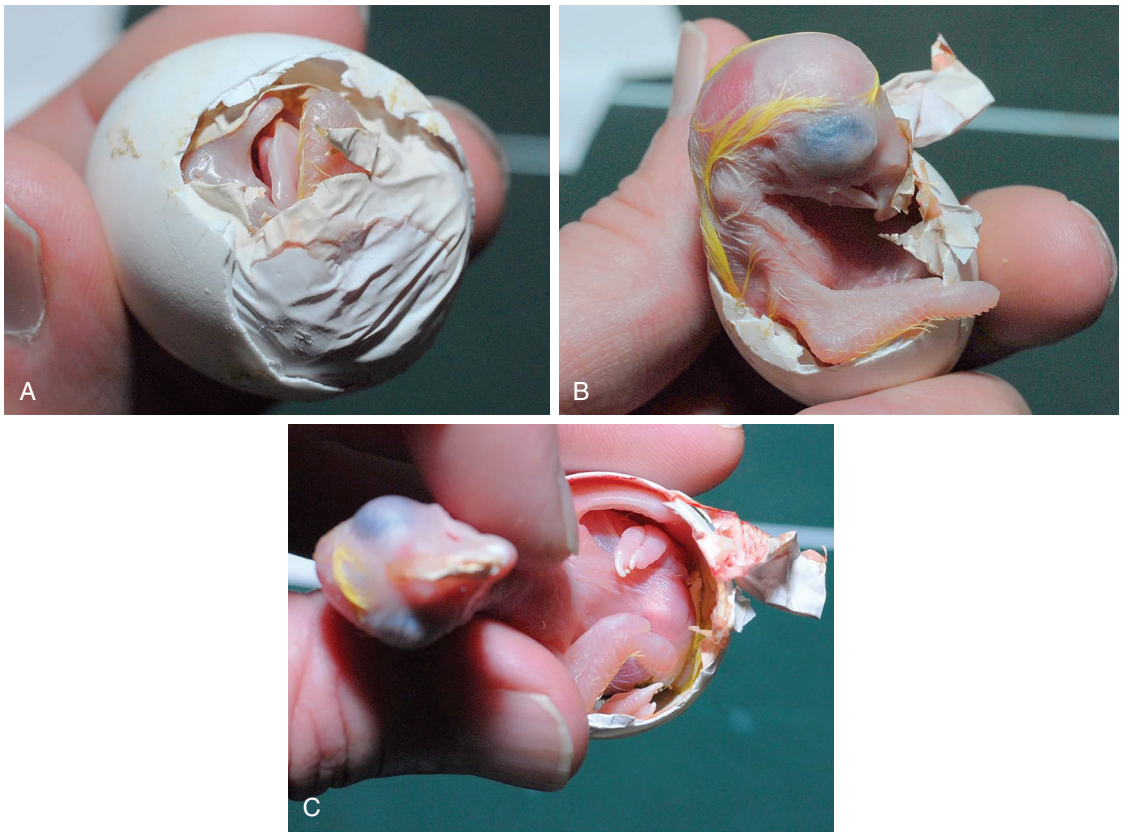

FIGURE 40.5 Assisted hatch of a cockatoo chick, which had lost excessive weight during incubation and was "dry." Note the desiccated shell membranes (A), slightly dry appearing skin (B), and the tight adherence of the chick to the inner shell walls (C). (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

target humidity in the incubator. Methods with which to adjust the RH are displayed in Box 40.6.[2]

Artificial incubation is a dynamic process. The author recommends what she sees most prevalent in psittacine aviculture, which is to have a goal of RH below 40% in the first half of the incubation period, whereas RH should remain below 45% in the second half of the incubation period. The goal is to end up with a weight loss within the appropriate weight loss range at the end of the incubation. To ensure that weight loss remains within the optimal range, parameters need to be observed daily and adjusted, as indicated (Box 40.7). The "right" humidity settings are the ones that work optimally in a specific incubator and in a specific location or environment. As this can be highly dependent on the environmental circumstances, every aviculturist should be encouraged to investigate which parameters work best in their situation. Careful monitoring of the eggs' weight loss during incubation is recommended to aid in identifying optimal incubation parameters for this reason (Box 40.8). Throughout incubation, the rate of weight loss follows a linear trend, which makes it easy to verify whether the RH is correct or whether it needs adjustment. From the day that the egg is laid until internal pipping, it should normally lose approximately 14% to 16% of its initial weight, depending on the species involved (Table 40.1).[2,13]

The most common egg weight loss management problem encountered during incubation is that the weight loss is

BOX 40.6 AVICULTURAL TECHNIQUES TO ADJUST THE RELATIVE HUMIDITY WITHIN AN INCUBATOR

- Use of a small (built-in) container with distilled water within the incubator unit.
- Reduction or increase of the airflow inside the incubator through adjusting the fan speed.
  This method will also alter the ratio between air and water. However, in the authors' experience, this method is generally not advised, as reduced airflow can result in reduction of oxygen concentration available to the eggs as well as slow down the removal of carbon dioxide produced by their metabolism. Similarly, decreased fan speed can reduce effectiveness of temperature circulation within the incubator.
- Use a humidifier or a dehumidifier in the incubation room.
  Generally, incubators are very effective at adding humidity to their internal environments, but less so in reducing it. Dehumidification of the air in the incubation room, to be circulated within the incubators themselves, can optimize incubator function. This is especially relevant when lower relative humidity incubation parameters are desired.
- Introduce (nonfertile) chicken eggs into the incubator.
  This addition can help to maintain humidity within the incubator. When using chicken eggs, it is preferred to use good quality eggs of which the origin is known, as contaminated or infected eggs may pose a risk for increased embryonic mortality and failure to hatch.

BOX 40.7 INDIVIDUAL EGG PARAMETERS TO MONITOR ON A DAILY TO WEEKLY BASIS

1. Temperature
2. Relative humidity (RH)
3. Weight of the egg/weight loss of the egg
4. Damage to the eggshell
5. Candling observations

BOX 40.8 EXAMPLE OF WEIGHT LOSS CALCULATION OF AN EGG DURING ARTIFICIAL INCUBATION

Egg weight losses can be calculated using the following formula:
Example:
Blue-and-gold macaw *(Ara ararauna)*
Egg weight at egg laying: 26 g
Current weight: 24.05 g
Incubation time: 28 days

1. Calculate the grams lost per day of incubation
   (Starting weight – Current weight)/Days incubated = Weight loss/day

$$\frac{26.00\ \text{g} - 24.05\ \text{g}}{14\ \text{days}} = \frac{1.95\ \text{g}}{14\ \text{days}} = 0.14\ \text{g/day}$$

2. Calculate anticipated weight loss for the total incubation period
   Daily weight loss/Day × Number of days of incubation period for the species
   Example:

$$0.14\ \text{g} \times 28\ \text{days} = 3.9\ \text{g}$$

3. Calculate anticipated weight loss as a percentage of the original weight
   Anticipated weight loss/Starting weight × 100

$$\frac{3.9\ \text{g}}{26.0\ \text{g}} = 0.15 \times 100 = 15\%$$

inadequate. Should the rate of weight loss be uniform for all eggs in the incubator, the RH will need to be reduced. However, should weight loss be inadequate for an individual egg, whereas other eggs from the same incubator have a weight loss that is within the desired range, a more specific approach tailored to the individual egg would need to be employed. To increase the rate of transpiration and resultant weight loss, a variety of different techniques can be applied. For example, to increase loss of moisture from the egg, one to two small (1.5–2 mm) holes can be drilled in the shell (1.5–2 mm) over the air cell. Alternatively, fine sandpaper can be used to abrade the cuticle in a select area, which will open the shell pores and increase the rate of transpiration. Conversely, when there is excessive weight loss observed in an individual egg, select portions of the shell may be covered, cautiously, with nontoxic materials. These corrective procedures should always be reserved for the second half of the incubation period and only be performed by an experienced operator.[2,14]

EGG POSITIONING AND TURNING

During natural incubation, birds turn their eggs several times a day. Dependent on the species involved, eggs are artificially incubated in either a horizontal position (e.g., most psittacine species and birds of prey) or a vertical position, with the air cell pointed upward (e.g., poultry and ratite species). Turning of the eggs is mandatory to allow for uniform development of the vascular supply of the embryo throughout the embryonic membranes.[15] Without this web of vessels, the developing embryo will become deprived of adequate oxygen exchange, which may potentially result in its death. General poultry recommendations for egg turnings are to perform 90-degree turn, minimally four times per day.[16] Turning of the eggs can be accomplished mechanically or manually but should always be performed smoothly and carefully, as rough turning can be associated with an increase in early embryonic mortality. When using an automatic turning system, careful monitoring and evaluation of the turning processes are advised to ensure the process occurs smoothly.

TABLE 40.1

Differences in Egg Weight Loss Recommended During Incubation in Some Selected Psittacine Species[2]

Common Name	Species	Egg Weight Loss (%)
COCKATOOS		
Citron-crested cockatoo	*Cacatua (sulphurea) citrinocristata*	13–17
Galah	*Eolophus roseicapilla*	15–18
Little corella	*Cacatua sanguinea*	14–16
Major Mitchell's cockatoo	*Lophochroa leadbeateri*	12–15
Moluccan or salmon-crested cockatoo	*Cacatua moluccensis*	16–20
Sulphur-crested cockatoo	*Cacatua galerita*	16–18
Sulphur-crested cockatoo (Eleonora)	*Cacatua galerita eleonora*	15–18
Yellow-crested cockatoo (Parvula)	*Cacatua sulphurea parvula*	13–15
Triton sulphur-crested cockatoo	*Cacatua galerita triton*	15–20
Yellow-crested cockatoo	*Cacatua sulphurea*	13–15
Umbrella or white cockatoo	*Cacatua alba*	16–18
MACAWS		
Blue-and-gold macaw	*Ara ararauna*	15–19
Buffon's macaw or great military macaw	*Ara ambiguus*	16–20

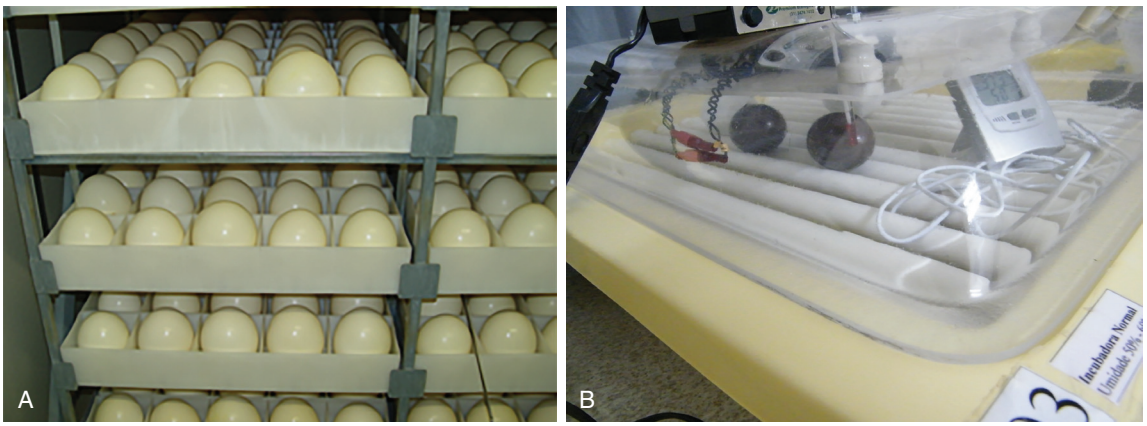
TABLE 40.1

Differences in Egg Weight Loss Recommended During Incubation in Some Selected Psittacine Species—cont'd

Common Name	Species	Egg Weight Loss (%)
Blue-throated macaw or Caninde macaw	*Ara glaucogularis*	17–20
Green-winged macaw	*Ara chloropterus*	17–20
Hyacinth macaw	*Anodorhynchus hyacinthinus*	17–20
Military macaw	*Ara militaris*	16–20
Red-fronted macaw	*Ara rubrogenys*	14–16
Scarlet macaw	*Ara macao*	15–19
OTHER		
Eclectus parrot	*Eclectus roratus*	14–17
Rose-ringed parakeet	*Psittacula krameri manillensis*	9–12



There are two basic methods by which a mechanical incubator may turn the eggs: rotation and tilting (Figure 40.6). Rotating incubators have trays with rollers of different sizes, and the eggs are positioned horizontally to allow the eggs to turn when the rollers move, which will prevent problems with chorioallantoic membrane development and malpositioning of the embryo.[17] When using tilting as a method to turn, eggs are positioned vertically with the air chamber up (note that this is not considered favorable for psittacine eggs). During the process, trays will tilt 45 degrees each way, hence having a 90-degree range of movement in total.

Manual turning of the eggs can be employed exclusively, or in addition to what is provided by the incubator. The use of an automated turning method combined with manual turning can be useful to help avoid inadequate turning–associated problems should the incubator mechanism fail to turn the eggs without the deficit being recognized. When manually turning the eggs, care needs to be taken to avoid contamination by dirty hands (i.e., wash hands carefully, or wear gloves) and to avoid forceful or rapid movements of the eggs. Inadvertent mechanical damage to the shells or developing embryonic membranes can occur due to forceful manual turning, and should the egg have already been turned mechanically, it is also possible to manually return the egg back to its original position.

CANDLING

Candling is used to evaluate eggs for evidence of fertility, to estimate the age of the embryo, and to assess the health of the developing embryo. Two different candling techniques that are commonly used are light candling and electronic or digital candling.

Light candling is the classic candling technique. Traditionally, this type of candling is done in a darkened room with a bright focal light source (e.g., lamp, torch). By holding a bright light up to the egg, the shell's contents can be

FIGURES 40.6 (A) Ostrich *(Struthio camelus)* eggs in a incubator. These vertically positioned eggs with their air cells upward are tilted 45 degrees to the right and then to the left, accounting for a 90-degree turning, at a minimum of four times q24h period. (B) Horizontally positioned eggs for incubation may be placed between the rollers in this incubator, which turns the eggs 45 degrees on their longitudinal axis each way, also accounting for a 90-degree turning roughly four times q24h. During the hatching phase of incubation, turning is not continued, regardless of the manner of incubation up to that point. (A, Photo courtesy Brian Speer; B, photo courtesy Lorenzo Crosta.)

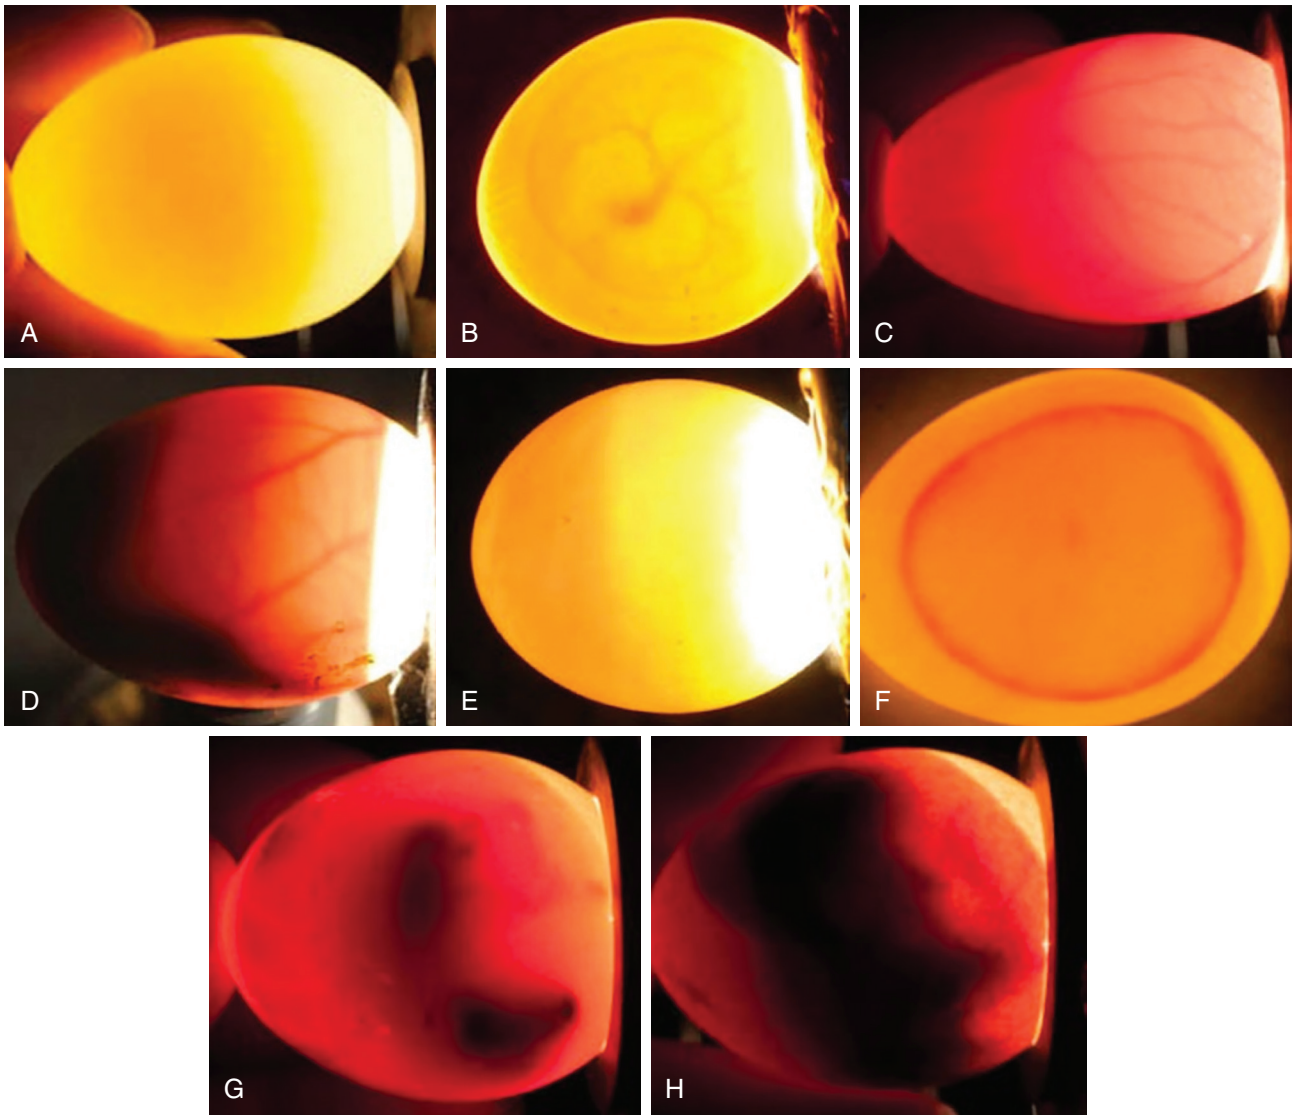


FIGURE 40.7 Examples of healthy embryonic development (A–D) as compared to embryonic mortality candling findings (dead-in-shell) (E–H). (A) Newly laid fertile egg. At this stage, vascular development should not be visible, but the normal central location of the yolk can be appreciated. (B) Early normal embryonic and vascular development at 4 to 5 days of incubation. (C) Continued vascular development at 14 days of incubation. (D) Maturing embryo and vascular development at 21 days of incubation. (E) Early embryonic mortality in the first few days of incubation. Note the apical location of the yolk in the left end of the egg, and stratified density of yolk. (F) Embryonic mortality demonstrated at days 4 to 5, with a classic "blood ring" visible due to disruption and degeneration of early vessels in the developing chorioallantoic membrane. (G) Embryonic mortality at 14 days of age. Abnormal vessel development is apparent, and there is no Doppler detection of a fetal heartbeat noted. (H) Embryonic mortality at day 21 of incubation. There are no visible vessels in the chorioallantoic membrane, the embryo is free-floating within the egg, there are gas bubbles visible slightly to the left of the embryo's shadow, and there is no Doppler detection of a fetal heartbeat noted. (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

illuminated, allowing the embryo and blood vessels to be identified. An experienced operator is not only able to recognize fertility but can also estimate the approximate age of the embryo (Figure 40.7). Depending on the species, fertility can often be assessed after 4 to 7 days, when the developing blood vessels of the chorioallantoic membranes are clearly visible (Figure 40.8). Other signs that indicate a healthy, developing embryo are the increased air cell size, and altered shape and activity of the embryo, which increase right before hatching (draw down). With early embryonic death, a dark band will usually be visible (Figure 40.9).[18]

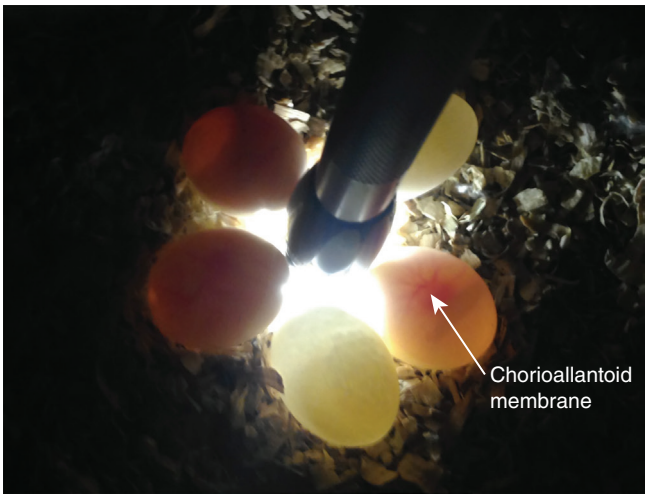

FIGURE 40.8 Candling can be performed in the nest as well as during artificial incubation procedures. This image shows the appearance of three fertile and two infertile eggs in a clutch. Bubbles visible in the lowest egg indicates the presence of a ruptured air cell, or faulty inner shell membrane, and this egg was removed from the clutch. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

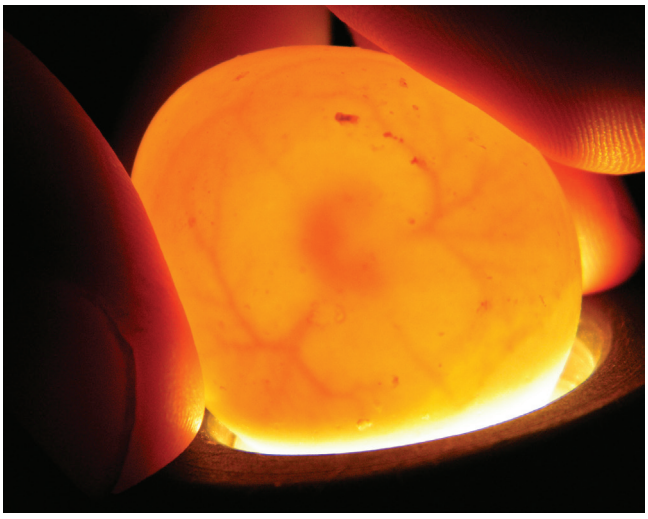

FIGURE 40.9 A dark band that surrounds the embryo in a candled egg usually indicates early embryonic death. (Photo courtesy Lorenzo Crosta)

An alternative and newer method of candling, which has been developed over the past decade, is electronic or digital candling. The monitors (e.g., Buddy; Avian Biotech International, Tallahassee, FL, USA and Bird Buddy; Avitronics, Truro, UK) used for this procedure use infrared transmitters and sound sensors to amplify the cardiovascular signal of the embryo, which can be detected a few days after the start of incubation. Although these instruments can provide valuable information about the embryo, its health, and development, they should likely never be presumed to be entirely capable of replacing classic candling techniques, as direct visualization of developing embryonic membranes as well as their cardiovascular signals both have value in assessment of embryonic health.

THE NORMAL HATCH

Depending on the species, the hatching process begins about 48 to 72 hours after the internal pipping process, where the beak of the chick penetrates the egg's air cell (Figure 40.10). Once the chick is breathing the air of the air chamber, it starts to vocalize. Following the internal pip, the egg should be transferred to the hatcher. The temperature in the hatcher (37.0–37.1°C [98.6–98.8°F]) is slightly lower than in the incubator, whereas the humidity is slightly higher (RH 50%–60%). During the hatching process, the egg is no longer turned. Many aviculturists recommend placing the hatching egg in a single container within the hatcher.[19]

The external pip occurs when the chick cracks or cuts the outer shell membrane and shell. The external pipping and completion of the hatch can take anywhere from 24 to 72 hours, dependent on the species involved (Table 40.2). During the hatching process, the chick will continue to cut the shell and progressively break out of the egg (Figure 40.11).

MALPOSITIONS AND THE ASSISTED HATCH

Malpositions of the embryo are often classified using poultry systems, which recognize seven different positions (Figure 40.12). Malpositions I and II are the most typically associated with hatching failure and will generally—though not exclusively—require hatching assistance.[18,20] Causes for these malpositions as well as the associated mortality rates are listed in Table 40.3. There are some variations from the poultry normal chick position noted in psittacine species, in which the head is rarely positioned underneath the wing.[21] The more commonly observed malpositions noted at one psittacine breeding facility are shown in Figure 40.13.[22]

Determining when assistance is needed for the hatch can be a challenge, and experience is required to make the right decision. Some malpositions, if identified by candling or other chick monitoring methods, may indicate a need for assistance (Table 40.3; Figures 40.14–40.16). Generally, assistance may be required when the chick's voice starts to get weaker or the heart rate is slower, which can be observed well with an electronic candling device. A hole should be made over the air chamber, to facilitate breathing for the chicks that are failing to start the external pip. Box 40.9 lists the general steps to perform this procedure. Often, this will be all the assistance that is required to help convert a stressful hatch into a successful one.

Box 40.10 provides an overview of common problems to be encountered during artificial incubation and their causes. Some of the differential diagnostic considerations, particularly regarding causality, are included.

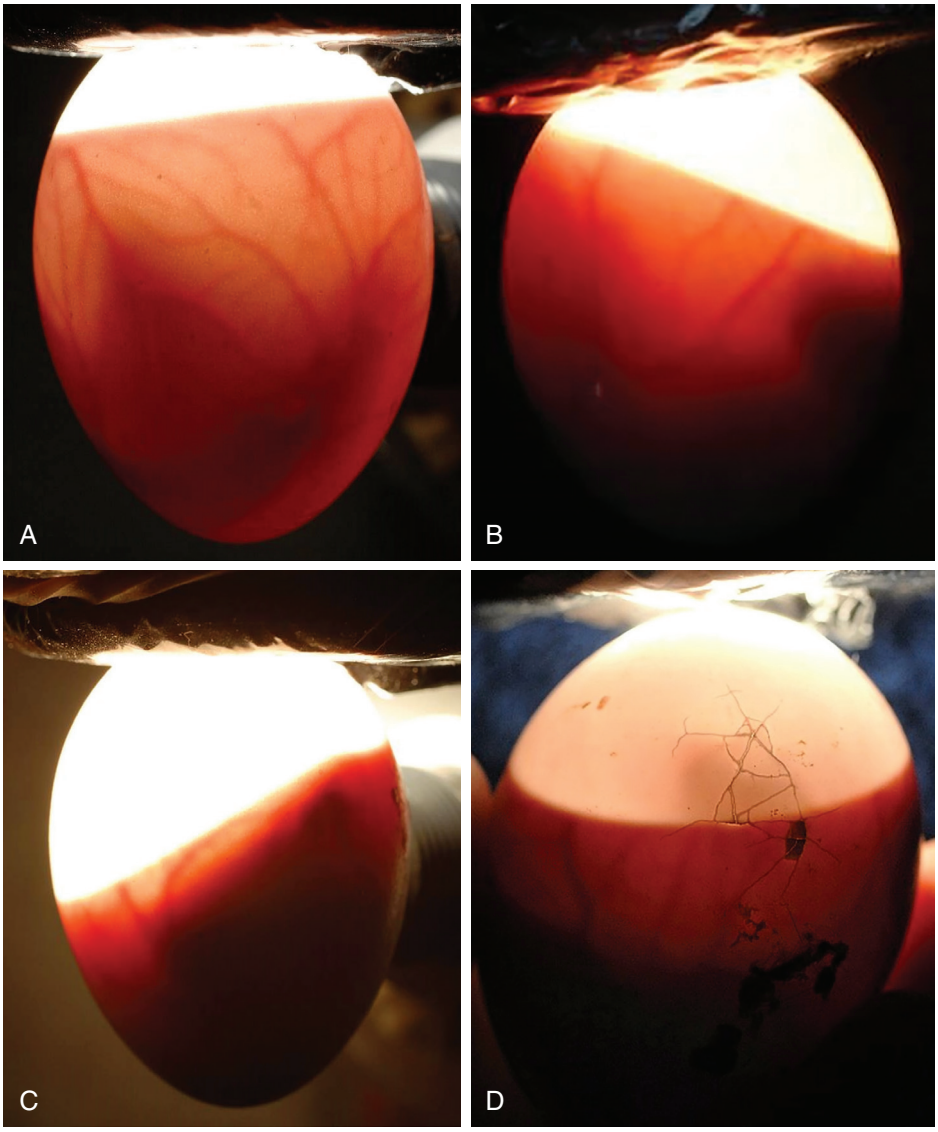

FIGURE 40.10 Candling of the normal internal aspects of the initial hatching process. (A) Embryo is visible with normal vascular development and a clear air cell at the blunt end of the egg. (B) Further development and initial retraction of vessels of the chorioallantoic membrane. There has been a slight increase in the size of the air cell, and its surface interface with the embryonic membranes is angled. (C) Draw down, where the embryo shifts its position in the egg, raising the inner shell membrane asymmetrically, in preparation for the internal pip into the air cell, and significantly altering its silhouette. (D) Internal pip. The shadow of the chick's beak is visible within the air cell. The cracks on the surface of the shell were sustained earlier and repaired and are not related to the hatching process. (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

TABLE 40.2

Incubation Period and Time From Internal Pipping to Hatch in Selected Psittacine Species[2,18]

Common Name	Species	Total Incubation Period (Days)	Pip to Hatch Interval (Hours)
Amazon, blue-fronted	*Amazona aestiva*	26	24–48

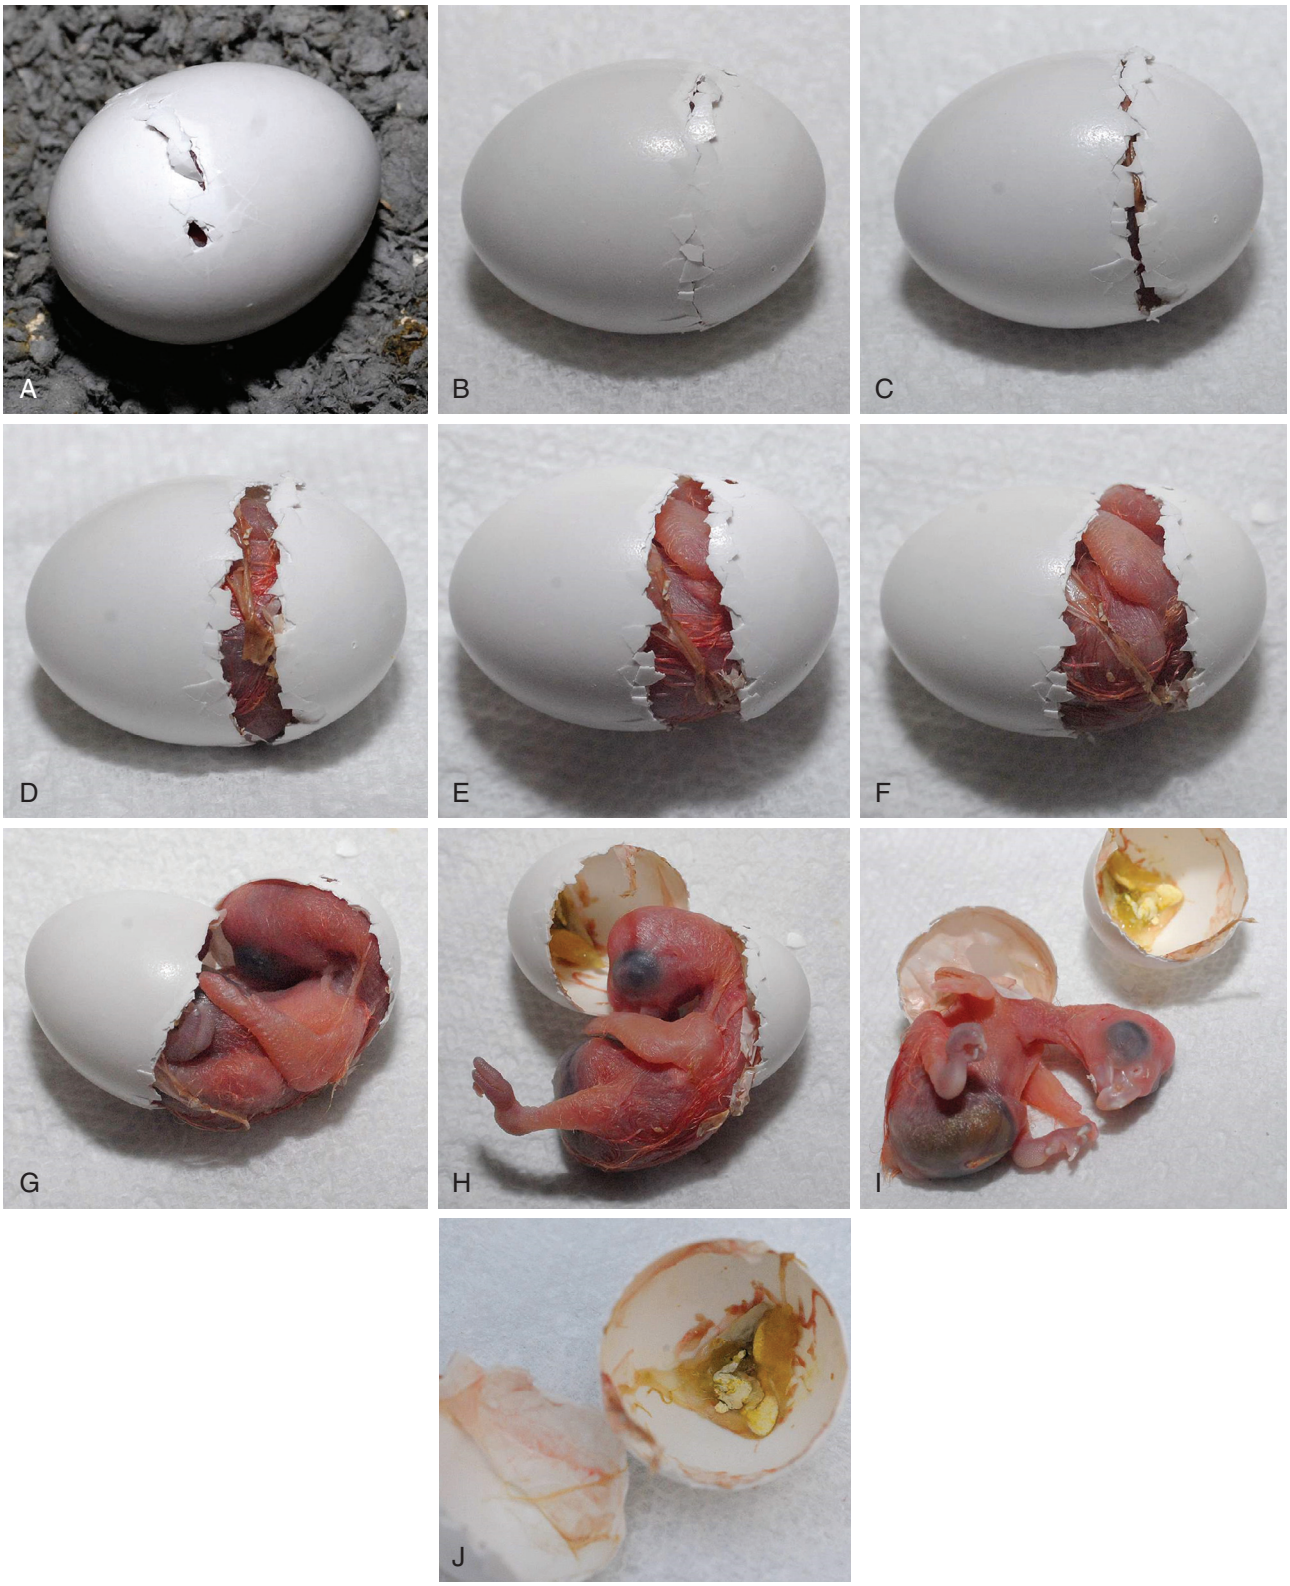

FIGURE 40.11 (A–J) A normal hatching sequence for a galah chick *(Eolophus roseicapilla).* Following a resting period after the internal pip, the chick perforates the external shell. The shell is progressively cut by the egg tooth and contractions of the complexus muscle, producing a functional cap that the chick is then able to push off and free itself from the egg. Note the apparent normal hydration of the chick as compared to the dry chick depicted in Figure 40.5. (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

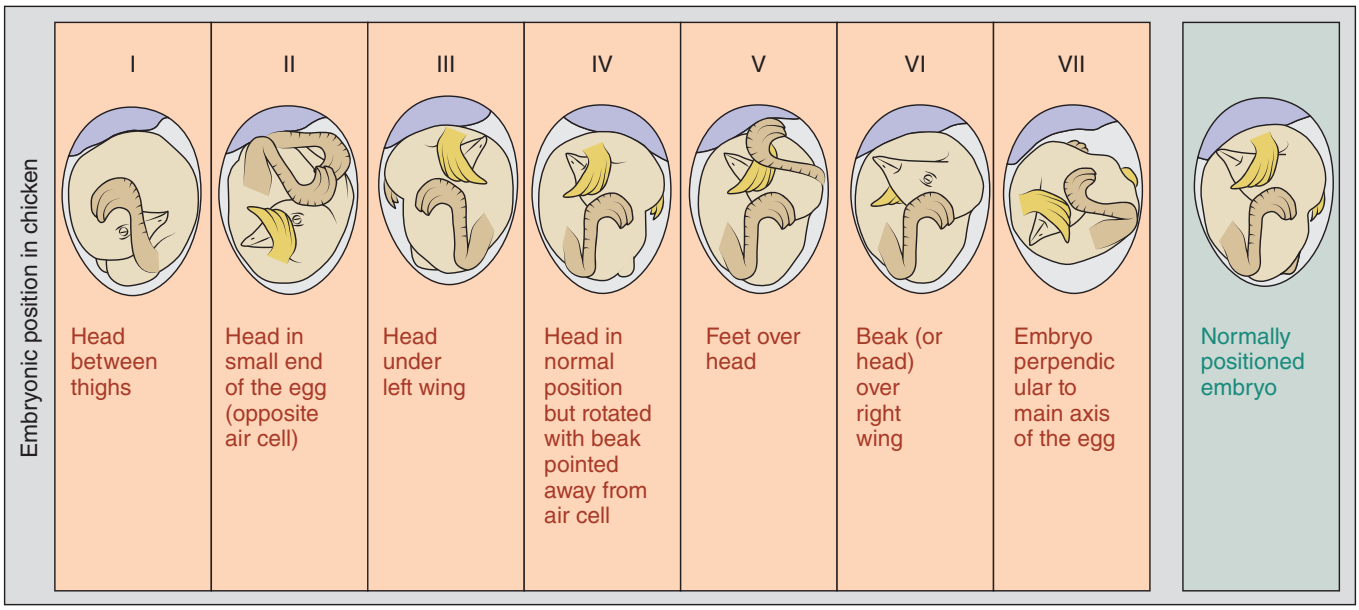

FIGURE 40.12 Embryonic malpositions in the domestic fowl. (Modified from Zhang Y: *Studies on chicken hatchability and its relation with egg yolk metabolites* (Ph.D. thesis), Gottingen, Germany, 2017, Gottingen University.[20])

TABLE 40.3

Normal Position and Embryonic Malpositions of the Domestic Fowl, Their Potential Lethality, and Causes

Position	Description	Lethality	Cause
Normal	Head at large end near air cell, head tucked under right wing upside down. Psittacines tend not to have the head tucked under the wing.	N/A	N/A
I	Head between thighs. Failure to lift and turn head right in last trimester of incubation.	Lethal	High incubation temperature
II	Head at the small end of egg opposite to the air cell, chick upside down.	50% lethal, assisted hatch often required	Incubator egg position incorrect, low incubation temperature
III	Head under left wing, rotates head left (not right). Body rotated on egg long axis.	Commonly lethal	Incubator egg position incorrect, incorrect incubation temperature, parental malnutrition
IV	Beak (egg tooth) directed away from air cell.	Slightly reduced low hatchability, assisted hatch may be required	Incubator egg position incorrect
V	Feet over head.	Commonly lethal, as embryo cannot kick or rotate for hatching	
VI	Head over right wing. Head in same plane as wing. (This is a normal position for psittacines.)	Slightly reduced hatchability (domestic fowl), assisted hatch may be required	Parental malnutrition
VII	Embryo perpendicular to the main axis of the egg.	Reduced, assisted hatch may be required	Incubator egg position incorrect

Modified from Zhang Y: *Studies on chicken hatchability and its relation with egg yolk metabolites* (Ph.D. thesis), Germany, 2017, Gottingen University.[20]

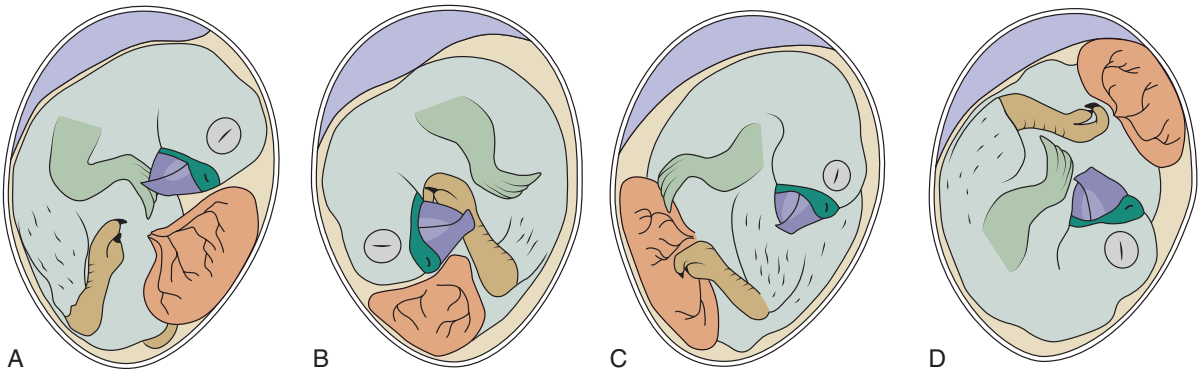

FIGURE 40.13 Common malpositions observed in psittacine embryos, as described by the Avicultural Breeding and Research Center.[21] (A) Position of the parrot embryo that most closely resembles the normal position of the chicken embryo. Unlike the chicken, the head is rarely underneath the wing. (B) Beak is rotated away from the air cell. Equivalent to malposition IV in the domestic fowl. (C) Breast is positioned toward the air cell, with the head turned back. (D) Head is in the small end of the egg (breech). Equivalent to malposition II in the domestic fowl.

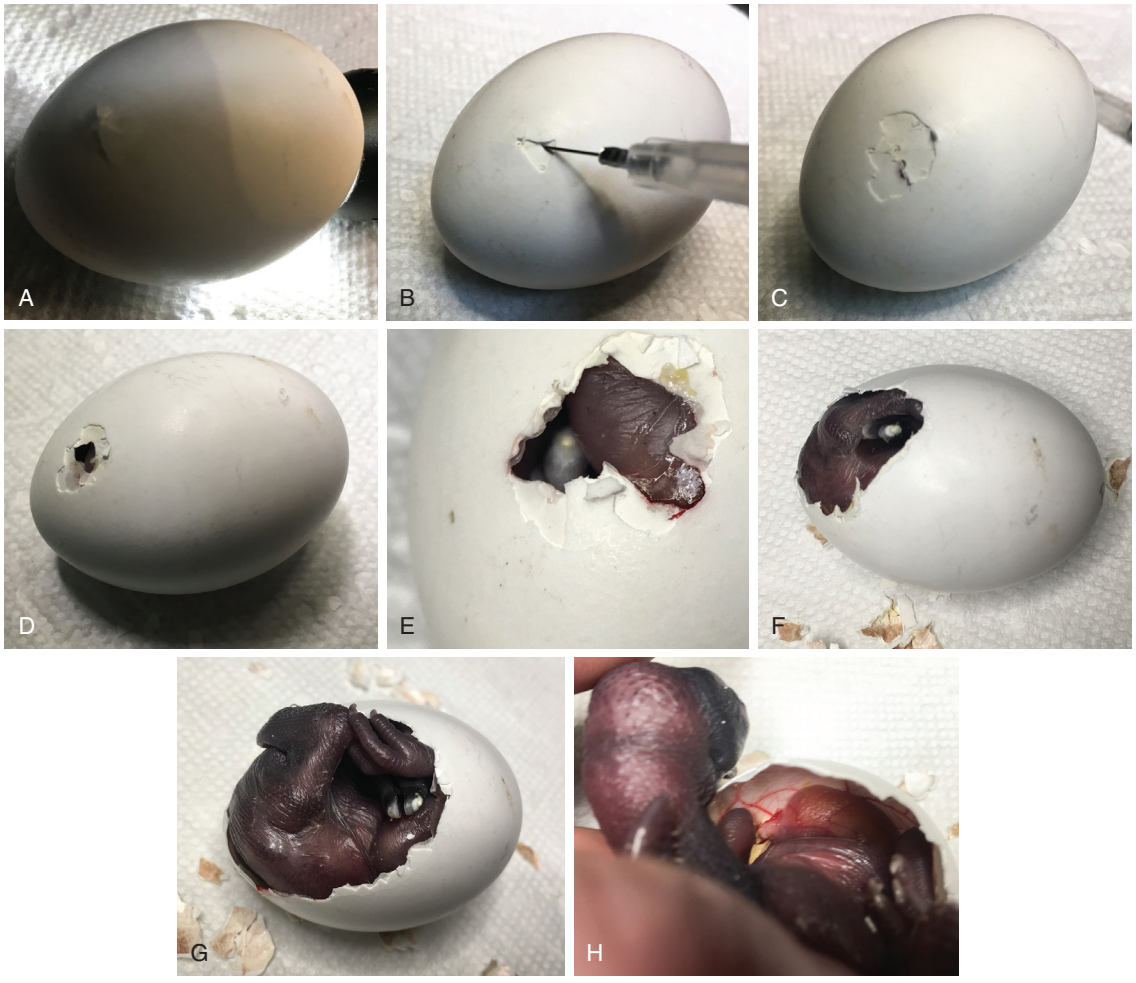

FIGURE 40.14 Assisted hatch in a blue crowned pigeon *(Goura cristata)*. (A) The chick has externally pipped well below the air cell. (B) Air is injected underneath the inner shell membrane to provide air to the chick. (C–E) Some shell is progressively removed to allow the underlying chorioallantoic membrane to dry for several hours, so it can then be opened to provide air to the head and beak. (F) With the chorioallantoic membrane and later some shell opened over the tip of the beak to allow continual airflow, the chick is allowed to rest while the yolk is retracted, and the lungs take over respiration. (G) Additional shell is removed as the blood vessels recede. (H) Full retraction of yolk is confirmed before the chick is removed from the remaining shell. (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

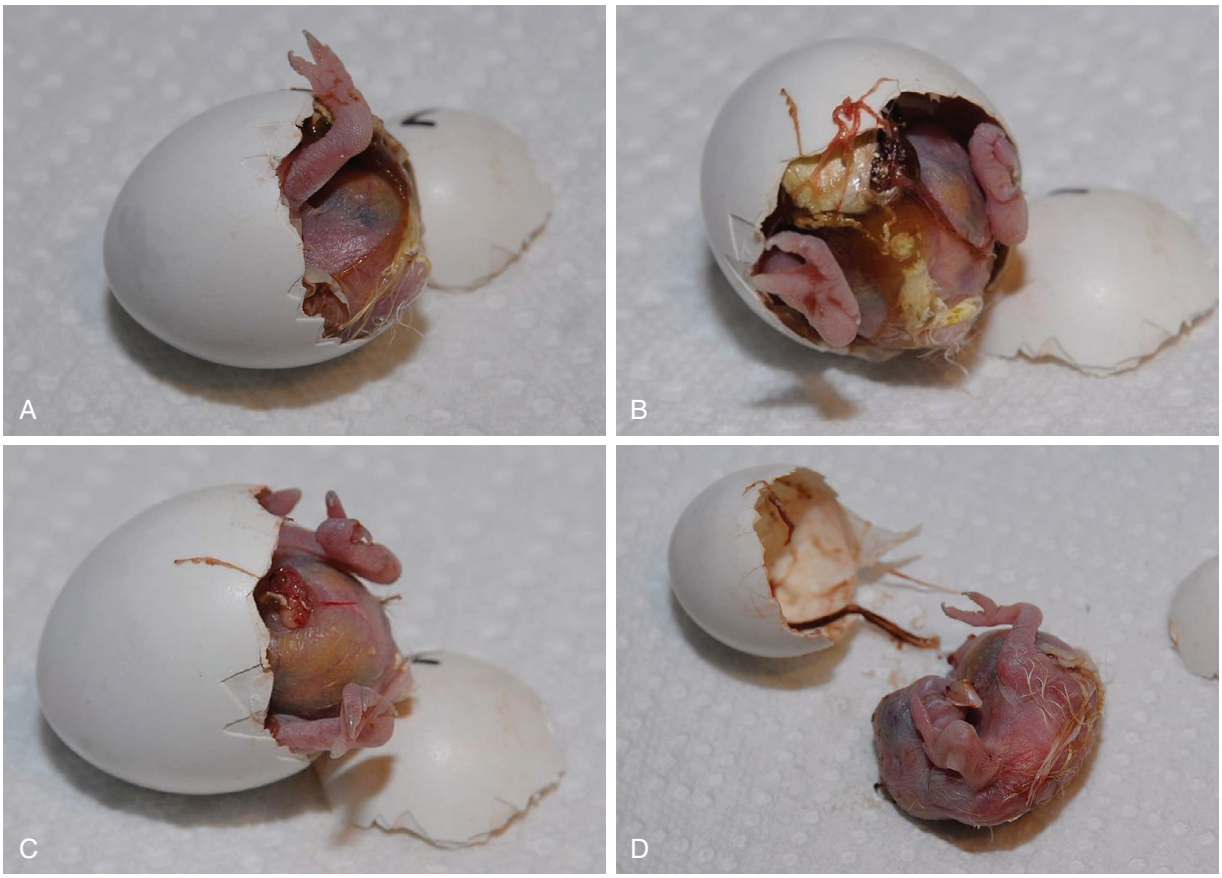

FIGURE 40.15 Assisted hatch in a malposition II umbrella cockatoo *(Cacatua alba)*. (A) Position of the chick was verified by opening the air cell and inner shell membranes, and a source of air provided to the chick's head in the narrow end of the egg. (B and C) A period of 2 to 4 hours was needed to allow for vessels of the chorioallantoic membrane to retract as well as for the yolk sac (visible in B) to be fully internalized. (D) Successful delivery of chick from the shell. (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

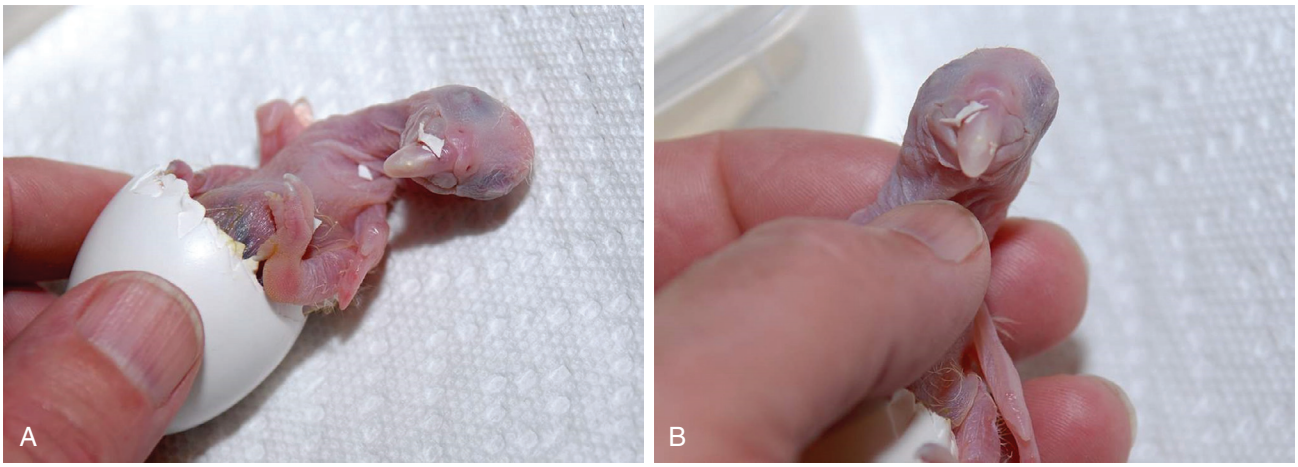

FIGURE 40.16 Completion of an assisted hatch of a green-winged macaw *(Ara chloroptерus)* from malposition II. The small end of the egg, away from the air cell, was perforated to provide air to the chick, and ultimately a cap of shell removed to enable a successful hatch. (B) Note the deformity of the head, with a flattening on the right side. This deformity rapidly self-corrected over the first 24 hours after hatch. (Photos courtesy Steve Duncan, http://www.avianresources.com/.)

BOX 40.9 STEPWISE BASIC PROCEDURES FOR PERFORMING AN ASSISTED HATCH

1. Maintain the egg in the same position as during incubation.
2. Using a sterilized needle or fine drill bit, drill a hole over the air chamber which is located at the blunt side of egg.
3. Using small forceps, take away small parts of eggshell until the hole is big enough to allow good visualization of the chick. Please note that the chick is likely covered by the shell membranes and/or portions of the chorioallantoic membrane.
4. Use a cotton-tipped applicator, or a small paintbrush soaked with distilled water or sterile saline solution, to moisten the membranes.
5. If there is a visible net of small blood vessels in the chorioallantoic membrane, the chick is not ready to hatch. In this case, place it back in the hatcher and WAIT!
6. If blood vessels are not visible, the membranes can be broken using a soaked applicator following which the bill of the chick should be located.
7. Repeat the same action after 1 hour, widening the hole on the membranes and maintaining them adequately moisturized.
8. Keep the chick moist, particularly around the bill.
9. Stimulate the chick to move and to free itself from the membranes with a gentle pressure of the applicator. At this point, vocalization is a good sign!
10. Always check the area around the umbilicus before freeing the chick completely to assure that the yolk sac has been adequately resorbed into the body and is no longer present externally.
11. When the chick is out of the eggshell, in some cases it may be necessary to ligate and remove a fully exteriorized yolk sac.
12. Disinfect the umbilicus topically as indicated and leave the chick in the hatcher for few hours to dry.

Considerable variation in timing and details may be needed, based on specifics of an individual case.

BOX 40.10 GUIDELINES FOR TROUBLESHOOTING PROBLEMS WITH INCUBATION AND THE HATCH[16,22,23]

Observation	Possible Causes
Early embryonic mortality	Delayed egg collection
	High egg storage temperature
	Long egg storage time
	Infected eggs
	Breeder malnutrition
	Rough egg handling
Mid embryonic mortality	Breeder malnutrition
	Infected eggs
	Inadequate egg turning
	Rough egg handling
Late embryonic mortality	Breeder malnutrition
	Inadequate ventilation
	Infected eggs
	Fluctuating incubation temperature
No internal pip	Weak chicks
	Dry chicks
	Wet chicks
	Malposition
	Infected egg
Internal pip and death	Hatcher temperature too high
	Hatcher temperature too low
	Hatcher humidity too high
	Inadequate ventilation
	Lack of social stimulation
Early hatch	Incubation temperature too high
	Incubation humidity too low
	Small egg size
Late hatch	Incubation temperature too low
	Large egg size
Malpositions	Inappropriate egg position
	Inadequate egg turning
	Rough egg handling
	Breeder malnutrition
Malformed chicks	Incubation temperature too high
	Breeder malnutrition
	Rough egg handling
	Chick malposition
	Genetic mutations
	Teratogens
"Wet chicks"	Inadequate air circulation
	Excessive humidity
	Large egg size
	Thick eggshells
	Low eggshell porosity
	Breeder malnutrition
Small chick size	Incubation humidity too low
	Small sized eggs
	Thin eggshells
	Porous eggshells
	Genetic predisposition
"Sticky chicks"	Incubation humidity too low
Externalized yolk sacs	Assisted hatching (premature)
	Infected eggs
	Breeder malnutrition
	Wet chicks
	Dry chicks
	Incubation temperature too high
	Fluctuating incubator temperatures
Yolk sac infections	Assisted hatching
	Inadequate umbilical care
	Unsanitary hatcher
	Infected eggs
	Inadequate egg harvesting technique

INTRODUCTION

Evolution has perfected avian parental neonatal care. As humans, we have tried to mimic the natural biological care of neonates and tried to provide for their needs to produce healthy viable young birds. Under ideal circumstances, leaving chicks in the nest with their parents would be the best choice for neonatal care.[1] Natural parenting is preferable if environmental conditions are acceptable to the parents, nutrition is adequate, and the pair is compatible and experienced. However, to enhance socialization for birds designated for the pet trade and to increase the number of chicks produced, aviculturists may elect to remove (pull) chicks from the nest for hand-rearing. In addition, chicks may be removed from the nest if parental care is inadequate, environmental conditions are hazardous for the chicks, or to increase the number of chicks produced by a breeding pair.[1,2]

In broad terms, precocial *(nidifugous)* chicks hatch from the egg with open eyes and thick coats of natal down. These chicks are strong enough to leave the nest within 1 or 2 days. Most shorebirds, ratites, game birds, gallinaceous birds, and waterfowl have precocial chicks. These species tend to have larger eggs and have a more abundant yolk sac that contains all the nutrients that the chick needs to survive the first few days of its life. Altricial chicks *(nidicolous)*, on the other hand, are hatched blind and virtually naked. They require long periods of feeding and parental care before they are strong enough to leave the nest on their own. Most tree-nesting and cavity-nesting birds have altricial young, which includes the psittacine birds.

Instead of a sharp dividing line between precocial and altricial hatchlings, a gradient can be recognized, with a wider variability in the degree or level of precociality recognized among birds (see also Chapter 45).[3] In birds, four levels of precociality are recognized, with megapodes (e.g., brush turkey, [*Alectura lathami*], Australian malleefowl [*Leipoa ocellata*]) representing precocial level 1 (superprecocial), which includes chicks that are totally independent of their parents. Precocial level 2 includes species of which the young follow their parents but find their own food (e.g., ducks, shorebirds), whereas birds from precocial level 3 have young that follow their parents and are shown food (e.g., game birds) and those of precocial level 4 have parents that feed the young that trail after them (e.g., grebes, rails). The so-called semiprecocial species includes birds such as gulls and terns of which the (nidifugous) chicks can leave the nest soon after hatching but stay in the vicinity of the nest while being fed by the parents. In semialtricial species, the downy chicks are also fed by their parents but incapable of leaving the nest. Chicks are either classified as semialtricial 1, which includes species of which chicks hatch with the eyes open (e.g., hawks, herons), or as semialtricial 2, which includes species of which chicks hatch with the eyes closed (e.g., owls). Finally, altricial species includes the species hatching with little to no down and closed eyes that are incapable of leaving the nest and fed by their parents (e.g., psittacine birds, passerines). These classifications are displayed in Table 45.1.

FACTORS INFLUENCING SUCCESSFUL PARENT-REARING IN AVICULTURE

Parental experience in raising chicks greatly influences the success or failure in the natural breeding and chick rearing process. Other factors essential for a successful outcome of this process include careful selection of breeding stock, proper genetic management, careful behavioral pairing, and a strong effort to provide an optimal environment for the breeding pair(s).[1,2]

With the notable exception of monk parakeets/quaker parrots *(Myiopsitta monachus)* that nest communally in large, growing nest structures constructed from twigs and sticks, most parrot species nest in tree hollows or cavities in cliffs, rock outcrops, or riverbanks (Figure 41.1; see also Chapter 39). In captivity, nest boxes are provided to mimic these locations, and their design (size, shape) and placement are critical factors that will attract the pair to use the nest box, which should provide comfort for the nesting pair while also enabling proper incubation of the eggs and rearing of the chicks. The substrate provided in the nest is also important and must be sufficiently attractive to the pair to encourage breeding and laying. Breeding pairs often discard nest material and may ultimately lay their eggs directly on the floor of the nest box. This can lead to damage to the shells, excessive movement of the eggs and hence to suboptimal incubation, embryonic mortality, and increased chick morbidity (e.g., developmental problems, leg deformities) and mortality (see also Chapter 40).

Environmental temperature extremes, the presence of excessive moisture in the nest, or dehydration of the chicks

FIGURE 41.1 Feral Quaker parrot *(Myiopsitta monachus)* communal nest on an electrical power pole. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

can be challenging for parents, and if they are unsuccessful in adequately supporting the needs of their fertile eggs or developing chicks, these types of environmental fluctuations can result in morbidity, mortality, and ultimately failure to reproduce (see also Chapter 39).[1,2] Parental care includes providing contact warmth for chicks and physically regulating their hydration status. In tropical climates, temperature fluctuations in the breeding and nesting sites are minimal. However, the majority of commercial and hobby psittacine aviculture is conducted in temperate climates, which are more prone to temperature fluctuations and possibly even extreme shifts in temperature.[1,2] Warmth is essential for embryonic development and survival, as well as for neonatal chicks. A devoted breeding pair can ensure adequate warmth even in reasonable temperature extremes. Most parrot species provide substrate for the nest by modifying the walls of the nest cavity. Some species such as peach-faced lovebirds *(Agapornis roseicollis)* or Goffin's cockatoos *(Cacatua goffini)* may carry vegetation to the nest tucked into their feathers. Nesting season is typically in the dry season to avoid rain flooding the nest, while chick rearing is typically timed to occur when climatic conditions are suitable for food availability for chicks. Pairs breeding under human care are free of these environmental challenges.

Predation, a major cause of nest failure in the wild, is more controllable in captivity. However, despite management controls that may be in place, rodents, snakes, raccoons, mites, etc. may enter the nest and harm the eggs and chicks. Additionally, predators or rodents can cause disturbance at night, which causes stress and affects the breeding pair's confidence regarding their own safety and their ability to safely rear their offspring. If birds are being bred in flocked setting, sharing the enclosure with other breeding pairs, there can be increased chances for aggression or competition for nests from other birds, with subsequent destruction of eggs or chicks. Coparenting by previous offspring or other conspecifics may help the pair in care of the chicks but can alternatively also result in jealousy or squabbling over eggs or chicks, possibly resulting in damage or abandonment.

The strength of the pair bond of the breeding pair is a key element for the breeding success of many species. Hence, an aviculturist should have a sound understanding of the nesting behaviors of each pair as this will increase the chances of a successful breeding outcome. Preferably, formation of a breeding pair should involve free mate selection, especially if this is important to the species. The aviculturist is recommended to evaluate for behavior signs indicative of a strong pair bond such as allofeeding, allopreening, and larger proportions of time spent in proximity to the partner (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). A strong pair bond facilitates the pair's ability to devote care to the eggs and chicks and increases the chances of success. Often, placid or fearful behavior is replaced by aggressive protective behaviors by one or both parents once the nesting cycle has begun. Some pairs become so aggressively protective that they may inadvertently damage or destroy eggs or chicks during or following nest inspection.

Egg destruction by one or both parents is a common cause of nest failure. This behavior is most often attributed to the male, which, upon entering the nest, breaks and often consumes the eggs. This behavior, if not identified, may lead the aviculturist to incorrectly assume the female is not producing eggs. Female birds have been observed eating eggs immediately following oviposition. Some birds can clean up every fragment of eggs, leaving no visible evidence that there were, in fact, eggs present. Some of these problem pairs can still be successful if the male is removed from the nest after copulation and prior to oviposition, although accurate timing for such a maneuver can be challenging. Egg drop boxes, which are designed to allow a fresh egg to roll into a protected drawer under the floor of the nest box, provide another possibility to save some of these threatened eggs (Figure 41.2). Alternatively, the aviculturist can check the nest frequently, particularly in the early morning when most eggs are laid or monitor oviposition by camera to ensure the eggs can be collected before they are damaged.

Water quality is important for the health of breeding pairs and neonates as water systems can be a common source of many pathogens. Automatic watering systems may easily become contaminated with gram-negative bacteria such as fecal coliforms or waterborne bacteria such as *Pseudomonas aeruginosa*. Overexposure and colonization by these organisms can lead to disease of both the parents and their chicks, including enteritis, sepsis, and death.[1] Common management strategies typically focus on regular flushing and replacement of water in the pipes of an automated system, resulting in a reduction of net bacterial counts noted at any point in time.

Nest cleanliness and quality are also important.[1] When nesting in their natural habitats, the success of a breeding pair is influenced by nest site availability and competitive ability of the pair to defend their nest, climatic factors, and predation or disruption by other creatures or organisms. In captivity these factors are much more efficiently controlled

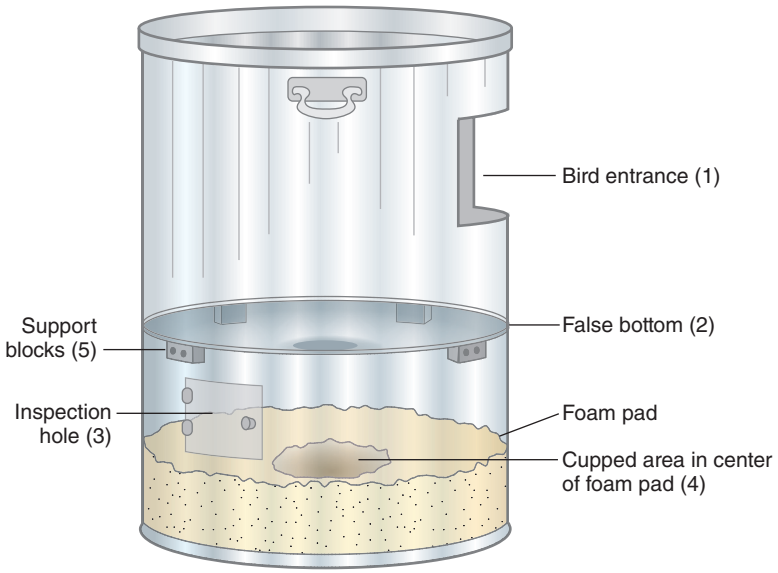

FIGURE 41.2 Nest box designs for breeding birds which have a tendency or predisposition to destroy their eggs. In this schematic, a fall-through design with a false bottom (2) mounted to support blocks (5) allows freshly laid eggs to fall down into a cupped area in the center of a foam pad (4), from where the eggs can be safely removed from the nest via the inspection hole (3) prior to being damaged or destroyed. (Photo from Abramson J, Speer BL, Thomsen JB, editors: *The Large Macaws*, Fort Bragg, CA, 1995, Raintree Publications, with permission.)

for by the design and placement of nest, the selection of nesting materials and substrates, and husbandry. Ensuring efficient techniques to clean the nest limits contamination with microorganisms, hence increasing the chances of successful breeding. Regular nest site inspection, accompanied by removal of damp materials and feces and followed by replacement of clean material, can significantly reduce pathogen buildup and potential risks.

Breeding under human care provides the opportunity to control and minimize many of the challenges faced by pairs nesting in the wild.[1,2] The educated and experienced aviculturist understands proper nest construction, size, shape, and placement, and its protection, and maintenance. Effective management of these variables removes many aspects of chance from the nesting cycle, hence, improving the probability of success. Ideally the environment should be designed such that the pair feels safe and free of disturbance, has proper perching for successful copulation, and plentiful of opportunities to provide proper parental care and nutrition.

Parental injuries to chicks in the nest typically occur with young or inexperienced pairs or when the parents do not feel secure in their nesting environment.[1,2] Pairs may not feed adequately, either in volume or frequency, resulting in stunting or even death of their chicks. Parents may nip the toes or wing tips of their chicks or sit excessively on the chicks in the nest, causing damage such as folding leg fractures, splay leg or other leg deformities, or back injuries. Young or inexperienced breeding pairs may remove, rearrange, or discard bedding from the nest, forcing the chicks to rest on hard, flat surfaces, which can lead to leg injuries and deformities. Panicked parents may also injure chicks upon hastily entering the nest following a perceived or real threat (Figure 41.3). Highly productive parents may also pluck or bite their chick's feathers once the pin feathers begin to emerge, which is largely viewed as an attempt to drive the chicks from the nest, so they can lay more eggs.

FACTORS INFLUENCING SUCCESS IN HAND-REARING CHICKS IN AVICULTURE

The Closed Aviary Concept

The closed aviary concept most likely serves as the single most unifying theme in modern aviculture. In the conceptually closed aviary, both clinical and subclinical diseases are controlled and monitored through adherence to the basic principles of designated areas and controlled flow of humans, animals, and materials. The concept of traffic control is used to reduce avicultural variables during or resulting from movements within designated areas of the aviary as well as within the aviary itself. Minimizing variables leads to reduced problems and maximizes the potential for attaining production goals.[4–6]

Coherence to the basic tenets of the closed aviary concept is an absolute requirement for the successful implementation of a flock health program. Without closed aviary management, the flock health program is easily violated, making disease incidence a random and unpredictable event. Realistically, such open facilities without coherence to closed aviary principles can only be managed on a crisis intervention basis, an approach which fundamentally undermines planned reproductive flock management (see also Figure 11.2).[6]

When chicks are being hand-raised, their dependency on their environment and nutritional needs dictates careful management, proper equipment technique, and adherence to procedural details. To provide altricial chicks with a microenvironment that meets their needs, brooder units that are

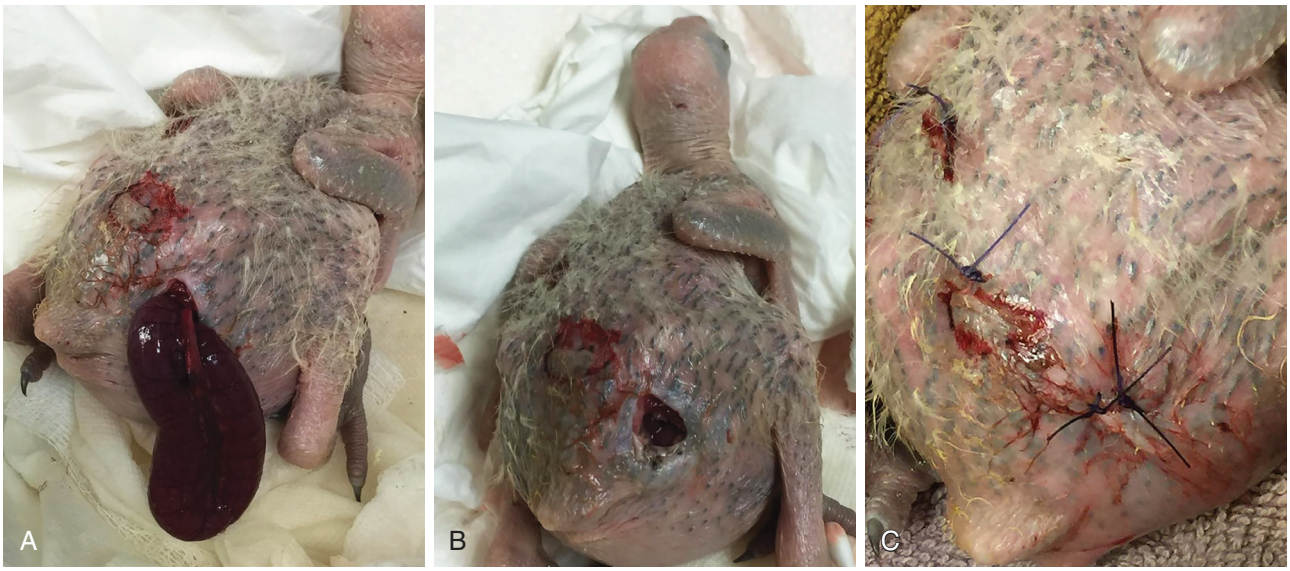

FIGURE 41.3 Parent-induced traumatic bite wound injury to a mealy Amazon chick *(Amazona farinosa)* during nest site inspection. (A) The lower penetrating wound has resulted in the protrusion of the duodenal ascending and descending loops, and their associated pancreatic heads. Surprisingly, when cleaned and inspected, there were no lacerations to the intestine itself or to the bones of the pelvis or appendicular skeleton. (B) Following cleaning, the intestine was replaced into the peritoneal cavity, and (C) the skin and body wall wounds were sutured. This chick recovered fully and was successfully hand-reared. (Photos courtesy Brian Speer.)

adjusted accordingly for the species and age of the chicks are required. In addition, appropriate nutritional support should be provided. High-quality and seasoned experience is probably the single most important factor responsible for successful artificial rearing of chicks. The American Federation of Aviculture (AFA) has developed a Fundamentals of Aviculture course, which is available online (https://afabirds.org/2018_WordPress/afa-fundamentals-of-aviculture-online-courses/) through a grant from Pet Care Trust and made possible by funding and other support from the Schubot Exotic Bird Health Center and the College of Veterinary Medicine at Texas A&M University.

Record Keeping

Chick records are perhaps the most dynamic and time-consuming records to keep, maintain, and analyze. The aviculturist may record parentage, date of hatch, daily or periodic weights, date eyes opened, age banded, identification, size of band, peak weight, and age at peak, weaning food started, perching, fledging, and weaning dates, sex determination method and results, any medical disorders encountered, and therapies administered. An example of a computerized record-keeping system is provided in Figure 41.4. Obviously, most facilities do not have the manpower or the time to record all the information listed previously, but the chick records give vital clues as to pediatric management. Remember, for most aviculturists and their attending veterinarians, increasing the numbers of viable chicks is the main production goal.[6]

Hand-Rearing or Fostering of Chicks

The ideal age to remove chicks from the nest to continue rearing in human care will depend on many factors, including the experience of the hand-feeder, availability of proper supplies and equipment, and experience of the chick's parents. The hobbyist aviculturist, wishing to produce future breeding stock, will often leave the chicks in the nest for natural fledging so chicks can learn about normal parenting techniques first hand. For those breeders who intend to hand-rear chicks for sale into the pet market or aim to optimize production, the decision may be made to pull chicks at various ages. Alternatively, compromised or at-risk chicks may be moved to nests of more successful parents to increase survival and production. Such fostering techniques offer a powerful avicultural tool when dealing with naive parents, which are often less successful in rearing their chicks, or when attempting to provide a rest period for extremely productive pairs. Likewise, many pairs will continue to be excellent parents after their own reproductive senescence.

Techniques for hand-rearing will vary by the species, the ages of the chicks, and the aviculturist (Figure 41.5). In the past, failures or challenges in neonatal care were mostly related to lack of knowledge regarding the specific neonatal nutritional and environmental needs. In recent years, however, many commercial hand-rearing formulas have been developed that meet the nutritional needs of commonly bred psittacine species. The feeding frequency and volumes for hand-rearing neonates are of particular importance (see Table 41.1 and Appendix 4A–E). Failure to provide enough food either due to inadequate numbers or volumes of feedings or due to inadequate concentration of nutrients can result in early stunting due to caloric deficiencies. The procedural challenges often depend on the stamina of the hand-feeder, because the needs of the chick must be balanced with those of the human caregiver to get adequate rest. Biphasic sleep cycles may help the

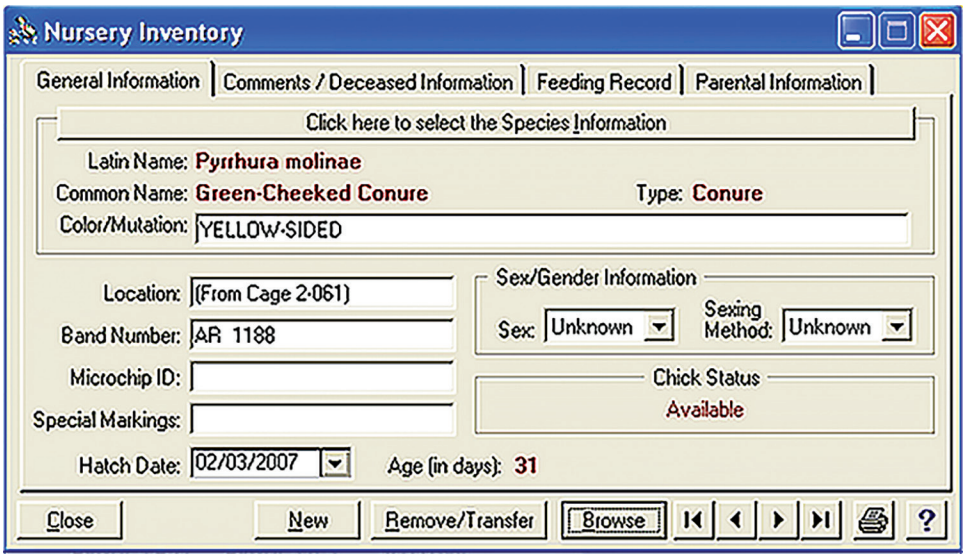

FIGURE 41.4 An example of a computerized record-keeping sheet for chick and nursery management data. Tabs for general information, comments or causes of death if appropriate, hand-feeding records, and parenting information can be seen. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

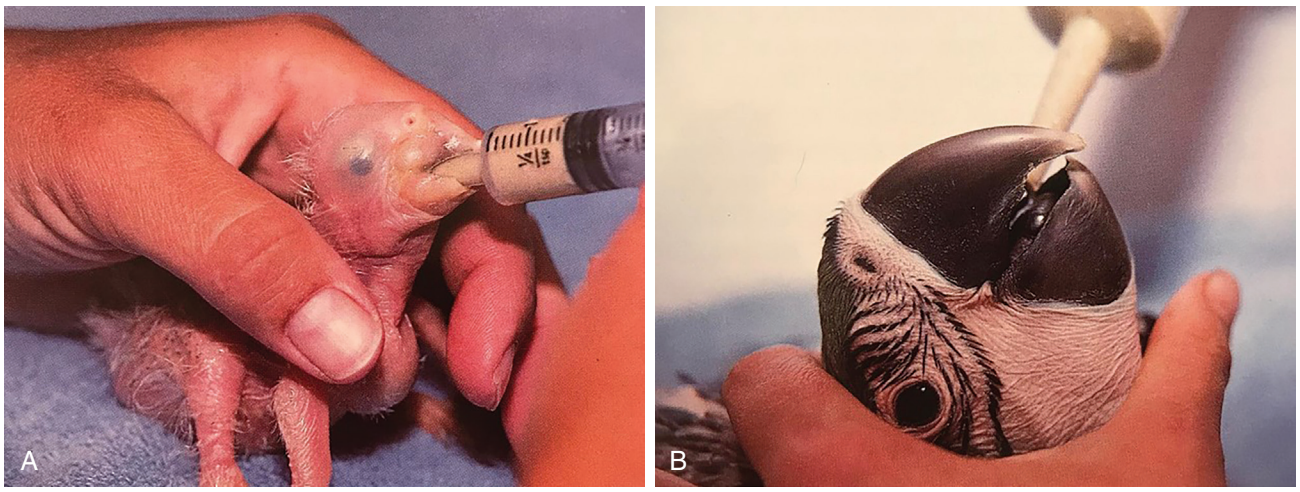

FIGURE 41.5 Hand-feeding neonatal (A) and nestling (B) macaw chicks. While stabilizing the head of the chick with the hand holding the syringe being used, risk of trauma during the pumping feeding behavior of the chick can be minimized. The chick is fed to the point of satiation, frequently filling the crop and the lower cervical esophagus. Current psittacine hand-feeding practices tend to use thicker formulas and to also not allow the crop to fully empty between feedings. (Photos from Abramson J, Speer BL, Thomsen JB, editors: *The Large Macaws*, Fort Bragg, 1995, Raintree Publications, with permission.)

human caregiver to meet a cycle of night feedings without risking inadequate sleep and associated health challenges. The prior debate as to whether the parents feed during the night has been resolved with nest cameras—the parents do feed during the night and in some species, this is done very frequently. Many highly successful hand-feeders will feed chicks every 2 hours initially with resultant rapid growth, mirroring growth rates of parent-fed chicks. Other breeders who hand-feed neonatal chicks for an entire breeding season have success feeding them using a schedule where the last feeding is administered at 11 or 12 p.m., while the first feeding the next day is provided at 6 or 7 a.m., allowing the caregiver to get adequate sleep.

Brooders

The function of a brooder is to provide an artificial environment for feeding and maintaining chicks immediately following hatching. A stable and warm environment is essential to successful hand-rearing, and newly hatched chicks should be maintained initially at incubation/hatcher temperatures,

TABLE 41.1

Feeding Frequency for Hand-Reared Psittacines

Developmental Stage	Feeding Frequency (Times per Day)
Chicks of 1–5 days old	6–10
Chicks with eyes closed	4–6
Chicks with eyes opened	3–4
Chicks with feathers emerging	2–3

Note: Chicks younger than a week may benefit from around-the-clock feeding; for older chicks feeding throughout the night is not mandatory/needed.

TABLE 41.2

Suggested Ambient Temperature Ranges for Psittacine Chicks

Recent hatchlings	33–34.5°C/92–94°F
Unfeathered chicks	32–33°C/90–92°F
Chicks with some pin feathers	29.5–32°C/85–90°F
Fully feathered chicks	24–26.5°C/75–80°F
Weaned chicks	20–24°C/68–75°F

Note that the actual temperature should be adjusted according to the needs of the individual chick.
Adapted and reprinted from: Harrison GJ, Harrison LR, Ritchie BW: *Avian Medicine: Principles and Application*, Lakeworth, 1994, Winger's Publishing.

following which temperatures can gradually be lowered as the chick matures (Table 41.2). Consistent and accurate temperature and humidity control is a key requirement for brooders, as it is for incubators. The design of these units should incorporate reliable and uniform control of temperature and humidity. A practical way to accomplish this is to have numerous brooders and to move the chicks to brooders with ever-lower environmental temperatures as they mature until they are sufficiently feathered to be maintained comfortably at room temperature. The cohousing with other chicks in such brooders can aid tremendously in both maintenance of body temperature as well as maintenance of normal hydration and provides bodily contact and auditory and visual stimulation that normally is received from siblings or parents. As such, companionship can help reduce stress-related issues, secondary opportunistic infections, and developmental abnormalities.

Many day-old chicks are initially placed individually in small cups or other plastic containers with paper towel substrates beneath them (Figure 41.6). This type of housing allows for individual attention to the chicks, while particular attention can be paid toward sanitation and cleanliness. Not all hatched chicks are placed in these types of environments, however. Some are maintained as a functional group or clutch together, and some chicks may be more comfortable if they are on shavings or other natural substrates. It is important to observe the behavior of the chicks as this helps to identify whether issues arise from an inadequate environment. Comfortable chicks will normally nestle calmly together, be relaxed, not show any panting, and will be warm to the touch.

FIGURE 41.6 Chicks are shown housed in a brooder, which provides uniform temperature and humidity for them at their young age. Room lighting is maintained dim. Separate groups or clutches can be housed within the same brooder, as demonstrated with the individual chick on the *left*, a clutch of two *centrally*, and a clutch of three on the *right*. Shared containers and brooders can facilitate early neonatal socialization development. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

Chicks that are hypothermic will be lethargic and feel cool to the touch. Hyperthermic chicks, on the other hand, will often be restless, redder in color, and will vocalize more. Most parrot species are nest cavity breeders, and their chicks generally are not exposed to much natural sunlight during the early aspects of their lives. In addition, providing a darkened recess into which a chick can retreat is consistent with their natural biology, and recommendable. As a result, it is recommended to maintain the lighting of the nursery and brooder environment comparatively dim, until the chicks become more developed and active.

An air circulation system with a low rate of air exchange or a passive airflow/heat delivery system is believed to be desirable to maintain an optimal brooder environment for newly hatched psittacine and other altricial chicks. A higher air turnover is more commonly used when managing precocial chicks.[7] Proper brooder temperature is essential to the well-being of the chick, especially if housed singly. A brooder that is too hot can result in dehydration, delayed gastrointestinal transit times, stunting, and other problems. A brooder that is too cold can also cause delayed gastrointestinal transit problems, while inadequate humidity is a common contributor to dehydration-related issues. Generally, humidity is maintained as high as possible with newly hatched altricial chicks and is decreased proportionately to common room conditions as natal down and contour feathers emerge. Brooders should be nonporous and easy to clean and disinfect. Substrate material that the chicks are maintained on should be clean (Figure 41.7). The ability to provide stable footing for the growing chick is an important consideration in substrate selection, and judicious concern for possible consumption of shavings by these chicks is needed. Extremely young chicks are frequently reared on toweling or fine shavings, whereas wood shavings are more commonly used in older chicks. Nest materials that should be avoided include those from aromatic woods including cedar,

FIGURE 41.7 A clutch of young green-cheeked conures *(Pyrrhura molinae)* are housed together on commercially manufactured paper product bedding as an entire clutch, in a single brooder. At this age of development, with significantly reduced bare skin exposed, brooder temperature and humidity are reduced as compared to what the chicks were maintained at while younger. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

redwood, and eucalyptus shavings, as well as soil, peat, and moist leaves, due to their potential to promote contamination and overgrowth of *Aspergillus* spores more easily as well as irritate the respiratory epithelium.

Diets

There are several formulated diets designed for hand-rearing psittacine chicks. These products are easily obtained from commercial bird retail stores or directly through online ordering sources in most parts of the world. Commercially manufactured hand-feeding products are utilized much more frequently in psittacine aviculture than home-made diets and recipes at the present time. Commercial formulas generally contain 16% to 26% protein, 3% to 16% fat, and 2% to 10% fiber. Some selected commercial diets and their compared guaranteed analysis are displayed in Table 41.3. Hand-feeding formulas should always be prepared fresh at the time of each feeding, using water heated to a temperature of 40°C to 41°C (103–105°F), according to the manufacturer's recommendations (Figure 41.8). Formula should be heated and mixed well, with particular attention to allowing uniform heat throughout it, as opposed to pockets that may be hotter than others, as may be seen in microwave-heated formula that is not stirred well before use. Excessively liquid diets can easily predispose to caloric deprivation of the chick. Excessively thick diets or cold formulas may predispose to delayed gastrointestinal transit time, dehydration, and secondary problems should the chick not already be in acceptable homeostasis (Table 41.3). Both extremes can result in stunting, or delayed growth, in the chicks, as well as secondary opportunistic bacterial and fungal infections, although thinner diets with reduced caloric content tend to pose greater risk in most opinions.

Hand-Feeding Equipment and Technique

Most psittacine chicks will have a variable degree of a feeding or "pumping" reflex. In most circumstances, the beak does not need to be held during hand-feeding, and by doing so, a hand-feeder may increase the risk of iatrogenic trauma to the immature beak tissues as a result of inadvertent pressure or bruising. Instead, by stabilizing the bird's head with the hand

FIGURE 41.8 Preparation of hand-feeding formula for a group of psittacine chicks. Note the relatively thick appearance of the mixture. This can be functionally made thinner if needed by adding a small amount of pancreatic digestive enzymes to the mixture, while retaining its total caloric content per milliliter. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

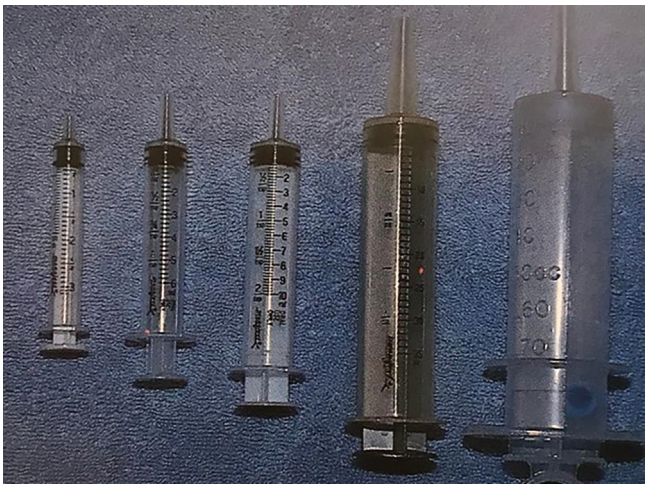

FIGURE 41.9 Catheter tip syringes of a variety of sizes that may be used for hand-feeding. Here, 3, 6, 10, 35, and 70 mL syringes are shown. In some circumstances, catheter-tipped syringes may also be used. (Photo from Abramson J, Speer BL, Thomsen JB, editors: *The Large Macaws*, 1995, Raintree Publications, with permission.)

holding the syringe, there will be reduced risk of injury (Figure 41.5). Variably sized luer-lock and catheter tip syringes (3–60 mL) are commonly used for hand-feeding psittacine chicks (Figure 41.9). Red rubber catheters or other soft rubber tubing can be used for tube or gavage feeding, if needed. Alternatively, manufactured metal gavage tubes can be used for feeding psittacine chicks. All items should be carefully cleaned and disinfected after use to minimize transfer of infectious disease agents as well as opportunistic contaminants.

The specific hand-feeding techniques that are used are aimed at supporting the head and neck of the bird, soliciting a feeding reflex, and delivering formula at a rate consistent with the swallowing rate of the chick. It is important to support the chick and feeding syringe concurrently, in a manner that prevents bruising or trauma to the pharyngeal tissues, or the rictal phalanges of the developing maxillary beak as traumatic or bruising injuries can lead to asymmetrical beak growth, resulting in lateral beak deformities or other problems (see also Chapter 31). A common, but currently outdated, requirement for hand-feeding young parrots was to allow the crop to completely empty between feedings. This practice predisposes many chicks to hunger, stress, inadequate caloric intake, and stunting. Parent-fed psittacine chicks are known to vocalize for parent attention and feeding prior to complete emptying of their crops. The more current hand-feeding techniques attempt to simulate this way of feeding and do not allow the crop to be empty in between feedings.

The volume of hand-feeding formula to be fed is dependent primarily on the crop capacity of the chick. A general rule of thumb is to feed approximately 10% of the chick's body weight with each feeding. Typically, the crop is filled to or close to the point of visualizing the formula coming up the upper cervical esophagus, which starts at the caudal aspect of the oral cavity and ends at the crop, down the right side of the neck. There is no specific requirement for feeding on the right side of the bird's mouth, contrary to common and popularly held belief (Figure 41.10). The frequency of hand-feeding also varies considerably depending on the species and age of the chicks but is dictated primarily by the chick's crop motility and growth rates (see Table 41.1 and Appendix 4A–E). The hand-rearing of some species, however, remains challenging. An excellent source of additional hand-rearing information for a large range of avian taxa is *Hand-Rearing Birds* by Duerr and Gage.[8]

The biggest variables in technique details are with the schedule of feedings and the percentage of solids of the food or formula, which influences caloric content. Monitoring the chicks while hand-feeding them will provide clues as

FIGURE 41.10 One common myth about hand-feeding young parrot chicks is that they must be fed from one side (typically the right) as opposed to the other because the cervical esophagus often lies on that side. In these two recently fed chicks, the filled crops and lower cervical esophagus can be seen on opposing sides of the necks. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

BOX 41.1 EVALUATION OF A CHICK'S WEIGHT

Chick weight at X days of age divided by "normal" weight for X days of age × 100 = Percentage of "normal"

to whether they are receiving adequate nutrition. Properly fed chicks will not beg constantly to be fed but are rather relaxed and will nestle together. They will be full-bodied and not appear desperate at feeding time. In addition, it is recommended to monitor chick weights during hand-feeding and to compare with established normal developmental parameters for the species as a point of reference, particularly if the hand-feeder is less experienced with a particular species.[5,9]

Parent-reared chicks are typically fed fluids along with the ever-increasing size of chunky foods by their parents rather than a liquid diet. An innovative aviculturist found this to be the secret to reducing intestinal stasis in palm cockatoo *(Probosciger aterrimus)* chicks, generally believed to be one of the most challenging psittacine chicks to artificially rear. This aviculturist developed a mixture of dried corn, nuts, seeds, and other grains, which was processed at home and fed to the chicks, initially starting with a finely ground mixture and gradually increasing the particle size to a chunkier mixture once the chicks matured.

One manner of utilizing a set of normal weight gain data in monitoring chick growth is illustrated in Box 41.1. This calculation can be serially evaluated during the hand-feeding process to assess if the weight gain represented by grams corresponds with this chick's comparison with normal. By not only monitoring the daily gain in grams for the hand-fed chicks but also monitoring the chick's relative percentage of normal, the hand-feeder is better positioned to detect developmental anomalies earlier. As a result, management changes can be made in a timelier manner, if needed, to have more opportunity and time to guide the chick's development back to normal. This highlights the importance of comparing the relative weight gain of chicks against a set of normal data for the species, as this may help a hand-feeder to identify subclinical developmental deficits that may otherwise remain undetected in a chick that is gaining weight (Box 41.2 and Figure 41.11). Appendix 4A–E present daily weights, growth rates, and food consumption for commonly bred psittacine birds.

Weaning And Fledging

Weaning refers to the maturation of a chick to the point where it can feed on its own, maintaining its body weight, often for a defined period of days to a few weeks. The weaned bird may or may not be fully fledged (i.e., capable of flight and leaving the nest) and will often still require parental and flock social interactions for continued acquisition of a full repertoire of adult behaviors. The age of fledging is variable among the many species of (psittacine) birds. In general, the larger the species, the longer the weaning and fledging period will be. As the chicks develop, their inquisitiveness, contour and flight feathers, and motor skills develop (Figure 41.12). During this key developmental time, fledgling chicks should be offered a variety of foodstuffs that help them to learn to eat. In general, the maintenance-type diet that is planned for these birds is the primary "weaning" food offered. During the weaning period, birds are allowed to become more active, to socialize and interact with other conspecifics, or even individuals of other species, when appropriate (Figure 41.13). They are also allowed to develop their foraging skills, to learn to accept different food items, and to still have a comfortable nesting environment to retreat to. Hand-feeding formula is still offered, but should the chick reject the feeding, no further efforts should be made to forcibly feed this. Ultimately, chicks will gradually accept less hand-feeding formula, to ultimately reject hand-feeding entirely. Some of the time-honored, but by many current standards antiquated, forced weaning techniques described in the past can be quite stressful to parrot chicks, resulting in secondary problems including but not limited to starvation, chronic stress, and increased susceptibility to opportunistic infections. Furthermore, these force-weaning techniques often downplay the importance of socialization, physical activity, and exploration aspects of the weaning and fledging period for the chick. During the fledging and weaning period, a normal drop in body weight of up to 15% can be observed in most parrot species. Typically, this weight is

BOX 41.2 AN EXAMPLE WHERE RELATIVE STATUS OF NORMAL DEVELOPMENT PERCENTAGE IS USED IN THE RECOGNITION OF AND MANAGEMENT OF STUNTING IN A BLUE-AND-GOLD MACAW *(ARA ARARAUNA)* CHICK

At 7 days old	Weight = 44 g Difference = 97% of normal	"Normal weight" = 47.3 g
At 14 days old	Weight = 89 g Difference = 68% of normal	"Normal weight" = 130.3 g
Management corrections: Increase from four feedings per day to eight per day, maintaining the same volume per feeding. Increase brooder humidity.		
At 21 days old	Weight = 229 g Difference = 75% of normal	"Normal weight" = 306.6 g
At 28 days old	Weight = 498 g Difference = 95% of normal	"Normal weight" = 522.2 g

Using a calculation of relative percentage of normal, the chick is identified as dropping from 67% normal at day 7 of age to 68% of normal at day 14 of age. Following management corrections, the chick is restored to 95% of normal weight by day 28.[10] Management changes that were instituted are inserted at the point of their implementation at day 14 and include an increase in feeding frequency of feeding but maintenance of the same volume per feeding, and an increase in brooder relative humidity.

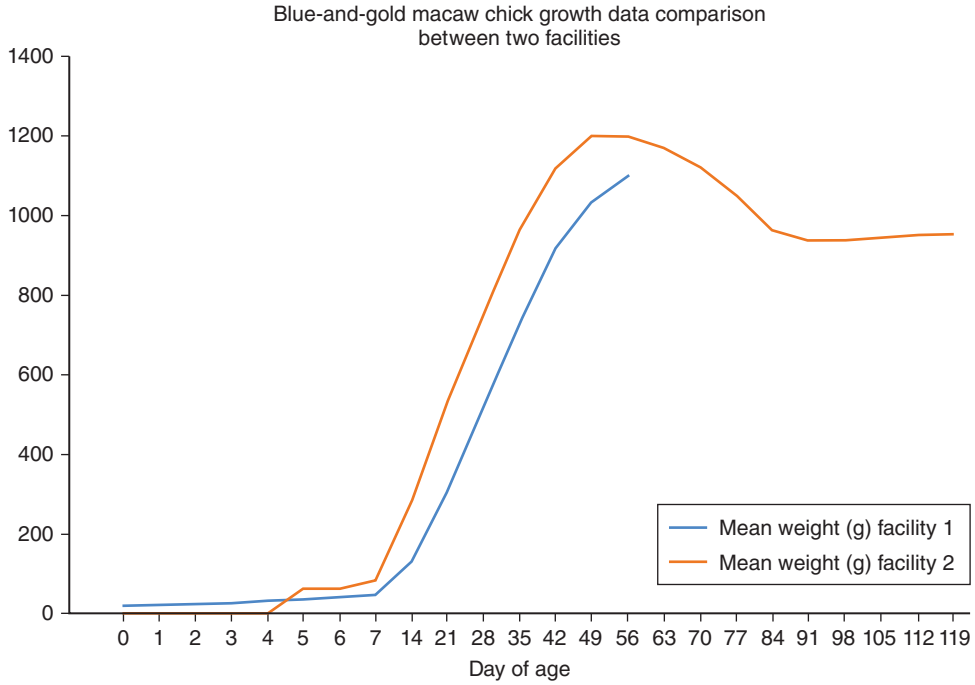

FIGURE 41.11 Example hand-feeding data and mean body weights by age for one species (blue-and-gold macaw, *Ara ararauna*) from two different avicultural sources. In source 1, the chicks were hand-raised from day 1, whereas in source 2, they were hand-reared starting at day 5 or older. Although the growth curves are similar in overall appearance, the chicks of facility 2 weigh more at any specific day of age as compared to those of facility 1. The greater the disparity from an optimal weight at any point of development, the greater the probability of the development of stunting-associated problems.[11,12]

FIGURE 41.12 Normal growth in scarlet macaw chicks *(Ara macao). From left to right:* 19 days old (315 g), 48 days old (1045 g), 17 days old (186 g), and 37 days old (965 g). regained over the next 6 months to a year of life for the medium-to-larger parrot species and earlier for the smaller species. During these formative months, socialization by the bird's parents or other conspecifics is important and likely plays a key role in the learned behaviors as the bird approaches adulthood and beyond (see also *Current Therapy in Avian Medicine and Surgery*, Volume 1, Chapter 5).

PEDIATRIC PROBLEMS IN DEVELOPING PSITTACINE CHICKS

It is important for the practitioner, and even more so for the avicultural veterinarian, to be familiar with the equipment, procedures, and techniques used during artificial incubation and hand-rearing and understand the natural biology of normal chick development. An understanding of the differences between a normal chick and a chick that is developing problems will enable timely recognition and implementation of a successful intervention plan. This level of requisite familiarity goes to a species level: even closely related species may develop in a

different way, and these differences can limit the ability of the caretaker, or the veterinarian, to act in a timely manner.[7,9,13]

Clinical Examination

Several parameters can be used to assess the health and the general condition of a chick, although monitoring its growth and weight gain rates generally is the easiest way to detect abnormalities.[9]

After a chick has passed the first critical weeks of its life, a more careful and thorough examination can be performed, which will increasingly resemble the examination as performed in an adult bird. In fact, one of the biggest advantages of these young birds is their fast growth, which allows them to approximate their adult size in just a few weeks and makes life easier for the avian veterinarian.

Physical examination of the chick can typically be performed with minimal restraint. While performing the examination, it should be ensured that the chick is kept warm. The crop should be palpated at the start of the examination. If food is present in the crop, the chick should be handled with care to reduce the risk of regurgitation and/or aspiration.[14]

The clinical examination of a young chick follows the same manner as is used for any veterinary clinical examination and consists of three parts: (1) obtaining a meaningful history; (2) performing a thorough physical examination, including initial observations of the environment and the chick's behavior; and (3) selecting appropriate ancillary tests, if and when indicated. While the desired information collected during the clinical examination of a young bird does not differ much from adult birds or across species, the importance attributed to the various parameters can vary considerably.[7,9,13]

Signalment

Familiarity with the species and its normal developmental phases is important, since different species, even when belonging to the same taxonomic order or family, may develop differently. A complete and accurate description of the animal is therefore important, as well as double-checking client-reported information. The owner or caretaker of a young chick may belong to one of three main categories, that is, aviculturist, dealer (which includes owners and employees of pet shops), and private owners who have recently acquired a young bird. Presently, in several countries and individual states within the United States, it is forbidden to sell unweaned birds. This rule is often ignored and violations are rarely enforced. As a result, in practice, it is still common to have inexperienced owners present these immature chicks for veterinary care. Clients will have different experiences, perspectives, and expectations, and unweaned chicks may particularly be at risk to develop management-related health problems in the hands of an inexperienced owner.

History

The history of a young bird should include details regarding the living environment, diet, medical history, and—if possible—the reproductive history of the parents. A thorough reproductive history of the parents and of the whole breeding center, if possible, may help uncover inappropriate management procedures, nutritional errors, and possible presence of subclinical infectious diseases circulating in the environment. Using this information, the veterinarian may be able to follow a more targeted approach, limiting the selection of diagnostic tests to merely include those that are indicated in the given situation.[7,9,13] It is also important to evaluate whether and what medication is currently given as this can affect the course of disease and the ability to identify pathogens involved with the disease process. Especially aviculturists, breeders, and pet retailers will frequently have initiated a treatment based on clinical signs they have observed or presume to be present prior to visiting a veterinarian. This is especially the case in countries where antibacterials are available as over-the-counter drugs, though this type of practice is changing in many countries. In 2015, ultimately taking in effect in 2018, the state of California was the first state in the United States to ban the over-the-counter sale of antibacterial drugs and require a veterinary prescription for their use.

The history should also include a description of the main or presenting complaint(s). In many cases this can be challenging, as clinical signs are often not as clear in birds as they are in their mammalian counterparts. This is often attributed to the fact that birds need to hide signs of disease to avoid becoming an easy target for predators. For altricial chicks, however, masking of clinical signs is typically not needed.[13] This reality, to a reasonable degree, could simplify certain aspects of the diagnostic process.

General Appearance

Assessing the general appearance of a young chick can be challenging due to the differences in the development across species.[9] As a result, mistakes can easily be made when assessing the age of a chick, the development of its plumage, and recognizing the early signs of stunting.

Parameters that should be taken into consideration, when performing a physical examination on a young bird include the following:

- **Symmetry—**Any asymmetry should be noted. Some asymmetries may, however, be normal. For example, the crop predominantly lies on the right side, although the reverse can also be seen (Figure 41.10).
- **Muscle condition and hydration status—**Using one of the standard scoring methods, which typically involve a 5- or 9-point scale system in birds, the muscle condition score (a term intended to be more specific than an overall body condition score) can be assessed. It should be kept in mind that, in young chicks, muscle mass loss is best assessed at the epaxial musculature over the back, rather than at the pectorals. Hydration status can generally be assessed by evaluating skin turgor, with loss of skin elasticity often being the first sign of dehydration. Dehydration can occur quickly in a chick. Clinical signs of dehydration may include a dull red appearance of the chick's skin and there may be a decrease in the amount of urine being passed.[7,9,10,13]
- **Mentation and reaction to environmental stimuli—**Chicks should normally be bright and alert and raise their head in response to any activity that could signal food. Generally, behavioral parameters are assessed qualitatively and should take into account species-specific responses. Some behaviors, such as the reaction toward a perceived predator, are innate and species-specific. As a result, the reaction of a young macaw facing a human (predator) will be different from the one displayed by a cockatoo of the same age. Comparison of the behavior with other chicks

FIGURE 41.14 (A) A newly hatched Buffon's macaw chick *(Ara ambiguus)*, resting appropriately on a cloth substrate. There is symmetrical placement of the feet, a vertical angle of the tibiotarsi, and relaxed posture of the wings. (B) A stunted 12-day-old Calico hybrid macaw *(Ara chloropterus* × *Ara militaris).* This chick weighs approximately 68% of projected normal developmental weight. Note the inability to stand plantigrade and bear weight on the feet, elevated wing posture, and that the left leg is abnormally folded inward beneath the body of the chick. (A, Photo courtesy Brian Speer. From Abramson J: Captive breeding and conservation. In Abramson J, Speer BL, Thomsen JB, editors: *The Large Macaws*, Fort Bragg, 1995, Raintree Publications. B, Photo courtesy Brian Speer.)

from the same species and age may be useful in case of uncertainty of the normalcy of the response.[7,9,10,13]

- **Posture** is also important and can vary somewhat among species. Nestling chicks will sleep most of the time and are most active when hungry. They may sleep in any position and will generally sit on their hocks rather than on their feet until weaning. When evaluating the posture, one should specifically look for signs of incoordination, abnormal limb placement, leaning toward one side, and inability to lift the head properly (Figure 41.14). All of these signs indicate possible physical weakness, musculoskeletal problems, or neurological problems.

Physical Examination—Vital Signs

During the hands-on physical examination, several vital parameters should be evaluated in relation to presenting complaint, history, and current health status. The most important parameters that the veterinarian should evaluate include the following:

- **Body weight—**The body weight is important data to gather on any bird. However, equally—if not more—important is the growth rate of the chick, and how it compares to published ranges for chicks of the same species and age or to observed growth rates of chicks of the same species and age within the same breeding facility.[9,12,13] Typically, four phases can be recognized in the growth curve of altricial birds: (1) an initial lag growth; (2) a steady log phase; (3) a plateau phase just prior to weaning; and (4) a weaning phase, during which the chick loses some weight as a result of loss of body fat and gain of muscle mass (Figure 41.11). When the growth rate of the chick deviates significantly from the curve, further evaluation to identify the underlying cause for the abnormal growth is important, even in the absence of clear signs of disease.[13]
- **Body temperature/environmental temperature—**While measuring the body temperature is usually not considered a useful tool in the health assessment of a bird, the environmental temperature plays a critical role in (particular stages of) the life of altricial chicks. As a result, it is deemed important to inquire about the housing conditions and environmental temperature and assess whether these are appropriate for the chick, given its age. During the examination, a chick that is too cold may feel cold to the touch, often will have gut stasis, and will be relatively inactive (Figure 41.15). A chick that is too hot may separate from other chicks, may be breathing at a more rapid rate, and feel excessively warm to the touch.
- **Head and neck—**The head and face should be evaluated for symmetry. The eyes should be assessed for size, position, and presence of discharge. Sunken eyes and microphthalmia occur more frequently in birds than in mammals and may potentially be related to toxicosis. The beak and nares should be evaluated for symmetry and deformities, such as scissors beak and prognathism, which are still common issues in hand-reared chicks (see also Chapter 31). Conformation of the nares and the presence of nasal discharge must also be considered.[9,13] The oral cavity should be examined for moistness and the presence of plaques or other lesions.[14]
- **The crop (ingluvies)** is a tubular organ which is an enlarged part of the cervical esophagus. Among bird species and their taxonomic orders, there are significant variations

FIGURE 41.15 Two hybrid macaw chicks *(Ara chloropterus* × *Ara militaris)* being supported and monitored in their brooder. These chicks were initially stunted and hypothermic, and this photo was taken after the second day of corrective husbandry maneuvers. The relative humidity and temperature in Fahrenheit are displayed on the portable digital monitor in the *left upper corner*. The chicks were moved from individual containers to a common shared one, and toweling was used strategically to help them rest in a more normal posture. Additional humidity is being facilitated for the chicks by the use of water baths with cotton balls in the *upper right* and *lower left corners* of the photo. (Photo courtesy Brian Speer.)

FIGURE 41.16 Galah chick *(Eolophus roseicapilla)* that is 8 to 10 weeks of age, weighing 157 g. This body weight is approximately 50% of normal weight for this age and species, and significant stunting is present. The crop is enlarged, and palpably thin walled. Although it is capable of emptying, the time required to do so is significantly delayed. The clinical complaint of slow crop-emptying time was the purpose of presentation by the hand-feeder. (Photo courtesy Brenna Fitzgerald.)

in crop size and structure. Depending on its anatomy, it is either classified as a rudimentary crop (e.g., Anseriformes) that is long and narrow and only occupies a small space; as a "false crop" (e.g., griffon vulture, *Gyps fulvus*) that presents as a simple diverticulum of the esophagus; or a "real crop" (e.g., Galliformes) that is well developed and has a characteristic round-shaped bilobed enlargement.[15] Other species (e.g., owls, ostriches, cassowaries, kiwis, rheas, and many piscivorous species) lack a crop, and if a crop is present, this must be observed for wall muscular contractions. In addition, inquiries should be made on when the chick was last fed and how much was fed, as this will help to determine whether the crop is emptying normally.[14] Additionally, the skin covering the crop should be palpated, while paying specific attention to the crop wall texture and thickness (Figure 41.16). These are good indicators of the health of the crop, as well as of the hydration status and overall condition of the chick.

- **Trunk and limbs—**The chick's body should also be inspected for symmetry. In addition each limb and joint should be carefully palpated for abnormalities in angulation, deformities, swelling, bleeding, bony protrusions, obvious fractures or joint luxations, range of motion, or muscular atrophy. The condition of the feet and positioning of the digits should also be evaluated, and the vertebral column palpated to assess whether deviations or deformities are present. In the author's experience, kyphosis or scoliosis seems to be a common spinal deformity in young psittacines.[13]
- **Heart rate—**The heart rate in birds ranges from 50 to >615 bpm.[16,17] Most psittacine birds will have a heart rate over 250 bpm which can be difficult to accurately count and assess. Practical and reliable ways to measure the heart rate are the electrocardiogram (ECG) and echocardiography, although in the latter case the ultrasound should be equipped with a Doppler function.[18] The veterinarian will therefore more often evaluate the rhythm, rather than the raw number of beats per minute. A Doppler flow detector can be a useful tool for this purpose as well and seems to cause less stress for the patient. A pulse can be appreciated by palpating or placing a Doppler probe on the basilic (or ulnar, or wing), the jugular vein, or over the caudal sternum. In addition, the heart should be auscultated for the presence of murmurs, though these can be particularly difficult to appreciate if the heart rate is high.
- **Respiratory tract auscultation—**Auscultation is an important component of the clinical examination of every species, but auscultation may be problematic in young birds due to their relatively smaller size. One issue may be the stethoscope used: the standard 45-mm bell of instruments used for dogs and cats is far too large and heavy to perform an accurate and sensitive auscultation in a young and small bird. Therefore stethoscopes specifically

designed for pediatrics or neonatology, with a 15- to 25-mm bell, should be used. Unfortunately, even with these smaller stethoscopes it can be difficult to locate the sounds precisely. In the experience of the authors, whenever an abnormal sound is diagnosed with a simple auscultation, the abnormal finding should be investigated with the help of additional diagnostic maneuvers, including—but not limited to—radiographic or computed tomographic (CT) imaging. An altered respiration pattern may also be a normal response to stress in some parrot species. For example, chicks belonging to the genus *Pionus* will deepen and accelerate their breaths when fearful. While this observation does not exclude the presence of a respiratory disease process, it must be taken into account as a normal response to a stress.[13]

- **Abdominal region—**Although birds do not have a true abdominal cavity, the term abdomen is often used to indicate the body cavity region that contains the gut (intestinal peritoneal cavity), the liver (hepatic peritoneal cavities), gonads, spleen, and kidneys. The abdomen should be evaluated for signs of distention, deformity, displacement, symmetry, and bruising (Figure 41.17). In chicks, the umbilicus should be inspected thoroughly: omphalitis is a well-known disease in young poultry,[19] and altricial chicks can suffer from an umbilical infection, which can cause severe and generalized disease. In case of omphalitis, the umbilical scar may appear moist, exudative, and not completely scarred.

In addition to the aforementioned parameters, there are many other indicators of adequate health and growth that should be taken into consideration when assessing the physical condition of a chick. Some of these parameters can be specific for a certain species (e.g., ability to swim in water birds), whereas others are more generalized across species.

FIGURE 41.17 Normal appearance of the abdominal region of a newly hatched psittacine chick. The umbilicus appears clean and dry and is not protruding. Transillumination of the abdominal region may reveal the still-absorbing yolk sac within. The ventriculus is visible cranial and left laterally positioned to the umbilicus, and intestinal loops can be seen in the caudal ventral abdominal region. (Photo courtesy Steve Duncan, http://www.avianresources.com/.)

FIGURE 41.18 Normal developmental phases in blue-and-gold macaw chicks *(Ara ararauna). Clockwise from the top:* 76 days old (1010 g), 33 days old (924 g), and 19 days old (456 g). (From Abramson J: Captive breeding and conservation. In Abramson J, Speer BL, Thomsen JB, editors: *The Large Macaws*, Fort Bragg, 1995, Raintree Publications, with permission.)

Veterinarians are recommended to pay specific attention to at least the following parameters:

- **Normal plumage development**—Normal plumage development can vary considerably among species. Even within the order Psittaciformes, the time at which the normal plumage develops will vary according to the size of the species (Figure 41.18). Generally, the smaller species will develop, wean, and fledge at a younger age, with their plumage maturing quicker and sooner than larger species. However, even for species that are of an approximately similar size (e.g., cockatoos and macaws), differences can be noted in plumage development.
- **Feeding response—**The feeding response is largely an innate behavior and is considered a very important parameter to observe when assessing the young chick. There are considerable species differences in the way that adult birds will feed their chicks, as well as the way in which chicks respond to the environmental stimuli signaling the presence of food. For example, chicks of most Columbiformes (pigeons and doves) will not open their mouth while awaiting their parents to feed them, but they will rather introduce their beak into the parent's throat and "suck" the food directly from their parent's crop. Within the order Psittaciformes, macaw and *Eclectus (Eclectus roratus)* chicks are known to show a strong feeding response, literally "pumping" with their neck and head, while Grey parrot *(Psittacus erithacus)* chicks display much milder feeding behaviors. These species differences must be taken into account when assessing the feeding response, as a feeding response that is weaker than normal could be a nonspecific sign of disease. Hence, awareness of and familiarity with normal feeding behaviors for the species and individual are important.
- **Normal production and appearance of droppings—**The urofeces of chicks differ from the feces of the adult bird, particularly when the chicks are being hand-fed. The higher water content of the hand-feeding formula results in relatively loose feces and a relative increase in the amount of urine passed. The color of the feces may vary,

depending on the (hand-feeding) diet fed to the chick. Depending on the type of substrate on which the chick is kept, it may be more or less difficult to evaluate the quality of the feces: most beddings are hygroscopic and will absorb most of the water from the stools, making them appear drier than they actually are. As the chick grows and develops, the feces will gradually start to resemble the droppings of adult birds, thereby facilitating the evaluation of the droppings as may be expected with adults.

Routine Evaluations of the Chicks in the Nursery

Pediatric evaluations not only involve the medical assessment of single ill chicks but also the examination and monitoring of the other chicks in the nursery. The performance of the entire population within a nursery can provide insight into to management of the facility and identify possible opportunities for change that could reduce the prevalence and incidence of presenting problems. Regardless of the nursery location being in a breeding center, in a zoo, or in a private breeding collection, routine evaluations of the nursery will allow the clinician and aviculturist to obtain a detailed history of every chick and identify deviations from normality. These in turn can lead to earlier intervention, quicker isolation of potentially contagious conditions, and more successful treatment outcomes.[13]

Following discussion with the aviculturist/breeder, the veterinarian may consider testing the chicks, even the clinically healthy ones, for the pathogens most commonly encountered in the species of interest. Knowledge of pathogens that have been identified as causing problems in the facility in the past is also helpful in selecting which tests to perform. Common pathogens that are known to cause disease in nurseries include *Chlamydia psittaci*, pathogenic and opportunistic bacteria and fungi, and some select viruses including psittacine beak and feather disease (PBFD) virus, avian orthobornavirus, and polyomavirus. Testing the healthy-appearing chicks may highlight the presence of these primary pathogens, which can aid in facilitating appropriate flock management interventional actions. In addition, environmental opportunistic pathogens can be identified and more proactively managed. Water and food used in the nursery may also be routinely tested for the presence of potential opportunistic pathogens, or if indicated. There are reports of pathogens transmitted through the food, such as *Bacillus cereus* infections.[20,21] Other pathogens, such as *Pseudomonas aeruginosa*, *Cryptosporidium*, and influenza A virus, are associated with water sources.[22] Other bacterial disease outbreaks in a nursery, such as infections with methicillin-resistant *Staphylococcus aureus*, may be linked to human infections.[23–25]

The Critically Ill Chick

Young chicks can decompensate and die very quickly when seriously ill. For this reason, symptomatic treatments often must be started immediately after identification of true illness in a chick. In most cases, test results will be available well after when it becomes clear whether the initial course of treatment is successful or not. Nevertheless, appropriate diagnostic samples should be collected before initiating treatment as it allows treatment to be adjusted based on the obtained results, as well as provides a presumptive or working diagnosis for other chicks with similar clinical signs in the same facility.[13]

Typically, critically ill chicks will show signs of hypothermia and dehydration. Dehydration can occur quickly in a chick, and, if chronic, can potentially lead to several health problems, including but not limited to the development of constricted toe syndrome, stunting and its sequelae, and some forms of renal disease. Clinical signs of dehydration may include a dull red appearance of the chick's skin and there may be a decrease in the amount of urine being passed. If detected, rehydrate the chick by feeding electrolyte solutions, by subcutaneous fluid administration, but most importantly by contact rehydration with other clutch mates in an environment with increased humidity. Typically, a critically ill chick will look dehydrated and cold and will feel cold to the touch. Further clinical signs that are very common with sick chicks are inability to pass urofeces, delayed or lack of crop emptying, a crop with gas being produced within it or swallowed, and oculonasal discharge.

Most commonly fluids will be administered subcutaneously, and this can be safely done also in relatively small chicks, but some cases may require intravenous (IV) or intraosseus (IO) fluid administration. Fluid deficit can be estimated by the clinical status of the patient:

1. Loss of skin elasticity corresponds to an approximate 5% dehydration;
2. Skin tenting and loss of the normal sheen corresponds to 10% to 12% dehydration;
3. A depressed, or comatose chick with signs indicative of shock corresponds to 12% to 15% dehydration.[26]

Since bacteria can have a role in many of the pediatric cases encountered, regardless that many are secondary or opportunistic pathogens, initial antibacterial treatment may be indicated. Efforts to restore hydration and provide warmth are often indicated. In some settings, antifungal treatment may be indicated to avoid opportunistic overgrowth or invasion by yeast or other fungi.

Food is often offered with normal feeding procedures if the chick can pass it from the crop and through the remainder of the gastrointestinal (GI) tract. Risk of regurgitation or excessive crop distension should result in alterations in the volumes offered, the frequency of feedings, and/or the caloric density of the formula being used.

In case of crop stasis, the crop can be washed with warm saline solution (NaCl 0.9%) or lactated Ringer's solution. A small amount of saline solution may be left in the crop, after it has been carefully washed. In one author's experience, administering an infusion of fennel seeds can also help well. This "fennel tea" can also be used as a replacement for the fluid being used to reconstitute the feeding formula, for the first days after the resolution of the stasis. A thick mixture of hand-feeding formula may be used in some cases, particularly where it is assessed that meeting the chick's caloric and nutritional needs is an immediate need. Thick formula can be rendered more functionally thin by the addition of a small amount of pancreatic enzymes. This maneuver can allow a thinner formula which may pass easier, but retains caloric density to meet the nutritional needs of the chick.[13]

PEDIATRIC DIAGNOSTICS

Clinical Pathology

In general, immature birds have lower packed cell volume (PCV) (20%–30%), lower total protein (1–3 g/dL, 10–30 g/L), and lower albumen (1–2 g/dL, 10–20 g/L) as compared to adults of their species. Higher concentrations of alkaline phosphatase are described in younger chicks. Significant and progressive increases with age in biochemically determined values are seen in total calcium, urea, creatinine, uric acid, cholesterol, glucose, aspartate aminotransferase (AST), total protein, albumin, globulin, and prealbumin.[9,27] In the Spix's macaw *(Cyanopsitta spixii)*, adult and juvenile birds differed in mean concentrations of glucose, total protein, amylase, cholesterol, and phosphorus.[27] In the orange-winged Amazon parrot *(Amazona amazonica)*, concentrations of total protein, bile acids, phosphorus, total cholesterol, low-density lipoprotein cholesterol (LDL-C), and high-density lipoprotein cholesterol were significantly higher in adult compared with juvenile birds, while uric acid concentration was significantly higher in juveniles.[28] In wild nestling scarlet macaws *(Ara macao)*, albumin, aspartate aminotransferase, globulin, glucose, total protein, sodium, and uric acid levels increased with nestling age to adulthood.[29] Creatine kinase, phosphorus, and potassium concentrations decreased with age to adulthood.[29] Calcium concentrations did not change between nestlings and adults.[29] Similar observations have been reported in other avian species, including white storks *(Ciconia ciconia)*,[30] captive white-naped cranes *(Grus vipio)*,[31] ring-necked pheasants *(Phasianus colchicus)*,[32] and free-living Swainson's hawks *(Buteo swainsoni)*,[33] and likely reflect physiologic and developmental changes as nestlings mature.

Hematologically, young birds typically will have higher estimated or total white blood cell (WBC) counts as compared to their adult counterparts. WBC, mean cell volume (MCV), relative and absolute heterophil percentage, and relative and absolute monocyte percentage progressively decrease with age and relative and absolute lymphocyte counts increase with age.[9,27] Young ostriches *(Struthio camelus)* had significantly lower concentrations of hematocrit, hemoglobin concentration, calcium, and magnesium, and higher levels of total protein and potassium, than the adult individuals.[34] Similar hematologic observations have been reported in white storks,[30] captive white-naped cranes,[31] and ring-necked pheasants.[32]

Microbiology

Although normal fecal flora is generally presumed to predominately include gram-positive bacterial organisms (*Lactobacillus*, *Corynebacterium*, *Staphylococcus*, nonhemolytic *Streptococcus* and *Bacillus* spp.), the presence or absence of other organisms does not necessarily represent infectants or the absence of infection. Hand-fed chicks establish their intestinal microflora by ingestion of bacteria present in their environment and diet. It has been suggested that the prophylactic usage of antifungal drugs and the supplementation of *Lactobacillus* is not necessary for establishment of what should be deemed to be normal microflora.[9] Cytologic as well as microbiological isolates need to be interpreted considering the clinical setting, prior to being used solely to justify and refine antibacterial treatments.[13]

Molecular Diagnostics

As with their adult counterparts, polymerase chain reaction (PCR) testing can provide rapid, sensitive, and specific identification of many pediatric pathogens. As with microbiology findings mentioned previously, PCR test results should be critically interpreted regarding the clinical presentation and the management strategies being implemented for the nursery.

Radiography

In immature psittacine bird species, the proventriculus and ventriculus typically are much larger in size as compared to their adult counterparts, and these organs may fill most of the intestinal peritoneal cavity. The hepatic silhouette, as a result, may be increased. The subpulmonary air sacs as a result are more compressed and less apparent. In immature birds, the epiphyseal centers of ossification (the avian equivalent of the mammalian growth plates) of the appendicular and axial skeleton are open and appear as diaphyseal, lucent transverse lines. In the appendicular and axial skeleton, the epiphyseal centers are open and immature.

PEDIATRIC PHARMACOLOGIC CONSIDERATIONS

There is no current pharmacokinetic data available for drugs administered to hatchlings, nestlings, or fledglings. Because of the differences between precocial and altricial chick anatomy and physiology as compared to their adult counterparts, significant differences are likely to exist, which may influence therapeutic decisions made. In humans, the absorption, distribution, metabolism, and elimination of many drugs differ among premature infants, full-term infants, older children, and adults. Similar differences have been observed at different developmental stages in domestic animal species. Many of these treatment principles, extrapolated in part from other species as well as clinical practice experience, can be in making treatment decisions.

Drug Absorption

The two factors influencing the absorption of drugs from the gastrointestinal tract are pH-dependent passive diffusion and gastric emptying time.[35] Human infants at birth have gastric pH levels ranging from 6 to 8, which decrease to 1 to 3 within 24 hours. As a result, high serum concentrations of acid-labile drugs, such as penicillin, ampicillin, and nafcillin, after oral administration in premature infants can be explained by their higher gastric pH. In birds, pH, storage function, and emptying pattern of the crop influence the drug blood concentrations.[35] In chickens and pigeons, there are indications that bioavailability of some macrolide antibiotics is reduced by *Lactobacillus* crop flora because of inactivation.[36,37] In addition, percutaneous drug absorption may be substantially increased in newly hatched birds, particularly in altricial species, as is the case with human newborn infants, because of an underdeveloped epidermal barrier and increased skin hydration.

TABLE 41.4

Leghorn Chicken *(Gallus gallus domesticus)* Fluid Volumes at 1 Week of Age Compared With 32 and 55 Weeks of Age[38]

Fluid Volume Measured	1 Week Old	32 or 55 Weeks of Age
Total body water	72.4%	52.9% (55 weeks)
Total extracellular water	61.0%	26.2% (32 weeks)
Interstitial water	52.3%	21.7% (32 weeks)
Blood volume	12.0%	6.5% (32 weeks)
Plasma volume	8.7%	4.6% (32 weeks)

Distribution

The total body water as a percentage of the total body weight in a precocial hatchling is estimated to be 30% to 40% higher than in adult birds. At the age of 55 weeks, the total body water in white Leghorn *(Gallus gallus domesticus)* females was 52.9% of body weight, whereas at 1 week it was 72.4%.[38] Extracellular fluid volume is also markedly different in young animals; the extracellular fluid volume may account for 50% to 25% in juveniles and 20% in adults. In white Leghorn chickens, total extracellular water, interstitial water, blood volume, and plasma volume changed from 61.0%, 52.3%, 12.0%, and 8.7% of body weight, respectively, at 1 week to 26.2%, 21.7%, 6.5%, and 4.6%, respectively, at 32 weeks of age (Table 41.4).[38] Generally, the distribution volume for gentamicin in juvenile mammals is 50% to 80% larger than in adult mammals.[39] The same situation can be expected in birds, regarding water-soluble drug distribution volumes.[40]

Metabolism

Drug metabolism is substantially slower in infants compared with older children and adults. Drugs that require hepatic hydroxylation and/or glucuronide formation for elimination, such as chloramphenicol, sulfonamides, and flumequine in birds,[41] are expected to have longer half-lives in nestlings than in adults. Significant differences may exist in maturation of the various pathways of metabolism between precocial and altricial birds. Generally, precocial chicks may be compared with young children, whereas altricial chicks may more fairly be compared to neonatal mammals or even premature patients, pharmacotherapeutically.[41]

Drugs and their metabolites are often eliminated by the kidney. The processes of glomerular filtration, tubular secretion, and tubular reabsorption determine the efficiency of renal excretion. These processes may take several weeks to 1 year after birth to develop fully in humans.[42] There is inconsistency among species noted in renal elimination rates of types of drugs studied in newborns. The rate of elimination of gentamycin and neomycin in calves was not influenced by age, whereas the rate of oxytetracycline elimination was reduced significantly in studies of younger calves.[43]

In addition to pharmacokinetic differences, factors related to drug efficacy and toxicity should be considered.[41] Risk of chloramphenicol toxicity is increased in a newborn infant because of immature metabolism and enhanced bioavailability. Similarly, propylene glycol, which is added to many injectable drugs, including phenobarbital, diazepam, vitamin D, and ivermectin, to increase their stability, can cause hyperosmolality in infants.[44]

PEDIATRIC PROBLEMS

Understanding the Not-Doing-Well Chick

Incubation-related problems can affect the neonate after hatch. An egg that is incubated at improper relative humidity may hatch in a state of either over or underhydration. When detected, overhydration of the newly hatched chick can be corrected by lowering the brooder/environmental humidity. Dehydration may be addressed by increasing the brooder/environmental humidity or by providing supplemental fluids. Brooder humidity can be increased by the addition of damp, warm substrates beneath the chick, allowing for increased surface absorption of fluids. Supplemental fluids can be provided by oral administration of balanced electrolyte solutions. Care must be taken with oral electrolytes, as overhydration can occur. If present, this may be recognized by the presence of ventral edema and a relatively bloated translucent appearance in the chick.

Prior to hatch, the yolk sac should retract completely into the abdomen (Figure 41.17). Prematurely assisted hatches may result in exposure of the unretracted yolk or may interrupt the process prior to its completion, leaving a poor umbilical seal. Preferably, the chick is left in its shell until all these tissues and fluids are properly absorbed. Exposed yolk sacs may be protected by a light adhesive bandage until they are completely retracted and in some circumstances, may be tied off and even removed if indicated by likely contamination or known or suspected infection. Yolk sac infection may occur either via vertical transmission or through acquired contamination and infection. Vertical transmission may be related to either ovarian or oviductal infections. Omphalitis-causing bacteria may be identified by aerobic bacterial culture of the yolk sac in a dead chick or suggested by cloacal bacterial culture of the neonate. Alternatively, other eggs from the same hen may also be cultured, lending increased suspicion of the hen's contribution to these organisms' presence by repeated isolations of the same organism. A chick may also contract a bacterial infection of its yolk sac from a contaminated incubator or hatcher or through contaminated hands and instruments during assisted hatch, hence the necessity of excellent incubator and hatcher hygiene. If diagnosed in a timely enough manner, surgical omphalectomy offers the best prognosis (Figure 41.19).

Developmental abnormalities may be visibly apparent (Figure 41.20), or there may be undetectable genetic developmental abnormalities which may affect the viability of the neonate. Parental nutritional deficiencies are well known in poultry chicks; however, these are not well documented in

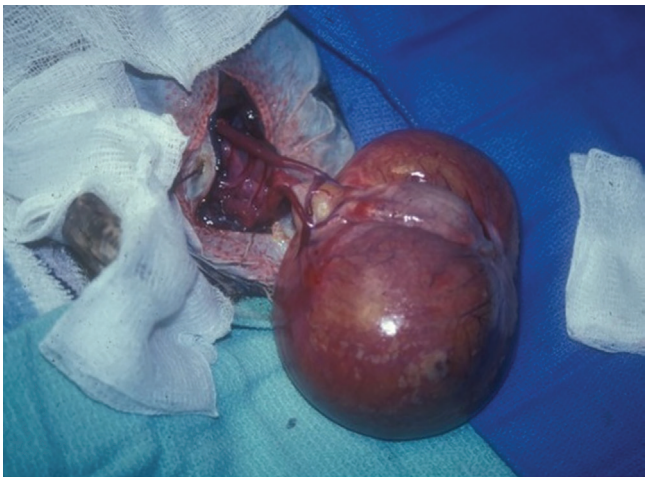

FIGURE 41.19 Surgical omphalectomy in an ostrich *(Struthio camelus)* chick. *Staphylococcus* sp. was isolated, and the infection was believed to be associated with opportunistic contamination during the hatching process, as the same organism was identified in the hatcher.

FIGURE 41.20 A large defect is visible involving the right nare, the lateral aspects of the maxillary beak, the right jugal, and the right pterygoid of this young blue-and-gold macaw *(Ara ararauna)* which was present at hatch. Although this deformity is congenital (present at hatch), its cause remained unclear. In this case, an acquired problem during incubation prior to hatch was suspected.

psittacine chicks. A lethal gene has been described and linked to the red factor gene. This gene is expressed in the F2 generation, when breeding two red factor birds together. Clinical demonstration of the central nervous system clinical signs appears around the time of weaning and continues until death.[1] Other documented congenital abnormalities include bilateral anophthalmia in a budgerigar *(Melopsittacus undulatus)*, varying degrees of cryptophthalmos and ankyloblepharon in cockatiels *(Nymphicus hollandicus)*, extrahepatic biliary cysts in a Grey parrot, and familial cataracts in scarlet macaws.[7]

Many presentations of problems within the realm of psittacine pediatrics tend to describe the ailment and its subsequent treatment. There is usually a mention of "secondary disease" and primary managerial problems, but there often is overall less emphasis on the underlying etiopathogenesis of many of these problems, as well as how to sort out the problem's origins, starting with the diagnosis. The information in Table 41.5 is provided to stimulate thought as to the underlying causes (hence true cure potential for individuals as well as management prevention for populations) that could be relevant for selected pediatric conditions. Keep in mind that pediatric medicine, in many ways, is an aspect of avicultural or flock medicine. The diagnosis and individual bird diagnoses lead toward potentially other thoughts and actions from the astute veterinary clinician.

INFECTIOUS DISEASES OF PSITTACINE CHICKS

Viral Infections

Polyomavirus

Psittacine polyomavirus infection was initially described as "budgerigar fledgling disease" causing high mortality of neonatal budgerigars in the nest.[45] Polyomaviruses are now recognized to infect and cause disease in a number of nonbudgerigar psittacine species and can vary in clinical signs among species and age groups. As a nonenveloped DNA virus, it is persistent in the environment and resistant to many disinfectants. Largely, infection and disease are seen in pediatric populations. In most cases, older psittacine birds (budgerigars over 1 month and nonbudgerigar species over 5 months) exposed to avian polyomavirus seroconvert and remain clinically normal.[46] The incubation period has not been evaluated in many species, but broad estimates of up to 15 days postexposure to onset of clinical signs, depending on age of the host, amount of viral exposure, and other host factors. It is believed that in the polyoma naive breeding and nursery population the risk of death and disease may be the highest risk. Clinical signs of infection and disease are outlined in Box 41.3.

There is no specific treatment for the disease, and the reported mortality rates have varied from 27% to 41% of the at-risk young birds in outbreaks.[46] Common gross necropsy findings include pallor of the skeletal muscle, hepatomegaly, subcutaneous hemorrhage or on the serosal surface of organs, and splenomegaly (Figure 41.21). Diagnosis is supported by history and gross necropsy findings and is confirmed with the identification of intranuclear inclusion bodies in several affected tissues at necropsy. Virus isolation or PCR testing can be used to further confirm diagnosis at necropsy. Antemortem screening for evidence of viral infection or exposure can be accomplished through serology or PCR testing of feces and cloacal swabs. Whole blood samples alone are generally viewed as a less sensitive means with which to screen for polyomavirus infection as compared to a combination of cloacal swab with whole blood. Disease prevention is accomplished through a combination of methods: high biosecurity in the nursery,

TABLE 41.5

Differential Diagnostic Approach to Common Pediatric Presentations[5]

Clinical Presentation	Differential Diagnostic Thoughts
Crop stasis	Dehydration
	Formula too hot
	Formula too cold
	Hypomotility related to stunting (see #9)
	Malnutrition
	Primary or secondary infectious disease (viral, bacterial, fungal)
	"Sour crop" as a secondary complication
	Brooder temperature too high
	Brooder temperature too low
	Brooder humidity too low
	Exogenous stressors (light, etc.)
	Foreign body obstruction of GI tract
	Normal variation in motility during 24-hour period
	Toxicoses
Regurgitation	Systemic disease
	Crop stasis (see #1)
	Normal behavior for species and age (weaning behavior)
	Inadequate feeding practices
	Excessive feeding, formula too hot or cold
	Imbalanced brooder environment
	Chicks too warm, too cold
	Localized ingluvial infections
Sinusitis	Inadequate brooder air quality
	Excessive temperature, poor ventilation, low humidity
	Foreign objects in nares
	Primary or secondary infectious disease (viral, bacterial, fungal)
	Inadequate feeding protocols
"Splay leg"	Inadequate brooder substrate
	Inappropriate nest/brooder design
	Lack of adequate nesting material
	Wet chicks
	Weak chicks
	Inattentive nursery management
Tibiotarsal rotation	"Splay leg"
	Traumatic injury
	Inattentive nursery management
	Inappropriate brooder substrate
Anteroflexed P1/P4 (zygodactylous species)	Inappropriate brooder substrate
	Malnutrition
	Inattentive nursery management
	Traumatic injury
Lateral beak deformity, mandibular prognathism	Likely multifactorial
	Hand-feeding trauma
	Malnutrition
	Sinusitis
"Diarrhea"	Normal fecal character for age and species
	Bacterial imbalance/dysbiosis
	Enteritis due to primary or secondary (bacterial, viral, fungal) infections of the GI tract
	Over medication (can result in dysbiosis)
	Malnutrition
	Hypermotility
	Hypomotility
	Pansystemic disease
	Endoparasitism
Stunting	Malnutrition
	Inadequate volume fed per day
	Inadequate calories fed per day
	Crop stasis (see #1)
	Inattentive nursery management
	Excessive brooder temperature
	Inadequate brooder temperature
	Inexperienced hand-feeders
	Inadequate adult breeder parenting
	Large interval between hatches
	Aviary disturbances
	Infectious parental disease
	Infectious disease (primary or secondary)

efforts to maintain a pathogen-specific population through serial testing and management procedures, and vaccination (Psittimune APV; Creative Science, Ballwin, MO, USA).

Psittacine beak and feather disease

PBFD was frequently seen in cockatoos during the years of highest importation into the United States (1975–1992) and remains endemic in wild parrot populations in Australia, Asia and Africa. In the decades following, a circovirus associated with the disease was identified. As with polyomavirus, psittacine circovirus is a nonenveloped DNA virus, and it is also persistent in the environment and resistant to many disinfectants (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). There are over 200 clades of different beak and feather disease virus genotypes currently described, and all psittacine birds are viewed to be susceptible to a diversity of these clades, with no one genotype considered more virulent than another.[47] A large number of susceptible species to infection and disease are listed, but the vast majority are Old World psittacine species (i.e. parrots originating from Africa, Eurasia or Australia). Conversely, naturally occurring infections and disease in New World parrots (i.e., species originating from North, Central, and South America) are rarely encountered. Although disease is described in adult birds, it is generally believed that infection and early onset of disease likely occur in subadults.[48] The incubation period has also not been evaluated in many species, but dystrophic feathers have been noted in experimentally infected galahs *(Eolophus roseicapilla)*, Grey parrots, umbrella cockatoos *(Cacatua alba)*, and sulphur-crested cockatoos *(Cacatua galerita)* at 21 to 47 days postinfection. The severity and onset of feather dysplasia are dependent on the phase of molt that the infected birds may be in; a bird that is not currently molting may not show classic

BOX 41.3 CLINICAL SIGNS ASSOCIATED WITH PEDIATRIC POLYOMAVIRUS INFECTIONS

General signs

1. Lethargy
2. Delayed crop-emptying time
3. Regurgitation
4. Lack of a normal feeding response

Budgerigars

1. Acute deaths in nestlings
2. Feather dystrophy in fledglings

Large psittacine species

1. Acute death (neonates within 12–24 hours after onset of signs)
2. Subcutaneous and systemic hemorrhage

Finches

1. Acute deaths (fledglings)
2. Beak keratin growth abnormalities (fledglings)

From Ritchie BW: *Avian Viruses: Function and Control*, Lake Worth, 1999, Wingers Publishing, pp 127–170.

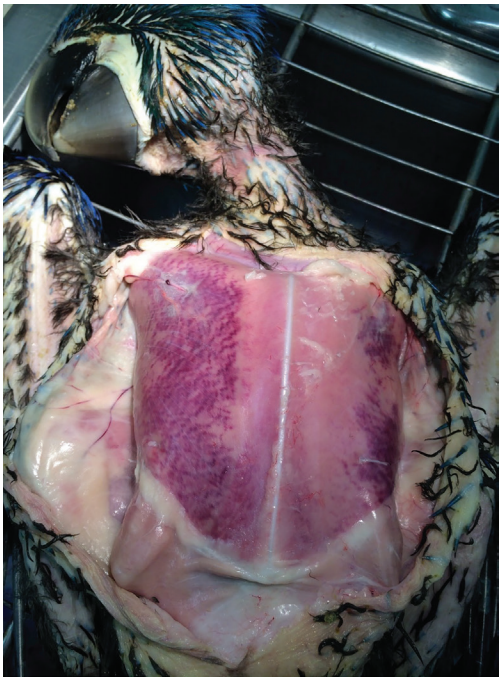

FIGURE 41.21 Ecchymotic hemorrhages are visible in the pectoral musculature of this hyacinth macaw *(Anodorhynchus hyacinthinus)* chick that died of polyomaviral infection. Hemorrhagic lesions were also present in the conjunctivae and over the brain beneath the skull cap. (Photo courtesy Susan Clubb.)

feather dystrophy signs until the next molt occurs.[48] Clinical signs of infection and disease vary among species and age groups. Peracute infections are typically presented with a rapid onset of debilitation and death, often with death occurring prior to the development of other clinical signs. Grey parrots may develop a necrotizing hepatopathy or nonregenerative

FIGURE 41.22 Psittacine beak and feather disease (PBFD, chronic form) in a young, approximately 6-month-old lovebird *(Agapornis roseicollis)*. Progressive feather dystrophy and loss are apparent, involving the contour feathers of the head and neck region shown. With magnification at examination, the dystrophic contour feathers were able to be more clearly identified. It was not clear if the rostral rhinothecal tomial overgrowth noted here is directly related to the disease. (Photo courtesy Brian Speer.)

anemia and granulocytopenia.[49] In the acute form of disease, pinched, clubbed, and dystrophic contour, down and powder down feathers are well described. Chronic disease is characterized by the progressive development of generalized feather loss and continued dystrophy. Beak and nail lesions may be noted in some species (Figure 41.22), typically in cockatoos affected by the chronic form of disease.[48] There is no specific treatment for infection or disease. Diagnosis is supported by physical examination findings and is confirmed with the identification of intranuclear or intracytoplasmic inclusion bodies in several affected tissues at skin biopsy or necropsy. PCR testing can be used to further confirm diagnosis and can be performed on biopsy samples or whole blood samples, as persistent viremia is believed to be a common characteristic in actively infected birds. Serologic testing is available in Australia only. Paired with a reduction in wild-caught bird trade, the use of targeted testing and removal of infected birds from breeding facilities appear to have aided in significantly reducing the prevalence of disease in captively managed collections in many parts of the world.[48] PBFD continues to affect wild psittacine populations in Asia, Africa, and Australia and can be a significant conservation issue in some species such as the red-vented or Philippine cockatoo *(Cacatua haematuropygia)* and the Cape parrot *(Poicephalus robustus)*.[50,51] There is no commercial vaccine available.[47,48]

Pox

Poxvirus can be transmitted from wild or other infected birds via mosquitoes and other biting arthropods to parrot chicks in the nest (see also Chapter 15). Pox infections overall are more commonly encountered in other taxonomic groups of young birds (Columbiformes, Galliformes) as compared to Psittaciformes, although disease is reported in many bird groups

FIGURE 41.23 Cutaneous pox in an ostrich *(Struthio camelus)* chick. (Photo courtesy Brian Speer.)

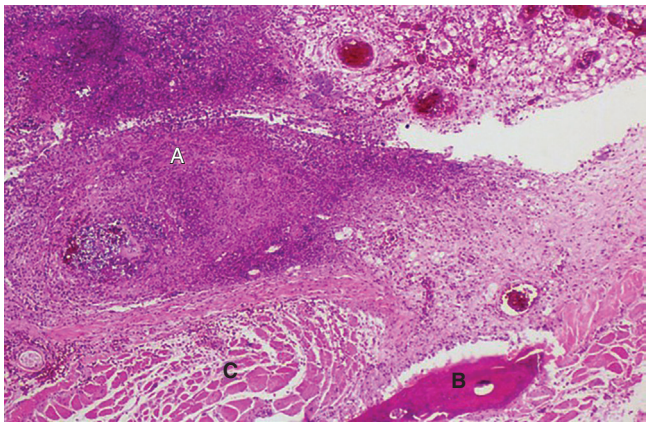

FIGURE 41.24 Histologic section of a young cockatiel *(Nymphicus hollandicus)* chick that likely died of complications from *Bordetella avium* infection (lockjaw). Note the extensive necrotizing myositis *(A)*. A fragment of bone involved in the reaction is also present *(B)*. Relatively normal skeletal muscle is also present *(C)*. These lesions may be secondary to infection that originated in the nasal cavity or sinuses, but they have also been associated with oropharyngeal trauma during hand-feeding. (Photo courtesy Robert Schmidt.)

(Figure 41.23). Infection can be transmitted by direct contact as well as fomites. Infected chicks may show cutaneous or diphtheritic manifestations, characterized by raised lesions on the skin, eyelids, inside the mouth, and on the exterior surfaces of the beak, feet, and in some cases lesions over much of the body. These cutaneous lesions will eventually scab over and when the birds recover. Secondary infections can complicate recovery, and diphtheric lesions may carry a more guarded to poor prognosis as compared to cutaneous lesions for this reason.

Proventricular dilatation disease (avian ganglioneuritis)

Proventricular dilatation disease, associated with avian bornavirus can cause disease in chicks as young at 20 days old (see also Chapter 14 and *Current Therapy in Avian Medicine and Surgery*, Volume 1, Chapter 2).[52,53]

Other viral infections

A novel metapneumovirus was identified by metagenomic sequencing in monk parakeets and associated with a disease outbreak in a psittacine nursery facility. Clinical signs included acute death and nonspecific signs of ill-thrift. Gross necropsy revealed yellow-colored livers with petechia, suggestive of an acute hepatic necrosis.[54] Avian adenoviral infections can function as comorbidities, increasing the prevalence of other infections or at times can function in the role of a primary pathogen.[55]

Bacterial Infections

Common environmental bacteria, particularly coliforms, are potential pathogens for neonates, especially if husbandry is not optimal. Many, but not all, of these organisms can become opportunistic infectants, often secondary to primary host and environmental factors that may be present. *Escherichia coli* and *Klebsiella pneumoniae* are commonly encountered environmental contaminants and infectants in many large commercial or zoological collection psittacine nurseries. The source of these bacteria often defy detection, and they may emerge and be found to be problematic even in the presence of exceptional hygiene. Common sources for consideration of contamination include the human caretaker, the cleanliness of the environment, the hand-feeding formula being used, water, and vertically passed organisms from the hen or her nesting environment. *Pseudomonas aeruginosa* and similar hydrophilic bacteria present a challenge to neonates because of their ubiquity in water sources and ability to form biofilms, which not only support their resistance to environmental factors but also protect other bacteria such as coliforms. These bacteria present no danger to humans unless exposed people are immunocompromised. Intestinal disease and sepsis are the most common clinical signs noted in chicks; however, *Bordetella avium* has been associated with infection of ciliated respiratory epithelium in turkeys *(Meleagris gallopavo)* and other poultry as well as a "lockjaw" syndrome in neonatal cockatiels and other psittacine species (see also Chapter 31).

Asymptomatic infection with *B. avium* has been demonstrated in adult breeding pairs and shedding of the organism in their oral secretions to their chicks is a common route of transmission.[56–58] Depending on the chicks' age as well as other management-related variables (timing of recognition of the problem, nutritional status of the chick, and hand-feeding practices), the affected chicks may die of acute pneumonia or may develop a disease progression characterized by coughing, sneezing, serous nasal discharge, progressing to prokinetic muscular rigidity "lockjaw" in chicks roughly 4 to 6 weeks old. The bacterium invades from the nasal mucosa into the suborbital sinus and directly into the prokinetic musculature. Inflammation at these sites causes the prokinetic rigidity and loss of range of motion of the associated joints manifested as "lockjaw" (Figure 41.24). Often, there is a characteristic raised lower lid and glassy appearance to the eyes. Affected chicks endlessly beg for food while being unable to open their jaws to accept formula from adult birds or hand-feeders. Some

FIGURE 41.25 Dilated hemorrhagic and edematous intestines, typical of what is seen on the serosal surface in cases of bacterial enteritis. (Photo courtesy Robert Schmidt.)

successful treatments have been noted, where paired antiinflammatory treatments, pain management, physical therapy, and antibacterial therapy were all utilized.[59] In a similar manner of clinical presentation, *Enterococcus* spp. believed to be a part of the psittacine normal gastrointestinal flora, invaded through mucosal injuries into the adjacent subcutaneous tissues. Susceptibility to this specific bacterial invasion is anecdotally believed to be seen in cockatiels.[57]

Clostridium spp. organisms are common components of the normal gastrointestinal flora and can often overgrow in numbers secondary to antibacterial therapy or other factors including stunting, dehydration, or delayed GI transit problems. *Clostridium* spp. overgrowth can result in primary or secondary intestinal disease in neonates, fecal malodor, gastrointestinal discomfort/distention, and including necrotizing enteritis and/or typhlocolitis (Figure 41.25). In general, most disease processes in neonates reduce intestinal transit time, which can result in overgrowth of anaerobic organisms, and as a result, not all clinical signs a chick may present necessarily have to have a direct causal relationship with the bacterial organism suspected or identified.[60]

Chlamydia psittaci infection and disease appear to be no longer nearly as common in US aviculture as compared to prior years in the experience of many US veterinarians, but neonatal infection with *C. psittaci* could be significant in other countries (see also Chapter 18 and *Current Therapy in Avian Medicine and Surgery*, Volume 1, Chapter 2). The apparent reduction in prevalence of chlamydiosis noted in US aviculture is attributed to the implementation of increased screening of breeding stock as well as young birds entering commercial trade. *Staphylococcus* spp. skin infections occur periodically in neonates and may be associated with damp nests, high relative humidity, or infection secondary to insect bites.

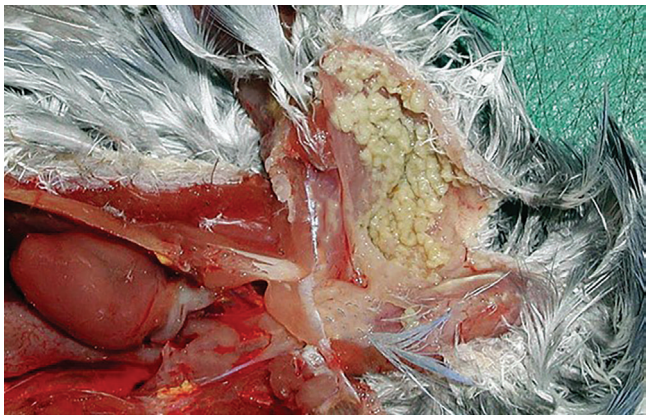

FIGURE 41.26 Ingluvial candidiasis. Note the "Turkish towel" appearance of the thickened and discolored mucosal surface. (Photo courtesy Robert Schmidt.)

Fungal Infections

Yeast infections

Yeast, most commonly *Candida albicans*, are another common component of normal intestinal flora which can become secondary pathogens in the face of antibacterial therapy or other factors as with *Clostridium* spp. Other *Candida* species are beginning to be increasingly recognized in birds as well. *Candida glabrata* and *Candida krusei* have been reported.[61] If husbandry is suboptimal, *Candida* can become a significant and sometimes aggressive pathogen. Mycotic ingluvitis is a superinfection of the mucosal surface of the crop (Figure 41.26), and infections also can occur in the intestinal tract. These intestinal tract infections can cause gastrointestinal stasis, reduce adsorption of nutrients, lead to stunting, and in advanced cases result in death. Prophylactic antifungal therapy in some situations is recommended at any time a neonate is given antibacterial therapy. Antifungals commonly used in neonates include fluconazole, ketoconazole, and nystatin (see also Chapter 8).[62]

Aspergillosis

Aspergillosis can occur if chicks are severely immunocompromised (e.g., in case of acute PBFD), or when exposed to large numbers of *Aspergillus* spores in the environment. This may occur if bedding is not changed with reasonable frequency and becomes contaminated. Cleaning this contaminated bedding in the same airspace as chicks can result in aerosolization of spores and excessive spore inhalation. Contamination of air conditioners that may be being used or hatcher and brooder fans and filters can also result in dissemination of dangerous amounts of airborne fungal spores in the nursery environment (see also *Current Therapy in Avian Medicine and Surgery*, Volume 1, Chapter 2).

Parasitic Infections

Cryptosporidiosis

Cryptosporidium spp. associated with enteric disease has been reported in outbreaks in a psittacine nursery.[63] Utilization of PCR for screening of neonatal chicks when removed from the nest has demonstrated that this may be a significant emerging pathogen in psittacines as well as being potentially zoonotic (see also *Current Therapy in Avian Medicine and Surgery*, Volume 1, Chapter 2).[64] *Cryptosporidium* infection and disease

have been reported in young passerine species,[65] waterfowl,[66] and bobwhite quail *(Colinus virginianus)*.[67–69]

Dermanyssus infestation

Red mites (*Dermanyssus* spp.) occasionally infest a nest box and can cause mortality of chicks due to blood loss. These nocturnal mites will typically not be visible during the day, hiding in cracks and crevices in the nest. They emerge at night to bite their host resulting in anemia and death. Adults will often be seen scratching or showing pruritic behaviors. Control requires extensive cleaning and spraying of insecticides in all parts of the aviary. Preferably the nest box will be burned (if wooden). Perches should be replaced, sprayed with insecticides, or baked. The addition of 5% carbaryl or permethrin powder to nest box substrate can help to control these parasites (see also Chapter 9).[1]

NONINFECTIOUS DISEASES

Nutritional problems are typically the most common noninfectious category disorder noted in psittacine chicks in their first 30 days of life. Metabolic bone disease, stunting, gastrointestinal disorders, and increased susceptibility to opportunistic infections are encountered. For psittacines, the commercially available formulas will meet the nutritional requirements for most species if mixed and administered properly. Percentage solids, the ratio of water to dry formula, is a critical factor in success. Most companies' directions for feeding their product typically show a more dilute formula for younger birds, with increasing percentage solids until it reaches around 24% to 25% solids (Table 41.3). To check mixing consistency divide the weight of the dry formula by the weight of the mixed formula in grams.[1,9,70]

Husbandry-Associated Problems

Crop burns

Thermal burns of the ingluvies result from feeding baby bird formula that is too hot (Figure 41.27). This can often occur when a microwave oven is used to heat the formula (not recommended because of the formation of hot spots within the formula).[14] Mild cases may result in red and inflamed skin around the crop and may have no other outwardly evident clinical signs other than a transient shift in feeding behaviors from what was normally seen. Second- and third-degree burns will be acutely inflamed and blistered, and these injuries may lead to tissue necrosis and fistula formation. In many cases, birds may be presented with food draining from a fistula through the crop wall and skin. Diagnosis is based on history, clinical signs, and physical examination findings.

Medical management often includes the use of antimicrobials for secondary infectants that may be present, supplemental parenteral fluids, antiinflammatory drugs and other pain management strategies, and nutritional support. Surgical repair is often required but should be postponed until the burned area is well demarcated (usually several days). In such cases, placement of a gastroesophageal feeding tube should be considered to ensure adequate nutritional intake. Surgical repair involves debridement of devitalized tissues, separating the crop wall from overlying skin, and closing the two layers separately. Prognosis is good if there is sufficient crop wall remaining for closure and the esophagus is intact.[1,26] Note that not all thermal burns to the crop need to be addressed with surgery at the time of initial presentation. Instead, healing by secondary attempt while ensuring appropriate supportive care in the meantime. An example of such a staged repair of a crop burn is represented in Figure 41.28.

FIGURE 41.27 Crop burn. There is a centrally necrotic area through which formula can be seen leaking from a fistula. Although there is a clear demarcation between necrotic and live tissue apparent at the bottom of the lesion, the lateral and upper aspects are not fully differentiated, supporting a need to delay surgical repair if possible. (Photo courtesy Susan Clubb.)

Aspiration of formula

Aspiration pneumonia is one of the most common causes of respiratory disease in hand-fed psittacine birds (Figure 41.29). Chicks can aspirate while being fed large quantities of liquid formula, especially when being fed by an inexperienced or inattentive feeder.[14] Aspiration of formula can result in instant asphyxiation and death if the volume of formula introduced into the trachea is sufficient to occlude the bronchi. Less severe aspirations can also occur when a chick inhales small amounts of formula resulting in the development of pneumonia. Clinical signs include increased respiration, respiratory distress, poor feeding response, and depression.[14] The most practical way to prevent aspiration is by conditioning the chick to accept the food rapidly, which is the natural way in which the parents feed the chick. When the chick is pumping to accept food, the glottis is closed preventing aspiration. Inexperienced hand-feeders often feel "safer" dribbling the food slowly into the chick's mouth. At some point in time, the chick must open the glottis to breathe and may aspirate. Treatment consists of oxygen therapy, nebulization, antibacterials, antifungals, warmth, supplemental fluids, and antiinflammatory drugs.[14]

Oropharyngeal trauma

Punctures of the pharynx may occur if the hand-feeder is using a small, firm tip on the hand-feeding syringe or is using a syringe with a sharp point. If the chick is bobbing to accept

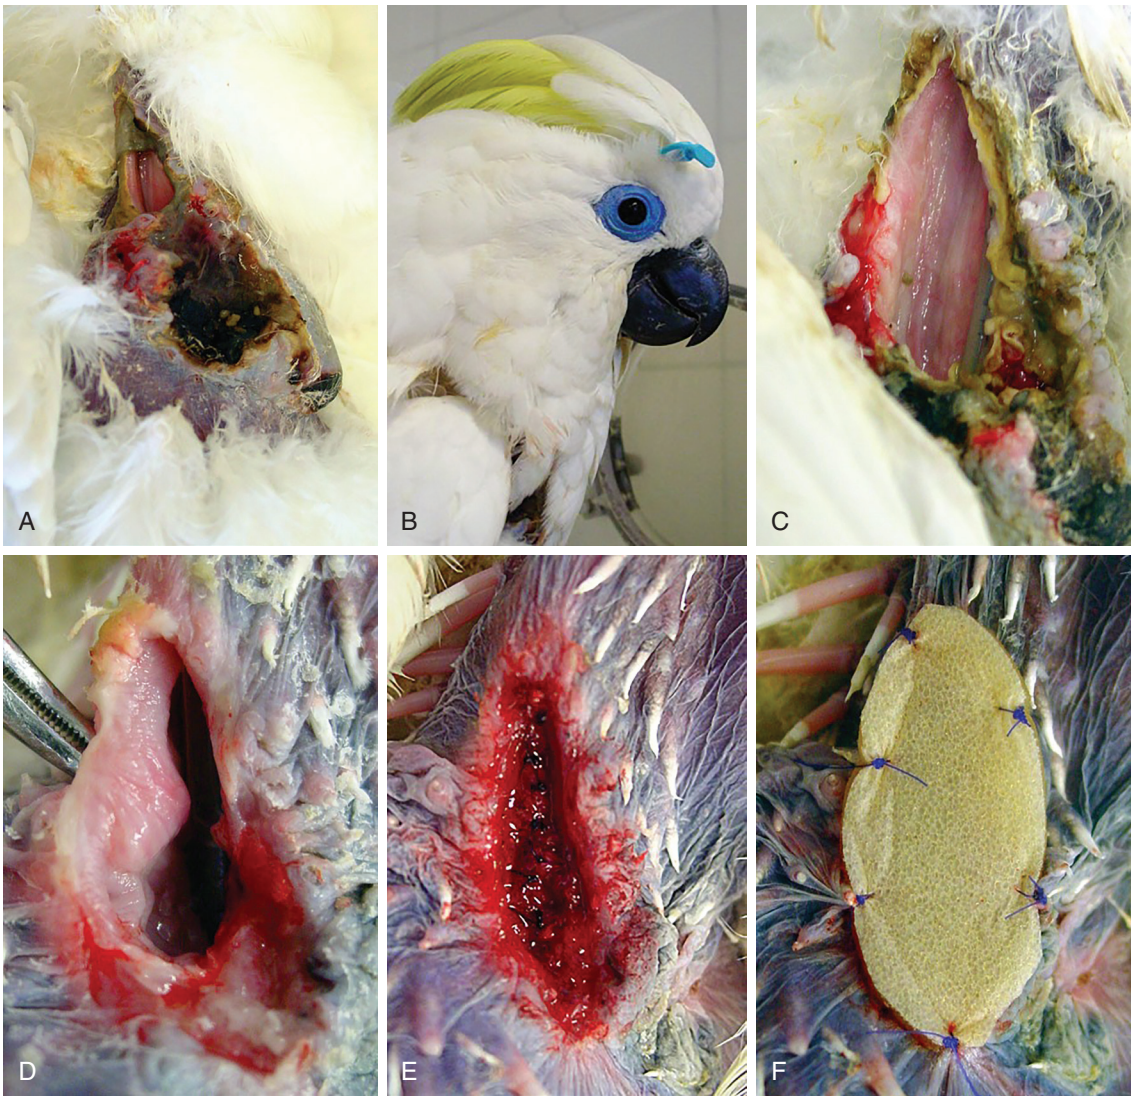

FIGURE 41.28 (A) Primary crop burn in a blue-eyed cockatoo *(Cacatua ophthalmica)*, with over 50% of the crop wall destroyed and large necrotic lesion ventrally at the initial day of presentation. (B) Placement of esophageal feeding tube attached to the head to bypass wound and allow provision of liquid formula until the necrotic tissues are better declared. (C) Wound appearance 1 week later. Demarcation is present in the proximal area, but the distal area is still not fully demarcated. (D) At 3 weeks after initial presentation, the wound had clearly decreased in size and was now well demarcated. (E) Crop wall could be closed with single monofilament sutures. (F) Wound was covered with hydrocolloid dressing (DuoDerm, Convatec, London. UK) to let allow for healing by second intent. (Photos courtesy of Nico Schoemaker/Yvonne van Zeeland.)

the formula from the syringe, the caudal pharyngeal tissue may be punctured or lacerated, and food material can be deposited subcutaneously into tissue of the neck. A relatively sudden onset of marked swelling in the gular region and upper neck is a commonly noted clinical sign, often due to cellulitis and infection/inflammation in the region. When recognized, this is an urgent situation, often requiring surgical exploration, cleaning of the area, irrigation, and repair of the inciting injury. If not addressed in a successful or timely manner, death is likely to occur due to toxemia and sepsis within 24 hours.[1] In addition to caudal pharyngeal injuries, punctures of the esophagus can also occur when tube feeding chicks. These injuries typically occur approximately halfway down the esophagus, where it is narrow, and the cervical spine has a normal flexure. The swelling that is noted will be in the lower neck and sometimes in the region of the crop. As mentioned earlier, when recognized, this is an emergency, often requiring surgical resolution within 24 hours to prevent toxemia and sepsis, which significantly reduce the chances of survival.[1,26]

Hepatic rupture

Hepatic rupture can occur when a chick is lifted with fingers surrounding the body and applying pressure to the liver or if there is a fall and abrupt blow sustained to the area (Figure 41.30). There

FIGURE 41.29 Aspiration and foreign body pneumonia. The lungs appear edematous and discolored. Hand-feeding formula can be seen in the adjacent air sacs grossly. (Photo courtesy Robert Schmidt.)

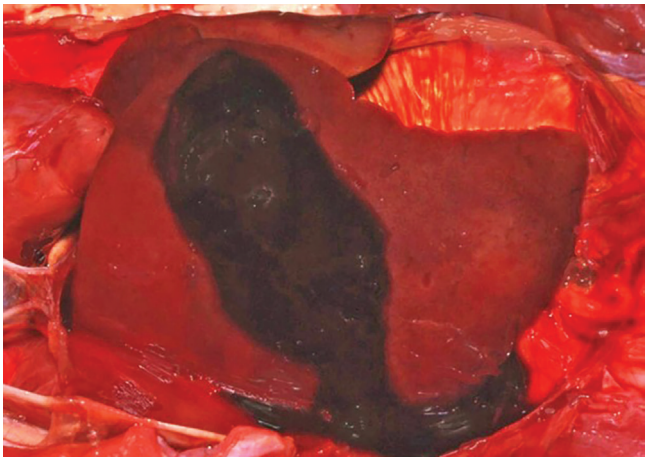

FIGURE 41.30 Hepatic rupture and grossly visible hemorrhage. Chicks may suffer acute death or present weak and pale. Some birds may survive with supportive care. (Photo courtesy Robert Schmidt.)

may be some underlying nutritional deficiency associated with this disorder, as one of the contributing authors has observed it primarily when chicks were being fed a formula made from primate biscuits.[26]

Obesity

Some species, typically large cockatoos, can have a tendency toward obesity which can result in fatty liver disease if they are given excessive amounts of food (Figure 41.31). Chicks with hepatic lipidosis typically are still being hand-fed and are overweight for their age. Affected chicks often exhibit marked signs of respiratory distress, largely due to reduced air sac space and increased vulnerability to hyperthermia. These birds must be handled gently and minimally. A cooler environment that is oxygen supplemented is often the best first step. By greatly reducing the quantity of crop food per feeding, adjusting the caloric content of the formula downward, many chicks can begin to stabilize and improve within days.[14]

FIGURE 41.31 Obesity in a sulphur-crested cockatoo *(Cacatua galerita galerita)* chick. The bird is standing in a more erect posture and gaping to breathe due to the significantly filled intestinal peritoneal cavity (largely hepatomegaly) resulting in air sac impingement and ventilatory impairment. Initial treatments included cooling the bird paired with passive oxygen support, followed by significantly reducing the calorie density of hand-feeding formula that was fed. (Photo courtesy Brian Speer.)

Gastrointestinal Problems

Ingluvial hypomotility or stasis and the development of "sour crop"

Crop atony, crop stasis, or failure of the crop to empty is a common clinical sign, often related to intestinal stasis or delayed GI emptying in young chicks. Under normal circumstances, the crop of the chick should be (nearly) empty in the morning before the first feeding, indicating effective GI transit at the start of the day. Failure of the crop to empty can predispose chicks to overgrowth of bacteria and fungi (Table 41.5).[1,70,71]

Should the ingluvies be delayed in its emptying time, it does not contract properly. As a result, some food content remains in the deepest part of the organ, which in turn sets the stage for opportunistic bacterial and/or yeast overgrowth. Acidity produced by some of the proliferating organisms can further augment development of a so-called "sour crop." These changes lead to continued alterations of the normal crop microflora, setting the stage for further secondary crop dysbiosis, infection and dysfunction.[13,26] This cycle continues to feed into itself, leading to progressive gross overdistension of the crop, marked acidity and sour odor of the content, secondary infections, and inflammatory changes, and to loss of body condition or failure of the chick to develop normally because of dehydration and malnutrition. However, most systemic and physiologic disease processes of young psittacines can result in slow gastrointestinal transit time and delayed

crop emptying,[26] which potentially sets stage for progressive development of "sour crop" and continued delayed emptying.

Crop stasis can be a sign of general illness for many infectious diseases, often associated with secondary and common bacterial and mycotic (*Candida* spp.) infections. An aerobic culture and possibly antimicrobial therapy pending culture results are often common steps in early intervention for affected chicks. Intestinal stasis can also result from other disease processes such as kidney disease, liver disease, or congenital malformations.[1,26,70,71]

Crop atony can result from overfeeding and resultant stretching of the crop musculature. The volume of formula per feeding for most species typically does not exceed 10% of body weight (1 mL formula equals 1 g). Some species can easily accept 15% of body weight per feeding. An easy way to calculate this is to divide the weight of the chick by 10 and administer that volume of formula in milliliters. It is not clear if an optimally developing chick can truly be overfed to the point of stretching the ingluvies, or if those changes are predisposed by subclinical stunting (see section on Stunting).

Treatment typically focuses on maintaining hydration or rehydrating the chick, as ingluvial motility can both be (partially) caused by dehydration and result from it. Hydration of a chick affected by crop stasis should be maintained by either increasing the amount of water content in the hand-rearing formula or by administering fluids parenterally. In case of signs suggestive of dehydration, rehydration may be accomplished by oral or parenteral administration of fluids, allowing for correction of the fluid deficit within 24 to 48 hours. The crop may be evacuated and lavaged, if indicated. Antibacterial and/or antifungal treatments may be indicated. In some cases where the crop is thin walled and markedly distended, a supportive bandage (crop bra) may be used.[13,26] Such bras can easily be prepared using baby socks or Vetwrap (3M Animal Care Products, St. Paul, MN, USA; Figure 41.32). Alternatively, if the crop is severely overstretched, reduction surgery may be necessary.

Gastrointestinal foreign body

Foreign body consumption and impaction usually occur when chicks ingest their bedding. This most often occurs if the chick

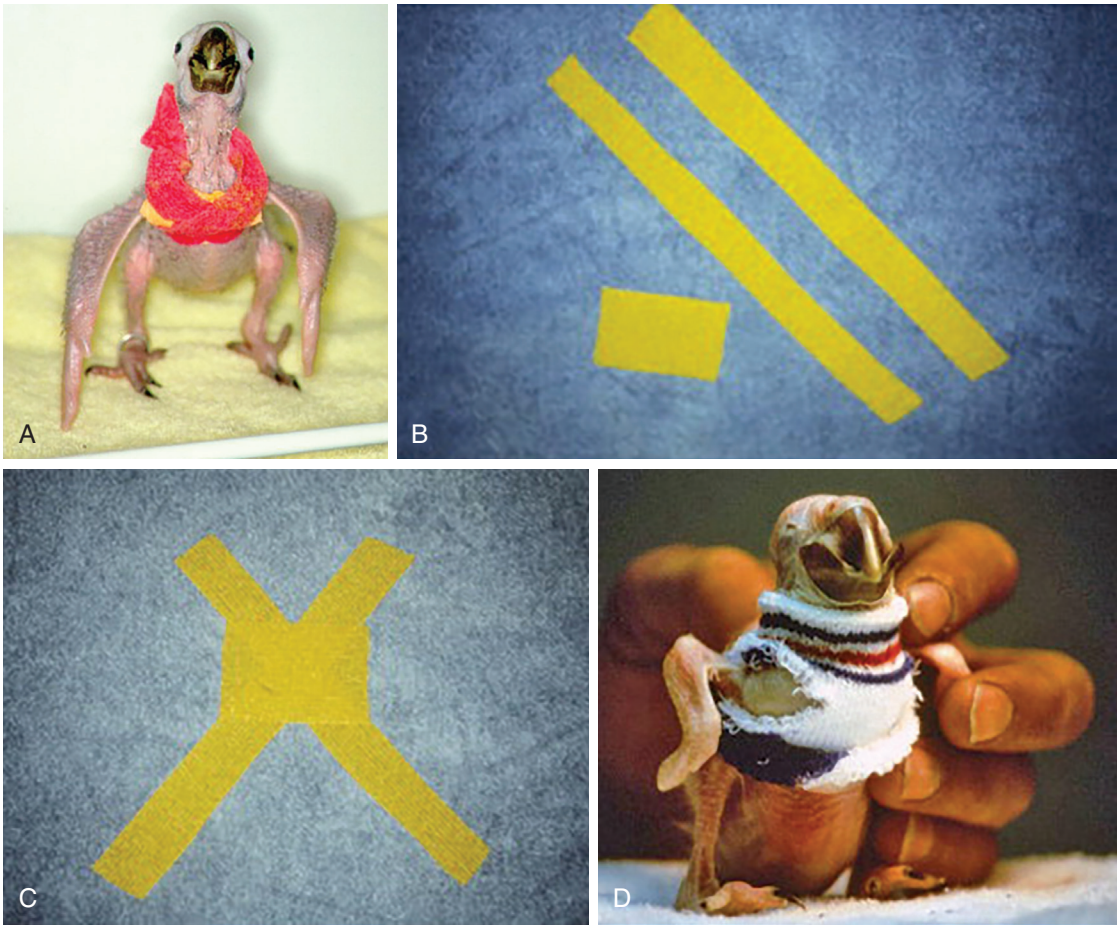

FIGURE 41.32 (A) A crop bra can be used to support an overstretched crop, as demonstrated in this slightly thin and dehydrated macaw chick. This self-made crop bra was prepared from (B) two strips of in-house of VetWrap (3M Animal Care Products, St. Paul, MN, USA) that are subsequently crossed. (C) A horizontal rectangular piece of VetWrap is placed across the area where the strips cross over. (D) As an alternative, crop bras can be made from baby socks. (A–C, From Romagnano A: Psittacine incubation and pediatrics, *Vet Clin North Am Exot Anim Pract* 15(2):163–182, 2012, with permission; D, From Worell AB: Current trends in avian pediatrics, *J Exot Pet Med* 21(2):115–123, 2012, with permission.)

does not get enough food to satiate its hunger or if there is an underlying disease process that causes pica. Bedding and brooder substrate are normally made of tiny particles that can fill the crop and can also proceed further, along the GI tract, causing problems, including more distal obstructions. Obstructions with these smaller substrate particles are more challenging to treat, as the endoscopic procedure can be long and risky, and a crop lavage can be dangerous in a small chick. In the experience of the authors, it is often safer, quicker, and less stressful to perform an ingluviotomy and retrieve the small foreign bodies directly from the crop.[13,14] Chicks may also accidentally swallow feeding tubes that are being used in their hand-feeding (Figure 41.33). Feeding tubes can be disconnected from the syringe and involuntarily swallowed by the chick. Long feeding tubes that are still in the crop can usually be retrieved from the beak, either manually or using a grasping forceps. Shorter tubes tend to reach the proventriculus quickly, but can often be retrieved with the help of an endoscope. Not all foreign bodies require endosurgical or surgical removal, and management details are dependent on clinical status and circumstances of the chick.

Intestinal intussusception

Intussusception may occur and may be confused with cloacal prolapse, although the tissue is usually jejunum and is tubular and red rather than round and pink (Figure 41.34). Intussusception is typically associated with bacterial enteritis and is usually fatal.[9,14] If detected in a timely enough manner, successful treatment requires surgery, with the potential need for resection and anastomosis should there be avascular or necrotic intestine involved.

Regurgitation

Regurgitation may occur as the result of management-associated problems or may be secondary to several primary or secondary medical conditions.[72] As a chick starts to wean, the crop naturally begins to reduce in its volume and cannot hold the previous volumes of food it was previously receiving. Refusal of formula or even regurgitation following hand-feeding may occur if the food is too cold, the chick is starting to wean, the chick does not like the taste of the food, or if the chick becomes excessively stressed or fearful. Excessive begging for hand-feeding formula can be associated with malnutrition, inadequate caloric intake, a hand-feeding formula containing an inadequate (too low) percentage solids, or continuous light cycles with no dark period for sleep. If fed while begging constantly and in the absence of correction of possible underlying antecedents, regurgitation can result. Begging behaviors may also become reinforced, as the result of suboptimal socialization during the weaning period. As an example, young cockatoos may learn to beg for food whenever they see a person, seeking attention even though the bird may be satiated. Feeding these birds large hand-feeding formula volumes can also result in regurgitation. Regurgitation is seen in young chicks secondary to many medical conditions that result in delayed crop-emptying capabilities. These may include bacterial or yeast enteropathies, foreign body ingestion and partial obstruction, renal disease, and polyoma virus infection.

FIGURE 41.33 Lateral radiographic image showing a rubber feeding tube lodged in the proventriculus and ventriculus of a 2-year-old yellow-naped Amazon *(Amazona auropalliata)* with a chronic history of periodic regurgitation and nonspecific signs of ill-thrift. This tube had apparently been present in the bird since prior to weaning and sale as a pet, without causing more significant life-threatening complications. The tube was removed endoscopically through an ingluviotomy incision. (Photo courtesy Brian Speer.)

Developmental Problems

Stunting

Stunting is defined as a reversible or permanent process that stops or slows down growth or development (Figure 41.35).[10,72] In many species, stunting is most frequently recognized and described when advanced and more permanent or severe changes are present in chicks.[72] Criteria that can be utilized to define stunting in psittacine chicks are itemized in Box 41.4. Some of these clinical signs are obviously more advanced than others.

Likely, one of the earliest observations should be expected to be subnormal weight gain. Items 2 through 8 in Box 41.4 can be easily viewed as secondary effects, the result of delayed weight gain and stress. Early recognition of problems can facilitate earlier, less involved, and more successful intervention. There are many causes of stunting, but generally these causes will include any factor that interferes with the homeostasis of the chick in its environment.[72]At its onset, stunting most likely starts with variation in adequacy of nutritional and environmental factors, with infectious causes being less likely as a primary causal role.[10] Common nutritional factors include inadequate formulas that do not meet nutritional or caloric requirements of the chicks, feeding inadequate volumes of formula, and inadequate feeding frequencies. A brooder environment with too much or too little heat or inadequate humidity all contribute to stunting. Opportunistic bacterial

FIGURE 41.35 Marked stunting in a blue-and-gold macaw chick *(Ara ararauna)*, 48 days of age, weighing 29 g. At this age, the eyes should be open, the egg tooth should have been shed, contour feathers should be emerging, and the skull should be more symmetrically shaped. Note the extremely thin skin, allowing the crop content to be easily seen, and the dark, dehydrated musculature to be seen beneath it. Normal weight for this species at this age would be 1192 g, with this individual being 2.5% of normal. This bird's progressive stunting and debilitation were obviously not recognized in a timely enough manner to allow for effective medical or nutritional interventions to be implemented.

BOX 41.4 CLINICAL SIGNS OF STUNTING IN PSITTACINE CHICKS

1. Subnormal weight gain for age and species (see Appendix 4A–E)
2. Reduced muscle mass and subcutaneous fat deposits
3. Thin elbows and toes
4. Malproportioned body—large head in proportion to the rest of the body
5. Delayed and abnormal feathering in particular areas and pterylae
6. Chronic, recurrent microbial infections
7. Constant vocalization and begging for food
8. General illness, including sluggish behavior, dehydration, and pale skin color

infections most often develop secondary to chick dehydration and stress and often are identified after the stunting of the chick has already begun. More severely stunted chicks should be expected to manifest the highest number of serious secondary effects. These include crop atony and stasis, bacterial and fungal infections, orthopedic deformities, beak deformities (mandibular prognathism, scissors or lateral maxillary beak deformities), and mortality.[10] Survivors typically have lower adult body weights than chicks that were only mildly stunted or not stunted at all. Chicks with mild-to-moderate degrees of stunting demonstrate an overall lower prevalence of aforementioned secondary effects (Figure 41.36).[10]

There are significant variations in normal developmental parameters available for reference, dependent on the age of initiation of hand-feeding, if the chicks were parent-fed prior

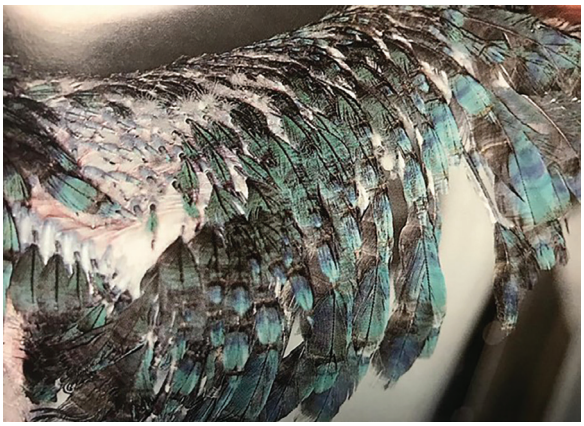

FIGURE 41.36 True stress bars of the primary remiges and dorsal wing coverts in a stunted blue-and-gold macaw chick *(Ara ararauna)*. The absence of segments of the normal development of the barbules produces visible "bars" in the feathers. Unlike feathers where the developing rachis may have been mechanically bent or injured with a palpable bend in it, the rachis of these physiologically induced stress bars have no associated palpable changes in their rachis. Normal plumage development can be seen in Figures 41.11, 41.12, and 41.13. (From Abramson J: Captive breeding and conservation. In Abramson J, Speer BL, Thomsen JB, editors: *The Large Macaws*, Fort Bragg, CA, 1995, Raintree Publications, with permission.)

to being transitioned to hand-rearing, the diet being fed, volume of formula being fed, and the frequency of feedings, and brooder temperature and humidity.[9,10,11,,73] Not all these data are available to allow easy cross comparison between datasets. A comparison of growth between two references is visibly displayed in Figure 41.11. Regardless, these data, when employed as a part of a nursery monitoring system, can allow earlier detection of weight developmental problems. By calculating the percentage of a specific chick with a normal set of data for that species and age, a percentage of "normal" can be determined. What these types of calculations provide is a comparison of growing chicks and their relative rates of growth, rather than merely weights. Almost all chicks, even those that are stunting, still will continue to gain weight, and that can mislead conclusions that it is developing properly. These trends, monitored over time, can allow for a more strategic intervention and reassessment. An example is provided in Boxes 41.2 and 41.2. This type of scenario illustrates that early recognition of subclinical stunting readily allows for simple and often successful corrective maneuvers.

The clinical management of stunting, when recognized, is dependent on the severity of the problem. Initially, if only mild stunting is present, correction of feeding volume/frequency is often sufficient to correct the problem. Chicks may be evaluated for bacterial or yeast opportunistic infections or microbial dysbiosis, but they do not necessarily always require treatment for all isolates recovered. When more significant problems are noted, including but not limited to ingluvial hypomotility, secondary infections, or other more advanced issues, the microbial isolates must more often be individually addressed. Concurrently, efforts to help these chicks move a higher caloric density food in volume per day through their GI tract must be maintained. Supportive measures to achieve this goal typically include an increase in

relative humidity of the brooder, dietary caloric content modifications, and alterations in the utilized feeding volumes and frequencies (Box 41.2).

Constricted toe syndrome

Constricted toe syndrome is believed by some to be a sign of at least regional dehydration in chicks, although a clear causal relationship has not been made. Affected chicks develop a progressive annual constriction typically around digits, leading to progressive edema and swelling of the distal aspect of the digit, and if untreated, avascular necrosis and loss of the digit (Figure 41.37). Common corrective maneuvers are done by placing a damp washcloth under the bedding of the chick so that the moisture and humidity rise upward to the feet and body of the chick, without directly getting the chick wet. This approach is the most natural and minimally intrusive way of correcting particularly regional if not systemic fluid imbalance in the chick, and the most effective way to reverse some early constricted toe syndrome issues, if not prevent them. By regularly massaging these constrictions and digits during each hand-feeding, often some of these cases may be reversed if detected early. More severe cases may require surgical intervention to prevent autoamputation. In such cases, by making a small lateral incision across the constrictions with some lifting of the cut sections of the constrictions can be helpful. Following surgical intervention, keeping the toes clean and providing surface moisture are essential to success. In particularly severe cases, repeated surgical intervention may be required. Amputation of severely affected toes that have become avascular may be required.[1,12]

FIGURE 41.37 (A) Constricted toe of the left fourth digit in a young macaw. Massage of the digit during each hand-feeding was unsuccessful, and this constrictive lesion was surgically released by incisions laterally on each side, followed by protective bandaging and massage afterward. This digit healed and appeared grossly normal when the bird was fully grown. (B) Constricted toe of the left first digit in a younger macaw chick. This lesion was more advanced at the time of its recognition, and although the digit was not lost due to avascular necrosis, it remained deformed. (From Abramson J: Captive breeding and conservation. In Abramson J, Speer BL, Thomsen JB, editors: *The Large Macaws*, Fort Bragg, 1995, Raintree Publications, with permission.)

Orthopedic Developmental Problems

Leg deformities

Appendicular skeletal deformities most often are described in the pelvic limbs, although in generalized cases of metabolic bone disease, several bones of the appendicular skeleton as well as the axial skeleton can be affected. Valgus position and/or rotation are the most frequent issues, leading to the common, sweeping, description of "splay leg" (Figure 41.38).

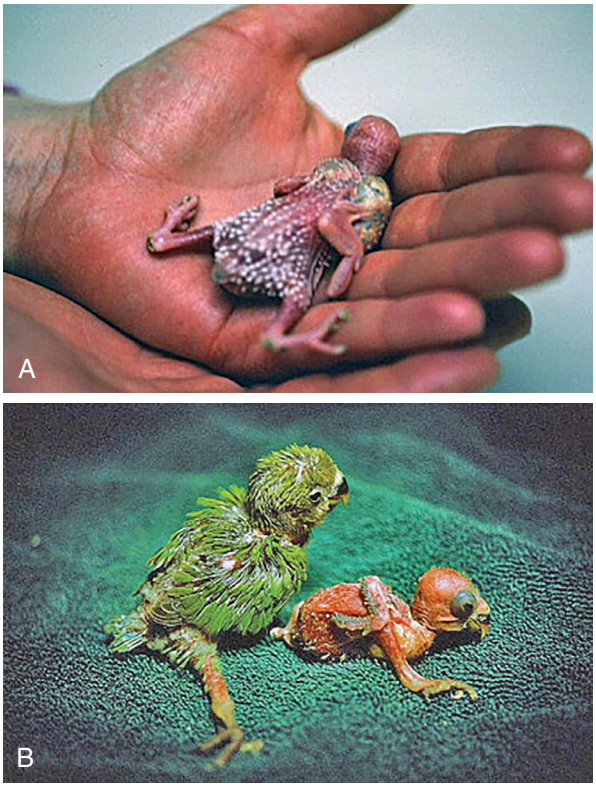

FIGURE 41.38 (A) Splay leg, also referred to as spraddle leg, in a baby budgerigar *(Melopsittacus undulatus)* and (B) angular limb deformity in a clutch of peach-faced lovebirds *(Agapornis roseicollis)*. These limb deformities are suspected to result from inappropriate substrate that prevents the bird from holding its legs in an anatomically correct position, dietary imbalances leading to nutritional secondary hyperparathyroidism, possible genetic influences, and/or other developmental problems during incubation. If caught early, conservative management using hobbles (Figure 41.39) can help to successfully manage these cases. (From Worell AB: Current trends in avian pediatrics, *J Exot Pet Med* 21(2):115–123, with permission.)

Splay leg or valgus deformities are believed to occur predominately in the nest but may also occur in the nursery. Specific deformities under this umbrella descriptor may include folding fractures or rotational deformities of the femur, tibiotarsus, and luxations of the knee. Bone deformities can occur either unilaterally or bilaterally and involve a single bone or several individual bones and their associated joints. Slipped extensor tendon of the intertarsal joint, or laxity of the collateral ligaments of the knee can also be seen, either independent or as a sequela to aforementioned bone deformities. Due to these changes, the chick is not able to stand in a normal bipedal manner, and long-term welfare may be compromised. Inadequate bedding or a parent who sits too tight on the chicks may also cause leg deformities. Similarly, chicks fed diets with improper calcium/phosphorus/vitamin D_3 levels may be predisposed, as are obese chicks that may have difficulty keeping the feet in a proper position.

A variety of different approaches have been used to address these problem(s). The use of selective bandaging, splints, hobbles, and physical therapy are the less invasive treatments that may be best applied prior to full bone growth of the chick (Figure 41.39).[26] However, the results obtained using these methods are often not as satisfactory as desired.[74] Only in mild cases, nonsurgical techniques can give good results, and they are typically achieved in very young chicks that are still growing, allowing more effective guidance of bone growth and alignment. If taking action in an early stage, leg deformities can be corrected using a variety of hobbles, taping the legs to a pad between the legs, U-shaped splints fixed to the lateral side of both legs, or simply keeping the chick packed with

FIGURE 41.39 Baby birds with (A) tape splint, (B) "snowshoe" made from tongue depressor, and (C) and (D) "snowboard" for treatment of splay leg. This type of hobbling will help to properly position the legs, whereby care must be taken that the toes face forward. For the best results, hobbling of either kind must be changed frequently to prevent soiling and ensure that the hobble is adapted to the growth of the chick. (A and B, From Worell AB: Current trends in avian pediatrics, *J Exot Pet Med* 21(2):115–123, 2012, with permission; C and D, From Romagnano A: Psittacine incubation and pediatrics, *Vet Clin North Am Exot Anim Pract* 15(2):163–182, with permission.)

paper towels or other materials that help to move the legs into a normal position. Careful monitoring of the chick during these corrective maneuvers is required, as changes in strategy and details should be expected as time progresses during these treatments.[13,75] Folding fractures of the long bones of the appendicular skeleton tend to be observed primarily in nest-raised chicks, in which their parents are receiving a diet deficient in calcium, such as a diet based primarily on sunflower seeds. Clinical rickets results (nutritional secondary hyperparathyroidism) and may be only first detected by noting the development of these skeletal deformities. If discovered early, affected chicks can usually be digitally straightened and stabilized with a split or supportive bandaging. These supports must be changed often, as with continued growth of the chick, they can become excessively tight, quickly.

Surgical approaches, including dome, transverse, oblique, or wedge osteotomy, can guarantee better results but are much more invasive.[76–78] These techniques are typically employed once the bird has attained full skeletal growth and maturity. A closed predrilled technique gives a good alternative to manage this problem in young birds and potentially also in adult patients. After the ostectomy, or osteotomy, depending on the case, a lightweight, customized cast made of aluminum can be applied, but this is limited to the smallest species. Larger birds will be treated with the application of an external fixator (Figure 41.40).[79] Tibiotarsal derotational osteotomies are typically the most common procedures. A step-by-step description for a derotational osteotomy of a valgus tibiotarsal rotation is provided in Box 41.5.

FIGURE 41.40 Postoperative ventrodorsal radiographic image of a 16-week-old domestic turkey *(Meleagris gallopavo domesticus)* following a derotational osteotomy procedure, where the intramedullary pin was preplaced as described earlier, the fracture created in a functionally closed manner, and then the pin advanced. There originally was a valgus 90-degree rotational deformity of the tibiotarsus. An extraskeletal type I tie-in fixator was then applied. Note that the intermedullary pin is less-than-optimally inserted in the distal tibiotarsus. This young turkey was functionally healed and the external skeletal fixator (ESF) type I tie-in fixator was partially deconstructed starting at week 4 postoperatively and completely removed at week 6. There was an excellent return to normal form and function achieved. (Photo courtesy Brian Speer.)

Hyperextension or luxation of the knee

In some young chicks the knee can become hyperextended or even luxated (Figure 41.41). This is most often seen as a unilateral problem; however, bilateral presentations can occur. Typically, the lower leg and foot distal to the knee are extended cranially while the intertarsal joint is hyperextended. Ligament and tendon contraction can cause the joint to become fixed in its abnormal position, rendering a poorer prognosis for more chronic luxations. An additional compounding variable is that additional bony injury can easily be induced during the manipulation process in attempts to reduce these luxations due to the poor ossification of the associated appendicular skeleton.[26] Application of a type I transarticular extraskeletal fixator can provide stability for some of these luxations in older chicks with adequately supportive bone density.[7]

Digit deformities

Crooked toes may occur due to luxation or subluxation of the interphalangeal joints, primarily of the third and second digits, although the first and fourth digits can be affected as well. (Sub)luxation may occur following placement of the chick on a hard or smooth surface, resulting in the nails becoming a pressure point and causing the last phalanx to luxate. If diagnosed early the nail can be trimmed, the toe stabilized by bandaging methods, and the chick placed in deeper bedding.[14,26] Anteroflexion of the fourth digit is another digit abnormality seen. If discovered early, this growth deformity is easily corrected by taping the toe in a normal position. In young birds, the foot can be bandaged with the toe pointing backward in the normal position for several days. Older chicks may need prolonged bandaging.[14]

Deformities of the axial skeleton

Deformities of the thoracic or cervical spine can occur in chicks resulting in scoliosis and other vertebral malformations of the spine. Rickets (nutritional hyperparathyroidism) is a common hypothesized cause, as well as trauma. In early detected cases, aggressive pain management, paired with some neck supportive bandaging may help select cases.[14,26] A spastic cervical muscular contraction is also noted in some psittacine chicks, which at least initially is not accompanied by vertebral malformation. A common loose avicultural descriptor for this condition is "wry neck." Conservative management approaches are common, and although some birds can be returned to an almost normal situation, many survive with moderate to sometimes more severe neck deformities.

Beak deformities

Malformations of the beaks are believed to most often occur in chicks which are suboptimal in development. Lateral maxillary beak deviations (scissors beak) deformities and mandibular prognathism are the most encountered in psittacine chicks. When detected early, there are several corrective options that can be implemented. Beak deformities and their corrective maneuvers are discussed in-depth in Chapter 31.

BOX 41.5 EXAMINATION FINDINGS SUPPORTIVE OF THE PRESENCE OF A VALGUS TIBIOTARSAL ROTATIONAL DEFORMITY AND PROCEDURAL DETAILS

The procedural indication can be verified typically at the examination. With the bird in dorsal recumbency, grasp the tip of the third digit, and flex the intertarsal joint completely. In the absence of tibiotarsal rotation, the toenail of that third digit should touch and align with the cnemial crest of the proximal tibiotarsus. In the presence of a valgus tibiotarsal rotational deformity, it will be positioned laterally to that structure. A similar examination of the opposite leg can be performed for comparison.

1. Drive an intramuscular (IM) pin normograde into the tibiotarsus, down to just proximal to the site where the fracture is intended to be induced. Typically, this will be done at the distal one-third location, where there is less muscle/tendon in the way, and the tibiotarsus can be cleanly palpated. The size of the pin needs to be smaller than the generic two-thirds of the inner diameter of the bone, as enough room is needed for the lateral threaded pins to get transcortical purchase around that IM pin.
2. Using a larger IM nonthreaded pin, that is about one-half to two-thirds the diameter of that bone, manually drill from the lateral cortex through the medullary cavity until the tip can be palpated penetrating the medial cortex. Withdraw, and repeat another one to two times at the same location, but different angles. The goal is to functionally weaken the cortex so that pressure can be applied manually and the bone be "cracked", inducing a functional fracture. Done well, there is still considerable periosteum that remains intact.
3. Without displacing the induced fracture, advance the prestarted IM pin down to the metaphysis/epiphysis of the tibiotarsus. This will provide good rigid linear stability. Measure to ensure that the pin is seated at appropriate length into the metaphysis/epiphysis of the bone.
4. The proximal portion of the pin that is exiting is bent 180 degrees and used to provide the rigidity for an IM tie-in. If possible, make sure that the pin is long enough to allow an adequate amount to extend down the length of that bone after bending it.
5. Clear plastic tubing, approximately the same inner diameter of the transcortical distance, can be placed over this bent pin, and provide the framework which will serve to hold the threaded pins that are placed, at least two above and two below the induced fracture.
6. The threaded pins are placed so that their points can be palpated just emerging from the medial cortex, without perforating the skin.
7. Cut the cross pins to allow them to be placed up and into predrilled holes in the plastic tubing and out its lateral aspect.
8. Once the pins are all set, the entire apparatus can be filled with methyl methacrylate or similar product and allowed to solidify. Spray a small amount of isopropyl alcohol on the apparatus, if needed, to reduce the heat that is being generated and transferred into the bone should an exothermic reaction be present.
9. Alternatively, in smaller species, the IM tie-in can be incorporated into a tape bandage or splint, without the use of threaded pins.
10. Functional healing will usually take about 3 weeks, after which the lateral pins can selectively be removed with the IM pin allowed to remain another week or two, depending on how the bird is moving and doing overall.

FIGURE 41.41 Luxation of the right knee in a young cockatoo chick. The proximal tibiotarsus is displaced cranially, and the distal epiphysis of the femur is caudal to the tibiotarsus. Some birds may be able to have these luxations reduced under general anesthesia by carefully stretching the associated musculature and manipulating the proximal tibiotarsus back into its proper alignment on the distal femur. (Photo courtesy Susan Clubb.)

Choanal Atresia

Choanal atresia is described most often in Grey parrots but has also been documented in the umbrella cockatoo.[80] The specific detailed anatomic deformities behind this developmental problem have not been definitively clarified yet. Clinical signs are increased mucus accumulation and possible infection in the nares and sinuses. Blunted choanal papilla may be detected on oral examination. Diagnosis is aided by endoscopic examination of the choana, paired with an inability of fluid flushed through the nares to be passed freely into the choana (see also Chapter 31). CT imaging may be helpful in localizing the specific location of the obstruction. Atresia can be treated by creating an opening in the choana through the nares with an intramedullary pin. A red rubber feeding tube is then threaded through the nares, out the choana, and back behind the head of the bird and is left in place for 2 to 3 weeks. This procedure is usually performed in stages, beginning with a small tube first and following with a larger tube (see also Chapters 29 and 31).[80]

INCUBATION AND HATCHING PROBLEMS

Incubation

A full description of avian incubation is beyond the scope of this chapter. For this, the reader is referred to Chapters 39 and 40. Owing to the high value of many raptor species, incubation is carried out to high standards in large commercial breeding projects, particularly those breeding gyrfalcons and their hybrids. Incubation parameters (time-to-pip and Kw constants) for a range of raptor species are listed in Table 42.1 (courtesy David Le Mesurier, unpublished data). This information has been extracted from the Avian Information Management System (AIMS) (www.visualaims.com; courtesy David Le Mesurier). AIMS is an incubation management system that will calculate the humidity needed to set incubators in order to achieve the correct percentage of weight loss during incubation. The desired weight loss to pip is 15% from the fresh weight. The Kw coefficient is used to calculate the fresh weight of an egg using the egg length and breadth (in mm). Note that Kw in Table 42.1 is Kw $\times 10^7$

$$\text{Fresh weight} = \text{Kw} \times (\text{egg length [mm]} \times (\text{egg breadth})^2)$$

Eggs from large falcon species are normally incubated at 37.3°C, although some breeders will incubate at 37.4°C for smaller species such as merlins (*Falco columbarius*) (D. Le Mesurier, personal communication, 2022). Different temperatures will be appropriate for contact incubators and still air machines; for example, in a contact incubator 38°C is appropriate, measured at the top of the egg. The humidity used depends on weight loss, so it is important to calculate the weight loss and adjust the humidity accordingly. Programs such as AIMS calculate the humidity eggs need to be moved to during the incubation process after they are weighed. In the absence of a fresh egg weight, humidity can be started at 45%.

Suboptimal temperatures and humidity can directly cause incubation failure. Figure 42.1 summarizes the main causes of hatching failure. Dataloggers are readily available and represent an inexpensive and versatile tool that can be used by vets and aviculturists to monitor and manage both incubators and the environment within the incubation room.[1] Small changes in temperature have profound effects on incubation. For example, a small difference of 0.5°C can result in a 12-hour delay in hatching, while a temperature less than 35°C will cause deformed toes and feet in chickens. The effects of low temperature are most severe in the first third of incubation.

Aviculturists are used to managing weight loss in eggs because there is a higher probability of hatching if the loss is controlled between 12% and 17% of the initial egg mass. Chicks that lose too much water have a decreased probability of hatching, and if they do hatch, they will be dehydrated.[2] Chicks that lose too little water will also have problems hatching and can end up puffy and edematous.

When hatchability falls below expected percentages, the incubation facility and its management should be investigated. Well-run breeding facilities will have records, not only incubation data for each individual egg but also records of incubators and the incubation room. The key environmental conditions to monitor are temperature and relative humidity, both within incubators and within the incubation room. Inadequate control of humidity in incubation rooms can result in knock-on problems to the eggs in an incubator. Figure 42.2 shows a fragment of data from an incubation room. While the temperature of the incubation room was stable, the relative humidity was too high, which had knock-on effects on the weight loss and hatchability of the falcon eggs within the incubators. The incubation room was in a facility in Wales during a period of very wet weather, and the problem was solved by installing dehumidifiers.

Dataloggers can be used to map temperature and humidity profiles in incubators, and it is good practice to map incubators before starting to incubate valuable eggs (Figure 42.3). Figure 42.4 shows the danger spots in a commonly used incubator. Temperatures in the corners and in front of the fan ventilator were greater than 1°C higher than in the "safe" zone of the incubator. In this case, the solution was simply to avoid putting eggs in the hot zones.

Hatching Problems

Most experienced raptor breeders deal with hatching problems without seeking veterinary intervention. Heck and Konkel[3] provide useful practical tips on when to intervene and when to be patient when chicks appear to be delayed in hatching. The "pip," defined as the first crack in the shell made by the embryo, is the first stage in the hatching process, and approximately 24 to 48 hours before, candling will reveal that the air cell expands and "draws down" on one side of the egg (see also Chapter 40, where the normal hatching process is discussed). Occasionally, intervention will be required to save chicks that are struggling to hatch, which—if done timely and by an experienced aviculturist—will have a

TABLE 42.1

Incubation Parameters (Time-to-Pip and Kw Constants) for a Range of Raptor Species

Common Name	Kw × 10^{-7}	Kw Std × 10^{-7}	*n* Kw	Pip Time (Days)	Pip Std	*n* Pip

The pip time is the time to pip from the day the egg is set in the incubator. *n* pip is the sample size for pip times for each species. *n* Kw is the sample size for the Kw species. Std is the standard deviation for the dataset. The Kw coefficient is used to calculate the fresh weight of an egg from the egg length and breadth (in mm). Note that Kw in the table is Kw × 10^7.
This information has been extracted from the Avian Information Management System (AIMS) (www.visualaims.com). Courtesy David Le Mesurier. Kw data is copyright Avian Management Services Ltd.

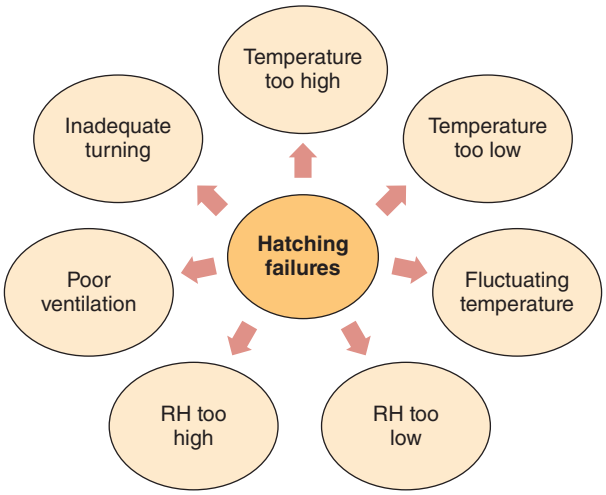

FIGURE 42.1 Causes of hatching failure. *RH,* Relative humidity.

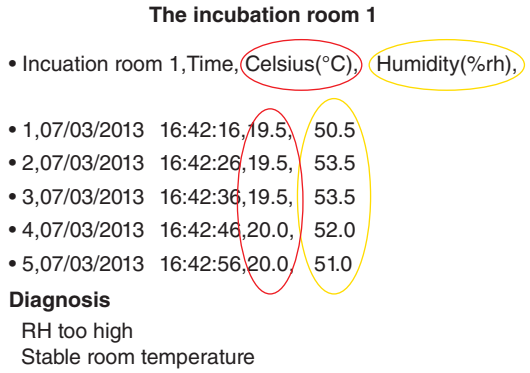

FIGURE 42.2 Fragment of data from an incubation room. *RH,* Relative humidity.

high chance of being successful. Most hatching problems are incubation related and are often linked to inadequate or excessive weight loss during incubation (see also Chapter 40). Generally, pipped eggs are left for 60 hours undisturbed before intervention.[3] The Buddy digital egg monitor (Buddy; Avian Biotech International, Tallahassee, FL, USA) is useful for checking problem eggs and to monitor heart rate. The embryo's heart rate in falcons and Eurasian goshawks *(Accipiter gentilis)* varies between 240 and 260 bpm, with an increase observed before hatching.[4] Extreme increases or decreases in heart rate can be useful indicators that an embryo is stressed, necessitating intervention. Assistance is

FIGURE 42.3 Datalogger within a dummy egg. (Photo courtesy Tom Bailey.)

FIGURE 42.4 The danger "hot spots" that are present in a commonly used incubator. (Photo courtesy Tom Bailey.)

also indicated if an embryo stops for an extended period after turning a quarter to a halfway around, or when it turns a bit but then reverses direction and returns to the pip site. Heck and Konkel[3] consider that these turning issues are often caused by the chick being too wet or having an unretracted yolk sac. Intervention may also be required if the site of the pip is too low down the egg, as this suggests poor or malpositioning of the embryo. At other times, for example, if the head is positioned at the small end of the egg, the chick may not be able to pip, which may make it hard to accurately identify where to open the egg without the use of diagnostic tools such as radiography. Fortunately, several zoological collections have the luxury of being able to radiograph an egg on site, which can lead to successful assisted hatching of malpositioned chicks by pinpointing where the head and bill are located (Figure 42.5).[5] In a review of 209 egg postmortems carried out by the author (unpublished) on large falcon species (gyrfalcons [*Falco rusticolus*], saker falcons [*Falco cherrug*], peregrine falcons [*Falco peregrines*], and peregrine-hybrid falcons) over two breeding seasons from 2012 to 2013, the commonest malpositions were (1) head in the small end of the egg (37%), (2) head above the right wing (21%), (3) head between legs (16%), (4) rotational alignment/chick positioned crossways in egg (16%), (5) head under the left wing/head twisted 180 degrees (5%), and (6) head away from the air cell because of spherical egg (5%).

If a hatcher is opened unnecessarily for too long, too frequently, or if the hatcher humidity is too low, excessive drying of the membranes may occur. Dry membranes around the pip site can conspire to prevent a chick from cutting out, causing a "stuck" chick. Generally, once an embryo has made a quarter turn after pipping, it is safe to remove it. Forceps are used to remove the shell, and a small sterile paint brush is used to "paint" saline onto the membrane to assess vascularization and check the position of the chick (Figure 42.6).

Sterile cotton buds are useful aids for manipulating delicate membranes and embryos. If blood vessels are functioning, the membranes can be moistened with saline, following which the hole can be covered with some tape, and the egg returned to the incubator before rechecking every 30 to 60 minutes.

FIGURE 42.6 A small sterile paint brush is used to "paint" saline onto the membrane to assess vascularization and check the position of the chick. (Photo courtesy Tom Bailey.)

Chicks with partially or completely unretracted yolk sacs have a more guarded prognosis, even with veterinary assistance. Care must be taken to avoid severing any of the large blood vessels that supply the yolk sac as this may cause significant, life-threatening hemorrhage. Fine suture material should

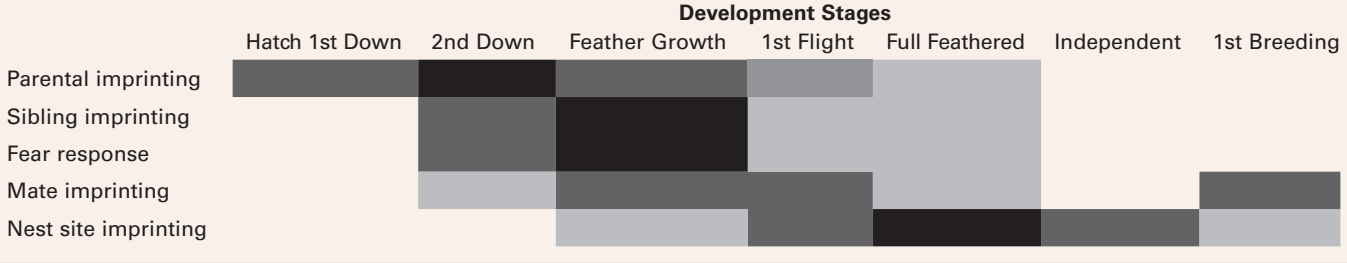
FIGURE 42.7 Surgical closure of a small umbilical protrusion of a gyrfalcon *(Falco rusticolus)* hatchling. (Photo courtesy Tom Bailey.)

be used to tie off the yolk sac completely or to reduce the size of the yolk sac and surgically reinsert the stump into the abdomen. Generally, small protrusions or partially unretracted yolk sacs can be surgically reduced with a fair prognosis, provided that proper hygiene is practiced. The procedure is to ligate the yolk sac close to the body cavity and amputate the sac (Figure 42.7). Depending on its size, the umbilicus may need closure with one or two sutures. Correction of large unretracted yolk sacs usually carries a poor prognosis, especially if caused by interfering too early in the hatching process. Heck and Konkel[3] provide more details on dealing with hatching issues.

Chicks that have had prolonged hatching or interventions are often dehydrated and will benefit from supportive fluids (oral, subcutaneous, intravenous, or intraosseous) and from a precautionary course of antibiotics, especially if yolk sac issues are present. It is sensible practice to swab the navel of all newly hatched chicks with 1% iodine or antiseptic ointment (e.g., F10 barrier cream) to reduce the risk of infection and omphalitis.

RAPTOR PEDIATRICS

Raptor (Falconiformes and Strigiformes) chicks experience a rapid growth rate relative to their body size in the first 20 days after hatching.[6] For example, great horned owls *(Bubo virginianus)* gain 18% of their body weight every 2 days during the first 20 days following hatching.[7] The normal maturation stages of young birds of prey have been summarized by Sherrod[8] and Fox.[9] Clum et al.[10] present a series of chronological pictures of young peregrine falcons from hatch to 40 days, showing key features in the physical development of this species. Holland[11] provides useful growth and rearing data for many unusual raptor species including eagles, vultures, owls, and small falcon species. Wellfair[6] reviewed records at the International Centre for Birds of Prey (Newent, UK) and published a comparative analysis of early growth and rearing protocols in 48 species of hand-reared raptors, and this resource is available online (https://www.handrearingresource-center.com/global-partners/). Appendix 4F presents daily weights, growth rates, and food consumption for five species of raptor including lanner falcon *(Falco biarmicus)*, pygmy falcon *(Polihierax semitorquatus)*, tawny eagle *(Aquila rapax)*, merlin, and saker falcon.



RAPTOR BEHAVIOR AND IMPRINTING

Many of the problems that arise in captive-bred birds of prey are "invisible" psychological or behavioral issues. An understanding of behavioral development is therefore important, especially since the success of a captive-bred falcon in its breeding or falconry role is—to a large extent—a consequence of the behavioral "molding" that occurs during the first 30 to 40 days of life.

Raptor behavior results from the interaction of inherited (innate), imprinted, and learned components. One piece of terminology that is important to grasp is the word "imprinting." Fox[9] defines imprinting as "a distinct genetically programmed learning mechanism in which there is a permanent attachment, during a specific sensitive period, of an innate behavior pattern to specific objects which thereafter become important elicitors of that behavior pattern." In raptors, five main types of imprinting can be identified, including (1) parent, (2) sibling, (3) fear response, (4) sexual partner, and (5) nest site and type. The sensitive times for imprinting each of these behaviors overlap chronologically (Box 42.1).

Birds of prey can be hand-reared individually by humans, group-reared with other raptors in a "crèche," reared by parent birds in an aviary secluded from human contact, or reared by a parent bird in an imprint pen with human contact, or by a combination of these methods. In the larger breeding projects, chicks are hand-reared for the first 6 to 8 days and

BOX 42.1 CHRONOLOGY OF SENSITIVE TIMES FOR IMPRINTING OF BEHAVIORS IN FALCONS

Shades represent the extent to which chicks in a particular developmental stage are susceptible to this type of imprinting. As imprinting is a gradual process, it expands across different developmental stages. The darker the color, the more susceptible the chicks are (Note: no shading means imprinting is complete). As an example, for the first row (parental imprinting), chicks are most susceptible to parental imprinting upon development of the second down, while susceptibility to imprinting on the siblings or nest is highest at later stages of development.

then placed in an aviary to be reared by surrogate parent birds. Falcon breeders with a good understanding of imprinting can hand rear a "human" imprinted raptor suitable for artificial insemination projects or—at the other end of the imprinting spectrum—a parent-reared falcon that knows it is a falcon and is imprinted on both its own species and an aviary nest site. This results in a bird that is well adapted to pair breeding in captivity. Depending on the level of imprinting and socializing, tame raptors can be produced for falconry. Such birds are well adjusted to the sights and sounds of human life (vehicles, dogs, people, etc.), which allows for greater control of the birds in the field without having to dramatically reduce the birds weight to get flying and hunting responses for falconry purposes. Unfortunately, malimprinted birds can be produced by errors in rearing, resulting in a screaming, aggressive, and "poorly mannered" bird that is unsuitable for falconry or breeding and that—in case of larger raptor species—may be dangerous to people. Readers with further interest in the development of raptor behavior are recommended to read Development and Behavior by Fox,[9] in which these developments of normal and abnormal behavior are thoroughly discussed.

GROWTH AND DEVELOPMENT

Immediate Posthatching Period

Newly hatched raptor chicks are covered with fine natal down. This density of down varies according to whether the species is from a colder or warmer climate. Most raptors have white down, but some species, such as Harris' hawks *(Parabuteo unicinctus)*, hatch with buff-colored down. The *musculus complexus* or occipital muscles at the back of the head used for pipping the shell are very pronounced and newly hatched chicks have bulging eyes (Figure 42.8). In the posthatch period, the chick struggles to lift its head and will spend most of the time resting with closed eyes. Although appearing feeble, a healthy chick will respond to the soft calls of its mother and raise its head and neck upwards and gape for food.

Days 1 to 7 after Hatching

The hatching muscle disappears within the first 2 days after hatching. During the first week of life, raptor chicks grow rapidly. The yolk sac is used up after 3 or 4 days.[9] Diurnal raptors may hatch with their eyes open or closed, but by day 2, the eyes start to open and become fully open by day 6.[12] By day 3, chicks can sit on their intertarsal joints and groom (Figure 42.9). As the chicks become more mobile, they start to feed themselves. In the wild, the chick moves toward the edge of the nest to defecate. Raptor chicks respond to any pointed object when being fed, and it is supposed that the parents bill provides the visual stimulus for the initial attempts of chicks to take the food.[13]

Days 7 to 14 Days after Hatching

After 7 to 8 days or 12 to 14 days for small falcon species and larger raptors, respectively, a second thicker coat of down grows through the natal down. This denser down enables the chick to control its own temperature and survive more easily with decreasing brooding times required.[9] In peregrine falcons, primary and tail feather sheaths start to emerge at this stage and will continue to grow at a rate of 2 to 3 mm per day.[10]

Days 14 to 21 after Hatching

By day 17, the contour feathers start to grow in peregrine falcons, which displace the secondary down, giving the chicks a fluffier appearance (Figure 42.10). This is a highly sensitive period when the chick is imprinting to its parents and siblings as well as developing appropriate fear responses.[9]

Days 21 to 28 after Hatching

By 18 days for smaller raptors or 22 to 26 days for larger species, the chicks have reached and may exceed adult body weight. Chicks can stand and walk but will still spend much time resting on their tarsi. The growing contour feathers start to become visible as they emerge through the down (Figure 42.11).

FIGURE 42.8 Newly hatched lugger falcon *(Falco jugger)*. Note the egg tooth, the prominent occipital muscles, and closed eyes. (Photo courtesy Holly Cale.)

FIGURE 42.9 Lugger falcon *(Falco jugger)* chicks between 2 and 5 days of age. Note the eye of the older chick *(middle)* is more round than slit-like. There are no signs of second down emerging anywhere on the bodies of these chicks. (Photo courtesy Holly Cale.)

FIGURE 42.10 The greater primary coverts have broken their sheaths and are visible in this image of 19-day-old lugger falcons *(Falco jugger)*. It is possible to see that some tail feathers have emerged from their sheaths as well. (Photo courtesy Holly Cale.)

FIGURE 42.11 Body contour feathers are visible through the down of these 27-day-old lugger falcons *(Falco jugger)*. (Photo courtesy Holly Cale.)

Days 28 to 35 after Hatching

The chicks are losing their down, and by day 30, peregrine falcon chicks appear to be half downy and half feathered (Figure 42.12). At this stage, chicks are generally attentive to their surroundings. The chicks will still beg and be fed by their parents, but they can feed themselves and will engage in squabbling with siblings and parents over food. The chicks are vocal and engage in robust wing flapping on the nest ledge.

At 4 weeks of age in small raptors or at 5 to 6 weeks of age in larger species, the chicks start to fly. At this stage, the feathers may have soft shafts inside the feather sockets, which in falconry parlance is referred to as not yet being "hard penned." Additionally, the skeleton is not yet mature, and it is best to keep young birds well fed at this stage to avoid any unnecessary handling as this may inadvertently damage their feathers and ossification centers.

FIGURE 42.12 By 31 days these lugger chicks *(Falco jugger)* appear to be about half downy and half feathered. (Photo courtesy Holly Cale.)

Days 35 to 42 after Hatching

At 5 weeks, peregrine falcon chicks are nearly fully feathered except for patches of down around the legs and wings and on the top of their heads. As a result, they are capable of weak flight. Full flying ability is not generally gained until the feather quills are strong and the bird is hard penned. Fledging periods for small falcons such as sparrowhawks *(Accipiter nisus)* and small falcons are short (21–25 days), but for large birds of prey, these are longer and may take up to 95 days in tropical eagles like Verreaux's eagle *(Aquila verreauxii)*.[13]

BONE GROWTH

There has been little published information on the process of ossification in raptors. Fowler[14] reviewed the literature on other avian species and published some information on the ossification of long bones in barn owls *(Tyto alba)*. This investigation confirmed that radiographically, long bone ossification in barn owls is comparable to that in chickens *(Gallus gallus domesticus)*, pigeons *(Columba livia)*, and house sparrows *(Passer domesticus)*.

All wing bones and the femur of barn owls develop without epiphyseal centers of ossification, while the distal tibiotarsus and proximal tarsometatarsus have epiphyseal centers similar to those described for chickens.[14] These epiphyseal centers resemble mammalian growth plates but are in fact the tarsal bones that have formed a center of ossified bones.[15] Harcourt-Brown[15] observed that skeletal problems in Harris' hawks can be caused by issues of metatarsal bone fusion. Damage or trauma to a single metatarsal bone is enough to slow or stop the growth on one side of the limb, resulting in deviations of the tarsometatarsus (Figure 42.13). Harcourt-Brown[15] reported seeing several Harris' hawks with deviations of the metatarsi at around 5 weeks of age.

Fowler[14] reported that in the barn owl, the humerus, radius, and ulna are completely ossified by 60 days, while the femur matures by day 50. The epiphyseal center of the distal end of the tibiotarsus and of the proximal end of the tarsometatarsus both appear on radiographs at less than 20 days,

FIGURE 42.13 Radiograph of the tarsometatarsus of a 5-week-old Harris' hawk *(Parabuteo unicinctus)* showing deviation of the tarsometatarsus, cranial caudal view. (Photo courtesy Nigel Harcourt-Brown.)

FIGURE 42.14 Lung consolidation in a juvenile falcon chick that had a *Cryptosporidium* infection of the alimentary tract and fungal pneumonia (aspergillosis). The image also shows how the tarsal bones that have formed centers of ossified bones that resemble mammalian growth plates in the distal tibiotarsus and proximal tarsometatarsus. There also appears to be a curvature of the right distal tibiotarsus. The image also clearly shows how the distal humerus and proximal radius and ulna develop without epiphyseal centers in raptors. (Photo courtesy Tom Bailey.)

and ossification is complete by day 50 (Figure 42.14).[14] Hawks are relatively slow growing compared to falcons, so there are likely to be some important differences, and a valuable area for future research would be a radiographic study of the normal ossification pattern of falcons and hawks.

NUTRITION AND DIETS

Diet quality is paramount for rearing healthy raptors successfully. Deficiencies in the quantity and quality of diet during growth can result in slowing or stunting of growth or more serious problems such as metabolic bone disease (MBD). In countries and locations where the supply of disease-free prey items cannot be assured, large breeding projects breed their own quail and rats to eliminate risks of introducing infectious diseases. A wide range of infectious agents can be contracted from feeding poorly sourced food where biosecurity or hygiene has been compromised. Diseases associated with poor-quality food include trichomoniasis, salmonellosis, colibacillosis, mycobacteriosis, campylobacteriosis, and chlamydiosis. In addition, infections with paramyxovirus infection, orthomyxovirus (influenza), and herpesvirus, as well as enteric parasites, have been reported.[16] Between 2002 and 2011, paramyxovirus infection, avian influenza, and cryptosporidiosis were diagnosed in falcon chicks by the author in a number of falcon breeding facilities in Dubai that were associated with biosecurity breakdowns in quail units from where the falcon rearing food had been sourced.

Externally sourced food should be purchased from reputable animal food wholesalers. Suppliers should have preventive medicine programs including vaccination and antiparasitic treatments as well as disease-screening protocols in place for the breeding stock and offspring. The method of killing the prey should also be known. This information allows for the prevention of food intoxications or contamination by medicines or euthanasia drugs. Nutritional analysis of the food and supplements fed to the food animals should be available for scrutiny. Cold storage facilities should have their temperatures monitored by sensors and alarms.[1] Attention should furthermore be paid to food transport and storage. Thawing and freezing during transport as well as long-term storage, even freezing, reduce the vitamin content of the food. Thiamine (vitamin B_1) deficiency can occur in fish eaters fed frozen fish caused by the activation of thiaminase, which inactivates the available vitamin.[16] Projects that produce their own prey animals should undertake health screening, which is important to perform prior to the breeding season. Representative animals should be killed and examined postmortem, and appropriate samples submitted for parasitology, microbiology, and virology. Externally sourced prey items represent one of the greatest biosecurity risks to large falcon breeding projects, and breeders should be advised to screen poultry that is used as feed at least biannually for *Salmonella*, *Campylobacter*, *Pasteurella*, *Mycoplasma*, *Chlamydia*, adenovirus, rotavirus, and routine parasitology.

Avicultural staff preparing food should follow strict hygiene protocols, and quality control should be rigorous to ensure that substandard food items are rejected and returned to wholesalers (see Box 42.2 for an example). Food should also

BOX 42.2 FOOD PREPARATION ROOM: DAILY, WEEKLY, AND MONTHLY TASK SCHEDULE

Tasks*	Sunday	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday
DAILY (AFTER FOOD PREPARATION IN THE MORNING)							
Cover food with plastic/cling film and store in cold room							
Collect and dispose of feathers and gut contents from food animals separately in a bag/bin							
Clean and disinfect all food preparation equipment and return these to their designated locations							
Clean and disinfect all food preparation and other working surfaces							
Clean sinks, taps, and draining boards with disinfectant (e.g., F10)							
Check and clean walls in food preparation area and cold room appropriately							
Sweep and mop all floors							
Rinse work clothes and hang to dry on dry rack							
Clean and organize food preparation room after food has been removed in the afternoon							
WEEKLY							
Clean and soak all food tools and cleaning brushes in disinfectant (e.g., F10 for 10 minutes)							
Check freezer temperatures							
Wash all clothing and towels							
Clean restroom							
Clean and organize workshop area and entrance (including floor)							
Clean and organize aviculture equipment room							
Replace fly papers as needed; empty electronic fly zappers							
Refresh foot baths							
Empty trash							
MONTHLY							
Disinfect preparation room (e.g., F10 for 20 minutes)							
Hose and scrub preparation and cold room floors							
Clean and disinfect bucket stands and log rests							

*Tick when task has been completed.

be slowly thawed dry, to avoid food from coming into contact with thawing water, which leads to an increased bacterial load. Breeding projects that prepare large quantities of chick food will purchase freshly killed prey items and process them into chick food that can be frozen.

It can be tempting for raptor breeders to reduce costs associated with feed. This might mean feeding shot or otherwise sourced free-living animals such as pigeons to raptors, which has been associated with an increased risk of ingesting agricultural toxins and exposure to known pathogens such as *Trichomonas* spp. and herpesvirus (see also Chapter 22).[17] However, despite the well-known risks of feeding wild prey, many projects surprisingly still include wild-sourced pigeons and gamebirds as part of the chick's rearing diet.

Diets for raptor species should always include bone, which is available to the bird's digestive tract. Chick diets are often prepared by mincing skinned and eviscerated prey items such as rat or quail for medium/larger species or mice for smaller species. It is vital that larger bone or tooth fragments, particularly from rats, are removed from minced baby falcon food, especially during the first stages of life (days 1–3). One way of minimizing issues with indigestible and potential obstruction causing bone fragments (Figure 42.15) is to mince the first-stage diet twice. Casting material is generally not offered to chicks during the first 10 days of age. Overfeeding hand-reared chicks during their first week can result in crop and/or gut stasis. To avoid this, chicks should be weighed before each feeding session to monitor growth rates. In addition, food intake should be controlled, whereby chicks are generally fed the same or slightly more than their previous feeding.

Nutritional deficiencies and associated diseases can result from feeding chicks with inappropriate diets. Vitamin E deficiency in captive avian species, including raptors, has been associated with low fertility, low hatchability, immunosuppression,

FIGURE 42.15 (A) Distended gut in a chick that died because of impaction with rat bone fragments. (Photo courtesy Tom Bailey.) (B) Rat bone and tooth fragments in poorly prepared baby falcon food. (Photo courtesy Tom Bailey.)

and specific clinical abnormalities such as encephalomalacia and muscular myopathies.[18,19] Biotin (vitamin B_7) deficiency, as another example, has been associated with a reduction in hatchability without adversely affecting egg production.[11] In birds, a diagnosis of vitamin deficiency, for example, vitamin B_1/thiamine[20] or vitamin E,[18] was traditionally based on clinical signs and the clinical response to supplementation. However, now that tests measuring vitamin levels in tissues and blood are more widely available, the ability of veterinarians to diagnose deficiencies and to provide more rational supplementation can improve. If there is concern about the nutritional status of chicks, then assessment of blood vitamin levels in the parent breeding falcons may be considered. Tissues from prey animals can also be submitted for nutritional assessment when deficiencies are suspected, and routine nutritional assessment may be advisable for large commercial falcon breeding projects. Vitamins, probiotics, and calcium-vitamin D_3 supplements can be added to the food being fed to young chicks, if deficiencies or imbalances are suspected or confirmed.

PEDIATRIC DISEASES

Jones[12] provides a very useful section on raptor pediatrics. Some (common) nutritional and noninfectious diseases of raptor chicks are presented in Table 42.2.

Gastrointestinal Disorders

Impactions

Mechanical obstructions of the gastrointestinal tract are not uncommon causes of death and morbidity in raptor chicks, particularly during the first week of life. Impactions are usually caused by chicks being fed indigestible hard structures such as bone fragments or rodent teeth (Figures 42.15 and 42.17). This can occur when the chick food has been inadequately prepared or quality control is poor. Impacted chicks will show signs of starvation and gastric stasis. Chicks will become dull and may stop passing feces. Septicemia is often a sequel to impactions, particularly if sharp material perforates the gut lining. Palpation of the abdomen often demonstrates hardened ventriculus or intestine. Radiography can be helpful, if available. While surgery is possible, it is rarely performed on young raptor chicks and generally carries a poor prognosis. Parenteral rehydration and the use of motility-enhancing drugs such as metoclopramide and laxatives such as lactulose or liquid paraffin can be helpful to help resolve mild cases.

Obstructions

It is particularly important to check the crops and stomachs of chicks under 10 days old that are being hand-reared. Overfeeding and obstructions can be fatal. A chick should not be fed until its crop is empty. The stomach should be checked, which can be done by checking its lower abdomen. The stomach should feel soft and flaccid, and the overlying skin should be pinkish in color. If the area appears dark or the stomach is hard to the touch, this indicates a large amount of food remains in the alimentary tract, and thus feeding should be delayed until the stomach has sufficiently emptied. A particular problem that can cause obstructions can occur when bones from adult prey (rats or quail, for example) are inadequately ground down in mincer units for young falcons. These dense bones are poorly digestible within the neonatal stomach and can accumulate, causing gastric disturbances leading to fatal impactions. Mineral oil or lactulose are commonly used to help ease the passage of ingesta through the alimentary tract. Prokinetic agents such as cisapride or metoclopramide are also helpful to stimulate motility of the gastrointestinal tract. It is important to ensure that the chick is adequately hydrated by administering appropriate fluid therapy.

Cloacal prolapse

Cloacal prolapses are not commonly seen in raptor chicks (Figure 42.18). In other species, prolapses are associated with diarrhea, impactions, nutritional deficiencies, and tenesmus, and similar causes may be expected in birds of prey.[23] Placement of a purse-string suture or a transvent vertical suture can be helpful until the primary cause is dealt with and the tissue is viable. Cloacapexy is an alternative technique to purse-string sutures (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, for a description of the technique).

Yolk Sac Infection

Yolk sac infections, as discussed under hatching, usually occur around hatching. In case of infection, it may be possible to see an inflamed area on the yolk sac wall around the navel or around the umbilical region. As with other bacterial infections in young birds, treatment must be initiated quickly, which often involves fluid therapy to correct dehydration and appropriate antibiosis, based on culture and sensitivity results.

TABLE 42.2
Selected Nutritional and Noninfectious Diseases of Raptor Chicks

Disease	Etiology	Clinical signs	Diagnosis	Treatment and Prevention
Vitamin B deficiency	Thiamine (vitamin B_1) deficiency	Stargazing, seizures, incoordination, and opisthotonos	History, clinical signs and physical examination. Plasma vitamin levels, if possible	Vitamin B complex dose based on thiamine (vitamin B_1) content (3–30 mg/kg IM q7d or 30 mg/kg in food q48h) until signs resolve[21]
Vitamin E deficiency	Vitamin E deficiency in food caused by storage or rancidity issues	Similar signs as for vitamin B deficiency	As above	Improve diet Give selenium and vitamin E (0.06 mg/kg IM q7d or 15 mg/kg PO once[21]
Hypothermia and hyperthermia	After hatching chicks are covered in natal down and cannot maintain their own body temperature. Poor parental brooding or inadequate brood temperature can cause hypothermia. Hyperthermia occurs when heat lamps are too hot or too close to the chicks	Chicks that are too cold will huddle together and shiver. In contrast chicks that are too hot will pant and create distance to the other chicks. Hyperthermia can cause dry wrinkled reddish skin, dehydration and contribute to impactions and gut stasis	Clinical signs or cloacal temperature	Brooder temperature should be 36°C (96.8°F) and reduced by 0.3–0.6°C (0.5–1°F) per day until the chick can be kept at room temperature at around 10–14 days. Chicks should be given a temperature gradient and allowed to choose their comfortable thermal zone. Hyperthermia is prevented by careful monitoring of temperatures with infrared thermometers or dataloggers
Splay legs	Usually caused by chick being kept on slippery surface	One or both legs deviate laterally	Physical examination	Hobble legs with an adhesive conforming bandage or place padding that allows chicks to sit with legs underneath them. A substrate of fine pea gravel provides a texture that prevents splaying
Angel wing	Increased weight of the rapidly developing primary feathers causes an overextension of the carpal joint and the outer wing starts to droop	The wing twists outwards at the carpal joint and the outer wing droops	Physical examination (Figure 42.16)	Taping of affected primaries in a natural position at first sign of outward turning will correct the deformity. See Zsivanovits et al.[22] for description of correction of valgus deformity in a goshawk

Metabolic Bone Disease

MBD is a common problem in all species of young birds. Avian MBD may be seen as splayed legs, fractures, folding fractures, rickets, beak malformations, crooked toes, bowed legs, tibiotarsal rotation, and slipped tendons (Figures 42.13, 42.19, and 42.20). An excess of either calcium or phosphorus results in the sequestering of the other in the form of an insoluble calcium phosphate.[24] In the intestine, this results in less absorption and lower availability of the element involved. Calcium deficiency is a common cause of nutritional secondary hyperparathyroidism in falcon chicks and is associated with a range of growth- and calcium imbalance–related issues. Tibiotarsal rotation can result in varus deformity, which is seen as rotation of the tibiotarsal bone laterally above the hock joint rotating the foot (tarsometatarsus and toes) laterally/to the outside.

Metabolic bone disorders are covered in greater detail in veterinary texts on poultry species and long-legged birds where more research has been conducted.[25] Historically in falcons, MBD used to occur when chicks were fed bone-deficient diets, but this is now rarely the case because breeders are better informed. Despite great attention to the provision of calcium and vitamin D supplements, and minced chick diets with crushed whole bones, sporadic cases of MBD do occur. Some breeders believe that crushed rat bones may not provide enough available calcium because of the thickness of rat bones compared to quail or mouse bones. It is also considered that enteric infections causing malabsorption of minerals such as phosphorus might be contributing factors.[25]

Radiographic imaging is important in demonstrating decreased bone density, growth plate abnormalities, fractures, and other skeletal malformations. Dietary review and appropriate supplementation are important in the prevention of MBD in chicks. Some falcon breeders are also using full-spectrum lighting in rearing nurseries to help increase the conversion of vitamin D into its active form.

Viral Diseases

Avian pox, herpesviruses, paramyxoviruses, and adenoviruses can cause morbidity and mortality in young raptors (see Chapter 15 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease). Volume 1 provides information on the clinical thought processes in diagnostic

FIGURE 42.16 Desert eagle owl *(Bubo ascalaphus)* with angel wing. (Photo courtesy Tom Bailey.)

FIGURE 42.17 An accumulation of dense quail bone fragments within the stomach of a gyrfalcon *(Falco rusticolus)*. The mincer used to prepare the food had been used with too large a diameter grinding head, allowing large bone fragments to be incorporated into the baby falcon food. (Photo courtesy Tom Bailey.)

decision-making pertinent to some of these viral disorders in birds. Adenovirus infection is discussed in the following section because it has been a significant cause of mortality in some of the smaller falcon species.

Adenovirus infection

Adenovirus infections have caused significant outbreaks of mortality in breeding projects and have been confirmed in the following species: aplomado falcons *(F. femoralis)*,

FIGURE 42.18 Cloacal prolapse in a falcon chick with a *Salmonella* infection. (Photo courtesy Tom Bailey.)

FIGURE 42.19 Radiograph showing severe metabolic bone disease in a juvenile Bonelli's eagle *(Aquila fasciata)*. (Photo courtesy Tom Bailey.)

American kestrels *(F. sparverius)*, goshawks, merlins, peregrine falcons, Mauritius kestrels, orange-breasted falcons *(F. deiroleucus)*, gyrfalcon × peregrine hybrids and Taita falcons *(F. fasciinucha)*.[26] The author has suspected the disease in New Zealand falcons (*F. novaeseelandiae;* Bailey, personal observations).

Clinical signs include anorexia, diarrhea, and sudden death. The primary lesion in affected chicks is multifocal random coagulation necrosis and inflammation of the liver. Adenovirus infection is diagnosed by demonstrating intranuclear inclusion bodies in affected organs and can be confirmed by adenovirus polymerase chain reaction (PCR).[26]

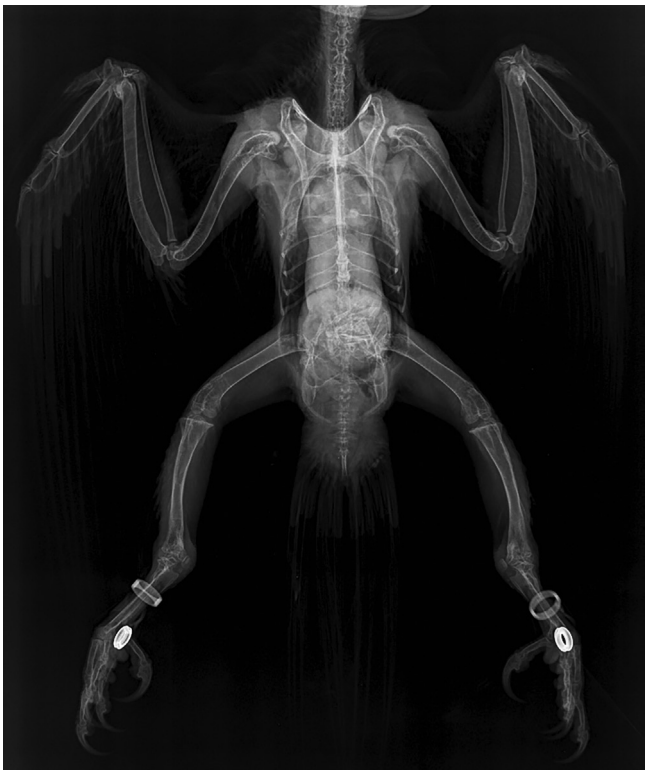


FIGURE 42.20 Radiograph of a juvenile gyrfalcon *(Falco rusticolus)* hybrid showing permanent bony changes caused by mild metabolic bone disease. Note the bowing of the femurs, tibiotarsi, radiuses, and ulnas. Although the radiographic signs appear obvious, the bird itself showed no obvious physical deformities. (Photo courtesy Tom Bailey.)

FIGURE 42.21 Feather dystrophy following suspected adenovirus infection in a New Zealand falcon *(Falco novaeseelandiae)*. (Photo courtesy Tom Bailey.)

Small falcon species seem to be most susceptible (aplomado falcons, Mauritius kestrels, New Zealand falcons), with young birds of less than 35 days of age predominantly being affected. The incubation period is approximately 6 to 10 days. Dystrophic feathers have been noted in New Zealand falcons (Figure 42.21) that were suspected to have survived adenovirus infection during the second week of life (Bailey, personal communication).

Forbes et al.[27] reported an outbreak in Mauritius kestrels and considered that turkey poults and domestic chicks fed to the birds were the source of the infection. Schrenzel et al.[26] were unable to identify the source of the adenovirus in the disease outbreaks that they described but considered that several members of the genus *Falco*, including peregrine falcons and gyrfalcons, may have been reservoirs of the virus. Contact with carrier falcons within a multispecies facility may transmit the virus to susceptible species, particularly young birds, and should therefore be prevented, if possible.

Bacterial Diseases

Bacterial enteritis can cause morbidity and mortality in falcon chicks and is influenced by many factors including intestinal flora, nutrition, environmental factors, and pathogens.

Intestinal Flora

Birds hatch from the egg with a completely sterile digestive tract, and microbes are quickly picked up within the nest or incubator.[28] The source of the microflora depends on the hygienic conditions of the environment and the presence or absence of the parents.[28] In intensive breeding projects, falcon chicks are incubated and hatched from sterilized eggs, incubators, and hatchers, and after hatching they are reared in a heavily disinfected environment. Under these circumstances, it is hard for chicks to acquire a normal intestinal microflora, which comprises useful bacteria that protect the intestine from infection with pathogenic bacteria by occupying the available attachment sites (competitive exclusion) and by creating an environment (pH and metabolites) in which pathogens cannot survive.

Bacterial organisms cultured from the upper digestive tract include *Staphylococcus aureus*, *Bacillus*, and *Corynebacterium*.[12] Bacterial organisms cultured from the lower digestive tract include *Escherichia coli*, *Enterococcus*, and *Proteus*.[12] These are "normal" flora, although they can cause problems in immunocompromised chicks. Gram-negative bacteria are the most important cause of enteric disease in young falcons and include *Salmonella* spp., *E. coli*, *Salmonella*, *Clostridium*, *Mycobacterium*, *Pasteurella*, and *Proteus*.[12] Battisti et al.[29] described neonatal mortality in a breeding center caused by salmonellosis. The main sources of *Salmonella* identified in this case were the infected poultry meat and day-old chicks that were used to feed the birds.

Staphylococcus (not *aureus*) and *Streptococcus* are considered normal flora of the raptor respiratory tract. *E. coli*, *Pseudomonas*, *Klebsiella*, *Pasteurella*, *Acinetobacter*, *Moraxella*, *Aeromonas*, and *Mycoplasma* have been isolated from chicks with respiratory

FIGURE 42.22 *Pseudomonas* sinusitis in a saker falcon *(Falco cherrug)* chick. The chick also showed neurological signs (head tilt). No viruses were isolated from this bird. (Photo courtesy Tom Bailey.)

disease (Figure 42.22).[12] Diagnosis of bacterial diseases in chicks requires clinical examination and bacterial culture of suspected lesions. Immediate antibiotic treatment and fluid therapy are warranted to treat the infection and correct dehydration.

Parasitic, Protozoal, and Fungal Diseases

Coccidial infections

Coccidian parasites that can cause health issues with young raptors include *Caryospora*, *Cryptosporidium*, *Eimeria*, *Frenkelia*, *Sarcocystis*, and *Toxoplasma gondii*.[12] While coccidia are not generally considered to be highly pathogenic in adult raptors, infections with *Caryospora* in juvenile raptors can be severe and even fatal. Clinical signs include lethargy, depression, diarrhea (sometimes with blood), poor body condition, and weight loss. The disease is readily diagnosed by the detection of oocysts in fecal samples by microscopy. Forbes[30] describes the clinical disease and control in juvenile falcons (see Chapter 9 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).

Aspergillosis

Young raptors, especially compromised or debilitated birds, are susceptible to fungal infections. Aspergillosis should therefore always be considered a differential for any young birds showing respiratory clinical signs (Figure 42.14), especially in gyrfalcons or gyrfalcon hybrids (see also Chapter 8 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 2, Infectious Disease).

Candidiasis

Infections with *Candida* spp. can cause oral and crop infections. Candidiasis in falcon chicks can also be a side effect of prolonged antibiotic therapy or poor food hygiene (see also Chapter 41).

Miscellaneous Conditions

Alula malpositions

The alula is the freely moving first digit, the bird's "thumb," and typically bears three to five small flight feathers. The alula is an aerodynamic device used when a bird lands to prevent stalling. Malpositioning of the alula occurs in gyrfalcons and gyr-hybrid chicks from 50 days old. The development of this deformity coincides with the period when young falcons are in groups of up to 30 birds in large hack pens and are hard to observe individually. When the birds are caught for sale at 70 to 90 days of age, the malposition, a ventrolateral deviation of the alula, is noted. It is most obvious when the wing is extended and can affect one or both wings (Figure 42.23). While the deformity does not appear to have any negative effect on flying performance, it is unsightly and reduces the commercial value of the falcon.

While no definitive etiology has been identified, breeders consider environmental conditions including inadequate humidity and temperature to be factors. Barbon et al.[31] reviewed surgical techniques to correct alula malpositions and reported that no technique is 100% effective. Fracturing the base of the first digit and stabilizing the alula to adjacent covert feathers using cable ties for 2 to 3 weeks seems to be a simple and

FIGURE 42.23 Gyr-hybrid falcon showing bilateral alula malpositioning. (Photo courtesy Tom Bailey.)

effective technique that is commonly employed by veterinarians working in falcon hospitals in the Middle East (Barbara Arca-Ruibal, personal communication, 2023). The technique is performed under anesthesia, followed by postoperative analgesic treatment, and appears to resolve in many cases presented between 60 and 90 days of age.

Growing skull fracture

A growing skull fracture has been reported in a red-tailed hawk *(Buteo jamaicensis)*.[32] Skull trauma to nestling raptors may lead to the development of this disorder and can potentially cause neurological signs and visual deficits. Three-dimensional computed tomographic imaging may reveal skull defects that are not readily visible on radiographs.[32] Growing skull fractures have been reported in humans, usually resulting from injury to the soft skull during the rapid growth phase of an infant's life. Nestling raptors have thin, fragile skulls, a rapid growth rate, and compete aggressively for food items; hence, this condition should be considered a potential diagnosis when unexplained neurological signs are seen in young chicks.

CONGENITAL PROBLEMS

Congenital disorders are occasionally seen, but unfortunately issues associated with inbreeding may become increasingly frequent in the future. Inbreeding has been shown to cause early embryonic death in passerine species.[33] Because of import restrictions, it is becoming increasingly difficult in Europe and North America for breeders to legally acquire wild-caught unrelated breeding stock. Given that only a few raptor breeders have good record systems and unscrupulous breeders sell related birds as unrelated, it is inevitable that the limited captive pool of birds used for breeding will become more inbred with each passing generation. Splay or spraddle legs, scoliosis, lordosis, opisthotonus, cerebellar defects, hydrocephalus (Figure 42.24), eye abnormalities, joint deviations, and stunted birds are examples of congenital and growth problems seen in psittacines and raptors.[23,34] Recently, Moore et al.[35] diagnosed photoreceptor dysplasia in peregrine falcons and peregrine falcon hybrids and suggested this to be heritable.

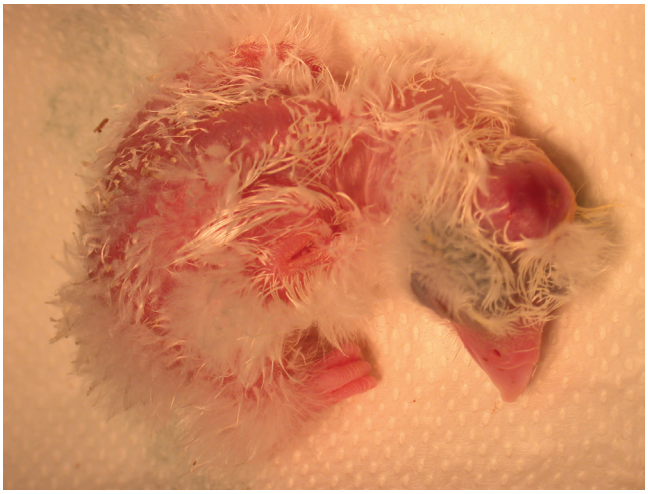

FIGURE 42.24 Hydrocephalus in a newly hatched falcon chick. (Photo courtesy Tom Bailey.)

It is likely that genetic testing will become an important tool for diagnosing genetic and inbreeding issues in the future. Relatedness can be tested through multiple gene loci comparison between birds and may be helpful to identify the genetic variety within a breeding collection, which can be an important tool for managing breeding in controlled study books for species conservation breeding programs.

ACKNOWLEDGMENTS

I thank Martyn Paterson from Desert Falcons and Nick Fox, Oscar Oliva, Sandor Sebastian, and Diana Durman-Walters for the avicultural knowledge they shared during the 3 years I worked at International Wildlife Consultants breeding falcons. Thanks to Jorge García de la Fuente and Barbara Arca-Ruibal for sharing their experiences of correcting alula deformities in falcons. Thanks to Holly Cale from the International Centre for Birds of Prey for sharing additional images. Information in Table 42.1 was extracted from the Avian Information Management System (AIMS) courtesy David Le Mesurier (www.visualaims.com).

CHAPTER 43

Incubation and Pediatrics of Columbiformes (Pigeons/Doves)

Shangzhe Xie

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

There are 371 species in the family Columbidae (order Columbiformes), out of which 12 have been classified as critically endangered and 20 have been classified as endangered by the International Union for Conservation of Nature and Natural Resources (IUCN) Red List.[1] As strategies to increase the reproductive efficiency of columbids become more important in countering decreasing population numbers in the natural habitat, artificial incubation and hand-rearing may become essential for the conservation efforts of these species.

INCUBATION

The artificial incubation of columbiform eggs follows a standard protocol. The incubation temperature is maintained at 37.2°C (98.6°F) and the humidity level at 55%. The eggs are weighed daily to ensure they maintain their 15% (±3%) total weight loss from lay. The daily weight loss can be controlled by moving eggs that lose either too little or too much weight into additional incubators set at 35% and 75% humidity, respectively. The automatic turning mechanism of the egg incubator should be set at 24 turns a day, that is, once every hour, with the turn occurring over 10-minute intervals. Forty-eight hours before the anticipated hatch date and/or at the time that internal pipping is observed, the egg should be moved into a hatching incubator with rollers removed and set at 75% humidity.

HAND-REARING PROCEDURES

Columbiform chicks are altricial and therefore require hand-rearing if hatched away from the parents. Hand-rearing protocols appear relatively similar among the different columbiform species (see Appendix 4G). There are a variety of hand-rearing formulae available in the market, and those formulated for columbiform species should contain 20% to 22% crude protein and 13.14 to 13.39 MJ/kg metabolizable energy.[2,3] An example of a columbiform hand-rearing protocol is summarized in Table 43.1.

NORMAL DEVELOPMENT

The development and milestone achievements of columbiform chicks appear consistent among species. An example is provided in Table 43.2, comparing these milestones among columbiform species of different sizes. Appendix 4G provides the growth curves of various columbiform species.

COMMON PEDIATRIC PROBLEMS

Like other species of avian neonates discussed in other chapters in this section, columbiform chicks can be affected by the full range of avian pediatric problems, including crop stasis, crop thermal injuries, crop perforations, valgus deformities of the wings, splay leg, beak malformations, omphalitis, and infectious diseases. Prevention and management of these common pediatric problems are discussed in another chapter, so only the more common columbiform-specific pediatric problems or those requiring a different, columbiform-specific preventive or management approach will be discussed here.

CROP STASIS

Complete or incomplete stasis appears to be common in the first few days post-hatch and whenever there are changes to the feeding regime. The crop should not be completely empty in between feeds, as this may predispose to crop stasis. Failure of the crop to empty at a normal rate should be readily picked up by the carer, and initial diagnostics should include a review of the feeding protocol and growth chart (see also Appendix 4G), to determine if there are systemic diseases that need to be investigated. Initial diagnostic tests should include crop and fecal Gram stain cytology and culture and sensitivity testing. Hematology, biochemistry, and radiographs may also be useful if an underlying systemic disease is suspected.

The hydration of a chick affected by crop stasis should be maintained by increasing the amount of water content either in the hand-rearing formula or parenterally. A crop lavage can be performed but should be done with caution, as completely emptying the crop can exacerbate the slow clearance of crop contents. Antibiotics and/or antifungals should be prescribed based on the results of crop and fecal cytology and culture and sensitivity testing. In the author's experience, bacteria and yeast overgrowth in the crop are equally common, so assumptions should not be made without diagnostic tests being performed. Metoclopramide can also be included as part of the treatment plan, if a foreign body obstruction has been ruled out, but its efficacy in this zoological group is unknown. If the crop stasis is addressed early, before the crop is overly distended, then

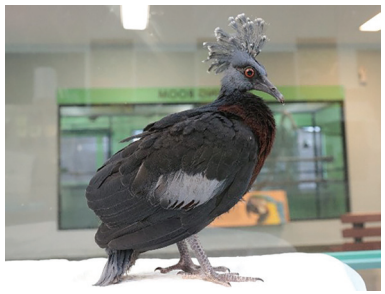
TABLE 43.1

Mandai Wildlife Group, Jurong Bird Park, Breeding and Research Centre, Columbiform Hand-Rearing Protocol

Days Post-Hatch	Brooder Temperature (°C)	Feeding Frequency	Food Intake by % of Body Weight (per Feeding)	Miscellaneous
0	35	Every 2 hours (= 7× a day)	10%	Apply betadine over umbilicus 2×/day for first 2 days. Feed using cannula infusion tip on syringe, clear rubber feeding tube or crop needle depending on chick size. Ensure there is no air in syringe before feeding. Feed formula at 38°C–40°C.
3	34			
5	33	Every 3 hours (= 5× a day)	12%	
6		15%		
8		Every 4 hours (= 4× a day)	17%	
9	32			
11				Daily weight gains over 15% after this age may result in valgus deformity of the wings.
13	31			
14				Offer lightly soaked pellets/ripe papaya with no skin hanging from a cup to omnivorous columbiform species. Offer millets to granivorous columbiform species.
17	30			
21	29	Every 5 hours (= 3× a day)		Expect daily weight gains to be less than 10%.
22	28			
23		Start reducing volume of second feeding (e.g., 20 g, 10 g, 20 g)		
24	27			
25		Every 8–12 hours (= 2× a day)		
26	26			
28				Most species are starting to eat well on their own and due to fledge.
30		Every 24 hours (= 1× a day)		
35–40		Discontinue feeding if chick is readily eating on own		

there should not be any need for external physical support of the crop using a crop brace. However, a crop brace is a useful adjunct in severe cases not addressed early.

The prognosis of crop stasis in columbiform chicks is usually good if appropriate treatment is provided early and there are no underlying systemic diseases involved.



TRICHOMONIASIS

Although infrequently observed at the author's facility, *Trichomonas* spp. is a protozoan parasite (see Chapter 22) that columbiform species, particularly young ones, are susceptible to. Trichomoniasis most commonly presents as unthriftiness and high mortality in young columbiform birds, with diphtheritic membranes a common finding on physical examination (Figure 22.4A). A definitive diagnosis can be obtained by finding motile protozoa on microscopic examination of a crop wash, throat swab, and/or feces. Another presentation of trichomoniasis in young columbiform chicks is omphalitis (Figure 22.4B), which presents most commonly with very large retained and inflamed yolk sacs comprising 20% to 40% of the chick's weight.

Treatment with a nitroimidazole (metronidazole, dimetridazole, ronidazole, carnidazole) is usually effective if diagnosis is made early. Supportive treatment with antibiotics for secondary bacterial infection may also be warranted. In flocks of columbiform birds where trichomoniasis is a persistent problem, improvement of husbandry conditions and strategic treatment of the flock may be indicated, for example, during the breeding season.

TABLE 43.2

Comparison of Milestone Achievements Among the Santa Cruz Ground Dove *(Alopecoenas sanctaecrucis)*, Jambu Fruit Dove *(Ramphiculus jambu)*, and Victoria Crowned Pigeon *(Goura victoria)*

	Santa Cruz ground dove		Jambu fruit dove		Victoria crowned pigeon	
Milestone	**Number of Days Post-Hatch**	**Chick appearance**	**Number of Days Post-Hatch**	**Chick appearance**	**Number of Days Post-Hatch**	**Chick appearance**
Full yolk absorption, pin feathers present	1		1–2		1–2	
Toes uncurled, able to grasp	2		3–4		3–4	
Eyes fully open	8		8–10		5–7

INTRODUCTION

Toucans are tropical birds that are easily recognized for their prominent beaks. The general term toucan will be referred to throughout this text as synonymous with all birds that belong to the family Ramphastidae, such as aracaris, toucanets, and toucans. Toucans are found in a wide range of biomes, from tropical forests to Brazilian cerrado, and therefore they are expected to have different diets, behaviors, or even disease susceptibilities. On the other side, with a few exceptions, there is still scarce information to support species-specific recommendations for husbandry and nutrition. An evidence-based approach for medical intervention in toucans is especially hindered by the lack of controlled studies, especially those related to therapeutics, which makes extrapolation from other species a rule. Large-scale investigations are difficult to conduct, because of the small number of chicks that are bred.[1]

Toucan neonatology has many similarities with other altricial birds, such as Psittaciformes and Columbiformes. For all those birds, breeding success depends on meticulous observation, proper sanitation, and nutrition. With a few exceptions, the basic procedures regarding artificial incubation and hand-rearing are the same as for psittacines. The ability to rear toucans can be considered rare.[2] Sensitivity, carefulness, and patience are essential attributes for good birdkeepers.[3] Most difficulties in breeding toucans are not related to pairing, egg laying, and incubation but to the survival of the chicks.[3]

This section will focus on the peculiarities of Ramphastides that affect hand-rearing, the incidence of diseases, and their management in neonate and juvenile toucans. Since medical conditions that affect neonate toucans depend on the husbandry approach that is adopted, they will be presented separately for parent-reared and hand-reared chicks.

PARENT-REARED CHICKS AND COMMON PROBLEMS

Whenever opting for parent-rearing, it must be assured that nests can be easily monitored, since parent neglect and diseased chicks are common events. Incubators and brooders should always be kept ready, if immediate removal of eggs or chicks turns out to be necessary. The use of infrared cameras (Figure 44.1) has been a valuable tool to provide a noninvasive method of nest inspection, during all breeding phases.[3,4] Removal of eggs from the nest should be done with care and planned, preferably at a time when none of the parents are inside the nest, for example, during feeding time. Quickly covering the nest entrance with a net or piece of cloth usually prevents parents entering the nest, so that eggs can be safely accessed through an inspection opening. Breeding toucans can be very aggressive, so these procedures should always be performed with assistance. Chick monitoring can be done by daily inspections and frequent weighing, in the case of pairs that tolerate those interventions.[5]

The most common causes of neonatal death in parent-reared chicks are predation, food or foreign material impaction, and parasitic diseases.

Predation

Any toucan that is reared in a nestbox has the risk of being predated by rats or opossums, but most of the predation events in neonate toucans are caused by their own parents. Parental predation may be related to several factors, ranging from stress to the destruction of chicks with congenital deformities.[3] The observation that predated chicks often end up being fed to their siblings leads to the conclusion that these events were caused by the scarcity of live prey in captivity. The increased supply of insects allowed a couple with a history of predation to successfully rear chicks.[3]

Impaction

In the urge of feeding their chicks, toucans might offer them items such as bark, sticks, and pebbles, which can cause impactions. For this reason, toucans should always have enough food available to avoid any other items being offered to their offspring. During this period, toucans will favor live food (mostly insects) as the main food for their chicks. Even with a enough supply of pellets, they might not be offered at all. For this reason, the best way to prevent impaction is to guarantee that the right food items and amounts are always available. Careful planning includes contacting a trustworthy insect supplier in advance or preparing your own facilities to produce a reliable number of insects. During the breeding season, one pair of toucans can consume thousands of crickets.[4] Toucans start to feed their chicks at sunrise, so from that moment on, they need to have something to offer. One way to increase the amount of edible items in the early morning is by installing lamps to attract insects to the aviary during the night.

The way the regular food is offered must also be taken into consideration, since it should be presented in smaller pieces

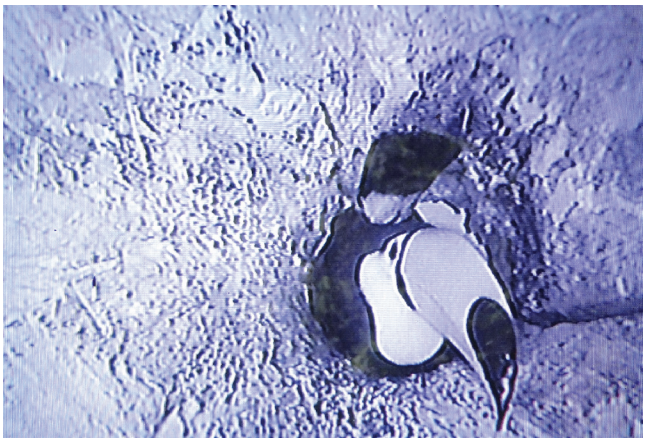

FIGURE 44.1 Infrared camera monitor view of a toco toucan *(Ramphastos toco)* hen in her nest. (Photo courtesy Mathias Dislich.)

than usual. Fruits, such as papaya, must have their skin removed, because it can also cause obstructions (Figure 44.2).[3]

Impacted chicks generally have poor weight gains and might have soil in the feces.[2] Chicks with complete obstruction will not defecate, which is difficult to recognize when other siblings share the same nest. Any suspect case must be removed immediately from the nest and treated as an emergency. Once it has been hydrated and placed in a brooder, the production of feces is assessed. If it begs for food, a small amount of diluted hand-rearing formula can be offered. If no stools are passed after 15 minutes, between two or three drops of mineral oil can be given. Impacted toucan chicks have a poor prognosis.

Parasitic Diseases

Toucan chicks raised by their parents may be subject to ectoparasite infestations, since enclosures do not limit parasites access to nests. Some of these infestations can be intense, leading to the death of individuals.

FIGURE 44.3 Toucan chick infested with *Ornithonyssus* mites. As the chick is devoid of feathers, these mites and the skin rashes they induce can be easily identified upon visual inspection of the chick.

Mites

Mites of the genus *Ornithonyssus* can eventually parasitize toucan chicks, which become disturbed and agitated, feeding less. Consequently, they become dehydrated and do not develop well. Since *Ornithonyssus* spp. are obligate hematophagous mites, high degrees of infestation can lead to anemia,[6] which can be fatal if left unattended. Because toucan chicks are devoid of plumes, mites and skin rashes are easily identified during physical examinations (Figure 44.3). Toucan chicks have a dirty appearance, due to the accumulation of cast skins, eggs, and mite feces.[6] Infested chicks must be removed from the nest, to be stabilized and treated. The application of small amounts of propoxur (Bolfo®; Elanco, São Paulo/Brazil) with a cotton swab near the vent and the removal of the bird from the nest are generally enough.

Nests showing signs of infestation should be removed and treated with the application of propoxur powder inside or fumigated with formaldehyde tablets. It is important that, when returning to the enclosure nests, they are free of any excessive residues of those substances.

Philornis

Infestations by botflies of the genus *Philornis* are common in free-living toucan chicks and may also occur in captive birds. Adult flies are attracted by the organic matter present in the nests and lay their eggs on the skin of the nestlings. As a result, larvae burrow into the host integument, forming individual cysts between the dermis and musculature.[7] These can be found in various anatomical regions, such as the head, back, and limbs. At the end of 4 to 8 days, the larvae leave the bird and form pupae in the nest's substrate.[7] Those infestations cause discomfort, but birds do not stop feeding and development. However, on some occasions, the larvae may be found in more sensitive areas, reaching the eyeball, ear, or oral cavity, causing important lesions (Figure 44.4). Larvae are easily removed with forceps. Topical application of antibacterial ointments might be used, but normally they are not necessary.

FIGURE 44.5 Normal hatching of a toucan chick. Note the circular cutting pattern of the shell during the hatching process, as was demonstrated in psittacine chicks. (Photo courtesy Mathias Dislich.)

Endoparasites

Although it is possible that toucan chicks are infested by endoparasites, through the ingestion of insects offered by parents or contamination of feces of adults inside the nest, there are no reports of such diseases in these birds before they fledge.

HAND-REARED CHICKS AND COMMON PROBLEMS

The decision to remove eggs for artificial incubation must be weighed carefully, since both approaches have their benefits and risks, which depend on the purpose of the breeding (e.g., conservation vs commercial breeding) and on intrinsic characteristics of the facilities (equipment, local climate, risk of predation, etc.). In most institutions, those decisions are based on previous events, especially those related to the rearing experience of the breeding pairs,[1,5] but also consider other management issues such as weather conditions.[1] On the other hand, with proper husbandry, toucans can successfully rear their young.[1,8]

The removal of eggs for artificial incubation has been advised as a manner of increasing productivity,[1] since this can stimulate a second or even a third clutch. In the author's experience, this recommendation is controversial, since many toucan females will resume egg laying only in the next breeding season.

Artificial incubation of eggs can be done with the same incubators used for Psittaciformes. Eggs should be kept between 36.9°C and 37.5°C,[1,3] while relative humidity should be between 50% and 65%.[1,3] Ideally, humidity is adjusted based on an egg weight loss curve, since many factors such as eggshell quality and local climate conditions influence this parameter. A weight loss of 15% is ideal, but weight losses between 12% and 16% have been reported.[1] An accurate measurement depends on knowing the fresh egg weight, which means that the egg must be pulled out of the nest on the day it was laid. The relatively short incubation period of toucans makes any further adjustment to the curve difficult. Toucanets and aracaris have an incubation period of around 16 days, while bigger toucans have an incubation period that ranges from 16 to 18 days.[1] Risk versus benefit of egg weighing should be considered as it implies greater egg handling. Toucan eggs, especially those of small species, are delicate and have thin shells, which can easily break or suffer fissures. Toucan eggs can be easily evaluated by ovoscopy, which should be done quickly. If the ovoscope uses an incandescent light, eggs can quickly heat up, which can cause the embryo to die. Toucan eggs can be safely monitored with Buddy® (Avitronics Ltd, Norfolk/United Kingdom). Hatching occurs quickly and usually without difficulties, with pipping occurring in the middle of the egg (Figure 44.5).

Chick Rearing

As with other altricial birds, toucans are born featherless. Yet, while psittacine chicks have down feathers, toucans' chicks are completely devoid of feathers when born (Figure 44.6). Therefore special care should be taken with temperature to avoid hypothermia. Toucans should be handled as quickly as possible when outside the incubator. After hand-washing, the friction of the hand provides a warmer surface for a clinical examination. Neonate toucans can be placed inside a cupped hand so that clinical examination can be made safely (Figure 44.6). The absence of feathers facilitates inspection. It is possible to observe the yolk sac in the first few days, which is useful for the evaluation of yolk absorption. Lungs can be assessed percutaneously; congestion or hemorrhage is easily recognized.[3]

As soon as they hatch, neonate toucans should be placed in a brooder at high relative humidity, between 93% and 95%.[1] Due to previous cases of aspergillosis, the author has used lower humidity settings (between 50% and 60%). In those cases, chicks were constantly inspected because of the higher risk of dehydration due to the dryer atmosphere. Brooder temperature recommendations for neonate toucans vary from 35°C to 37°C. During all the rearing period, chicks must be observed carefully and the temperature must be adjusted according to visual cues. When it is too cold, chicks stay close to each other, shiver, or get lethargic.[8] When the temperature is too hot, they tend to extend their necks, stay away from each other, and their skin gets hyperemic.[8] Those may be mechanisms to increase temperature loss. As they grow up and the

FIGURE 44.6 Young, newly hatched toucan chick being handled with cupped hands to facilitate support of the neck and safe examination. (Photo courtesy Mathias Dislich.)

FIGURE 44.7 Single toucan chick with the head and neck being supported by rolled paper toweling during the first few days post-hatch. (Photo courtesy Mathias Dislich.)

first feathers erupt, brooder temperature can be gradually decreased.[1]

The best way to keep toucan chicks is to use deep bowls, lined with paper towels. Groups of toucan chicks provide each other warmth and support, especially in the way they rest their long necks. When only one chick is raised, a paper towel can be wrapped around the chick to provide similar support (Figure 44.7).[3] Toucan bedding should be changed often, since they defecate frequently. Constant monitoring of the stool volume, consistency, and odor is an important cue for early detection of medical conditions such as impaction and enteritis.

As soon as they are born, toucans are very active and beg for food. Neonate toucans have long necks and, when active,

FIGURE 44.8 Postmortem image of a young toucan. The large heel pads at the caudal aspects of the intertarsal joints and proximal tarsometatarsus are readily visible. These pads are shed at or about the time of fledging and weaning. (Photo courtesy Mathias Dislich.)

move them intensively, sometimes losing their balance. In order to keep their necks extended during feeding time while maintaining an upright position, they lean on the floor forming a tripod consisting of their abdomen and pelvic limbs (Figure 44.7). Toucan chicks have heel pads on the plantar surface of the intertarsal joints, which provide them with additional support (Figures 44.6 and 44.8). At the time of the fledging, they lose these appendices.

Feeding

Most differences between toucans and other bird species in hand-rearing are observed during feeding procedures. Toucans do not have a crop and have a shorter gastrointestinal tract. As a consequence, the transit time is shorter; therefore feeding intervals are shorter and meals have to be offered more frequently. Even though toucans can be considered eager feeders, accepting hand-feeding well, the time devoted to each feeding is prolonged when compared with psittacines.[1] This difference is even bigger when they grow older and start to receive solid food.

Hand-rearing protocols have been published elsewhere and can serve as a basis for the development of each facility's own protocols.[1,2]

The first day is devoted to hydration and stimulating the absorption of the yolk sac. First feedings are important to evaluate the feeding response and to adjust the feeding technique. Toucans do not have crops. To evaluate food ingestion, abdominal repletion is assessed. After feeding, the entire intestinal tract is filled with food, from the proventriculus to the intestines. The abdomen becomes rounded, and it is common for the chick to lose balance. Experience is needed to properly assess the filling of the gastrointestinal tract. Although toucan chicks usually stop feeding when full, this is not always true.[1] One-milliliter syringes are the most practical way to feed toucans in the first week, since food of different consistencies can be slowly delivered, drop by drop with full control. Since neonate toucans swing their necks when begging for food, their heads must be gently supported during feedings. After feeding, the beak is cleaned with a moistened paper towel to

remove any residues that can favor yeast or bacterial overgrowth.

At the beginning, feeding formulas start very diluted, and the amount of water is slowly decreased so that a more consistent (and energy-dense) food can be offered. The number of daily meals that must be offered depends on the energy content of the hand-rearing formula and the volume of food that the toucan chick accepts. After determining the best consistency (i.e., dilution), the number of meals and frequency can be estimated. Adjustments should be made daily, and good communication between the animal nutritionist and the nursery staff is essential. Daily weighing is essential. During protocol adjustments weighing every 12 hours is advised, because it allows the prediction of the daily weight gain and the option of additional feeds.[2] From the second or third day on, toucans are expected to gain between 8% and 12% of their weight daily for the next 2 weeks. With the inclusion of solid food, the growth rate slows down to approximately 2% to 5%, until chicks reach their adult weight (see Appendix 4H). Different growing curves have been described in which remarkable growth is considered to start just after the 10th day and extend for a longer period.[1] These differences might be attributable to husbandry and nutrition.

Most facilities use good-quality psittacine hand-rearing formulas during the initial phase.[1,3,8] There is a controversy over the use of those formulas for toucans, because of their propensity to develop iron storage disease. In nature, toucan chicks consume animal protein, and since toucan neonates are growing, they have a high demand for iron. Therefore the development of iron storage disease is unlikely in the first few weeks. The author investigated the presence of liver hemosiderosis in 13 deceased toucans, at less than 2 months of age and none had even mild iron deposits (unpublished data). Yet, once the toucan chicks start accepting food pellets, those should be the same as adult toucans receive.

Shortly after the first week, the liquid diet is slowly discontinued, and the adult diet is presented to the chicks.[1] At this age, toucan chicks already accept small pieces of food, which can be offered between regular feedings. These items include skinless fruit pieces, insects (moths, crickets), pinky mice cut-in pieces, and moistened adult pellets.[3] During this phase, toucan chicks must be closely monitored by constant evaluation of passed stools and growth rate. Since a loss in the daily weight gain is possible in the first few days, it is important to rule out the presence of any disease.[1] Over the next few days, the size of the pieces can be increased and also the amount of food. At about 2 to 3 weeks, soft food is completely discontinued. Extreme care should be taken to provide proper nutrition to the developing chicks, since developmental metabolic diseases can give rise to severe postural abnormalities. Strict commitment to feeding protocols is imperative. Toucan chicks tend to prefer fruits over other items, so that whoever is feeding them can be tempted to offer a higher proportion of those than necessary, thus unbalancing the diet. Feeding older toucan chicks requires patience, since they become more and more restless, and feeding procedures consume more time compared to parrot chicks.

Most toucan species fledge between approximately 6 and 7 weeks. At this time, they should have reached the weight of an adult or be slightly heavier. While smaller species are generally self-sufficient at around 45 days, larger species such as toco toucan become self-sufficient at about 60 days.[1]

Fungal Diseases

There is a high prevalence of fungal diseases in toucan chicks, to the point that several institutions adopt prophylactic measures for this at the beginning of the artificial rearing period.

The humid environment of the brooder chicks added to the fragile immunocompetence of the chicks favors the development of these diseases. Despite the much more contaminated environment in the nests, the incidence of fungal diseases is lower in parent-reared chicks.

Candidiasis

Candida infections are considered common in toucan chicks,[5] being observed in the oral cavity but also along the gastrointestinal tract of deceased toucans during necropsy.[1]

Since toucans do not have crops, the clinical signs of candidiasis are slightly different from those seen in parrots. Stunted growth can be observed, but in many cases, toucans die without premonitory signs. For those reasons, many institutions include in their hand-rearing protocols candidiasis prophylaxis starting from the first day. There are slight variations regarding the dosage, frequency, and length of treatment. The recommended dose is 300,000 UI/kg twice a day and should be adjusted as the bird gains weight.[3] Treatment length varies from 1 to 4 weeks.[1,2] Nystatin is considered safe for neonate birds, acting only locally. There are no reports of intoxication in toucans using those protocols.

Aspergillosis

There are few reports of aspergillosis in toucan chicks; however, in the author's experience, they are one of the main causes of death in hand-raised toucans, with a prevalence of approximately 20% (4/25). This disease was not observed in any of the parent-reared toucans that were born in the same period.

Aspergillosis can develop rapidly and is most often detected postmortem. Although it might cause stunted growth,[8] sudden death in chicks with normal development is also observed. The death of a 2-week-old toucan motivated treatment of its sibling with itraconazole. However, despite this, 1 week later, the second toucan died. At necropsy, two granulomas were observed, one in each lung. It is difficult to make an early diagnosis because the birds do not show clinical signs and the initial granulomas are too small to be detected with conventional tests, besides the risks of antifungal therapy make the prognosis of these cases very unfavorable. Contrary to nystatin, drugs recommended for the treatment of aspergillosis have a greater potential to cause intoxication, especially in neonates. For this reason, preventive protocols like those used for the control of candidiasis in toucans are not used for aspergillosis prophylaxis.

Beak Problems

Neonate toucans have short, slightly prognate beaks (Figure 44.8). This feature apparently facilitates feeding by their parents. As the chick grows, the beak gradually assumes its characteristic shape and size. Compared with parrots, juvenile toucan beaks are much softer and delicate. Until about 3 weeks of age, toucan beaks are extremely malleable.[2] During that time, extreme caution must be taken so that beaks are not traumatized during handling. It takes a few months for juvenile toucans to have their beak trabeculae completely developed and ossified.

FIGURE 44.9 Traumatically induced injury to the maxillary beak in a parent-reared toucan. (Photo courtesy Mathias Dislich.)

Beak deviations may occur for several reasons, such as syringe pressure during feeding.[2] Because of custom or ergonomics, chicks might always be fed from the same side, which forces the developing beak to deviate. Gentle handling and alternating sides when tube feeding are generally enough to prevent this condition. If this defect is observed, it can be corrected by applying gentle pressure to the tip of the bill in the direction that opposes the curvature, three or four times per day, bending the tip of the mandible about 20 to 30 degrees.[2]

Trauma

Once toucan chicks become more active, usually after the eruption of feathers,[1] care must be taken to prevent trauma. As their beaks grow and get heavier, they are more susceptible to lose balance and fall.[2] Their beak is still very soft and vulnerable to blunt trauma, which can result in hematomas. Perforation of the beak, although uncommon, can be a port of entry for bacterial disease, such as rhinosinusitis, which can be difficult to treat.

Fledging is the riskiest period for trauma accidents in juvenile toucans, because during this period they tend to be restless, have low control over their flight, and are not completely aware of their boundaries. This holds especially true for parent-reared toucans, which can damage their beaks trying to fly against the mesh (Figure 44.9). To prevent such accidents, the best strategy is to revise the enclosure furniture, such as perches and plants, and position them in a way that they obstruct direct flight attempts. Perches can be placed at different heights not too far from each other. One perch should be placed about 25 cm (10 inches) from the mesh. In this way, the fledging toucan can try short flights, slowly develop its skills, and get a better sense of its surroundings. For most species, fledging starts at about 6 weeks of age.[1,2]

CHAPTER 45

Neonatology of Precocial Birds

John R. Chitty

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Precocial birds are defined as those birds that are relatively mature and mobile at the time of hatching. The term *Aves precoces* was first used by Sundeval (1836).[1] This chapter will discuss the early development of the precocial bird in comparison to the altricial species with which clinicians are usually more familiar. Potential clinical consequences of these differences will also be discussed. For a full discussion, readers are referred to the excellent texts by Starck and Ricklefs (1998)[2] and O'Connor (1984).[3]

CLASSIFICATION AND SPECIES

Originally, the terms *Aves precoces* and *Aves altrices* were used to distinguish two methods of rearing. Nowadays, a wider classification of rearing strategies is recognized within the so-called altricial-precocial spectrum (see also Table 45.1; Chapters 39 and 41).[2] The naming of these strategies is based on Starck (1993),[4] although other sources may group these strategies typically as follows:

- Precocial = Superprecocial (Precocial 1) and Precocial 2 and 3
- Semiprecocial = Precocial 4 and Semiprecocial

DIFFERENCES BETWEEN PRECOCIAL AND ALTRICIAL STRATEGIES

The different strategies are defined according to the stage of development of the hatchling and the degree of parental care given, as is demonstrated in Table 45.1. From this table it may be derived that the primary diagnostic feature of precocial birds versus altricial birds is the fact that altricial birds have closed eyes at hatching. Another variable is that of thermoregulation. Altricial species are usually poikilothermic at hatching and develop endothermy at varying stages thereafter. Most precocial species demonstrate at least some degree of endothermy immediately after hatching. Other differences in post-hatch development will be discussed later in this section.

EVOLUTIONARY ADVANTAGES/ DISADVANTAGES

There is no straightforward relationship with evolutionary development of species and the rearing strategies. Both systems convey advantages and disadvantages (Tables 45.2 and 45.3) and there appears no ecological driver to these, that is, within an ecological niche many different strategies can be observed. The varying advantages would explain the development of hybrid rearing strategies in aviculture.

EMBRYOLOGY

As described earlier, the cost for a more mature chick at hatching is a longer incubation period. In the captive-rearing situation, this puts a large onus on incubation conditions, where any problems in the incubator or hatcher conditions (temperature, humidity, hygiene, etc.) are more likely to produce a compromised chick at hatching. These may include "wet" chicks, nonretracted yolk sac, or simply ill-thriving, less mobile chicks.[5] With less post-hatch development than in altricial birds, incubation problems are likely to cause higher chick mortality in precocial species.

EARLY GROWTH RATES AND DIET

Precocial birds have a slower growth rate than altricial birds *in the natural situation*. In the captive situation, the need for precocial species to move and lay down skeletal muscle quickly can be utilized in meat production of chickens and turkeys. However, consequences of this *artificially* high growth rate on the skeleton are well known. In the avicultural environment, high growth rates can lead to skeletal issues. These may include "angel wing" (Figure 45.1) and rotation or fracturing of long bones (Figure 45.2).

Contrary to most bird rearing, growth rates may actually need to be held low—for example, in buff-crested bustards *(Lophotis gindiana)*, growth rates should be held below 10%.[6] In the author's experience, in great bustards *(Otis tarda)*, reducing protein feeding and increasing fiber levels in the first week of life has produced lower rates of skeletal deformities in chicks. Olsen (2009) described 64% of fractures in young crane birds that occurred in the first 5 to 16 weeks of age, which they attributed to both a high-protein diet and lower exercise rates.[7] In addition, it was suggested that group size plays a role in growth rate, hence also affecting the incidence of skeletal deformity.[7]

Exercise rates are also implicated in other species. For example, Langgemach (2008) described positive effects on

TABLE 45.1
Levels of Precociality and Their Characteristics Recognized in Birds

Type of Development	Plumage Present?	Eyes Open?	Mobile?	Feed Themselves?	Parental Care?	Nest Attendance?	Examples
Superprecocial (precocial 1)	Yes, contour feathers	Yes	Yes	Yes	No	Leave nest	Megapodes (Megapodidae)
Precocial 2	Yes, down	Yes	Yes	Yes	Yes, brooding only (follow parents and find their own food)	Leave nest	Anatidae (ducks), Charadriiformes (plovers)
Precocial 3	Yes, down	Yes	Yes	Yes	Yes, showing food	Leave nest	Rheiformes (rheas), many Galliformes, including Meleagrididae (turkeys), Phasianidae (quail, pheasants), Numididae (guineafowl), Tetraonidae (grouse)
Precocial 4	Yes, down	Yes	Yes	Yes/No	Yes, parental feeding	Leave nest	Podicipediformes (grebes), Rallidae (rails), Gruiformes (cranes), Cracidae (guans and currasows), Turnicidae (buttonquail)
Semiprecocial	Yes, down	Yes	Yes/No	No	Yes, parental feeding	Remain in nest area	Laridae (gulls and terns), Alcidae (auks), Stercorariidae (jaegers and skuas)
Semialtricial 1	Yes, down	Yes	No	No	Yes, parental feeding	Remain in nest	Accipitriformes (hawks), Pelecaniformes (herons, pelicans), Ciconiidae (storks)
Semialtricial 2	Yes, down	No	No	No	Yes, parental feeding	Remain in nest	Strigiformes (owls)
Altricial	No	No	No	No	Yes, parental feeding	Remain in nest	Passeriformes (passerine birds), Psittaciformes (parrots)

Modified from Starck JM, Ricklefs RE, editors: *Avian growth and development: evolution within the altricial-precocial spectrum*, Oxford, UK, 1998, Oxford University Press.

TABLE 45.2
Advantages of Precocial Rearing Over Altricial Rearing

Factor	Advantages Conveyed
Self-feeding and parental fecundity	◆ Lack of parental feeding reduces feed-gathering ability as a limiting factor on reproductive rate ◆ Chicks follow their parent to the feeding site rather than their parent having to make repeated trips back to the nest ◆ Increased chick fitness may increase survival rate from predation—it is less likely for an entire brood to be predated ◆ Reduced dependence of chicks on requiring survival of both parents
Thermoregulation	Increased ability to thermoregulate increases ecological flexibility

skeletal development from early introduction to free space in first-week great bustards and exercise regimes in older chicks.[8] In the UK great bustard reintroduction program, increased exercise provision also was found to have a beneficial effect on skeletal development. The mechanism behind this is summarized by Ricklefs et al. (2008).[9] In birds, there is an inverse relationship between tissue maturation and growth rate, that is, if tissue is functional and maturing, the growth rate will be reduced. This appears to hold true for skeletal muscle in precocial birds, so it may be presumed that increased exercise in young birds (mimicking following of adults) may be reducing the growth rate of bone and muscle by prioritizing metabolic constituents to functioning of the tissues. Olsen (2009) also identified curled toe because of reduced exercise rates in

TABLE 45.3
Advantages of Altricial Rearing Over Precocial Rearing

Factor	Advantages Conveyed
Metabolic and developmental	◆ More gradual increase in metabolic intensity posthatch ◆ Delayed maturation of skeletal muscles (and effects on growth rate) allows higher growth rates to pass more quickly through vulnerable stages ◆ Lower metabolic rate allows faster growth rate ◆ Shorter egg incubation periods ◆ Increased postnatal brain development and, presumably, increased learning ability

cranes.[7] This observation also appears to be true for captive-reared great bustards in the author's experience.

THERMOREGULATION

Precocial species tend to have an increased ability to thermoregulate compared to altricial species. This may be in part due to better-developed plumage and in part due to shivering function by better-developed skeletal muscle.[3] However, these species may conversely be at increased risk for developing hypothermia than less mobile altricial chicks.

Increased mobility may increase the risk of wetting or being trapped in cooler areas (e.g., if stocking rates are high enough to lead to chicks being driven away from heat sources). As a result, water dishes for precocial chicks should be constructed such that immersion or tipping are prevented, and appropriate heat sources should be provided in various sites in an enclosure such that all chicks are able to obtain heat.

DEVELOPMENT OF THE GASTROINTESTINAL TRACT

Other than a proportionate increase in size with overall growth rate, there is little change in the structure of the precocial bird gut. This contrasts with the altricial species where the gut is comparatively underdeveloped at hatch and develops rapidly post-hatch. This—in part—may relate to the increased need for rapid growth rate in altricial species. In terms of precocial species, it does imply that the diet of the hatchling varies little from that of the adult bird, which may yet be another factor in controlling growth rate in young precocial species. It has also been noted that active, foraging young precocial birds may be at increased risk for gastrointestinal foreign bodies and impactions. As such, environments should always be carefully checked for any material that can easily be ingested.

DEVELOPMENT OF THE SPECIAL SENSES

As stated, altricial and precocial species may be distinguished by the eyes being open immediately (or within the first day in some species) after hatch. Given the advanced state of the senses in young precocial birds, light cycles and levels appropriate for adult birds may be provided from hatch. This contrasts with the situation of altricial birds where sensory flooding may occur with excess stimulation.

DEVELOPMENT OF PLUMAGE

Precocial birds (other than megapodes) are hatched with a covering of down. The first "mature" plumage will start appearing within the first 2 weeks, with primary feathers being among the earliest to emerge. The timing of this emergence varies with species.

One syndrome related to this plumage development is "angel wing." As stated earlier, this may be considered a skeletal deformity as it is typified by outward rotation of the distal wing (distal to the carpi) related to the weight of primary feathers and undercalcified bone. If identified early, corrective bandaging for a few days will be successful (Fig. 45.1). Bandages should always be changed every 3 to 5 days to allow physiotherapy to reduce the risk of joint contracture. In advanced cases, or in more mature birds, permanent changes which will preclude or reduce flight are likely.

Other than addressing underlying disease, prevention is key. Over the years, several underlying causes have been identified:

- Genetic factors[10];
- Growth rate and high-protein diets.[7] Growth rate may also be affected by group size[11] and has been related to angel wing incidence and severity[10];
- Underlying inflammatory disease. The effects of ingested T-2 toxin and antioxidants on alkaline phosphatase activity and on angel wing incidence and severity imply that underlying inflammatory processes may play a role in the incidence of angel wing in a flock.[12]

Based on the aforementioned risk factors, prevention is best achieved via growth rate control. Knowledge of the timing of primary feather development is essential, and reduction of dietary protein and growth rate around this time will affect both incidence and severity of angel wing, as the author has observed in captive great bustards.

BEHAVIORAL DEVELOPMENT

Advanced senses (especially vision) in the hatchling precocial bird enable early imprinting on parents and/or conspecifics, enabling them to follow their parents to food sources. A consequence of this is the potential for inappropriate imprinting on rearers (or other species) that may have long-term implications, especially for birds to be released into the wild. To prevent this, "dehumanizing" suits and reduced handling have been frequently used in a range of projects involving crane species and bustards (Figure 45.3; see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 23, Conservation of Avian Species).[8,13]

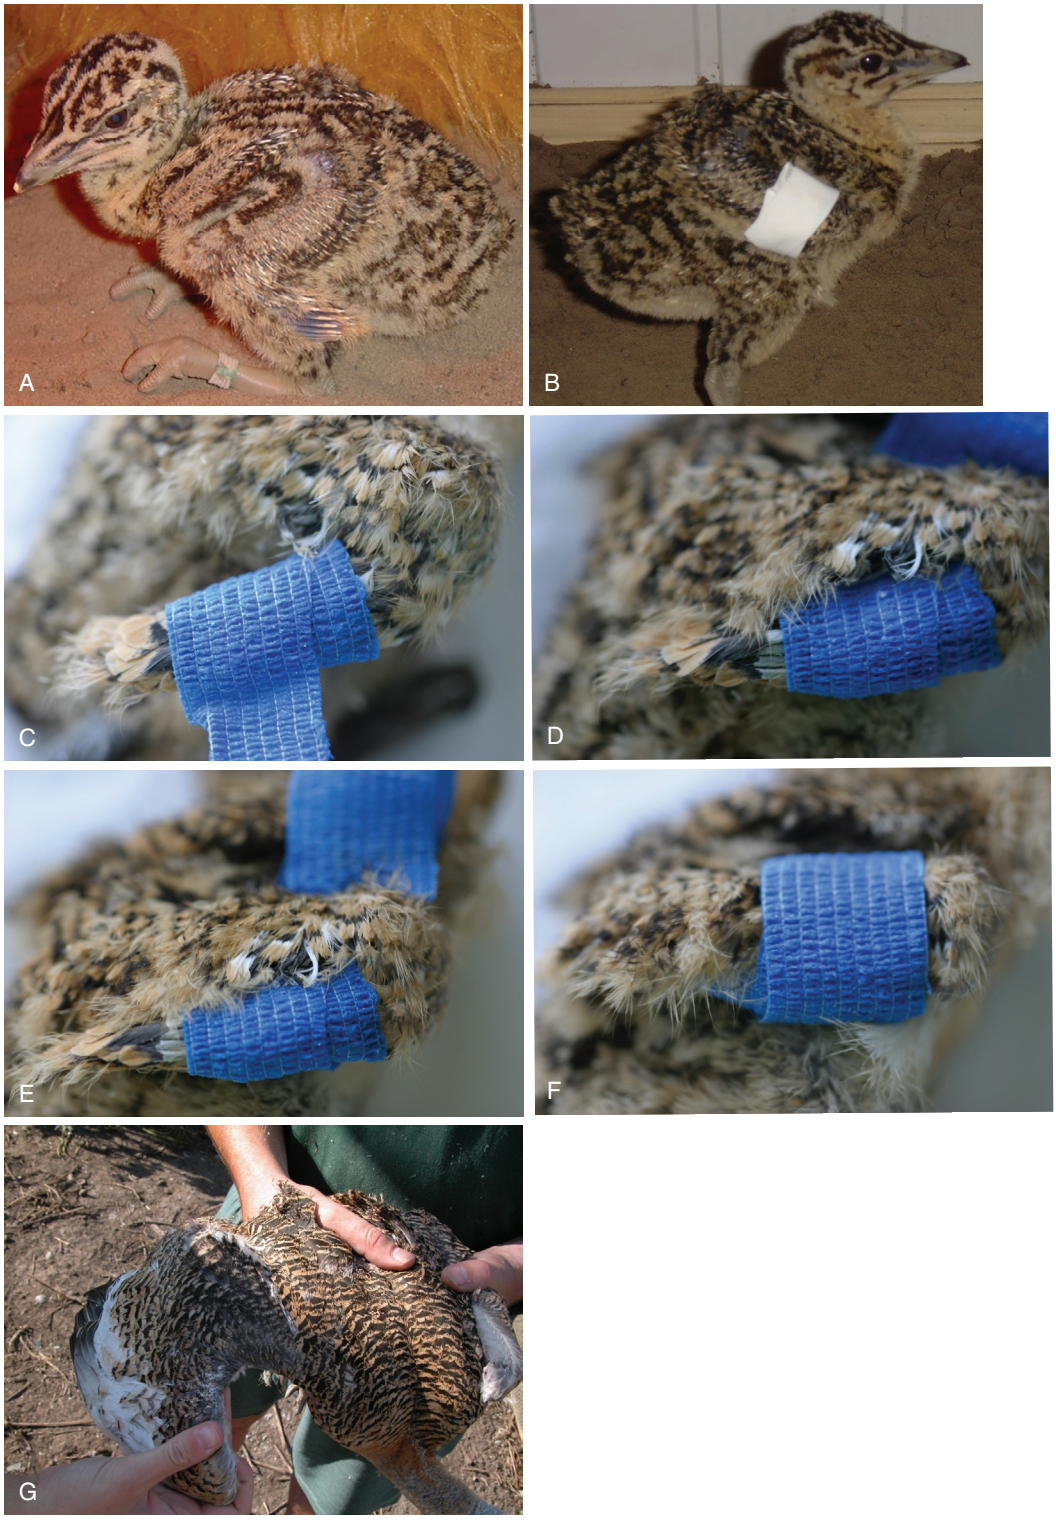

FIGURE 45.1 Excessive protein feeding in the first weeks can result in excessive development of primary feathers. Associated with poorly calcified long bones, "angel wing" can develop. Initially this appears as dropping of the distal wing (A) but will then progress to rotation of the distal wing and inability to fly. In the early stages of angel wing, a simple tape strip will suffice to hold up the distal wing and prevent rotation (B). In older chicks a heavier bandage is required. Images (C)–(F) show how the feathers are bound and the distal wing rotated medially. These bandages should be removed every 3 to 4 days until the wing is no longer dropped. When the bandage is removed, physiotherapy should be performed on the joints to prevent fibrosis of the joints and restriction of movement. Image (G) shows a great bustard *(Otis tarda)* that has been bandaged for several weeks resulting in joint fibrosis. The wing is being held at maximum extension. (Photos courtesy John Chitty.)

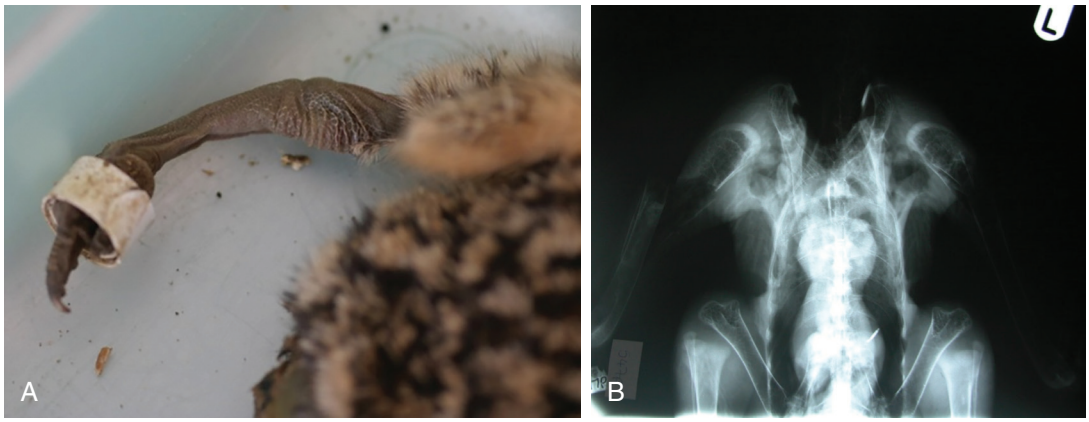

FIGURE 45.2 (A) Precocial species are generally fast-growing post-hatch compared to altricial species. Imbalances in dietary protein, calcium, phosphate, and ultraviolet/vitamin D_3 provision can result in soft, easily deformed long bones as seen in this great bustard *(Otis tarda)* chick at postmortem examination. (B) In juvenile birds this may be seen as reduced bone density and accompanying pathological fractures. This great bustard shows bilateral humeral fractures sustained during handling and associated with poor-density bones with very narrow cortices. (Photos courtesy John Chitty.)

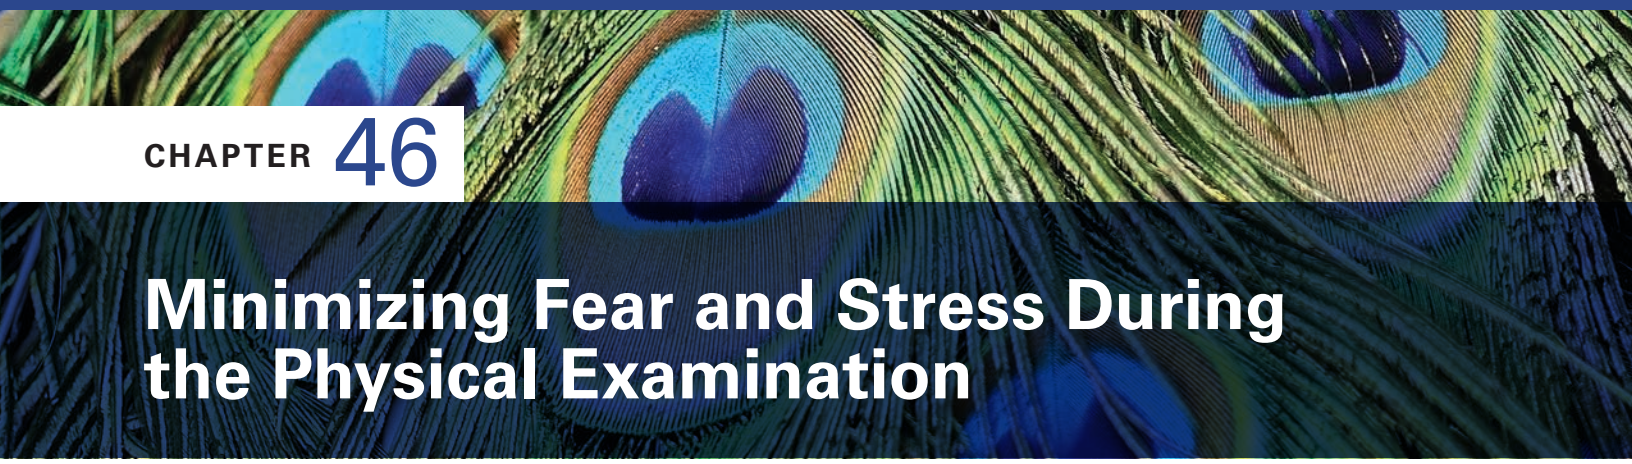
FIGURE 45.3 Social imprinting on handlers must be avoided when rearing precocial birds if they are destined for wild release. Images (A–C) show the use of dehumanizing suits in rearing great bustard *(Otis tarda)* chicks—both for feeding and to act as attractants to stimulate normal social group following behavior and exercise. Frequent moderate exercise has been shown to be extremely beneficial in long bone growth.



SUMMARY

While the comparative lack of "parental care" required of bird rearers may imply that precocial species have lesser needs, the converse may be true as precocial species are seemingly very sensitive to inadequacies or imbalances in the diet and exercise regimes. Behavioral needs in terms of parental imprinting may also be hard to replicate in rearing. Another problem relates to the increased difficulty of observing the more mobile precocial species in the wild, which hampers transfer of data to the captive rearer.

CHAPTER 46

Minimizing Fear and Stress During the Physical Examination

INTRODUCTION

Veterinary practitioners who see dogs and cats (as well as other species) have begun to embrace less stressful methods for administering veterinary examinations and treatment. This tends to result in a higher standard of care and can lead to increased compliance with medical recommendations due to improved client and patient experiences. Multiple resources exist for these practitioners (www.fearfreepets.com; https://cattledog-publishing.com; https://karenpryoracademy.com/courses/better-vet; https://www.fenzidogsportsacademy.com; etc.). Many practices specifically advertise their focus on behavioral wellness to let potential clients know their approach.

Clients are often particularly worried about the stress that their birds experience during veterinary visits, which results in many birds not being brought in for medical evaluation until the late stages of illness. By embracing the goal of minimizing stress during veterinary visits, avian medicine practitioners can improve the quality of life and longevity of their patients. Behavioral health is a crucial component of patient care that is often overlooked by busy or untrained veterinarians due to perceived time constraints or lack of knowledge.[1–3]

Avian behavior is poorly understood by most pet owners, and captive husbandry leads to a variety of issues that affect both the physiological and psychological health of birds. In fact, behavioral problems are a common reason for psittacine birds to be rehomed.[4] While succesful resolution of behavior problems often requires intervention by a knowledgeable veterinarian or behaviorist, most bird owners rather seek behavioral advice from other sources before talking to their veterinarian.[5] Many clients are likely to turn to social media where an explosion of behavior information is available, most of which is not evidence-based and can be harmful. Clients must therefore be encouraged to turn to their veterinarian as a trusted resource of information. Veterinarians can achieve this by partnering with clients to reduce stress during visits and/or providing resources to address training and behavior challenges, in addition to medical problems.

PHYSIOLOGICAL AND BEHAVIORAL IMPACT OF FEAR, ANXIETY, AND STRESS

A stress response is defined as the set of physiological and behavioral changes that occur in response to a stressor, which can be any stimulus or environmental condition that is an actual or perceived threat causing emotional or physical trauma to the animal. The goal of a stress response is to return the body to a normal baseline. Stress responses vary in intensity and may escalate quickly depending on the stressor involved. The "fight-or-flight response," which is evoked by extreme stress, creates a hormonal and chemical cascade within the body that is supposed to increase the animal's chances of surviving the aversive situation. The animal may choose to fight or flee the stressor depending on the surrounding environment, the type of stressor, and the animal's learning history.[6] Another behavior that may be seen in response to stress is the "freeze response," where the animal freezes in place to escape notice of the perceived danger.[7] Stress responses are normal but can become problematic when they are chronic in nature or if they lead to long-term changes in the animal's emotional state.

The stress response consists of two phases: the immediate response and the delayed response. The immediate response is mediated by the sympathetic nervous system and triggers epinephrine (adrenaline) and norepinephrine (noradrenaline) release from the adrenal medulla, leading to the fight-or-flight response. In contrast, the delayed response is initiated by corticosterone secretion, which originates from the adrenal cortex.[8] The amygdala initiates hormone secretion of corticotropin-releasing hormone (CRH) from the

hypothalamus in the presence of a perceived threat, which stimulates release of adrenocorticotropin-releasing hormone (ACTH) from the anterior pituitary, triggering release of glucocorticoids in the adrenal cortex. This may stimulate either a fearful or an aggressive response. The amygdala may stimulate release of additional hormones (noradrenaline, glutamate, gamma amino butyric acid [GABA], serotonin, etc.) to trigger the fight-or-flight response, a defensive state that prepares the organism to either escape or confront the threat. This hormone cascade is regulated by the hypothalamus.[9–15]

The general impact on the body in response to this hormonal cascade includes blood flow diversion toward major muscle groups and to the liver, increased cardiac output with increased arterial pressure, increased glucose release, and increased oxygen perfusion. All of these factors prepare the body to escape the (actual or perceived) threat. Some of the potential negative sequelae to fear include selective vasoconstriction to areas not critical for movement (which may lead to cardiovascular accidents or organ failure); changes in growth, reproductive function, and pain perception; altered memory, sensory, digestive, and immune function; creation of inflammatory responses in both the digestive tract and the skin; and even structural and functional brain damage. The physiological stress response impacts all body systems, and the immediate phase can occur within minutes of the inciting stimulus.[9,14,15] The immediate stress response causes heart and respiratory rates to increase, diverts blood to the muscles, and increases blood glucose. The animal may have decreased pain perception to facilitate escape from the stressor or alternatively may have increased pain perception (based on human studies).[16]

Stress affects both the ability to perform previously learned tasks and memory consolidation.[16–21] The amygdala stimulates creation and storage of fear memories in the medial prefrontal cortex. These memories are consolidated more easily when there is a strong emotion associated with the event.[18] This allows the memory to be quickly recalled when the animal is faced with similar environmental stimuli in the future. Fear in response to something painful or disturbing can sensitize an animal into a conditioned response to experience more fear when exposed to similar stimuli later on.[22] Because fear can have such a powerful long-term impact, it can be difficult to overcome the behavioral effects of even one exposure to a perceived aversive stimulus (such as a visit to a veterinary practice).

Some of the physiological responses of the body may be visible in lab work. A typical acute stress response results in a leukocytosis characterized by a mature neutrophilia/heterophilia, lymphopenia, and eosinopenia, along with hyperglycemia, although this varies with the individual. These changes are usually short lived. The delayed stress response is associated with a more chronic stress to the body, such as chronic illness, and repeated or prolonged stressful events. Effects include immunosuppression, delayed wound healing, muscle wasting, and development of behavioral disorders. Permanent brain damage or life-threatening illness associated with immunosuppression may result. Many species of birds are particularly prone to stress-induced illness. Aspergillosis secondary to immunosuppression is a common concern for captive waterfowl, penguins, and birds of prey.[15,23–28]

Fear and anxiety are emotional responses that often occur simultaneously. Fear results from the presence of a specific, known, and observable threat from which distance is desired, whereas anxiety results from the anticipation of a potential threat, which may be poorly defined or unknown and more oriented toward the future. Anxiety also results when the task requirements exceed the learner's competency. In other words, the animal is unable or unprepared to cope with the situation. It does not have behaviors in its repertoire it can use to address the current conditions.[29,30] A fear response can be triggered automatically in response to a known stressor. Animals that are afraid may not be able or willing to respond to known behavior cues and may behave differently than they would normally. Fear and anxiety can create vivid sensory memories of the circumstances (environment, people, animals, and inanimate objects) surrounding the stressor. Because these memories can be easily recalled when in similar settings, many animals begin experiencing anxiety and fear even when exposed to a milder version of the previous stressor in the future.[22]

ORIGIN AND IMPACT OF FEAR IN THE VETERINARY PRACTICE

Veterinary visits may cause fear, anxiety, and stress for a variety of reasons. Patients are subjected to an unfamiliar environment with their owners (who are typically worried/stressed) and experience uncomfortable or novel stimuli. Many birds are sensitive to their owner's emotional behavior, which can exacerbate their own stress reaction. The veterinary team can have a profound impact on these factors through carefully chosen body language and environmental management. Stress may lead to death in some avian patients, likely secondary to undiagnosed heart disease and/or an extreme fear response leading to a massive catecholamine release.

Body language reflecting fear may remain unrecognized by veterinarians and staff. Fear may be viewed as a normal part of the veterinary visit and tolerated due to time constraints and lack of knowledge of methods to mitigate it. Some birds may be perceived by owners and/or vets as "calm" and "resigned to their fate," when they are actually terrified and show a freeze response rather than attempt to escape, flee, or fight to protect themselves. Many of these patients have experienced or are experiencing "flooding." Flooding, as defined in behavior science literature, is a form of behavior therapy used in humans to treat phobias and posttraumatic stress disorder.[31–34] It involves sudden, full-intensity exposure to the aversive stimulus without means of escape until the patient no longer resists. Flooding triggers the physiological and psychological effects of the "fight-or-flight" response, with the goal of quickly habituating the patient to the aversive stimulus. While it may be effective in some situations, it is easy to misapply (especially to animals, who cannot consent to the technique). The potential behavioral impacts of flooding may include increased sensitization to the aversive stimulus, increased aggression, and learned helplessness. Learned helplessness is observed in both animals and humans who have been conditioned to expect pain, suffering, or discomfort without a means of escape. Eventually, the patient will stop trying to avoid the undesired experience, even if escape is possible. The resultant behavior may be misinterpreted as a

willing compliance with restraint, as the patient is anticipating a frightening procedure and is showing a lack of autonomy and empowerment to actively respond. Learned helplessness can lead to immunosuppression and depression.[35] Preferred alternatives to flooding are systematic desensitization, counterconditioning, and operant conditioning, which have been discussed in *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior, and will also be discussed in more detail later in this chapter.

The patient's stress decreases the quality of veterinary medicine that is possible. Repercussions include a requirement for sedation or anesthesia to accomplish procedures, problems with healing due to immunosuppression, injuries to team members or the patient, decreased staff morale, poor compliance on the owner's part, and loss of revenue for the hospital. Providing care in the least stressful manner possible empowers patients and everyone involved with their care, resulting in an improved quality of life.

Client perceptions are equally detrimental to patient care and practice revenue. Those who perceive rough handling of their birds or other unpleasant experiences during a visit are less likely to follow through with recommendations for treatment, progress examinations, and preventative care. They are also less likely to return for appropriate follow-up examinations or seek care in the future, which results in delayed diagnosis of health concerns and even death. Stress associated with forcefully administering medications to birds may lead to physiological side effects for the patient, as well as a loss of the human-animal bond and reduced quality of life for both the pet and the client. In one study,[36] 26% of dog owners and 38% of cat owners said that their pets hate going to the vet. This percentage is likely significantly higher for bird owners.

BENEFITS OF A LOW-STRESS VETERINARY EXPERIENCE

Veterinary teams can ensure increased client compliance with medical recommendations, improved staff morale, and more enjoyable patient interactions if they provide medical care in an environment that reduces patient and client stress to the greatest degree possible. Some of the benefits of sensitive handling include improved patient care, increased accuracy in physical examination findings, and reduced injuries both to veterinary staff and patients.[37] This approach also leads to improvements in client trust and retention, which increases referrals and hospital revenue.[38]

The goal of the veterinary visit should be to provide a minimally stressful experience while laying the groundwork for improved future experiences. Sensitivity to avian behavior and body language, combined with skillful application of operant conditioning or systematic desensitization and counterconditioning, can often result in minimal restraint examinations. Depending on the patient's stress threshold, sedation may be a better choice compared to restraint.

CHALLENGES ASSOCIATED WITH PROVIDING LOW-STRESS AVIAN MEDICINE

There are some additional challenges associated with providing minimal stress veterinary visits for birds compared to dogs and cats. Awareness of these issues allows veterinary staff to accommodate and circumvent them.

While most clients will be very happy to see an increased focus on behavioral wellness for birds, some may have reservations regarding this change in approach. The need to slow down the speed of appointments may be seen as an unnecessary waste of time. Recommendations to use sedation to reduce fear may be viewed as an unacceptable risk, as clients may confuse conscious sedation with brief anesthesia and not fully understand why this is preferable. Respectfully and thoroughly explaining the benefits of the changed approach can make a huge difference in the client's willingness to trust and cooperate.

Many birds are not brought into veterinary practices until they are in advanced stages of illness. Reasons for this include both the avian tendency to hide clinical signs of illness until decompensation occurs and a lack of understanding on the client's part regarding the value of preventative care. Thus, many birds have their first veterinary visit after several decades of life. Even if birds are not visibly displaying signs of illness, they often have underlying disease present. Most birds presenting to a veterinary practice need to have some form of diagnostic testing performed because of these factors, and every patient should be treated as if they may have a serious health problem. This reality limits the usefulness of some strategies recommended in Fear Free™ dog and cat medicine, including postponing sample collection in favor of prescribing anti-anxiety medications that can be administered at home or waiting until a behavior has been trained using positive reinforcement.

Many birds display neophobic responses, defined as a fear of new things. This survival mechanism helps them to avoid attack from predators or being poisoned by an unknown, toxic food item. This response makes it difficult for birds to tolerate veterinary visits, which involve many unfamiliar stimuli, including tools and other items from which escape is often prevented. The use of operant conditioning or systematic desensitization and counterconditioning can teach birds that these aspects of the visit can be experienced without undue stress (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). However, it can be challenging to overcome a neophobic response within the short amount of time allotted for a typical veterinary visit.

Many clients do not provide their companion parrots with intentional behavior guidance or training. Thus, their birds have no previous experience responding to cues or receiving reinforcement for desired behavior. The lack of familiarity with this process may retard initial efforts during a first vet visit. In addition, these untrained parrots lack the resilience that birds who receive regular training possess. Many of these birds are also poorly socialized to new people and environments.

Reading bird body language is an involved and complex skill that is not commonly taught in veterinary curricula. As a result, it is common for veterinarians and veterinary staff to misinterpret or disregard signals presented by avian patients. In addition, many of these patients can fly, which provides a uniquely difficult challenge when it comes to providing force-free care and keeping the patient, client, and staff safe. Finally, many of these patients have strong memories associated with previous aversive experiences at veterinary offices, which continue to influence their behaviors for years later.

Despite these factors, providing minimally stressful avian veterinary visits is absolutely possible and should be considered standard of care. The best way to accomplish this is through adequate education (both of staff and clients), appointment preparation, and thorough understanding of both avian body language and the science of behavior change.

NECESSARY SKILLS TO MASTER

Veterinarians must develop a variety of skills in order to accomplish low-stress veterinary visits, including knowledge, confidence, technical competence, compassion, client communication, patience, and flexible case management.

Knowledge is the most important of these skills. A knowledge of the behavior and body language of parrots will lead to accurate recognition of the stress in the patient (see Figure 46.1 and Box 46.1 for examples) and allows for behavior questions to be answered for the client. An excellent resource for helping clinicians to recognize signs of fear and stress in multiple species of birds can be found in the Avian Fear Free™ Online Modules. Up-to-date medical knowledge will permit the problem to be handled in the most efficient manner, eliminating excessive trial and error. Clients will feel more confident in a veterinarian who can identify the species of their bird on sight and can easily communicate their medical and behavioral recommendations.

FIGURE 46.1 Moluccan cockatoo *(Cacatua moluccensis)* displaying signs of arousal, including a tall and erect body posture, open beak with vocalization, and feathers slicked to body but erect around the head and crest. Recognition of these initial signs of arousal is important to prevent further escalation of the behavior.

Clinicians who are confident in their ability to practice high-quality avian medicine will be less stressed and elicit less stress from the staff, clients, and patients. Confident clinicians are better able to handle birds safely, assess the medical issues at hand, and address the concerns of the client. However, confidence must be gained honestly through time and repetition; false confidence when interacting with avian patients can increase the risk of injuries to patient and veterinary staff.

Handling birds safely is a mechanical skill that should be actively developed, both in a clinical setting and in a social interaction setting. Confidence in technical skills can be gained by attending wet labs, practicing techniques on models or cadavers, and finally by applying techniques to live birds. Skilled bird handlers improve the examination experience for the client, veterinarian, and patient.

Compassion is an important part of ethical practice of veterinary medicine. It is easy to be compassionate toward a tame, talking parrot; it is harder to have the same compassion for a terrified bird that is biting and screaming. It can also be difficult to have compassion for some clients when there are significant barriers to productive communication, including values mismatches, lack of understanding, and personality conflicts. Until the clinician can overcome these challenges, they will not be successful at practicing low-stress avian medicine.

The combination of knowledge, confidence, and compassion allows the practitioner to develop a balanced practice philosophy. Aggressive diagnostic and therapeutic measures are necessary at times, while a conservative approach may be more appropriate in other situations. The client should be made a part of this decision process. Both sides of issues should be presented, including risks, costs, and all other relevant factors. This requires excellent client communication to avoid misunderstandings and set appropriate expectations.

Patience is also essential to this process. Clients may take a while to make decisions. Patients may take some time to calm down before another step can be taken. Rushing through any phase can increase errors and worsen patient stress. All the above requires adequate time to be set aside in the appointment schedule and a commitment to patience on the part of the veterinary staff.

Even after a plan has been approved and instituted, clinicians must be willing to alter their plan based on the changing needs of the patient. Patient stress levels, worsening clinical conditions, and availability of equipment are all factors that may require adjustments to a treatment plan. A competent clinician will monitor these and make changes as necessary.

BEHAVIOR DEFINITIONS AND TECHNIQUES

Veterinarians are presented with a difficult challenge of attending to the immediate medical needs of the animal, while trying to minimize impact on behavior and maintaining the human-animal bond. It is helpful to understand some basic principles and strategies that influence behavior, in particular ones that can facilitate overcoming fear responses (Table 46.1).

Habituation occurs when exposing an animal to stimuli without regard to how the stimulus influences behavior. Upon repeated exposure to a (mild aversive) stimulus, a decrease in response may be seen as a naturally occurring phenomenon.

BOX 46.1 EXAMPLES OF SIGNS THAT CAN POTENTIALLY INDICATE STRESS, ANXIETY, AND/OR FEAR IN BIRDS[a]

Facial expressions

- Eye pinning or flashing (particularly in psittacine birds)
- Wide open eyes
- Slight opening of the beak
- Gaping mouth (beak is wide open for an extended period, in birds of prey)
- Raised head or crest feathers

Note that birds have minimal muscles that can contribute to facial expressions, hence providing limited options to recognize stress, fear, or anxiety from these.

Postural changes

- Freezing, tensing up with feathers tight against the body
- Standing tall, elongating the body
- Wings spread and held away from the body
- Fanned tail
- Leaning away from the feared person or object
- Withdrawal in a corner
- Lifting foot toward the feared person or object (psittacine birds)
- Firming of the grip with the feet (in birds of prey)
- Crouching or cowering

Behavioral changes

- Absence or cessation of comfort behaviors, e.g., preening, social interaction, eating
- Darting looks across the examination room to try and escape or fly away
- Vision oriented toward the perceived threat, following its every movement
- Increased alertness to stimuli
- Chewing on the leg band, feet, or toes (psittacine birds, in particular grey parrots [*Psittacus erithacus*])
- Feather plucking
- Shivering, shaking, trembling
- Headshaking, pacing, rocking back and forth, or other stereotypic/repetitive behaviors
- Quivering or flapping of the wings
- Hitting or beating with the wings in an attempt to escape or avoid capture
- Kicking with the legs (particularly in backyard poultry and waterfowl)
- Struggling profusely (when restrained)
- Moving, leaping, or flying away from the feared person or object
- Flying around frantically in the cage (particularly in small birds)
- Thrashing or biting on cage bars
- Rolling onto the back (usually last defense mechanism in psittacine birds)
- Backward flip, falling off the perch or hand/glove (birds of prey, psittacine birds)
- Bating (jumping of the perch to the length of the leash, in birds of prey)
- Biting (often quick, short nip) or lunging toward the feared person or object (usually in situations when there is no more option to escape)

Physiological changes

- Increased respiratory rate, panting, breathing with open beak (e.g., poultry, birds of prey)
- Gular flutter (feathers at throat flutter in and out, e.g., in owls)
- Increased heart rate, tachycardia
- Hyperthermia
- Bleeding from the eyes (grey parrots) or nares
- Copious feather loss (e.g., pigeons, turacos)
- Seizure activity (e.g., grey parrots, cockatiels)
- Collapse or sudden death due to cardiac arrest (in extremely stressed birds, particularly passerine species)
- Elimination of feces and urine; loose, watery droppings

Changes in vocalization

- Decreased vocalizations, extreme silence
- Excessive vocalization, e.g., screaming, screeching, squeaking, squawking
- Repetitive chirps or alarm calls, e.g., high-pitched "twittering" in Harris' hawks *[Parabuteo unicinctus]*, or "kek-kek-kek" sounds in accipiters
- Growling or hissing
- Snorting and wheezing (Pionus parrots [*Pionus* spp.])
- Clacking with the beak (particularly in owls)

[a]Note that body language and behavior differ across bird species. In addition, different behavioral intentions may underlie the same behavior. Hence, when interpreting the behavior of a bird, the species-typical patterns and context should be kept in mind.

However, when the fear response to the stimulus is too strong, habituation cannot be relied on to change behavior, as it is ineffective at overcoming the fear response. For example, a parrot may never set foot on a new perch placed in the habitat through the process of habituation alone.

Systematic desensitization is the process of exposing the animal to a stimulus in a graduated manner, so that it does not evoke a substantial fear response. This requires close and thorough observation and understanding of body language. The observation of the slightest body language indicative of a fear response is information that the bird has reached its threshold and that the item evoking a fear response must be placed at a greater distance from the patient. A very observant practitioner can use this approach to slowly introduce a towel to a bird that is showing a fear response to that object. This can provide a more optimal option for introducing a towel for restraint compared to immediately capturing the bird with the towel (which will also lead to an increased fear response to the towel on future occasions; see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).

Systematic desensitization is even more effective when used in conjunction with the association of desired items or experiences such as preferred food items, desired touch, toys, and so on. This process is known as counter conditioning. The intention is to pair desired experiences and items (preferably in conjunction with systematic desensitization) with the introduction of the stimulus. Counter conditioning is used to change the perception of an experience or situation from aversive to appetitive and can allow practitioners to progress rapidly through steps of introducing novel items such as dosing syringes, stethoscopes, nail clippers, and other medical instruments. Again, sensitivity to bird body language is critical. There is a common tendency to push for the result as opposed

TABLE 46.1
Behavior Definitions[39–44]

Term	Definition	Key Points
Positive reinforcement	A learning process in which the presentation of a stimulus following a behavior increases the probability or likelihood of that response.	For example, delivering preferred food items to a patient after stepping onto a scale.
Negative reinforcement	A learning process in which the removal of a stimulus following a behavior increases the probability or likelihood of that response.	For example, removing pressure when the bird relaxes during restraint to increase presentation of calm behavior.
Positive punishment	A learning process in which the presentation of a stimulus following a behavior decreases the probability or likelihood of that response.	For example, a "wobble correction" (destabilizing a perching surface) when a parrot attempts to bite to decrease biting behaviors.
Negative punishment	A learning process in which the removal of a stimulus following a behavior decreases the probability or likelihood of that response.	For example, removing fingers from the mouth of a young parrot when gentle mouthing becomes too painful for human fingers.
Reinforcer	The stimulus (aka consequence) that increases or maintains the behavior.	For example, a desired food item. Only becomes a reinforcer if behavior change occurs; otherwise, it is a "potential reinforcer."
Threshold	The point at which conditions become so aversive that a bird is unable to exhibit normal behaviors and responses.	See "Under threshold" and "Over threshold."
Under threshold	The bird is experiencing minimal stress and showing normal behaviors.	This is the goal throughout the veterinary examination.
Over threshold	Following a significant stressor, behaviors observed may include escape, avoidance, increased rate of respiration, and no receptivity to food or other appetitive.	Time is required to recover from this level of stress. Anxiolytic medication may be required short term. Training is necessary to achieve long-term goals of stress-free medical care.
Habituation	Decreased response to a stimulus following repeated exposure to the stimulus. If this is done without regard to how it influences behavior, it is not always successful.	Always occurring, but not usually successful if the fear response is too strong. Flooding is an extreme version of intentional habituation.
Systematic desensitization	Exposing the bird to a stimulus in a graduated manner so as not to evoke a substantial fear response.	Can work alone with good sensitivity to body language. Works better when paired with counterconditioning.
Counterconditioning	Pairing a desired object, experience, or stimulus with a previous experience or situation to change the perception from aversive to appetitive (or vice versa).	For example, a bird can be taught to engage with towels instead of fearing them by pairing towels with desired food items.
Flooding	Exposing the bird to what it fears all at once at the fullest intensity until it no longer resists.	Flooded patients appear to be compliant, but the flooding process is stress inducing for the patient. Not recommended.
Sensitization	The process of becoming highly sensitive to specific events or situations.	May be triggered by unskilled application of systematic desensitization.
Stimulus fading	Gradually introducing or removing a stimulus that may evoke a desired or undesired response.	When done skillfully, this can be used to introduce items such as towels and medical instruments without evoking fear responses.

to focus on the process, which can result in sensitization. The patient will then react with a fear response to stimuli associated with the procedure earlier in the process.

For those individuals who are receptive, positive reinforcement can be used to train voluntary cooperation in behaviors that facilitate examinations such as stepping onto a scale, accepting oral medications from a syringe (Figure 46.2), allowing wrapping in a towel, loading into a transport container, stepping onto strangers, and more. This is the preferred approach when possible. This involves shaping behavior with successive approximations and reinforcing each step with desired consequences (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). Ideally, clients should be encouraged to train their birds at home in advance and generalize those behaviors to many locations. Since many clients do not train or have the skillsets to train, it is important to demonstrate and provide proper guidance and resources for clients to achieve the goals that are set and/or refer them to qualified behavior consultants or animal trainers to help during this process. However, even if prior training has not occurred, some patients are receptive to learning at the veterinary practice, either during an appointment or while hospitalized or boarding (Figure 46.3). Take advantage of these opportunities when possible.

FIGURE 46.2 Many birds, in particular parrots, can readily be trained to participate in medical procedures using shaping and positive reinforcement. This brown-headed parrot *(Poicephalus cryptoxanthus)*, for example, has been trained to voluntarily accept medication from a syringe.

FIGURE 46.3 Training for medical behaviors can be implemented while the bird is hospitalized. Initially, training can be done through the bars of the enclosure to reduce the risk of escape or exhibition of aggressive behavior, as performed here with the white-bellied caique *(Pionites leukogaster)*.

Other behavior modification techniques involve the use of negative reinforcement, negative punishment, positive reinforcement, and positive punishment (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). Each of these techniques has the potential to achieve a desired result. However, there are many undesirable consequences that can occur, particularly associated with positive punishment. The use of positive punishment is not recommended in a veterinary setting.

PREPARING FOR THE LOW-STRESS VETERINARY VISIT

Once the tools for good "perch-side" manner have been developed, the next step is to develop a comprehensive strategy for minimizing the stress of the entire veterinary experience.

Scheduling Guidelines

Realistic scheduling guidelines are the first step in achieving our goal of stress-free visits. Appointment times should be more generous than those used for dogs and cats, since these patients often take more time. Overbooking often forces veterinarians to rush through the visit. In these situations, client education and the necessary, patient-centered approach to the examination are often curtailed in the interest of time (see Chapter 1 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 24, Practice Management).

Since many ill birds are much sicker than the client originally understood when making the call, some flexibility in the schedule will be necessary. A best practice is to include in each day's schedule a few emergency slots for critical same-day appointments. Sick birds cannot wait to be seen.

Generally, appointments are best scheduled early in the day, specifically in the situation where conscious sedation may be needed to accomplish the visit goals. Moreover, sick birds may require hospitalization, which can allow more to be accomplished following admission when the client comes in early as opposed to at the end of the day.

For routine appointments, the client service representative (CSR) must schedule skillfully to attain the goals of a low-stress appointment. The arrival of the client should not coincide with that of especially loud patients or during exceptionally busy times, such as the mornings of surgery days. Some thought should be given also to matching patient needs with the talents of specific technicians or assistants. For example, certain team members may be more skilled at client education or with handling large macaws. If conscious sedation is anticipated based on previous visits, access to oxygen anesthesia equipment should be given consideration as well.

This type of scheduling may limit the number of patients that can be handled each day. Fees may need to be adjusted accordingly (see Chapter 1).

Team Member Roles

It is vital that all team members be fully committed to the goal of a minimally stressful examination and fully trained in their roles. They must deliver to the client a consistent message about the value of this approach. Having a handout that describes the goals of the visit and standard practices, which can be available online or given to the client at check-in, may help achieve greater understanding and buy-in. Readers are referred to Fear Free™ website (https://fearfreepets.com/), which has resources and handouts available for hospitals to provide to clients. Team members must also work together closely to meet the needs of individual patients, practicing flexibility in scheduling when needed.

Adopting low-stress practices practice-wide can be difficult, especially given the different backgrounds and experiences that team members may have. Since the success of the

visit is dependent upon so many factors and the cooperation of so many different team members, it is best to have for reference a printed resource of job descriptions and hospital protocols, as well as client instructions and scripts for scheduling appointments.

The CSR is the first team member to convey appropriate expectations to the new client regarding the minimal stress approach and is responsible for facilitating the client experience from start to finish. When scheduling appointments, the CSR must describe the practical details for a typical appointment, gather pertinent client/patient information, and provide initial coaching for transporting the patient to the practice in a stress-free manner. If there is any question about meeting any special needs that the client or patient might have, the CSR will also consult with appropriate team members to decide upon the best scheduling options. The CSR will also make sure that the process of entering and exiting the building is as smooth as possible.

The role of the technician or assistant is also multifocal. Any technicians and assistants who will be handling avian appointments must maintain communication with receptionists and veterinarians to streamline visit flow and optimize patient care. Additionally, a large part of the technician's role is that of client education, including discussions about training challenges and behavior modification.

The technician is responsible for restraining patients, administering anesthesia (if indicated), and performing procedures/treatments in a low-stress manner. They are also responsible for providing care for hospitalized patients and being a patient advocate by recognizing and addressing patient distress. Technicians may also be responsible for providing training to patients while they are hospitalized or during office visits. They may be expected to help clients develop and implement training plans to cover both cooperative medical care and participation in normal husbandry.

The veterinarian plays an overarching role in establishing the practice as one that has committed to low-stress medicine. The practice needs a strong mission statement by which team members can measure the approach they intend to take with a patient or client. The veterinarian must lead by example, providing to their staff a clear duplicatable image of what low-stress medicine looks like when interacting with patients. This will indicate the vet's own commitment, which sets the stage for the veterinarian to demand 100% commitment to the force-free approach among other team members.

The veterinarian is responsible for educating both team members and clients about the body language signals that indicate unacceptable levels of stress in a patient. The veterinarian also conveys information about both the harmful physical and behavioral ramifications of stress. The veterinarian must also be instrumental in developing an in-house training plan so that all team members have the opportunity to learn the skills necessary for a low-stress examination and client interaction. Hands-on training with live birds will be necessary for this. Options may include using birds owned by staff members, those currently in sanctuary or fostering situations, or even birds owned by consenting clients. Technicians and assistants should not be allowed to participate in restraint or care until they have demonstrated proficiency in reading body language and basic handling skills.

During the examination itself, the veterinarian has an opportunity to communicate value to the client regarding the force-free approach and to discuss specific appointment details. The veterinarian then manages the flow of the appointment and is responsible for making medical recommendations.

The veterinarian then performs an examination, making every effort to avoid eliciting stress in the patient. The vet will evaluate the need for sedation and, if necessary, develop a sedation or anesthetic protocol. The vet will also have a driving role in establishing a plan for the best system for collecting diagnostic samples that are indicated and achieving other diagnostic processes in order to minimize stress for the patient.

At the end of the examination, the veterinarian will help the client to develop an ongoing plan for behavioral wellness, including the training of any behaviors that will make future examinations less stressful. A last step will then be to enter into the patient record information relating to the degree of stress observed for the patient during that visit, what was done to mitigate this, and a plan for future examinations.

Team Member Training

Ongoing training for each team member must be a priority and is best conducted in practice during staff meetings. Establishing the practice of mandatory regular staff meetings is important. Identify which time of the week is slowest for the practice and schedule a 1- to 2-hour meeting at this time. The benefits of the information sharing and training that take place during these meetings will far outweigh the disadvantages of being able to schedule every possible appointment slot.

The first part of the meeting can be dedicated to practice business according to a previously agreed-upon agenda. The bulk of the meeting can then be spent in smaller groups training team members using role play, hands-on training with healthy birds, or for any other skills necessary to accomplish the goal of a satisfactory visit. The most skilled team members can be chosen to help those needing to build skills. For this purpose, "Awesome Visit" role plays, which involve each level of team membership, can be exceptionally helpful.

In addition, team members should be encouraged to attend any applicable continuing education, including the Fear Free™ Avian Modules. Continuing education should be paid for by the practice and wages paid for attendance, which helps team members to understand the importance of their roles. The individual should be expected to return and provide a summary of their learning to the entire team during a subsequent meeting.

Each day, before appointments begin, the CSR, technicians, assistants, and veterinarians who will be handling appointments should meet to discuss the cases of the day. This affords them an opportunity to brainstorm any individualized approach that might benefit any special needs of clients or patients. A brief end-of-day meeting enables staff to evaluate their performance and look for opportunities for improved case management. These "all staff rounds" provide a valuable training opportunity and will optimize staff engagement.

When all team members are trained to the highest level, practices can truly be integrated to offer best practices from the start to finish of every appointment. A consistent staff mindset and clinical approach is critical to both effective client education and patient care. Team members who are

self-assured in discussing behavior and training and in handling birds will inspire client loyalty and confidence.

Scheduling the Appointment

When a client contacts the practice to set up an appointment for their bird to be examined, the CSR must first assess the possibility of the patient being ill. This is often the case, since routine preventative care visits are still relatively uncommon for companion parrots in many practice settings. If illness is suspected, the patient should ideally be examined the same day, since birds tend to hide symptoms of illness until they are in an advanced stage of disease. For these cases, the focus of the CSR should be on helping the client bring the bird into the hospital for assessment as soon as possible. While there are still many ways to minimize the stress of sick birds (see sections on Restraint of Poorly Socialized or Birds Showing Extreme Fear or Aggressive Behavior, and Conscious Sedation as Part of the Low-Stress Avian Examination), birds that are sick are unlikely to respond well to training procedures and postponing a visit until a bird is trained is not an option.

The approach to scheduling an appointment for a healthy bird is different. It is important for the CSR to educate the client regarding the goals for the visit and establish appropriate expectations. This includes the fact that the appointment may take more time than they are used to spending at a veterinary visit, and the examination itself may proceed more slowly to keep the patient's stress levels as low as possible. The client should receive instructions on getting the patient to the practice in as stress-free a manner as possible (emailed handouts are an excellent way to accomplish this efficiently; see Box 46.2), including which types of carriers are appropriate for the species. Birds should always be transported in an appropriate carrier (not free within a vehicle on a client's shoulder) for a variety of safety reasons. The CSR should also inform the client that the bird must remain in the carrier while being transported from the car to the practice, while waiting in the lobby, and while acclimating to the examination room (see

BOX 46.2 EXAMPLE OF A CLIENT HANDOUT WITH INSTRUCTIONS ON HOW TO MINIMIZE STRESS DURING TRANSPORTATION

Tips for transporting your bird to the veterinary practice

Transportation to the veterinary clinic may be a stressful event for your beloved bird. To maximize safety and minimize the amount of stress involved, we recommend you do the following:

- Make sure to use a comfortable, safe, and secure carrier.
  - A carrier should be appropriate to the size of your bird. For small birds, you may choose to transport them in their own cage if it fits in your vehicle, as the familiar surroundings will cause the least amount of stress. Alternatively, you can use a small cage or box that has sufficient air holes to provide adequate air flow and ventilation. For larger birds, a well-ventilated carrier with front opening is preferred. The opening must be large enough to facilitate entry and exit from the carrier, but not so large that the bird can easily escape.
  - To prevent escape during the ride, the enclosure should preferably be constructed of nondestructible materials (e.g., wire, acrylic, or hard plastic) and have a secure closure. For parrots that are known escape artists, the use of an extra lock is recommended! If you are using a cardboard box to transport a small bird, remember that they can chew their way out of the box, so be sure to always monitor them and leave them in the box for the least amount of time possible!
  - To ensure your bird sits comfortably during the ride, the carrier or cage should be fitted with an adequately sized perch that offers a sturdy, stable grip so that your bird can maintain its balance during the trip. If your bird is suffering from trauma, weakness, seizures, or other conditions that hinder its ability to perch, a flat-bottomed container or box without perches is more appropriate to use. All toys and swings should be removed to prevent injury to your bird. Food or treats can be provided during the trip (unless you have been advised otherwise) in a dish that is securely attached to the carrier or cage. Water dishes should be emptied to prevent spillage; during long trips, ice cubes or fresh foods that contain moisture can be provided as an alternative water source. Make sure that there is a towel, absorbent padding, or paper on the bottom of the enclosure as this will allow for collection of droppings that can provide helpful information during the visit.
  - **NEVER allow your bird to roam freely in the car while you are driving as this is neither safe for you nor for your bird!**
- Unless your bird is curious or accustomed to regular travel in an uncovered carrier or cage, it should be covered during the ride. This will help to reduce the level of stress (especially for nervous or fearful birds!) and car sickness. Once in the examination room, the cover can be removed to allow your bird to acclimatize to the new surroundings.
- Place the carrier or cage on the floor of your car and prevent it from sliding during transport. If placed on a seat, use a towel to keep the base horizontal and secure it safely with a car seat belt to prevent movement or shifting.
- Protect your bird from the elements! Be sure to consider the weather conditions during the travel. If it is cold or damp outside, prewarm your car and cover the cage or carrier using towels or blankets. When it is hot outside, be sure to provide adequate ventilation or fresh air and never leave your bird unattended in the car as you may risk overheating it.
- A carrier ideally should be a familiar space where your bird feels safe and comfortable. If possible, allow your bird to get acquainted with the carrier by placing it in clear view for at least 1 week prior to the visit. You can offer highly favored treats or toys in the carrier to motivate and train them to voluntarily step into the carrier. Alternatively, you can consider using the carrier as a "night cage" where your bird sleeps every night, so that entering and exiting the cage becomes a daily routine.
- Do not forget to bring items that can be of importance during the veterinary visit, such as your bird's food, medication, or favored toys. If your bird has ingested something that you suspect to be toxic, do not forget to bring these items either, or take pictures so that information can readily be retrieved.

sections on Hospital and Examination Room Preparation; The Lobby Experience; and The Low-Stress Examination).

CSRs should advise clients to bring preferred food items, small toys, familiar towels, and/or other items that can be used during the visit. In some cases, it may be appropriate to recommend withholding the bird's preferred food item for the week prior to the visit to increase receptiveness to this potential reinforcer. The CSR should also ask the client about any known aversive stimuli (previous experienced objects, colors, handling methods, etc.) that may result in increased patient distress. These aversive stimuli should be clearly flagged in the medical record so that the clinician and staff can adjust their plan accordingly.

Before the close of the conversation, the CSR should encourage the new client to complete the necessary paperwork in advance of the visit (online, via email, or by obtaining a hard copy directly from the hospital) and request that the client send it in (e.g., via email) photos (and/or video) of cage with surroundings, nighttime cage, play spaces, and so on. This will minimize time spent in the receiving area.

Technicians and veterinarians should provide support to the receptionist as needed during the scheduling process. This may take the shape of brainstorming the best appointment time (including fitting patients into the schedule on an emergency basis), or how best to meet the special needs of either the client or the patient. In some cases, these team members may need to have an additional phone conversation with clients to clarify details of the appointment or to consult on ways to get the bird into a carrier in a low-stress manner.

Offering wellness plans to clients with avian patients may help increase compliance with preventative health care. It is helpful to include additional office visits as part of the wellness package to be used as training sessions and habituate the bird to the practice environment and staff.

Hospital and Examination Room Preparation

The setup of the hospital and the examination rooms can contribute greatly to the success of the visit. A crowded waiting room is not a good place for a sick or nervous bird. Ideally, the patient should spend minimal time in the reception area and move straight into the examination room upon arrival.

If this is not possible, the bird should wait either in an avian-specific reception area or in the client's vehicle until the examination room is available, environmental conditions permitting. If neither of these options is acceptable or available, reception areas dedicated for cats are preferable to those used for dogs. Partially covering the carrier with a towel to decrease visibility may help decrease fear responses in some birds. Similarly, ensuring that the carrier can be placed higher up rather than on the ground can help to alleviate stress.

Examination rooms should be in a quiet area of the hospital, where the patient is not disturbed by the sound of slamming doors or the banging of wagging tails against a wall. Examination rooms with windows carry the risk of potential injury (if a bird flies into the window) and may be a source of aversive visual stimuli for some patients. There are various options available to make the window less of a risk (decals, shades/blinds, commercial window coatings, etc.) although their degree of efficacy may vary.

Preparation of the examination room prior to the visit is necessary. This should be done with the expectation that the entire examination will take place there in the presence of the client.

Patients can be disturbed by the opening and closing of drawers and the movement of equipment. All items that might be used during the visit (including materials for diagnostic sampling, grooming, etc.) should therefore be out and ready in their intended location for use prior to the entrance of the patient into the room. A laminated photo of the correct setup arrangement can be kept in a drawer to serve as a reference for newer team members. Once the room has been set up, team members should communicate with each other that it is "In Use" to avoid disrupting flow of the appointment.

If the client has brought their own scale or towels, these can be substituted as needed when the client enters the room and before the patient exits the carrier.

Included in the examination room setup should be the presence of potential food reinforcers (Tables 46.2 and 46.3). A variety of preferred food items should be available and selected based on the species of bird being examined (Figure 46.4). Another helpful reinforcer to have on hand for parrots is small foot toys; these can be as simple as a paper towel tied in a knot or some tongue depressors zip-tied together (Figures 46.5 and 45.6).

The Lobby Experience

The CSR should greet clients as they arrive and direct them to transport the bird's carrier into the practice in a stable fashion (not swinging, held in an upright position, not bumping the carrier against any objects, etc.). Ideally, the client should hold the carrier by its base instead of grasping it by a handle to facilitate this. It may be necessary to help some clients enter the building by holding doors open for them, particularly if the carrier is bulky.

Once the bird is inside the practice, CSRs should advise clients to place the carrier in a location that decreases stress, such as on an elevated surface in a quiet area. Placing carriers on the floor increases stress for most perching birds, as it places them at eye level for many other animals entering the lobby and may increase the possibility of collisions with the carrier from foot traffic. Species-specific exceptions may exist (large poultry, for example). As previously mentioned, a towel can be used to cover the carrier if this appears to reduce patient stress, and the amount of time spent in the receiving area should be minimized.

Ideally, the bird should be moved directly from the client's vehicle into the examination room and allowed to habituate for several minutes before exiting their carrier. The CSR should give a cursory glance at the bird to judge the level of stress that the bird might be displaying. If stress levels seem elevated, the CSR should ask for assistance from a technician or an assistant.

THE LOW-STRESS EXAMINATION

The examination is generally a significant source of stress during the veterinary visit. Thoughtful preparation will minimize the length of the examination, resulting in reduced stress. This includes prior setup of the examination room as described previously. Obtaining husbandry information and a

TABLE 46.2
Potential Reinforcers for Parrots

Potential Food Reinforcers for Parrots	Comments
Sunflower seeds in the shell—low oil preferred	Some parrots do not recognize shelled sunflower seeds.
Shelled sunflower seeds	Preferred by many parrot species.
Almond pieces	Preferred by many parrot species.
Walnut pieces	Preferred by some individual parrots.
Pistachio pieces	Preferred by some individual parrots.
Pine nuts—out of the shell	Preferred by many larger parrot species.
Millet spray	Preferred by many smaller parrot species. Conure-sized and smaller. Of the large parrots, Eclectus species often respond to millet.
Macadamia pieces	Preferred by hyacinth macaws.
Safflower seeds	These bitter seeds are often preferred by parrots in the genus *Poicephalus* and some conures.
Unsulfured papaya bits	Moluccan *(Cacatua moluccensis)* and umbrella cockatoos *(Cacatua alba)* and some Amazon parrots (*Amazona* spp.) often respond to this food item.
Peanut pieces	Preferred by many parrot species—however must be used with caution due to aflatoxicosis risk.
Lorikeet nectar, grapes, and apples	Preferred by lories and lorikeets.
Nut butters (almond, cashew)	Can be helpful for masking oral medications.
Parrot hand-feeding formula	Can be helpful for masking oral medications.
Human baby food (banana, winter squash)	Can be helpful for masking oral medications.
Potential Nonfood Reinforcers for Parrots	**Comments**
Touch, head scratches, toys	Evaluate on a case-by-case basis for individual response.

TABLE 46.3
Potential Reinforcers for Non-Parrots

Potential Food Reinforcers for Non-Parrots	Comments
Fresh corn, thawed frozen corn, cracked corn	Preferred by chickens and other poultry
Live mealworms, dried mealworms, crickets	Preferred by chickens and other poultry
Shelled sunflower seeds, nut pieces, vegetables, meat, cooked egg	Preferred by chickens and other poultry
Mice, pinkies, fuzzies	Hawks, owls, eagles
Beef heart	Caracara, vulture
Quail, fresh pigeon	Falcons
Peanut pieces	Pigeons

FIGURE 46.4 Different bird species respond to different types of food items. Smaller birds such as cockatiels *(Nymphicus hollandicus)* and budgerigars *(Melopsittacus undulatus)* often prefer millet spray. Even if a bird is not trained, they can potentially be lured onto scales and into crates to avoid the stress associated with a capture and restraint.

medical history (including flight status) can be accomplished at the same time as a hands-off assessment of the bird's clinical state and behavior (posture, reaction to unknown individuals, vocalizations, symmetry and position in cage, respiration rate, and effort). If the bird is not in a carrier, make note of how the bird is interacting with the client, and consider the best way to approach the bird. These observations may be adequate to determine the need for conscious sedation before the examination starts in some patients.

The goal should be to have the bird restrained for the shortest amount of time possible (if required at all), and restraint should be characterized as optimizing welfare (maximizing benefits and minimizing harms). Veterinarians and team members who are experienced in reading avian body language and accurately interpreting hands-off examination findings are much more likely to be able to successfully handle and treat birds. Careful observation, gentle handling, and conscious sedation (when indicated) all improve safety of patients.

Birds can display a variety of behavioral and physical changes secondary to stress. If noted, some of these symptoms require an immediate shift to a hands-off approach, and others may even require oxygen support. If signs such as aggression, panic vocalizations, red tears (in grey parrots; Figure 46.7), profuse feather loss (in Columbiformes and Musophagiformes;

FIGURE 46.5 Parrots that are not interested in food may respond to small toys as potential reinforcers for desired behaviors. It is recommended to keep a supply of small bird-safe destructible items on hand for this reason.

FIGURE 46.7 Occasionally, grey and Timneh parrots (*Psittacus erithacus* and *Psittacus timneh*) may secrete red, bloody tears while being manually restrained for physical examination or diagnostic sampling. While the exact cause is not known, it has been hypothesized that a rise in blood pressure due to stress from handling could be involved, especially in already nervous animals. Screening for underlying pathologies, such as chronic respiratory infections, cardiovascular disease, or ocular disease, may be indicated, but in the majority of cases, workup may be unrewarding with no underlying cause identified. (Photo courtesy Richard Jones, Avian Veterinary Services.)

FIGURE 46.6 This Moluccan cockatoo *(Cacatua moluccensis)* is playing with a foot toy created in an examination room out of two tongue depressors and some VetWrap. Toys can be an excellent reinforcer for some birds.

FIGURE 46.8 This dove lost all her tail feathers secondary to stress of capture. This is a common defensive mechanism for Columbiformes, Musophagiformes, and other species.

Figure 46.8), open mouth breathing (in absence of respiratory disease), hyperthermia, tachycardia, tachypnea, and hypertension are noted, release the bird from restraint and consider a different approach, potentially including conscious sedation.

Signs of extreme stress include dyspnea, changes in mentation, seizures, and collapse. If you see any of these extreme symptoms, the patient may be on the verge of going into cardiovascular collapse secondary to underlying disease combined with extreme stress. The patient should be **immediately** placed in an oxygen chamber and handling should be minimized thereafter. If actions are taken quickly enough, the bird may recover (at least in the short term). Further supportive care, such as IV catheterization and fluid therapy, may need to be delayed until the patient has stabilized in oxygen, unless the patient has gone into full cardiorespiratory arrest and cardiopulmonary resuscitation (CPR) is indicated

(see Chapter 34). Birds that experience a collapse like this are critically ill; their owners must be prepared for the possibility of death at any moment. These patients must be handled with extreme caution, and procedures (including further examination and supportive care) must be staged carefully in order of importance.

Clinical History and Relevance to Low-stress Veterinary Medicine

Collecting a thorough history, including husbandry and diet information, is critical to success with avian cases. Interpretation of the history prior to the examination will allow for a more efficient and tailored diagnostic approach, often reducing the number of diagnostic modalities required to reach a diagnosis.

Obtaining information regarding the patients' prior veterinary experiences is extremely helpful for minimizing patient stress. This may include handling techniques (by the client and previous veterinary staff) and exposure to relevant objects/situations (how the patient has reacted to approach by unfamiliar people, whether the bird has experienced pleasant interactions with towels, etc.). An example of the depth and breadth required for an avian behavioral history is provided in (Box 46.3 is online only and can also Box 5.3 from *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). Although it seems that routine visits may not require as much detail in the history, it is all relevant.

Knowing how often the bird is handled and *how* the bird is handled is important for the initial approach to handling the bird in the hospital. Companion birds experience a wide variety of home situations. Some birds stay in a cage all the time; some birds are brought out only on a stick/perch; some birds are handled by their owners routinely and may be more willing to step up to unknown individuals. However, just because a bird is handled a certain way by their owner, does not mean that it will respond the same way with an unfamiliar person. Ultimately, the method of approach to the bird should be chosen based on the bird's behavior in the examination room.

It is ideal when clients have previous knowledge of how to train their parrots to perform behaviors using positive reinforcement. This allows staff to more easily explain how to incorporate training for medical behaviors into the case management plan. If a client lacks such knowledge, the treatment plan will need to incorporate the demonstration of shaping plans for targeting, taking oral medications, stepping onto a scale, going into a crate, and so on.

Obtaining a thorough history can be accomplished by sending a technician into the room to speak with the client prior to the veterinarian's entrance, by having the veterinarian collect the history during the examination, or by having the client complete a form online prior to the appointment. There are advantages and disadvantages to each approach.

Having the technician take the history can serve to create rapport with the client, ferret out details and impressions important for the veterinarian's success with each unique patient, allow the patient more time to habituate to the examination room, and buy the veterinarian time to complete the last examination. This approach does, however, take additional time and may be a disadvantage in a tightly packed schedule.

There are similar benefits and challenges to having the clinician take the history. It can be difficult for some veterinarians to get all the information necessary in a timely manner before jumping into the examination. However, this approach may be more efficient in some clinicians' hands because the hands-off examination, development of client rapport, and patient acclimatization to the clinician can occur simultaneously.

Having the client complete the form electronically allows the information to be entered more quickly into the patient record and to be reviewed prior to the appointment. Such a review may facilitate a more efficient and tailored diagnostic approach, as well as increased success with handling. On the other hand, clients often do not provide information in as much detail as needed when filling out a generic form and/or may lack the technical skills required. Therefore, all client-completed forms should be edited for clarity/details by veterinary staff at the time of the appointment.

Wording on the form must be precise to collect sufficient detail. Some questions should be open-ended. Others should offer multiple-choice options that will identify common husbandry concerns. For example, when asking about UV light exposure, including "through a window" as an option (in addition to time outdoors, exposure to a UV light, etc.) will provide an opportunity to discuss how to improve effective exposure.

Interacting with a Bird during the Hands-off Examination

Observation of the unrestrained patient prior to handling is a critical part of the physical examination. Not only can many important health concerns be identified, but also the temperament of the bird can be evaluated, including receptiveness to handling.

When initially approaching a bird, consider utilizing sidelong glances rather than a direct gaze, as this may increase patient comfort. During this process, the clinician can begin to associate desired items or experiences with their presence. Allowing the bird some time to habituate can be helpful to some birds if they are under threshold. Talking may be viewed as a desired experience by some parrots; for others it can create high levels of arousal that can quickly evoke aggressive behavior. It should be used with caution. Preferred food items and desired toys can be helpful to reinforce voluntary cooperation (Figure 46.9).

Birds are very alert to changes in the surrounding environment and have a reputation for exhibiting unexpected fear responses in examination room settings. Potential triggers for these behaviors may range from something visible outside a window to an insect, a color, pattern, or style of clothing, examination room furniture, or something that reminds the bird of a past aversive experience (objects, people, or other stimuli). Careful observation may allow staff members to identify stimuli that evoke fear responses, but this is not always possible due to the subtlety of certain stimuli and the fact that many of these patients have incomplete behavioral histories. In many cases, the response may be rooted in neophobia rather than an aversive history with a stimulus. Collecting data over time and recording reactions in the behavioral medical record can sometimes reveal patterns or trends and allow identification of stimuli that evoke fear responses. If a stimulus cannot be

BOX 46.3 AVIAN BEHAVIORAL HISTORY FORM

Date of consultation:

OWNER INFORMATION:

Name:
Address:
Phone: ..... (day) ..... (evening)
Email:
Who is the bird's primary caregiver?

BIRD INFORMATION:

Name of the bird:
Species:
Age: ... years/... months Unknown
Sex: Male/Female/Unknown
If the sex is known, how was this determined?

HOUSEHOLD INFORMATION:

List all people in household and people who interact with bird on a regular basis:

Name	Age	Relationship (e.g., Spouse, Son, Daughter, Pet Sitter, Housecleaning Service Workers)

List other birds and/or pets in household (list these in the order in which they came into household; include the patient in this chronologic list as well):

Name	Species/Breed	Current Age	Age when Acquired	Sex

Provide a brief description of the interaction between the birds (e.g., do they have vocal/visual/physical contact, share a cage)

ACQUISITION AND REARING HISTORY:

Reason for acquisition:
Acquired from (circle the answer that is applicable):
Breeder/Pet Store/Previous Home (Rehomed bird)/Own bred/Shelter/Other (describe):
If your bird is a re-homed bird, describe briefly below what is known about its previous home environment (e.g., married couple? children? length of time in home)
Your bird was (circle the answer that is applicable):
Bred in captivity/Wild caught/Unknown
Hand-raised/Parent-raised /Unknown rearing method
If hand-raised, by whom? (e.g., breeder/you/unknown)
Raised with: siblings/similar-aged birds but different species/birds of other ages/unknown
At what age was your bird separated from its parents?
At what age was your bird rehomed to its new home?
Briefly describe the weaning process and stimuli (e.g., social contact and enrichment) the bird was confronted by during early life:

HUSBANDRY:

Cage(s) and playpen:
- Size (approximate dimensions) and materials of which the cage is made
- When used (e.g., sleeping, daytime, outside)
- Location(s) (i.e., inside/outside, where in the house and where in the room)
- Cleaning (frequency, products, procedure of cleaning)
- Furniture in cage (include information on which types of enrichment are provided, which of these are used, frequency and way in which these are used, and how often these are changed, if applicable):
  - Perches and other climbing materials/toys
  - Bowls
  - Chewing toys/materials
  - Puzzle toys
  - Foot toys
  - Nest boxes
  - Other

NUTRITION:

- Diet: % fed (offered and % actually eaten)
  - Main diet
  - Treats and supplements (including which and how often provided)
  - How fed (bowl, foraging enrichment)
  - Water source (how provided and frequency of changing)

SLEEP RHYTHM AND LIGHTING:

- Hours awake/asleep
- Hours light/dark

Cage covered: Yes/No
What type of lighting is available to your bird (e.g., daylight, UV-light, fluorescent light)?

Continued

BOX 46.3 AVIAN BEHAVIORAL HISTORY FORM—cont'd

FEATHER CARE (BATHING/MISTING/CLIPPING):

- Do you provide your bird bathing/misting opportunities: Yes/No
  - If yes:
    - How often?
    - Method?
    - Bird's response to bathing/misting?
- Are wings routinely clipped? Yes/No
  - If yes, how is the clipping performed?
- Does your bird come outside? Yes/No
  - If yes, how often and where? (e.g., garden, park, friends/family)

HUMAN/BIRD INTERACTION:

- What tricks or commands does your bird know?
- Provide a brief description of the interaction between the bird and the people in the household (e.g., how often does the bird interact with the different people, characterize the interaction [cuddling/physical contact, playing/training, care and feeding]).

DAILY ROUTINE:

- Describe a typical day in your bird's life, starting with when and where bird wakes up in the morning. Be sure to include when, where, how, and who feeds bird, exercise/training/play (what type, how much, where), where bird is when people are not at home, where bird sleeps at night, and anything else you think is important (use additional pages as needed):

BEHAVIOR OF YOUR BIRD:

- Give a short description of your bird's behavior to the various people/animals/stimuli as mentioned as follows:
  - How does your bird react to its daily caregiver?
  - How does the bird react to familiar people (other than the daily caregiver)?
  - How does the bird react to unfamiliar people?
  - How does your parrot respond to other parrots?
  - How does the bird react to new items or toys?
  - How does the bird respond in a new environment (other than its familiar environment)?
- Does your bird allow petting?
  - If yes, does it actively ask for it (e.g., by offering its head) or not?
- How does your parrot respond to handling (e.g., using a towel)?

PROBLEM BEHAVIORS:

Indicate whether bird displays any of the following behaviors:

Behavior	No	Yes (Indicate Frequency in Next Columns)	Daily	Weekly	Monthly
Chronic egg laying					
Chewing/biting/tearing its own skin (self-mutilation)					
Damaging its own feathers (feather-damaging behavior)					
Destructive chewing of furniture or other materials in the environment					
Screaming					
Rubbing cloaca/vent on objects or people					
Regurgitating					
Repetitive behaviors such as somersaulting or weaving					
Hiding/trembling/trying to get away from people or other animals (fearful behavior)					
Lunging at/biting people or other animals					
Other (provide a description)					

MEDICAL HISTORY:

Does your bird have any known medical conditions or physical problems?
If yes, describe these briefly.
Does your bird take any medication?
If yes, describe which, what dose, and how often?
Details regarding your bird's problem behavior:

- What is the behavior problem for which you are seeking advice?
- Did a specific event prompt you to address this problem now?
  - If yes, describe this briefly.
- When did you first notice the problem, and what did the behavior "look like" at that time?
- When the problem first began, how frequently did it occur?
- How often does it occur now?
- Do you feel that there were any inciting factors?
  - If yes, describe these briefly.
- How has the problem changed or developed over time?
- When does the problem behavior occur now?
- Do you feel that there are any specific situations that seem to "trigger" the behavior?
  - If yes, describe these briefly.

BOX 46.3 AVIAN BEHAVIORAL HISTORY FORM—cont'd

Date of most recent incident of behavior:
Description of most recent incident of behavior:
How do you respond when your bird performs this problem behavior?

What, if anything, have you done to try to treat the problem (e.g., medical treatment, behavioral therapy, medications, supplements, herbs)? Indicate if the attempted treatment made the problem better, worse, or if the behavior remained unchanged.

Treatment Attempted	Behavior Better	Behavior Worse	No Change in Behavior

FIGURE 46.10 Stationing to obtain an accurate body weight.

definitively identified and removed or desensitized/counter-conditioned, conscious sedation may be necessary to prevent escalation of the fear response.

Obtaining a body weight from a bird should be done prior to restraint, if possible, as it allows the clinician to quickly calculate dosages of sedatives if deemed necessary. There are a variety of techniques for obtaining a body weight from a bird, including asking the bird to step onto a perch placed on the scale, standing on the scale itself, and weighing the bird in its own carrier or a separate box to prevent escape (Figure 46.10). In general, veterinary staff should seek to make this process as easy as possible for the bird. It is important that the surface the bird is standing on is not slick and that the bird does not have to be in an uncomfortable position to stand on the perch (including not touching its tail on anything). If the bird is not well socialized, obtaining a body weight should be delayed until the veterinarian enters the room to minimize the risk of unnecessary stress.

Low-stress Handling and Restraint

> *"By restraining pets in a forceful, crude, or unskilled manner, you could be breaking your promise to do no harm. Such handling can make pets behaviorally worse and even lead to aggression and, ultimately, euthanasia."*
>
> **Dr. Sophia Yin**

Based on what the client (and patient) have experienced in the past, they will anticipate the examination to unfold in a certain way, such as a low-stress examination or the traditional "capture and restraint." Veterinary staff need to be aware of this, communicate clearly to set appropriate (possibly novel) expectations, and be sensitive to body language of both clients and pets to maximize success. Information offered about the bird's preferences for handling can help save time and reduce stress for the bird and should be entered in the medical record.

Avian species (and individuals within species) differ in their need for restraint for various procedures. Many well-socialized birds (parrots, poultry, birds of prey) will tolerate the entire or majority of the examination with minimal restraint. The focus of each veterinary-patient interaction should be to utilize the most optimal method of restraint to safely obtain diagnostic information. When choosing the restraint technique to be used with a patient, it is important to take into consideration possible sources of injury to veterinary staff, which varies depending on the species of the patient.

Parrot bites can be painful and even debilitating. Although they do not have the grip strength compared to raptors, sharp nails on a parrot can cause punctures and lacerations to the handlers. Loud vocalizations of some species can be damaging to the ears. Poultry may kick or strike with their wings or spurs. Some raptors species have powerful grasping feet that can cause severe injuries, and some species may also bite (eagles, owls, etc.). For these reasons, proper protective equipment is essential for certain species.

Ear protection should ideally be worn by those that will be within a meter or so of certain bird species (especially macaws and cockatoos) to prevent hearing loss secondary to loud vocalizations, should this be an issue with a particular patient. Consider ear plugs rather than headphone-style hearing protection, as they are unobtrusive and can minimize the possibility of creating a fear response. Thick leather gloves should be avoided in all non-raptor species. Although they may provide some protection against bites and scratches, leather gloves allow minimal dexterity for needed procedures and may create a fear response. Additionally, a large parrot bite has substantial crushing power and a bite through a glove can still be quite painful.

When an animal is presented with an aversive stimulus that evokes a fear response, in most cases the animal chooses to escape. When escape is not an option, an animal may default to aggressive behavior to cause the aversive stimulus to go away. Aggressive behavior should not be "expected" in veterinary practices, although biting, lunging, and other types of aggressive behavior may be noted when the patient is exhibiting escape/avoidance behavior or fear response. Staff or owner behavior is typically the primary antecedent for bites or strikes. Coercive handling often creates aggressive responses. Providing choice in interactions and pairing interactions with desired consequences is a much better approach.

BOX 46.4 EXAMPLES OF SUBTLE BODY LANGUAGE DISPLAYED BY PARROTS THAT, IF IGNORED, CAN LEAD TO A BITE

- Pinning or flashing eye pupils
- (Slight) opening of the beak
- Raising or flattening of the (crest, head, or body) feathers
- Tensing up of the body, rigid body posture
- Spreading and arching of the wings away from the body
- Tail fanning
- Leaning away and then toward the hand
- Rocking back and forth
- Crouching
- Vocalizations, e.g., hissing, growling

TABLE 46.4

Injuries Resulting From Improper Restraint and Stress Responses

Suffocation	Birds must expand their keel bone in order to breathe normally. Placing pressure around the body of a bird during restraint can lead to suffocation.
Blunt trauma	Attempts at escape from aversive stimuli may lead to blunt trauma from flying into windows or walls or falling to the floor. Even skilled fliers may be injured due to their heightened emotional states, but unskilled fliers are at the highest risk for injury.
Musculoskeletal injuries	Many birds kept as pets have osteoporosis from inadequate dietary calcium and lack of exposure to natural sunlight, increasing their risk for pathologic fractures. Capture myopathy can occur in any bird but is a higher risk for certain species (long-legged wading birds, waterfowl, and ratites).
Hemorrhage, wounds, bruising	Broken blood feathers or toenails, wounds on carpi resulting from wing flapping, bruising on the cheeks (particularly in macaws and grey parrots) from excessive force during restraint.
Feather loss	Many bird species (especially Columbiformes and Musophagiformes) will lose feathers as a distraction ploy when faced with a perceived predator attack—may impact thermoregulation/flight in addition to patient appearance.
Seizures and/or cardiac arrest	Particularly common in small birds with other underlying health problems.

Another common cause for injuries is inaccurate interpretation of avian body language and poor management of the environment. True unprovoked aggressive behavior is rare. Birds are more likely to bite when subtle body language presented as a precursor to a bite has been repeatedly ignored (see Box 46.4 for examples), and compliance is gained via coercion.

If physical restraint is necessary for the individual patient or stage of the veterinary visit, it must be administered skillfully to avoid patient injury. Improper restraint and patient stress responses can lead to life-threatening injuries, which are documented in Table 46.4.

Tools for low-stress restraint

Most veterinarians utilize towels as a method of restraint. Towels are inexpensive, soft, yielding, and effective at preventing staff injury when used competently. They can also be very well tolerated by many birds when they are thoughtfully implemented. Birds can be easily trained to accept and even seek out contact with towels using positive reinforcement. Every bird owner has access to towels for training at home. Towel size, thickness, flexibility, and material type can be tailored to the individual patient/species.

Towels provide excellent handling dexterity and protection of staff hands against bites or grasping injuries and for most avian species. Although bites can easily penetrate even a thick towel, a towel can provide a visual barrier that does not allow the bird to purposefully bite a hand. Only portions of the towel without hands underneath should be placed in a position to be bitten by the patient. By holding a bird's wings against the body, towels also prevent wing strikes and inadvertent patient injuries. In addition, parrots will often chew on towels, which can be a useful distraction during the examination.

One concern with towel restraint methods is that a towel can trap heat close to the restrained bird. This can lead to significant overheating, often resulting in the bird panting as an early symptom. Close monitoring of the bird's responses is therefore warranted during restraint, and prolonged restraint should be avoided.

Hooding is another technique to minimize avian stress, most often used in raptors and Struthioniformes. The hood is a leather or cloth "cap" custom-designed to fit over the bird's head. It covers the eyes and ears, limiting visual and auditory stimuli, while leaving the beak and nares exposed (Figure 46.11A and B). Limiting stimuli can reduce observable fear responses and make it possible to examine some hooded birds with little to no restraint. Individual raptors will have different histories with hooding. Birds with a great deal of experience with hooding, especially paired with positive reinforcement, can present as quite relaxed when wearing a hood, as well as when it is removed and put in place again. While decreasing visual stimuli can reduce expression of the fight-or-flight response, it should not be an excuse to replace training with coercive handling.

Thick leather gloves may be used as a perch for trained falconry birds to facilitate handling. These birds may also have jesses attached to their legs, which can be useful to help keep them safely on the glove and provide some protection from footing injuries during minimally invasive handling (Figure 46.11C).

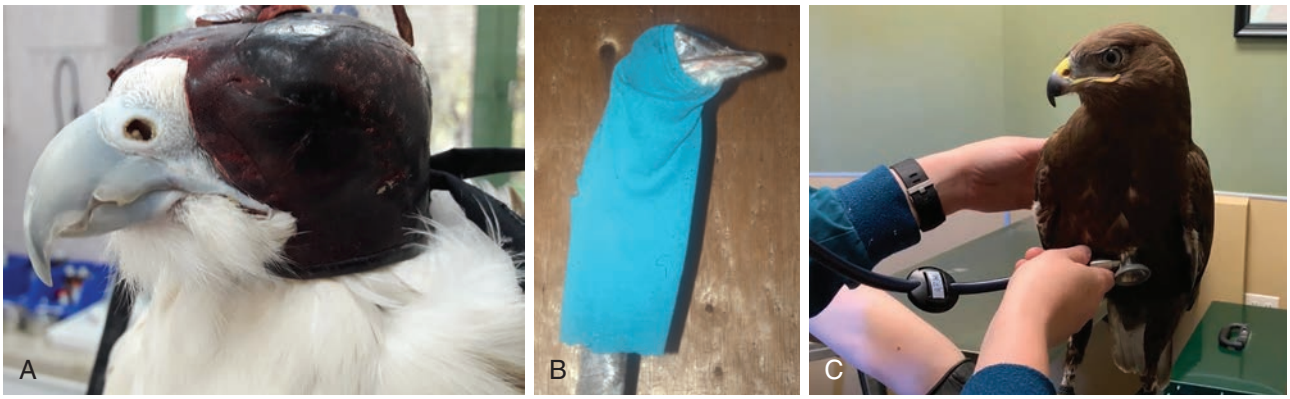

FIGURE 46.11 (A) Hooding is a technique that is commonly applied in raptors and Struthioniformes. By covering the eyes and ears, exposure to visual and auditory stimuli can be limited, hence preventing a stress response. (B) For this adult ostrich hen *(Struthio camelus)*, a functional hood was created using the cutoff end of sweat bottom pants. (C) A ferruginous hawk *(Buteo regalis)* is examined on the falconer's glove. The jesses are held tightly to prevent a footing injury to the veterinarian during auscultation.

Handling and towel restraint techniques

Unfortunately, many avian patients have a history of coercive handling at the veterinary office or in the hands of groomers, which will affect their behavioral responses regardless of the chosen approach to the contemporary examination. Traditionally, parrots have been rapidly grabbed from behind with a towel or gloved hand. This method often evokes a severe fear response and should be avoided for most patients, as veterinary professionals have options to provide more optimal restraint procedures.

There are a variety of handling and restraint techniques available that may have varying degrees of efficacy for each individual bird, depending on its learning history and individual preferences. The method(s) used should be recorded in the medical record along with the relative success or failure of the technique. This allows the best method to be used on subsequent visits. Keep in mind that some birds have multiple methods that may "work" depending on the circumstances surrounding their visit, so there may need to be additional stipulations within the medical record for behavior cues to watch for to modify your approach.

Ideally, the bird should remain in the carrier until handling by the veterinary staff needs to commence. There are several benefits to this approach. First, it minimizes the risk of a patient injury due to a startle response (as it cannot fly into a window or wall). Second, it usually allows the patient to be picked up in the safest manner, preventing escape. Third, leaving the bird in the carrier allows the bird time to habituate to the examination room while confined to the (relative) safety of its carrier. Finally, it allows the veterinarian to perform a hands-off examination with the bird in a minimally stressful way and reduces examination artifact caused by exercise from flying around the room or stress associated with capture. However, some pet owners will remove birds from carriers despite recommendations of veterinary staff.

The techniques described in the following section can be modified for socialized birds that are exiting their carriers or have already left the carriers. Birds that have already been removed from the carrier should be transferred to a perch the bird is more likely to leave (such as the examination table, or the top of the bird's carrier) prior to asking them to step up, rather than asking them to step up while perched on the client's hand or shoulder. Some parrots may be more likely to bite the veterinary team member, or exhibit redirected aggressive behavior, if they are seated with their owner.

Handling and towel introduction in the well-socialized parrot. Picking up a well-socialized parrot is typically straightforward. These birds show mild or zero signs of stress and are familiar with the step-up behavior, regardless of whether they are within their carrier or on another perch. The bird is offered a hand to step onto; in general, the hand should be turned sideways to offer an easier perching surface, rather than the palm pointed upward. This would not apply for birds that have been trained to step onto a flat upward facing palm, or to very large or non-psittacine perching birds (such as chickens). While most birds prefer to step up onto a hand in front of them, some prefer to step onto a hand behind or to the side of them. Some clients may know their bird's preference, so be sure to ask. A flexible approach that is responsive to body language of the patient is essential.

In some cases, birds may respond better to standing on an examination table or a perch for the examination, rather than perching on a hand or being restrained in a towel. It is possible to perform entire examinations with no restraint in well-socialized parrots and many poultry. The most intrusive parts of the examination should be saved for last, as this may push birds over threshold and lead to the need for restraint for the remainder of the examination. This varies with species, but in general, parts of the examination that require utilization of tools near the bird (stethoscope, specula, etc.), coelomic palpation, and cloacal examination tend to be most intrusive.

Once the examination reaches the point where restraint is necessary, one of the most common techniques for getting the bird into the towel starts with them perching on the restrainer's hand. Depending on the individual patient, it may be safest to grasp the toes by the thumb to prevent the bird from jumping or flying off (Figure 46.12). Be aware that this step may be poorly received by some birds and precipitate a

FIGURE 46.12 The handler is restraining the toes of this umbrella cockatoo *(Cacatua alba)* with her thumb prior to attempting towel restraint. This method can help prevent injuries in flighted birds but may lead to injuries to the handler as the bird may try to bite.

startle response or a bite. If the bird is not tolerant of this, a different approach is needed. It may be possible to get the bird wrapped in a towel without concurrent foot restraint, although injuries may occur if the bird is flighted. Other options include having the bird standing on a perch or standing on a towel-covered hand. In extreme cases, some birds may need to have their restraint experience initiated from within the carrier.

After the bird is comfortably in hand, the bird is then brought close to the veterinary staff member's body, and systematic desensitization is used to bring the towel up from the side or below the bird gradually. This means the practitioner pays close attention to the bird's body language and moves the towel so that it does not evoke an excessive fear response. The towel moves in increments to slowly cover the bird's body and head as opposed to moving up and down repeatedly, which may evoke escape and avoidance. Negative reinforcement can also be used in which calm body language causes the towel to be removed. It is important to start far enough away that calm responses can be emitted. This distance is gradually decreased as calm body language increases. Moving too quickly may cause the animal to become sensitized to the towel's approach. This may require the practitioner to start over, try again later, or consider another technique. While it may seem that this would take an excessively long time to accomplish, in many cases it takes less than a minute; in general, the slower/more gradual the approach to start with, the faster and better the results.

When the towel is almost touching the bird, the bird's neck can be gently grasped from behind. The towel is then wrapped around the body for restraint of the wings and feet. The bird should be held vertically in a natural standing posture, as this is less stressful than lying on the back and will minimize exacerbation of medical conditions that affect breathing. If possible, allow parrots to grasp something in their feet (a hand, a perch, etc.) during restraint, like standing on a perch. The restraint technique may need to be shifted multiple times within the examination room based on the patient's behavior.

While this method is successful for many birds, it is far from the only technique available and could result in patient or staff injury if applied to certain patients. For example, birds that show fear responses or aggressive responses to hands; birds that have phobic responses to the presence of a towel; birds that are poorly socialized; and bird species other than parrots would respond poorly to this approach. In the following paragraphs, several alternatives are explored.

Alternative methods of towel introduction in parrots. Fear responses to the hand can be very common depending on reinforcement history (grabbed by hands/gloves, fallen off a hand, etc.). Parrots with this history and behavior response may prefer to step to a toweled hand. To start "The Potholder" technique, cover the hand with one end of the towel and leave the rest of the towel hanging down (Figure 46.13A). For large parrots, the towel can be folded at the end to provide two layers over the hand as well as to pull it up over the forearm. Once the bird has stepped up to the toweled hand, the handler gently holds the parrot's toe to keep the bird on the towel. Use systematic desensitization or negative reinforcement to cover the bird with the towel as described in the first technique.

This technique can be modified into "The Butler" technique for birds that show a fear response to towels but are willing to step to a bare hand (Figure 46.13B). Place one end of the towel over the handler's forearm, letting the remaining length of the towel to hang down. Ask the bird to step up using the same hand as the towel. Next, decide if it is needed to gently hold onto the bird's toes or bring the towel forward to cover the handler's hand, which will prevent the handler from being bitten. Drape the towel slowly, as described previously, covering the entire bird with the towel.

For patients that prefer to step to the towel and respond to tactile contact as a desired consequence, we can use "The Toga" technique (Figure 46.13C). The handler drapes the towel over their shoulder, covering the front of their body. With either hand, ask the bird to step up and offer desired touch. Bring the bird in against your body and the towel while cuddling and with the free hand slowly bring either end of the towel around the bird. Many birds will accept (and enjoy) this type of restraint, provided they like tactile contact. Food can be substituted for tactile reinforcers if the bird is receptive to food in the veterinary setting (Figure 46.14).

When interacting with the patient and client in the examination room, some parrots will not step off the perch for a towel, hand, or dowel. These birds might do well with "The Yoda" technique, in which the handler uses stimulus fading (gradually introducing the towel so that it does not draw the bird's attention) to slowly bring the towel behind the perched bird and wraps the towel around the bird (Figure 46.13D). The handler's arms are on either side of the bird, limiting its movements. The handler may talk to the bird while this happens or remain quiet depending on the individual patient. This technique may be particularly effective for parrots that seek to acquire attention from people, as they can receive

FIGURE 46.13 Toweling techniques for handling parrots. (A) The "Potholder" technique encompasses covering of the hand with one end of the towel (thereby protecting the hand), while the rest is left hanging down and is gently draped over the bird while holding its toes after it has stepped onto the towel. It is often used in birds that will step to the towel but not to the hand. (B) The "Butler" technique is very similar to "The Potholder"; only here the end of the towel is positioned over the handler's forearm rather than held in the hand. This will often work well for birds that will step onto the hand voluntarily but may be nervous about the towel. Once the bird has stepped up, the towel can be moved up to cover the hand and then gently lifted and draped over the bird, as done during "The Potholder." (C) For birds that like to cuddle and prefer to step to the hand or towel, "The Toga" technique can be used whereby the handler drapes the towel over the shoulder and drapes it gently over the bird once it has stepped onto the hand and is being cuddled. (D) The "Yoda" technique often works well for birds that are glued to the perch. Talking to the bird during the procedure can help keep them focused while the handler slowly brings the towel up from behind and then gently wraps it around the bird. (E) The "Lap Dance" technique works well for parrots that are responsive to attention and touch as desired consequences and are tolerant of standing on the lap of the handler while the towel is gently draped over the bird from the sides or behind. Like "The Yoda," talking to the bird may help calm it down.

FIGURE 46.14 Some birds, like this Goffin's cockatoo *(Cacatua goffini),* will accept food reinforcers during a restraint experience.

copious amounts of attention as a desired consequence while the towel approaches them. Keep in mind that the heightened state of arousal that is often triggered by bouncing up and down, vocalizing, and so on, may trigger undesired aggressive responses with a parrot.

"The Lap Dance" technique works very well for parrots that respond to both attention and tactile contact as desired consequences and are tolerant of standing on the lap of the handler (Figure 46.13E). While the bird is perched on the lap of the handler, slowly bring the towel toward the handler's knees. Deliver tactile or other appetitives while the towel is brought toward the bird and draped over the body. The bird is corralled against the handler's body and the handler's arms help limit the bird's movement, making it easy to gently cover the bird.

It is also possible to combine techniques, such as "The Potholder" with "The Toga," where one end of the towel is draped over the shoulder, and the other end covers the hand that is offered to the bird. This provides a little more protection for the restrainer's hand. Additionally, working with a bird in a corner of the room can functionally replace arms on either side of the patient (as in "The Yoda" or "The Lap Dance") while using a different technique, such as "The Toga." The combinations are limited only by your creativity. Videos of these techniques can be viewed at https://animaltrainingfundamentals.com/vet-text-videos/.

Restraint of poorly socialized or birds showing extreme fear or aggressive behavior. In some cases, it may be preferable to shape a restraint experience for a bird from within the carrier rather than allowing the patient to exit the carrier unrestrained. This is especially true for some flighted birds, birds that are known to panic and drop to the floor (risking injuries), and birds showing aggressive behavior (biting, lunging, etc.) that is unchanged with alterations of the environment and time to habituate. Standard pet carriers can have narrow front openings, increasing the difficulty of these restraint efforts; carriers with an opening on the top are safer and easier to use.

The towel should be slowly moved toward the bird while blocking the entrance to the crate to prevent escape. Some birds tolerate this very well (especially if the towel is slowly lowered onto them from above). Parrots often have a strong grasp on the cage's ventilation openings and will have to be carefully separated from the carrier. Some parrots (particularly Amazon species [*Amazona* spp.]) will flip onto their backs as part of a defensive strategy when approached by a towel, making it much more difficult to access the back of their neck. A technique that is useful in these cases is to approach the bird with several layers of bunched-up towel between your hands and the parrot. Bring the ends of the towel around the sides of the bird, slowly enveloping them, while placing gentle pressure on the sides of the neck to keep the head restrained. Once the bird is in hand, the bunched-up towels should be replaced with a more traditional single towel wrap around the back of the neck for better control.

Small birds, such as finches and canaries, may require more strategic planning for safe acquisition of restraint. These birds are typically severely frightened on presentation and are agile fliers. Chasing these patients around their cage is exceptionally stressful for them and may lead to them escaping into the examination room.

For birds brought in their own cage, you may need to start by taking out the perches and toys inside, which work against you as obstacles when trying to get the bird in hand. Once the perches are out, assess if you can take the top or bottom off of the cage. Cover the large opening with the towel and slowly bring the towel to the other end, allowing you to restrain the bird. By removing obstacles from the cage, the bird is not able to hide and avoid the towel, which generally shortens the timeline for acquiring effective restraint. Additionally, slowly bringing the towel in through a larger opening like the top or bottom of the cage will minimize stress from the patient being chased around the cage. The handler may find that laying the cage on its side is more helpful with this process.

Another method to restrain these small birds with minimal chasing is to mentally note the position of the bird, completely darken the room, and grasp the bird in the dark. When the lights come back on, the bird is in hand and already restrained for the tasks required. While this is most certainly still stressful, the elimination of the chase can shorten the duration of the stress event. This approach, if frequently repeated, could induce fear of the dark for the bird or precipitate stress-induced seizures, so it should be avoided if possible. The authors only recommend its use when prolonged attempts at acquiring restraint would be dangerous for the patient. Researchers at Stanford University have expanded upon this technique by incorporating inexpensive night vision goggles and using infrared lights (like techniques used to calm down poultry in commercial farms) that have reduced and/or eliminated stress of restraint procedures for regular health checks of psittacine birds participating in scientific studies.

Different birds respond to restraint in different ways. Some will fare better if handled for several brief periods of time, with handling and restraint repeated as needed to finish

the examination. Others are difficult to get restrained initially and therefore should have everything done during one episode of restraint. Flexibility in restraint decisions is essential.

Training in the Examination Room

When a bird moves away from something, this is often described as a fear response. When the bird cannot get the distance it desires, the bird may respond with aggressive behavior to drive the aversive stimulus away. In both situations, the attempt to gain distance is maintained by negative reinforcement. The bird's behavior (either escape or aggression) is increased by the removal of an aversive stimulus. Understanding that negative reinforcement is maintaining the fear response or aggressive behavior is important. This is because this information can be used to shape new desired responses. Distance can be provided as an outcome for calm and relaxed behavior.[45] For this strategy to be successful, the animal must be calm and relaxed at the outset of the session. The aversive stimuli must be presented from far enough away that it does not evoke a response. For example, a person may hold a towel in their hands and stand 5 feet away from the bird. The person would then approach the bird until a slight response is observed, such as if the bird looks at the towel. At this moment the person with the towel stops moving and waits for the bird to habituate to their presence and present any desired behavior, such as engaging in preening or other acceptable activities. When this is observed, the person with the towel calmly takes a few steps away from the bird. In some cases of history of extreme fear responses, it is better to walk away even before any slight response is observed. This process is repeated and with each repetition the person with the towel attempts to get closer before a response is observed.

When applied well, negative reinforcement can quickly teach a bird to present comfortable body language around a towel. Because the bird is now relaxed around a towel, this can then be transitioned to using positive reinforcement by providing desired food items, preferred touch, or experiences for interactions with the towel. This same strategy can be applied to syringes, medical instruments, new people, and so on. This is also helpful for teaching a bird that relaxing when restrained is the desired behavior. When a bird struggles, pressure remains constant. When the bird relaxes, pressure can be removed slightly. This can be gradually implemented so that very little pressure is required to maintain restraint resulting in a less-coercive restraint procedure. In both examples, the procedures teach the bird it has the power to cause the aversive situation to change by changing its behavior.

Conscious Sedation as Part of the Low-stress Avian Examination

Conscious sedation is a safe and effective option for minimizing the impact of fear and stress on avian patients. This underutilized tool should be considered in many contexts, even with debilitated patients. Ill birds should not be subjected to intense fear, anxiety, or stress and the associated physiological and psychological effects. Both benzodiazepines and opioids are very safe for the great majority of patients. Dosages of medications and route of administration can be altered if indicated to tailor the sedation protocol to the patient's condition and level of stress.

Unfortunately, many birds arrive at veterinary practices already so far past their stress threshold that it would take hours to hit the "reset" button, and neither the client nor the clinician can move forward at the pace the bird needs due to the client's schedule, other patients needing care, and so on. Rescheduling appointments for fearful patients may not be possible if the bird is presenting for illness and due to the infrequency of routine wellness visits in avian patients. The best option to help these patients while minimizing the effects of fear is often conscious sedation.

The decision to sedate a bird should be based on the individual birds' body language in response to environmental stimuli. In many cases, how the veterinarian and veterinary team handle the bird can make a huge impact on whether sedation is needed. For example, a mildly fearful bird that is given time to habituate to a new situation, paired with systematic and counter conditioning, may become less fearful and allow a procedure to be performed without restraint (Figure 46.15). However, if the bird is immediately restrained in a towel, the fear response is likely to escalate so far past threshold that no additional unrestrained procedures may be possible that day.

Bird owners may be fearful of sedation due to concerns about perceived risks, appearance of sedated birds, past aversive experiences, and perceived time constraints. If they have never had a pet sedated before, they typically will not have a frame of reference for the benefits of sedation and may not appreciate the positive impact this can have on their bird's experience. It is important for veterinarians to be able to clearly communicate their reasons for recommending sedation with bird owners in a way that demonstrates sensitivity to their fears and confidence in the medical recommendation. Some helpful strategies are listed as follows.

Many pet owners are unaware that stress can have severe long-term consequences to their pet's physical and emotional

FIGURE 46.15 Counterconditioning techniques by provision of food reinforcers can facilitate voluntary cooperation during the physical examination, as shown in this male eclectus parrot *(Eclectus roratus)*.

health and welfare. It usually is not difficult to convince the bird owner that their pet is experiencing fear, anxiety, and/or stress during the veterinary visit, as this is typically already one of their biggest concerns. The concept that sedation with benzodiazepines can decrease the development of fear memories, as well as the "needle-less" aspect of intranasal (IN) administration, is often very attractive to pet owners. Referring to sedatives as "anti-anxiety medications" can make them sound more palatable to many clients, as "sedatives" or "drugs" often carry a negative connotation. Comparing the use of anti-anxiety medications in the veterinary practice to the use of diazepam (Valium) or midazolam (Versed) for fearful humans in dentistry offices may also help the veterinarian connect to the client.

Some clients appreciate learning the difference between sedation and anesthesia, especially the safety and reversibility of the drugs utilized; however, reviewing this information in detail may prove more frightening for others. Discussing anesthetic/sedation monitoring protocols and staff expertise with bird sedation/anesthesia can help alleviate many client concerns. It may be helpful to mention how many avian sedation procedures are performed on average per week/per month and the rate of positive outcomes to illustrate your staff's competence.

Veterinarians must accurately and thoroughly explain the sedation procedure itself, as well as how the bird will look while sedated and during/after sedation reversal. This includes discussing duration of effects and warning clients that it may take several hours for the bird to begin behaving "normally" again, especially if there is underlying metabolic dysfunction (although this is unlikely with sedation reversal). Clients should also understand that each bird responds differently to individual dosages of sedatives and be aware of the range of "normal responses," which can range from completely unaffected to laying on their back and minimally responsive (Figure 46.16). They should also be advised that if this is the first time their bird has been sedated, the dose will be selected based on the patient's overall demeanor and perceived level of fear, anxiety, and stress; the patient's reaction to the chosen dosage will allow the veterinary team to tailor future doses to the patient.

Veterinarians should have a clear picture of their personal/ethical boundaries regarding willingness to forego sedation and attempt sample collection versus refusing to perform procedures without sedation in these patients. We hold responsibility as the medical experts to stand our ground on standards of care.

The goal of conscious sedation is to have the patient be standing, but very relaxed and calm. Most used protocols in birds utilize either midazolam alone or a combination of midazolam and butorphanol. These drugs are fully reversible, can be administered either IN or intramuscular (IM), and have a consistent onset of action. The depth of sedation achieved varies depending on the patient and dose.

Midazolam is a benzodiazepine drug with a wide safe dosage range in the medical literature.[46–53] The dosage range that is most helpful for reducing stress in most avian patients is between 0.5 and 3.0 mg/kg. Lower doses are more effective if administered IM or in combination with butorphanol. IN administration typically requires higher dosages to obtain the same effect. Dosages over 3 mg/kg should only be

FIGURE 46.16 While sedation helps to reduce the level of stress experienced by the bird, the level of sedation may not always be sufficient to fully eliminate all responses. This mildly sedated macaw is showing signs of stress related to towel restraint, including panting, ruffled feathers, and drooped wings.

administered IN. Onset of action is consistently less than 5 minutes postadministration, regardless of the route of administration; duration of action ranges from 20 minutes to 2 hours.[46] Midazolam does not have any analgesic properties but may prevent creation of additional fear memories due to its amnesiac properties.[54] Side effects include transient ataxia, disinhibition of aggression, nausea, transient dysphoria following reversal, and increased appetite.[46,55–57] A mild monocytosis may be seen on hematology associated with this drug (Kendall Harr, unpublished data, 2018).[14] Undesirable side effects, such as disinhibition of aggression or nausea, are typically resolved following reversal with flumazenil (0.025-0.1 mg/kg). These events should be recorded in the medical record and a different protocol or dosage should be considered in the future.

Butorphanol is rarely effective as a sole sedative but can enhance the effects of midazolam and functions as an effective and safe analgesic in many avian species.[46,50–53] It is an opioid analgesic with partial agonist/antagonist activity at the mu receptor and partial agonist activity at the kappa receptor. Administration of 1.0 to 4.0 mg/kg butorphanol IM or IN in conjunction with midazolam should be considered for birds undergoing potentially uncomfortable/painful procedures, or for birds that are not adequately sedated with midazolam alone.[52] This combination sedation protocol typically results in smoother induction and recovery in many species, particularly macaws. Onset of duration is less than 5 minutes, and duration of action ranges from 2 to 4 hours. Butorphanol is reversible with naloxone 0.04 mg/kg IN or IM. Side effects of butorphanol may include transient ataxia, excitement,

respiratory depression, and mildly decreased blood pressure and heart rate. Butorphanol should be avoided in cases of central nervous system trauma and dysfunction, as this may hinder the neurological assessment and can induce respiratory depression, thereby exacerbating cerebral hypoxia and raising intracranial pressure.[53]

IM administration of sedatives typically results in a rapid onset of more marked sedation compared to intranasal administration, and this route of administration is preferable for radiographic imaging or more delicate procedures. IN administration is often preferred by clients as it does not require any needle punctures, but many birds tolerate small-volume IM injections surprisingly well. IN administration may be easier to accomplish with less restraint in some patients and carries a lower risk of bleeding or bruising. Syringes should only be used without the needle present to avoid accidental damage to the patient's nares during administration. Patients may sneeze or show mild upper respiratory congestion immediately after intranasal administration.

IN midazolam (2.0 mg/kg) provides excellent standing sedation for most patients that are experiencing mild to moderate stress, allowing physical examination, phlebotomy, and other minor procedures to be performed without distress to the patient. Lower doses may be adequate for some patients (such as cockatoos, or very sick patients). The addition of 1.0 to 2.0 mg/kg butorphanol should be considered if the procedure has the potential to cause discomfort to the patient, if the patient is highly stressed, or if the procedure requires a heavier level of sedation (diagnostic imaging, for example). Administration of midazolam 2.0 mg/kg ± butorphanol 2.0 mg/kg IN usually results in a bird that can stand, although perching may not be possible. IM administration at these same doses tends to result in birds with a much higher level of sedation; some patients may be ventrally or dorsally recumbent following onset of effect. This can be frightening for clients to observe, and veterinarians should provide a detailed description of the possible range of symptoms that their pet might exhibit prior to any sedation event to help prepare them for this appearance.

Following the physical examination and/or sample collection, midazolam can be reversed with flumazenil. The dosage range of flumazenil is 0.025 to 0.1 mg/kg, and the medication can be administered IN or IM. IM administration may lead to dysphoric or other undesirable responses, especially if serious underlying medical conditions exist; IN administration typically results in smoother recoveries. A 0.05 mg/kg dose administered IN is effective for most patients. Since the half-time for flumazenil is shorter than that of midazolam and diazepam, this procedure can be repeated if reversal is inadequate. If butorphanol is used in the sedation protocol, reversal with naloxone is usually unnecessary.

Sometimes it may be preferable to discharge the patient without reversing the sedative to allow a more gradual recovery and decrease stress of the trip home. This may be appropriate if the sedation was extremely mild, if transport is historically excessively stressful for the patient, if the client typically has difficulty transporting the patient from the carrier into the home enclosure, or if the patient's medical condition would benefit from administration of anxiolytics or analgesics. Any decision to avoid sedation reversal must be discussed thoroughly with the client, including potential complications and benefits. One of the potential risks of this decision is the patient may become more sedated after leaving the practice due to drops in adrenaline levels; this could precipitate a fall or injury. Discharging these patients in a flat-bottomed, dark enclosure without bars to discourage the patient from either attempting to perch or hang on the side of the cage is advisable to reduce this risk. Cardboard disposable pet carriers may serve admirably as long as they are too sedated to attempt chewing through the cardboard and escaping. It may be beneficial for the practice to keep a few flat-bottomed plastic carriers available to loan out to clients for the trip home for birds that are more awake or facing a longer car ride; these carriers can be returned to the practice later and reused.

Sedated birds should not be discharged in the same enclosure as other birds until the effects of the sedative have fully worn off, as abnormal behavior associated with sedation may precipitate aggressive responses from others.

Other sedation/anesthetic options

Other reported IN or IM sedatives in birds include diazepam, xylazine, detomidine, dexmedetomidine, and ketamine.[46,50,51,53,55,56,58–61] However, all these drugs have disadvantages compared to midazolam and butorphanol, and effectiveness/safety varies significantly. They should not be considered first-line choices for sedation in avian patients.

General anesthesia may be more appropriate than conscious sedation for some patients and some medical procedures, including prolonged or delicate procedures (e.g., splinting a fractured bone), and surgery. The most frequently used anesthetic agents in birds are isoflurane or sevoflurane gas.[53,62,63] Both of these anesthetics are effective in birds and relatively safe. However, there are more risks of serious side effects such as hypotension, respiratory depression, and arrhythmias compared to conscious sedation. Additionally, gas anesthesia does not provide analgesia.

At-home sedation?

A mainstay of Fear Free™ dog and cat medicine is to have pet owners administer sedatives at home so that the animal does not experience increasing fear, anxiety, and stress on the way to the veterinary practice. In an ideal world, this would be an option for bird owners, as well. However, there are several reasons why this is logistically challenging at the present time. Most bird owners do not seek veterinary care until their patient is sick, and as such frequently do not have the valid veterinary-client-patient relationship legally necessary for medication dispensation. Bird owners may not have an ability to accurately assess the health status of their pet, which would influence the safety of medication administration, and many bird owners are unable to handle their birds safely or administer medications to them. The most obvious reason is there are currently no proven, safe, consistently effective oral sedation options for birds. Options that may be considered in the future include gabapentin and tramadol, but appropriate dosages are unknown and may vary significantly depending on species. If a valid veterinary-client-patient relationship exists, and the client can safely/effectively handle their bird, a single dose of midazolam can be dispensed for intranasal use at home prior to transport to the hospital.

Diagnostic Sample Collection

An organized and thoughtful approach to a diagnostic protocol will help to reduce patient stress. Developing a list of differentials for the current symptoms provides a targeted list of indicated diagnostic tests. This prevents the bird from being subjected to unnecessary procedures. In larger birds, it may be desirable to draw a larger blood sample than needed for initial testing. This allows the practitioner to avoid collecting additional blood samples if further testing is indicated by the results. It will also prevent any alteration of the test results secondary to early supportive care and treatments. This is not possible for smaller birds and the decision to do so must be evaluated considering the patient's stability.

In some cases, it may be beneficial to postpone sample collection to allow for the client to spend time training the patient to voluntarily accept restraint and potentially participate willingly in medical procedures. For example, a healthy, young parrot that is presenting for a wellness examination and is owned by a dedicated pet owner with an interest in training and behavior could have routine screening phlebotomy postponed until a training protocol has been implemented. It may be challenging to obtain compliance in these situations, so building value for this process with client education and providing appropriate resources and support for training is essential.

Developing a Treatment Plan

When designing a treatment plan, the most effective therapy with the minimum of undesirable effects should always be selected. One of these undesirable effects is increased stress. Intravenous or intraosseous fluid therapy is highly effective in many situations but can be stressful. Subcutaneous fluid therapy may be preferred in many patients, especially small birds. When selecting drugs, those with the longest dosing intervals should be selected if all other factors are equal. Some injectable drugs are more painful than others. Some oral drugs have extremely unpleasant flavors. Some suspensions require a huge volume to be administered. All of these factors should be considered when the plan is developed.

Outpatient treatment is usually less stressful than inpatient treatment. However, if the client will be medicating the bird at home and has not previously trained this behavior, the veterinary staff must help them develop a plan for this to be accomplished and demonstrate how to administer the medications safely and effectively (Box 46.5). In general, hospitalization should be reserved for patients that require treatments that are beyond the client's capabilities.

BOX 46.5 METHODS FOR SAFE AND EFFECTIVE ADMINISTRATION OF MEDICATION BY BIRD OWNERS

- Training the bird to voluntarily accept medication from a syringe
  - Use a syringe that glides easily. Fingers should be wrapped around the syringe, while the plunger is pressed with the thumb for optimal control.
  - Habituate the bird to the syringe by leaving it in sight at a distance where it does not elicit a fear response. Reinforce engagement with the dosing syringe. This can include voluntarily approaching the syringe or allowing it to be brought closer to the bird. Potential reinforcers can include preferred food items, toys, attention, or praise.
  - Target training using positive reinforcement can be used to teach the bird to touch the tip of the syringe with its beak or tongue. The syringe should be held at a distance where the bird can barely touch it with its tongue (which will help prevent it from biting the syringe). If a bird does not reach for the syringe, the desired treat or toy may be positioned near the tip of the syringe to prompt desired responses.
  - Once the bird is fluently touching the tip of the syringe, add water to the syringe. Reinforce for touching the syringe with water in it. Next, a drop of water can be suspended from the syringe. Reinforce for drinking the drop of water from the syringe. If the bird shakes its head following touching the droplet of water, go back to the syringe training without the drop of water and rebuild reinforcement history.
  - Once the bird readily accepts the droplet of water, gradually increase the volume of fluids delivered before reinforcing.
  - Expand the procedure to include delivering palatable fluids from the syringe. Reinforce for taking these fluids from the syringe. Follow this step by offering less-palatable fluids from the syringe such as diluted apple cider vinegar. Start with small amounts first and gradually build the amount upon acceptance.
  - Preferably, this procedure is trained prior to the need for medication.
- Use of food vehicles to hide medication, which the bird readily accepts. It is recommended to prepare the food away from the bird, as this may increase the chances that the food is accepted. The best vehicles mix easily or act as an absorbent, have high perceived value for the animal, and are small enough to encourage rapid consumption, yet large enough to hide the taste of medication. Examples of commonly used vehicles in birds include the following:
  - Parrots: hand-feeding formula, human baby foods, peanut butter, oatmeal, winter squash, sweet potato, small pieces of fruit (e.g., banana, grape) or fruit juice, yogurt, scrambled eggs, small pieces of bread, crackers, or pastries soaked in liquid medication
  - Poultry or waterfowl: grapes, cheese, tomatoes, bread
  - Birds of prey: prey animals
- Compounded drugs can be flavored to help mask unpleasant tasting medications to facilitate acceptance. For medications of which the taste cannot be effectively masked, hiding in vehicles is not recommended as the bird may start avoiding the preferred food. In such instances it is better to administer the medication directly, followed by provision of a favored treat upon acceptance of the medication. Use of gentle handling techniques and toweling is recommended, and owners should be taught and demonstrated on how to apply these techniques at home.

Hospitalization may be required in situations where owners are hesitant and unsure as to whether they are capable of delivery of medication. In cases where owners are willing to attempt medication at home, a follow-up consultation by phone is recommended to evaluate the success of treatment.

Hospitalization

All birds experience some degree of increased stress when away from their home environment. Stressful stimuli include unfamiliar sights and sounds, restraint required for medical treatment, and hospital housing conditions. Consider the natural history of the species when designing housing for birds in your avian ward. Some species such as parrots and raptors may prefer housing that is elevated, while other species such as large waterfowl may prefer enclosures lower to the ground. The barking of dogs, the sight of cats or even larger birds, and excessive staff foot traffic can all increase the stress of hospitalized birds. Wards should be kept separate from canine and feline wards and hospital cages should face in a direction that allows minimal visual contact from one cage to another (see also Chapter 1). Providing a visual barrier, such as a towel or newsprint taped to the front of the incubator or cage, gives the bird the ability to hide from staff attention while still allowing regular patient evaluation. Providing soft background noises (such as a white noise machine or classical music) to balance out sudden noises is also recommended. Some companion birds may respond favorably to social interactions with hospital staff members independent of procedures. Birds should have access to their regular diet while hospitalized to increase their willingness to eat. Clients should be encouraged to visit the bird in the hospital and potentially to bring in other familiar items from home that may increase comfort (toys, perches, caging, etc.; Figure 46.17). Some hospitalized birds will do better if housed with a companion bird; however, sick birds may also be traumatized or bullied by conspecifics, so this should be evaluated on a case-by-case basis.

Pain Management

One of the primary responsibilities of the veterinarian is to reduce pain and suffering. Pain should be controlled by the selection of the least painful treatment option, by preventing self-inflicted trauma, and by the judicious use of analgesic drugs when indicated (see Chapter 35 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 20, Recognition, Assessment, and Management of Pain in Birds).

FIGURE 46.17 Enrichment opportunities are important for hospitalized avian patients. When hospitalization is anticipated, clients should be encouraged to bring familiar items such as toys, perches, towels, cages, and so on, from home along with the visit to increase comfort. Even the boarding of a cage mate or companion can be considered to minimize stress during the hospitalization period. However, as sick birds may also be bullied or traumatized by conspecifics, this should be evaluated on a case-by-case basis.

Grooming

Birds can develop significant problems because of inappropriate grooming. Excessive wing trims can cause birds to be clumsy, frequently resulting in injuries to the beak tip, sternum, wings, and tail. The subsequent pain can lead to excessive levels of stress in these birds. Techniques for trimming wings are somewhat controversial, but clearly the cutting of all the primary and secondary feathers is excessive (Figure 46.18; see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 22, Advancements in Management of the Welfare of Avian Species). Cutting the nails short enough to induce bleeding is a painful procedure that can make birds more fearful of restraint. Beak trimming is never required in a healthy bird. The stress associated with beak trimming can be life-threatening, especially considering the possibility of a severe underlying disease process. For this reason, strong efforts should be made to attempt to determine and treat the underlying cause for the beak abnormalities to minimize ongoing risk (see Chapter 31).

POSTEXAMINATION PRACTICES

If an examination resulted in excessive stress to the patient, consider short-term supplementation with omega-3 fatty acids, which has been shown to be neuroprotective following traumatic brain injury in rats.[64–68] The authors recommend the use of omega-3 fatty acid supplementation (VetOmega, North Salt Lake, UT, 84054, USA) at a dose of 0.22 to 0.44 mL/kg orally once daily for 3 to 5 days. Benefits of prescribing this treatment must be weighed against the stress of administration. This supplement may be administered on a preferred food item to minimize stress.

The CSR should check the client out in a calm place (ideally, the examination room). If examination room checkout is not possible, the client should be escorted to a quiet place in the receiving area with the same precautions that were in place for check-in. If the weather permits, the patient could even be returned to the car and the client return to the practice for checkout.

Upon completion of the veterinary visit, team members should plan to reach out to the pet owner within 24 to 48 hours to investigate their perceptions of the visit. This information should include the following questions:

1. How is your bird doing today?
2. How do you think your bird responded to the veterinary visit?
3. If applicable: How did your bird respond to the sedation? How long were the effects noted? Do you think it helped reduce your bird's stress level?
4. Is there anything we could have done better?

Other questions may also be appropriate depending on the procedures that were performed during the visit and the individual bird's medical condition.

Management of the Medical Record

The medical record is generally centered around medical information, typically using the SOAP (Subjective, Objective, Assess-

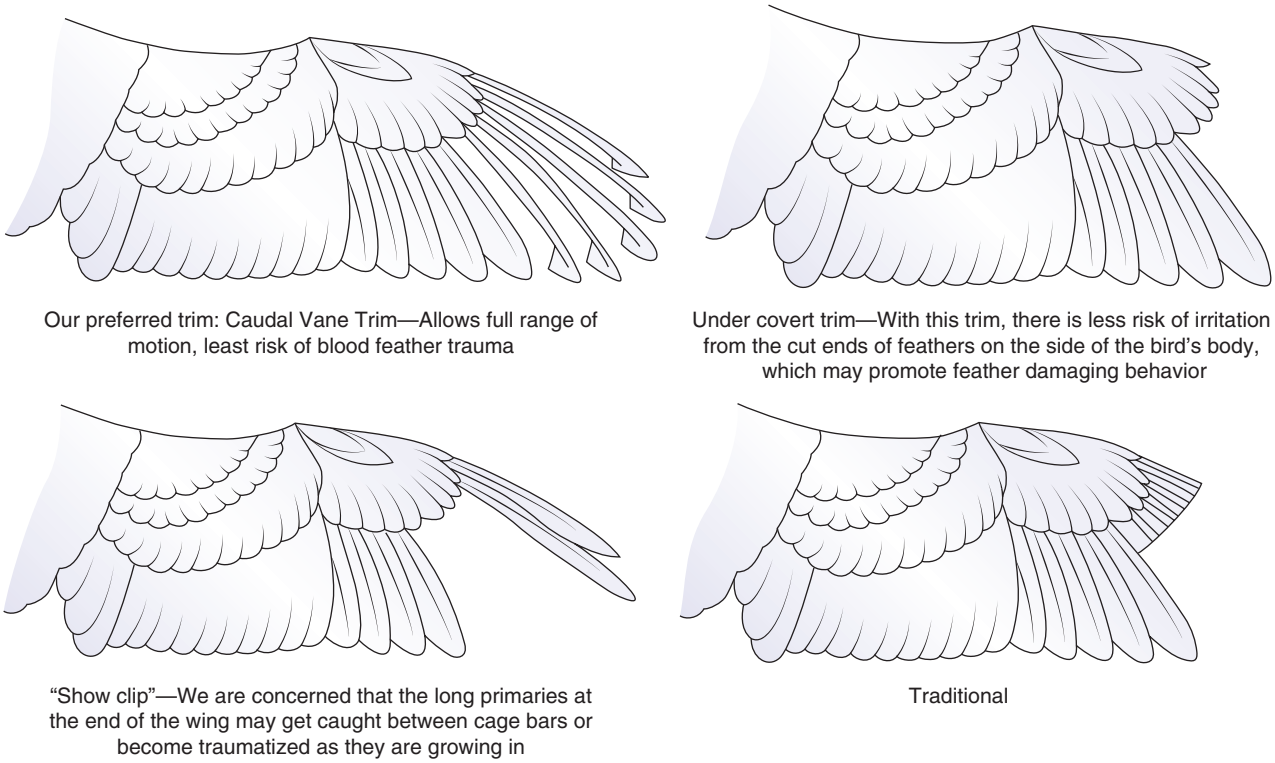

FIGURE 46.18 Wing trim preference form.

ment, Plan) format. Including details about behavior in the medical record is an excellent way to provide consistent interactions from visit to visit and from one staff member to another. It also provides a way to track progress with training goals. Information that should be added to the record includes the following:

1. Information about the patient's demeanor during history gathering
2. How the patient reacts to staff
3. Presence of towel (if needed), and how it was used and responded to during the visit
4. Flight ability
5. How well the client can manage handling the patient in the examination room versus at home

There are many practice management software options that allow development of an Electronic Medical Record (EMR). These typically provide options to create templates for medical notes, which can be used to create consistency of information gathering/reporting. While behavior information can be included with each SOAP, some clinicians prefer to place it within an individual behavior note/alert that staff can see quickly. Regardless of the chosen method, training of doctors and staff to use the system consistently is required for maximum efficacy. It is critical for both detailed notes to be recorded from each visit, as well as previous information reviewed prior to stepping into an examination room with a bird that has been seen before.

FACILITATING STRESS-FREE FOLLOW-UP CARE

Follow-up care may require training of clients and patients to facilitate proper administration of treatment protocols. Veterinary staff should facilitate this by following these steps:

- List treatment protocols required for patient follow-up care.
- Identify patient treatment protocols that can benefit from on-site training by veterinary team.
- Implement training to gain voluntary cooperation of the patient prior to discharge (oral medications, scale training, etc.).
- Identify patient treatment protocols that will require maintenance by the client and therefore client education.
- Identify additional behaviors that will further reduce or eliminate stress for future medical care of the patient.
- Identify and prioritize behavior goals list for the patient.
- Provide education/educational resources for the client to facilitate achieving these goals.
- Create follow-up plan with the client to facilitate success and compliance.

FOUNDATION BEHAVIOR GOALS

Helping clients further develop the behavioral repertoire of their companion birds is an important opportunity to reduce or eliminate stress for veterinary care. Veterinary professionals can enhance the bond between practice and client by providing guidance, resources, and support to achieve these goals. Healthy patients can often be trained during a well-bird examination to present behaviors such as targeting, voluntarily stepping onto a scale, and to accept fluid from a dosing syringe. This can demonstrate how quickly a behavior can be trained that can impact cooperation in medical care (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).

Clients can be given the opportunity to practice under the guidance of the veterinary professional to ensure success and gain confidence. Self-study educational resources such as handouts, videos, books, and referrals to additional materials can be provided to continue making progress at home. This can lead to training additional behaviors to facilitate stress-free medical care, such as allowing restraint in a towel and voluntarily loading into a crate or other transport container (Figure 46.19).

While ultimately improving animal welfare is the incentive for implementing a training protocol, client compliance is not guaranteed. Veterinary professionals can help increase participation by reinforcing clients. This can be done by featuring clients (with permission) on social media, in the waiting room video feed, or bulletin board. Clients can also be offered items such as free dosing syringes, product samples, or discount coupons after successfully training a behavior.

It can also be helpful to take an incremental approach to building a repertoire of behaviors. Allow clients to have success with one behavior. Celebrate this success, before providing tools and resources to work on the next behavior. Overwhelming a client may lead to inaction instead of enthusiasm.

Depending on the patient, some of these behaviors can be trained while on site. These behaviors may include target training, touching the tip of a dosing syringe, and standing on a scale. Many of these behaviors can be shaped and trained, while also administering treatments with restraint for hospitalized patients. A key to facilitate this requires careful attention to reading patient behavior and minimizing the severity and degree of disempowerment or fear generated during treatments as well as daily reassessment of patient response to treatment procedures, particularly when the patient has worked through desensitization and counterconditioning and may also be employed for patients during the process of ongoing treatment of medical problems. Other patients require an investment from the client, which can be supported with educational resources provided or referred by the veterinary staff. Periodic rechecks by phone or in-practice ensure the client's success in their training progress by addressing questions and offering feedback/reinforcement for the client. Depending on what staff is available to provide these training checkups, the veterinary hospital can enlist the help of a trainer as well.

FIGURE 46.19 Transport containers come in a wide variety of designs. Creative thinking can lead to clever approaches for teaching birds to voluntarily enter for desired items to help reduce or eliminate stress.

FOSTERING GROWTH IN THE INDUSTRY

Veterinary medicine and evidence-based animal training technology are two disciplines with a common goal of attending to high standards in animal welfare. Because of this, we have seen tremendous growth in training birds to cooperate in medical care in recent years. Progressive veterinary professionals may find it advantageous to have team members skilled in training birds for behaviors beyond the basics. This can include behaviors such as the following:

- Nail trimming (Figure 46.20)
- Tactile examination (Figure 46.15)
- Voluntary auscultation
- Voluntary injections
- Voluntary intranasal drug administration
- Voluntary mask induction (Figure 46.21)
- Voluntary phlebotomy

Behaviors are commonly trained by breaking them down into small steps or approximations. These are described as shaping plans.

See the following list for a Voluntary Injection Training Shaping Plan[69]:

- Reinforce for stationing in a specific location or perch
- Build duration for stationing
- Use stimulus fading to introduce syringe without needle to pectoral muscle
- Transition to touching the body first and delivering reinforcers afterward

FIGURE 46.20 Training birds to cooperate in grooming procedures can be a realistic goal for clients. Veterinary professionals can facilitate by providing instruction and/or directing clients toward trusted resources that focus on force-free training.

FIGURE 46.21 By breaking down complex behaviors into small steps or approximations, even more complex medical behaviors can be taught through the process of shaping and positive reinforcement. For example, this brown-headed parrot *(Poicephalus cryptoxanthus)* has learned to voluntarily place its head into the anesthetic mask through target training.

- Add capped needle to syringe and repeat process of introducing syringe
- Repeat process using a dull metal object such as an open paper clip
- Repeat process using a toothpick
- Repeat process using a blunted needle on syringe
- Repeat process using a rubber band and snap against pectoral muscle (increase intensity gradually)
- Pierce skin with sharp needle on syringe
- Inject a small amount of saline

To train a bird to allow injections, begin by reinforcing for staying in a particular location for duration. This can be a designated perch or mat on the floor or table. For birds of prey trained to sit on the glove, this behavior can also be accomplished while the bird is perched on a gauntlet.

As with introducing nail trimmers, towels, etc., a critical step is introducing the syringe to the pectoral muscle in a manner that does not evoke a fear response. A good method is to offer preferred food items and slowly moving the syringe closer while observing body language (stimulus fading). Once introduced successfully, transition to touching first and reinforcing after.

The subsequent steps of this shaping plan are designed to teach a bird to tolerate many different sensations including different levels of pain. Before proceeding to any new sensation, the bird's body language should be relaxed and comfortable while experiencing being touched with the current object. Snapping the chest with a rubber band simulates the sting of some medications. The intensity of this can be increased gradually.

By the time you are ready to pierce the skin with a sharp sterile needle, the bird will have experienced many different sensations and remained calm and relaxed throughout the process.

Piercing the skin and/or injecting saline solution should only be done one time during a session and only once every few weeks to maintain the behavior. The location should change each time to avoid injecting into the same location within the same muscle.

Select clients may also show enthusiasm for training beyond the basics. Those team members skilled in training can foster client growth and development. The more support an eager client has to help teach their bird to cooperate in medical care, the more potential to reduce or eliminate stress for future health care. Additional benefits include that the client is more likely to collect data such as regular weights, preventative care is more easily accomplished, and illness may be detected earlier.

Step-by-step instructions to train the behaviors described in this chapter can be found at these outlets:

CHOOSING A TRAINER OR BEHAVIOR CONSULTANT

Current technology allows information to be easily shared across many platforms. Many clients look to the Internet for advice when seeking assistance for a companion animal behavior problem or training challenge. The veterinary professional can be an important resource for guiding clients toward quality information that teaches best practices. Animal training/behavior consulting is not a regulated industry. Therefore, it requires critical thinking to evaluate credentials. Ideally the veterinary professional can make a trainer/behavior consultant recommendation based on a working relationship, known use of force-free training strategies, client testimonials, and proven results.

As with any skill-based profession, it can be challenging to evaluate an individual's expertise. Many biographical sketches include words such as "professional," "certified," "published," "international speaker," "President," "Director," "CEO," "emeritus," "PhD," and a long list of memberships to professional organizations, speaking engagements or other potentially exaggerated credentials. For many, these words are accurate descriptions of their qualifications. For others these may require further exploration.

Important questions to ask when evaluating certifications include: What was measured? Was knowledge or practical application skills measured? Who did the measuring? How often is this measured to maintain certification? Are courses required? Must they show case work? Is testing required? Must the applicant reapply regularly? And even with certification, does it prove this person can address your needs?

Important questions to ask when evaluating a PhD include: Is the degree relevant to this field? Does he or she have practical application experience? Does he or she run a lab, practice, do research? Does he or she oversee/produce

graduate students? Does he or she teach in a university? Has he or she published in peer-reviewed journals? What professorship rank did he or she achieve?

Words like "international speaker," "president," "CEO," 'Director," "Emeritus," and "all species" are often used to exaggerate one's credentials or experience. An international speaker may have only presented in two countries. Titles can be self-appointed, especially if the person in question owns the company. Emeritus is often inferred to mean a distinguished professor who left a legacy with a university and still holds the title. However, a retired PhD without such a contribution may request to use this designation as well. Saying one trains "all species" is quite a statement, and hopefully a red flag for a critical thinker.

There is a difference from being an expert and being *perceived* as an expert. Experts do not require degrees, titles, certifications, years accrued, memberships to professional organizations, popularity, Internet visibility, although they may certainly have these things too. They are less likely to exaggerate credentials or misrepresent experience. Experts can produce solutions to problems rapidly based on experience with many prior situations. It becomes intuitive from so much practice of putting all the tools of practical application together to get results over and repeatedly.

To help with the process of choosing a trainer, invite them to give your hospital a "Lunch and Learn" to introduce themselves and allow staff members to learn and ask questions. A good working relationship with a trainer should have good communication between veterinarian, trainer, and pet owner. This includes training and behavior notes and SOAPs in the patient's record from both veterinarian and trainer, like adding records from a referring veterinarian.

Animal training/behavior consulting is a practical application–based skill that is also rooted in learning science. Read biographical sketches with a critical eye. But most importantly choose an animal trainer/behavior consultant who demonstrates the following criteria[70]:

- Your animal trainer/behavior consultant should be science- and evidence-based. This means they understand the science of behavior analysis. They will be able to communicate to you about topics such as operant conditioning, the four quadrants, classical conditioning, counter conditioning, and systematic desensitization. Your consultant should provide data-driven resources and also be interested in collecting, measuring, and analyzing data when providing interventions.
- Your animal trainer/behavior consultant should be focused on effective, efficient, and optimal (maximizes benefits/minimizes harms) intervention strategies (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). This means they understand which behavior modification principles and procedures to choose to effectively address behavior challenges and reach behavior goals while at the same time maintaining high standards in animal welfare.
- Your animal trainer/behavior consultant should be able to demonstrate excellent practical application skills. This can include a sensitivity to animal body language, an ability to respond in a manner that creates a relaxed and comfortable animal, excellent mechanical skills (timing, observational skills), ability to arrange environments for success, etc.
- Your animal trainer/behavior consultant should be knowledgeable about the natural history of the species. They should understand ethology, phylogeny, modal action patterns, and their role in species-specific behavior.
- Your animal trainer/behavior consultant should show transparency and integrity, meaning they will openly discuss behavior intervention methodologies and their limitations and not misrepresent their experience.

CHAPTER 47

Strategic Use of Enrichment: What, When, and How

Kenneth R. Welle • Melody Hennigh • Brian L. Speer • Yvonne R. A. van Zeeland

Visit eBooks.Health.Elsevier.com for a complete set of references.

INTRODUCTION

Taking any animal into the home carries a great deal of responsibility. While the basic needs of food, water, and shelter are obvious, it is also necessary to provide for the more abstract needs of companion animals. Psittacine birds are intelligent and socially complex animals that can suffer physical and behavioral consequences when these needs are not met. So much so that the suitability of parrots as companion animals is sometimes questioned.[1] Captivity, by necessity, restricts some natural behaviors and, in response, alters time allotment to others, setting the stage for development of new (displacement) behaviors to fill the void. A wide variety of behavior problems are prevalent in the companion parrot population, including biting, screaming, feather destructive behavior, and other abnormal repetitive behaviors (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).[2] Enrichment is often seen as means to prevent these undesirable behaviors. Additionally, enrichment increases possibilities for animals to display appropriate, species-typical behaviors, allows them to exert control over the environment, and increases their adaptability to environmental changes, thereby reducing inappropriate fear responses and stress (Box 47.1).[3–7]

Enrichment is defined as the act of improving the quality of something, or the act of making it better. In the case of captive animals, this means making their life better. Enrichment in the broadest sense involves creating a life that provides for all physical, psychological, and emotional needs of an animal. The larger the behavioral spectrum an animal has, the more challenging but critical this enrichment will be. In this chapter we will explore some methods of enrichment that are appropriate for companion parrots. Some will involve trying to replicate natural behavioral opportunities for these birds, while others will involve replacement behaviors that can benefit the bird rather than creating further stresses.[5,8–11]

TIME BUDGETS

One of the challenges of enrichment is the drastic alteration of the time budget in captivity compared to the time budget of a wild conspecific.[12,13] Although time budgets for wild animals can vary considerably across individuals, species, and throughout the year, some things are reasonable to assume. For instance, tropical (equatorial) birds would typically have a light cycle approximating 12 hours of light and 12 hours of dark. This reduces the range of time that birds will be active. Those inhabiting ranges farther from the equator will have day length that fluctuates with the season. In these species, the changing day length is often involved in regulation of certain endocrine processes, such as reproduction and molting. Companion birds are often tied to the daily schedule of their caretakers. In many cases, this creates a consistently long photoperiod. Long days are inherently more difficult to fill with enriching activities for these birds. Additionally, long day length is often linked to the breeding season for seasonal, long-day breeders. This stimulus can create further stress and frustration when appropriate conditions for breeding are not available. One relatively simple measure to prevent this is to reduce light cycles to somewhat short, consistent duration throughout the year. While this can be challenging with some schedules, it is usually much easier to accomplish than creating adequate activities for an active, intelligent parrot.

The daylight hours may be utilized for feeding, socializing, performing self-maintenance, moving to and from feeding areas, and playing. Of course, many of these usages overlap significantly. Time cannot always be strictly budgeted into one category. Feeding, self-maintenance, and play are all social activities, so a given hour may be budgeted to more than one category and the total time budget would exceed 24 hours. In captivity, some of these activities are necessarily restricted. This void will sometimes force a shift toward other activities or create pathologic displacement behaviors such as stereotypies, apathy, or self-damaging behaviors. Much of the goal of enrichment is to manage the time budget to recreate the activities of a wild bird or to replace proportions of them with healthy, stimulating, and appropriate activities.[14–16] Figures 47.1 to 47.3 show some sample time budgets.

Photoperiod

Most psittacine birds come from tropical to subtropical latitudes. The photoperiod in these areas varies minimally and will always be close to 12 hours of light and 12 hours of dark. By comparison, most pet birds have prolonged day lengths. This affects the time budget significantly by reducing the amount of dark, quiet time when the bird would be sleeping. As in humans, it can be assumed that inadequate sleep would be a significant stress to these birds. Additionally, it creates a greater void in the time budget that must be filled in some way. Although photoperiod is highly critical for signaling

BOX 47.1 POSSIBLE GOALS WHEN DEVELOPING AN ENRICHMENT PLAN

- Prevention or reduction of problem behaviors, including abnormal repetitive or stereotypic behavior.
- Offer choices that enable the animal to exercise control over the environment (empowering autonomy).
- Promote expression of natural, species-typical behaviors (e.g., foraging behavior).
- Stimulate activity and physical fitness, offer opportunities for exercise.
- Provide mental stimulation by increasing complexity of the environment and/or stimulating problem-solving capabilities.
- Increase variability and diversity in behavior.
- Increase (positive) utilization of the enclosure or living environment.
- Increase the ability of the animal to cope with changes and challenges (increased adaptability and resiliency).
- Stimulate a healthy owner-bird relationship.

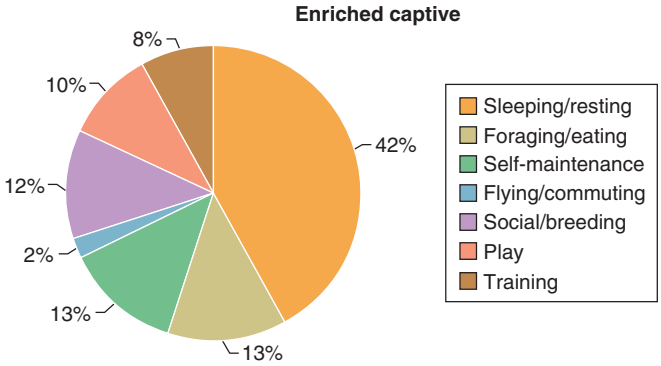

FIGURE 47.3 This graph represents a bird with an enrichment program in place. The sleep time is increased to 10 hours daily. A robust foraging program increases the foraging time to 3 hours daily. Training occupies 2 hours daily and the bird engages in flight exercises for 30 minutes daily. Ample opportunities for play and social interactions are made available.

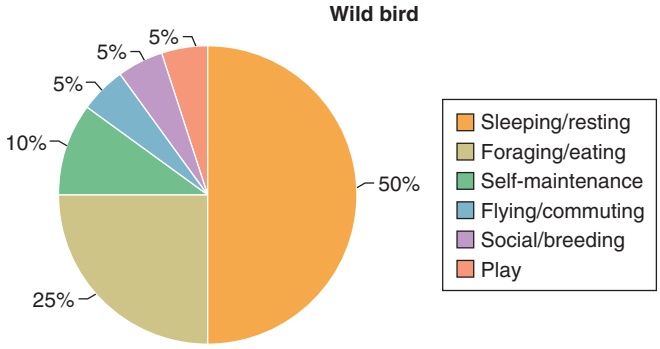

FIGURE 47.1 Sample time budget for a wild bird. While time budgets vary greatly between species and even seasonally within a species, some generalizations can be made. Many psittacine birds are tropical to subtropical, meaning that their light cycles will tend to be around 12 hours of light and 12 hours of darkness. Foraging for food, preening and other self-maintenance behaviors, play, and flying make up the remainder of the time. Nearly all of these behaviors are done socially.

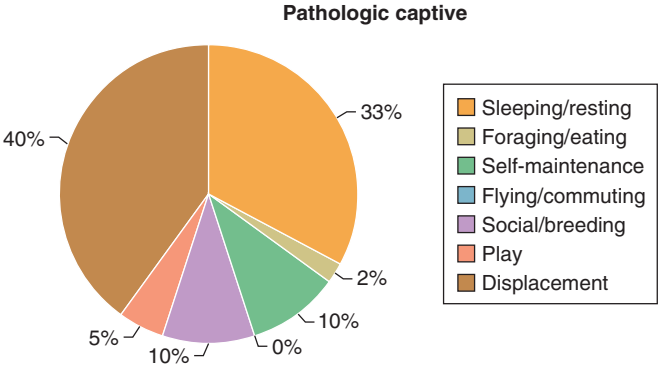

FIGURE 47.2 Sample of a pathologically skewed time budget for a captive bird. This bird gets only 8 hours of darkness each night. Foraging time is negligible. If other behaviors remain similar to wild birds, there remains 40% of the time for displacement behaviors to occur. Displacement behaviors often are pathologic, although there are beneficial displacement behaviors as well.

reproductive cycles in temperate species, in tropical species these effects will be variable. Other parameters such as food abundance, rain, and availability of a partner and/or nest site may have a larger effect in these cases. When there is photoperiod dependence, it is primarily dependent on changes in the light cycles rather than the actual day length, with prolonged exposure to constant photoperiod inducing photorefractoriness during which the physiological and behavioral changes normally induced by prolonged photoperiod are no longer recognized.[17] Thus, whenever possible, maintaining a consistent cycle of 12 hours of light and 12 hours of dark is preferred over a constantly changing light:dark schedule. While this rarely is practical for those with typical work schedules, the goal should be to stay as close to this schedule as possible.

ENERGY BUDGETS

Most birds are naturally high-energy creatures. The various activities of wild birds require a high caloric input. Flight is the most obvious high-energy activity. During flight, oxygen consumption goes up by about 1300%, and birds generally have energy requirements that are 50% to 75% higher than an equivalent-sized mammal.[18] In managed care, flight is generally restricted at least to some degree, sometimes via feather trimming and other times as a consequence of confinement to enclosures inadequate in size for flight. Additionally, many of these birds are provided unlimited access to high-energy diets. The resulting caloric surplus can either be manifested in an overabundance of active energy or in deposition of adipose. Although providing an outlet for flight may be the most efficient means of utilizing this energy in a healthy way, a variety of other activities can be utilized to fill some of the void. Enrichment can be chosen to encourage low-, moderate-, and high-energy activities. Ideally, a combination of all of these should be incorporated into the strategy. The ratio should be tailored to the physical condition of the bird. Table 47.1 lists some examples of high-, moderate-, and low-energy activities of parrots.

TABLE 47.1
Examples of High-, Moderate-, and Low-Energy Activities for Parrots

High-Energy Activities	Moderate-Energy Activities	Low-Energy Activities
Flight	Climbing	Chewing
Wing flapping	Swinging	Vocalization
Hop/flap	Bathing	Puzzles
Swing/flap	Walking	Preening

POPULATION-BASED STUDY OF ENRICHMENT

For enrichment to be applied scientifically, specific enrichments must be investigated to determine whether they are having the desired effects. This can be very challenging, given the highly variable individual preferences between species and even between conspecific individuals. A variety of studies have investigated the behavioral and physiologic effects of enrichment, enrichment preferences, and motivation to utilize enrichments. Most of these studies are applied at the population level and provide a good framework for the design of enrichment programs. Some of these studies suggest that birds show a great deal of motivation to work for their food, a concept called contrafreeloading.[19] This motivation suggests that foraging, in particular, is an essential component of parrot welfare. Table 47.2 lists some studies that have investigated enrichment.

BEHAVIORAL ANALYTICAL ASSESSMENT OF ENRICHMENT

Behavioral analytical methods may be an alternative method of assessing enrichment at the individual level. Single-subject design (SSD) evaluations of behavioral interventions determine the efficacy of an intervention in an individual subject. Since welfare itself is assessed at the individual level, this may be an appropriate way to evaluate enrichment programs.[50] After all, although a population study can determine what the color most favored by the majority of the group may be, that information is relatively useless in the individual as it may have different preferences. For veterinarians counseling clients, a "study of one" is certainly the most appropriate method of assessment. There is a great deal of literature on human physical and behavioral disorders using this methodology.[51–55] Studies often track behaviors at baseline, after the institution of an interventional program, and sometimes again after the reversal of the interventional components.[50] Whether or not reversal is used is dependent on whether the changed behavior is unlikely to revert back as with a trained or learned behavior, and whether it is humane or ethical to reverse an intervention that is improving the welfare of the subject.

TYPES OF ENRICHMENT

There are five generally accepted categories of enrichment: social, occupational, physical, sensory, and nutritional.[56] Social and sensory enrichment are self-explanatory. Occupational enrichment is the provision of activities or challenges. Physical enrichment is the enhancement of the physical environment. Nutritional or foraging enrichment involves both the type and the presentation of food. Some types of enrichment can fit into more than one category. For example, training a bird provides both social and occupational enrichment. When designing and implementing an enrichment plan, as many of these categories as practical should be incorporated.

SOCIAL ENRICHMENT

Most parrot species are obligately social animals.[23,57] While it is common to remark about birds being "spoiled" because they demand constant attention, it is unnatural for most parrots to be alone. The only time most parrots are ever alone in the wild is when incubating eggs. At other times, they would be with their parents, offspring, clutch mates, juvenile flock, adult flock, or their mate. While flock size and composition may differ across species and seasons, being alone is generally unnatural, except for solitary species such as the kakapo *(Strigops habrotilus)*. Flocking is primarily a protective mechanism to reduce the pressures of predation. Being within a group allows for multiple sentinels looking for signs of danger. A group of birds can "mob" a predator and chase it away. Even thinking less altruistically, a bird in a group of 10 birds has a 10% chance of being the target of a predator, while an individual bird has a 100% chance.

Despite their importance, social skills must be partly learned. While many of the social behaviors do not need to be learned initially, they do need to be modified and improved by learning. Early socialization starts with parental care. Even before hatching, the parent birds start interacting with a chick. Like mammals, the parents will stimulate defecation and carry the waste out of the nest initially. Parental care is constant and involves feeding, preening, vocalization, and other interactions. This is not readily replicated in incubator-hatched and hand-raised chicks. Most species will also have clutch mates in the nest with them. This also helps them learn social skills. Once they fledge, there still is a great deal of parental care and teaching. Many parrots also have a crèche system, a flock of juvenile birds that move about together and learn about the environment, feeding, predators, and other important life skills.[58] One of these skills is how to interact with other birds without conflict.

Hand-raised birds have somewhat displaced imprinting. While filial imprinting on humans may have some early advantages, sexual imprinting on humans can have severe behavioral effects. Birds that are sexually imprinted on humans often pair bond with humans and will present aggressive behavior toward others, can redirect aggressive behavior to their perceived mate under certain conditions, or will defend a perceived nest territory.[59] Other birds may become frustrated and engage in self-damaging behaviors such as feather-damaging behavior (FDB).[60] In addition, birds that are completely imprinted on humans may exhibit poor socialization with other birds. Many bird owners have multiple birds, and one with poor social skills may either attack or be frightened of and attacked by other birds. Even if no aggressive behavior is displayed, some of these birds will be uninterested in socialization with other birds. These challenges can be addressed; however, it can take extensive work under the guidance of a

TABLE 47.2

Overview of Studies Investigating the Effect of Enrichment in Psittacine Birds

Species	*n*	Enrichment Type	Duration	Parameters	Outcome	Reference
Orange-winged Amazon parrot *(Amazona amazonica)*	21	Social enrichment (conspecific companionship)	12 m	Stereotypy development, feather-damaging behavior, fearfulness, aggression	Pair housing resulted in higher activity and more diverse behavior. Stereotypies reduced; fear responses modified	Meehan et al., 2003[20]
Orange-winged Amazon parrot *(A. amazonica)*	19	Social enrichment (different rearing environment: parent reared ± human interaction, human reared)	12 m	Latency to feed and fearfulness	Hand-reared birds less neophobic until 6 m of age. At 1 y similar fear levels in all groups	Fox and Millam, 2004[21]
Orange-winged Amazon parrot *(A. amazonica)*	64	Social enrichment (neighboring conspecifics); foraging and physical enrichment	N/A	Stereotypies, feather-damaging behavior	Parrots with more neighbors show less stereotypies; proximity to the door associated with feather-damaging behavior	Garner et al., 2006[22]
Grey parrot *(Psittacus erithacus)*	45	Social enrichment (social isolation)	N/A	Telomere length (chromosome stability)	Telomere length shortened significantly in socially isolated birds, suggestive of exposure to chronic stress and reduced life span	Aydinonat et al., 2014[23]
Mixed species	18	Social enrichment (video calling other birds)	N/A	Engagement of the parrot; perceived benefits by the caretaker	Parrots exhibited high motivation and intentionality to use the system and caretakers all reported perceived benefits	Kleinberger et al., 2023[24]
Buffon's macaw *(Ara ambiguus)* Green-winged macaw *(Ara chloropterus)*	2 2	Cognitive enrichment (behavioral training for artificial insemination procedures)	15 w	Behavioral activity, stereotypies	Training did not result in stress or affected reproductive behaviors in *A. ambiguous*; female *A. chloroptera* stressed, male did not complete training	Leblanc et al., 2011[25]
Ornate lorikeet *(Trichoglossus ornatus)* Josephines lori *(Charmosyna josefinae)* Fairy lorikeet *(Charmosyna pulchella pulchella)* Hooded parrot *(Psephotus dissimilis)* Coconut lorikeet *(Trichoglossus haematodus moluccans)* Mulga parrot *(Psephotus varius)* Orange-billed lorikeet *(Neopsittacus pullicauda)* West Papuan lorikeet *(Charmosyna papou goliathina)* Eastern bluebonnet *(Northiella haematogaster)* Red-rumped parrot *(Psephotus) haematonotus)*	14 10 12 14 12 14 14 14 14 14 14	Physical/cognitive enrichment (novel objects: rope, cotton mop and two small plastic blue tiles)	2 d	Latency to touch novel object, number of objects touched, duration of exploration	Resident species showed earlier exploration; exploration positively correlated with feather damaging	Mettke-Hofmann et al., 2000[26]

TABLE 47.2

Overview of Studies Investigating the Effect of Enrichment in Psittacine Birds—cont'd

Species	*n*	Enrichment Type	Duration	Parameters	Outcome	Reference
Orange-winged Amazon parrot *(A. amazonica)*	8–10	Physical enrichment (wooden and rawhide cubes, different colors)	>13 d	Preferences for enrichment characteristics	Color, hardness, size, and material, all influence use of the enrichment device; preferences appeared to reflect properties of foods native to Amazon's natural habitat	Kim et al., 2009[27]
Orange-winged Amazon parrot *(A. amazonica)*	12	Physical enrichment (ropes of different colors and sizes)	57 d	Preference for enrichment characteristics	Item properties may trigger different motivation behaviors; nonfrayed rope preferred; sex-specific preferences for length and diameter	Webb et al., 2010[28]
Cockatiel *(Nymphicus hollandicus)*	18	Physical enrichment (wooden sticks with a hole, iron rings with beads)	3 m	Behavior changes	Enrichment resulted in less time spent on eating, preening, locomotory behaviors, less undesirable activities, and improved fitness	Assis et al., 2016[3]
Grey parrot *(P. erithacus)*	3	Sensory enrichment (acoustic stimuli)	N/A	Behavioral changes, preferences for music	Musical preferences appeared influenced by personality; differences in behavior dependent on the acoustic environment	Péron et al., 2012[29]
Grey parrot *(P. erithacus)*	15	Sensory enrichment (acoustic stimuli)	N/A	Behavior observations, musical preferences	Parrots intrinsically participated in the experiments and provided positive feedback to the devices; preferences for certain music types observed	Gupfinger and Kaltenbrunner, 2017[30]
Grey parrot *(P. erithacus)*	15	Sensory enrichment (acoustic stimuli, musical enrichment)	Three test phases of 3–4 d over 3 m	Behavior observations, musical preferences	Preference for continuous beat to single notes, but no obvious preference for faster or slower beats; individual preferences exist. Birds voluntarily and positively interacted with home-made musical instruments	Gupfinger and Kaltenbrunner, 2020[31]
Yellow-headed Amazon parrot *(A. oratrix)* Grey parrot *(P. erithacus)* Hyacinth macaw *(Anodorhynchus hyacinthinus)* Scarlet macaw *(Ara macao)* Military macaw *(A. militaris)* Blue-and-gold macaw *(A. ararauna)*	1 2 1 2 2 2	Sensory enrichment (auditory enrichment), social enrichment (rearing method, social environment)	36 d	Behavior (vocalizations, stereotypies, enrichment interaction)	Exposure to talking radio and pop music significantly reduced psittacine vocalization; hand-reared birds showed more stereotypy and interacted less with enrichment than parent reared; solo-housed birds showed more stereotypy than group-housed birds	Williams et al., 2017[32]

Red-fronted macaw *(Ara rubrogenys)* Thick-billed parrot *(Rhynchopsitta pachyrhyncha)* Green-winged macaw *(A. chloropterus)* Chattering lori *(Lorius garrulus)*	4 2 2 2	Foraging enrichment (length of wood with two variations in food distribution)	4–5 d	Preference on enrichment's food supply	More appropriate species-typical behaviors induced following provision of foraging enrichment	Coulton et al., 1997[10]
Grey parrot *(P. erithacus)*	18	Foraging enrichment (puzzle feeders)	2 m	Feather-damaging behavior	Pipe feeder increased foraging times and improved feather condition	Lumeij and Hommers, 2008[33]
Grey parrot *(P. erithacus)* Healthy Feather damaged	22 11 11	Foraging enrichment	1 m	Contrafreeloading	Contrafreeloading displayed by both healthy and feather-damaging birds; birds with feather-damaging behavior displayed less contrafreeloading	van Zeeland, 2009[19]
Grey parrot *(P. erithacus)*	12	Foraging enrichment	>12 w	Foraging activity	9/11 enrichments significantly increased foraging activity	van Zeeland et al., 2013[16]
Red-tailed black cockatoo *(Calyptorhynchus banksii)*	6	Foraging enrichment (sliced cucumber, fresh grass, baffle cages, and millet disks)	25 d	Oral stereotypic behavior, foraging activity	All foraging enrichment increased median percentage of time spent foraging compared to control. 2/4 enrichments (grass, millet disks) significantly decreased oral repetitive behaviors	Fangmeier et al., 2020[34]
Orange-winged Amazon parrot *(A. amazonica)*	30	Social enrichment (pair separation), physical enrichment (misting, nest hole restriction, larger nest boxes), nutritional enrichment (fruits)	2 y	Egg laying	Parrots' sexual activity stimulated by enrichment protocols	Millam et al., 1995[35]
Crimson-bellied conure *(Pyrrhura perlata)*	10	Foraging enrichment, physical enrichment (addition of perches)	24 w	Feather-damaging behavior	Stabilization of feather-damaging behavior during study, natural and edible materials more successful	van Hoek and King, 1997[36]
Orange-winged Amazon parrot *(A. amazonica)*	16	Physical (increased cage complexity), foraging enrichment	1 y	Responses to novelty and human handlers	Enrichment reduced fear and motivation for interaction/exploration	Meehan and Mench, 2002[11]
Orange-winged Amazon parrot *(A. amazonica)*	16	Physical (increased cage complexity), foraging enrichment	48 w	Feather-damaging behavior	Feather damaging prevented and reduced following provision of enrichment	Meehan et al., 2003[37]
Orange-winged Amazon parrot *(A. amazonica)*	16	Physical (increased cage complexity), foraging enrichment	48 w	Development of stereotypic behavior	Stereotypies prevented following enrichment	Meehan et al., 2004[38]

Overview of Studies Investigating the Effect of Enrichment in Psittacine Birds—cont'd

Species	*n*	Enrichment Type	Duration	Parameters	Outcome	Reference
Nanday conure (Aratinga nenday) Social enrichment birds	48 27	Physical enrichment, social enrichment, handling by humans	6 w	Novel object, novel conspecific, open field, emergence, latency to feed, learning tests, and behavioral assessment	Enrichment protocols reduced fear levels and increased exploration in several tests	Luescher and Sheehan, 2005[39]
Cockatiel *(Nymphicus hollandicus)*	16	Physical enrichment (collard green stalks)	20 d	Behavior changes	Stalks increased the feed intake and decreased sleep activities	Carvalho et al., 2017[40]
Red-winged parrot *(Aprosmictus erythropterus)* Jandaya conure *(Aratinga jandaya)* Sun conure *(Aratinga solstitialis)* Blue-winged or Malabar parakeet *(Psittacula columboides)* Green-winged macaw *(Ara chloropterus)* Rose-ringed parakeet *(Psittacula roseate)* Red-breasted parakeet *(Psittacula alexandri)*	2 1 1 6 1 6 1	Physical enrichment (ladder, continuous rings, mirror, rope with knots); foraging enrichment (skewers with fruits)	8 d	Preference and use of the items	Ladder was highly preferred; rope with knots was least preferred	Prathipa et al., 2017[41]
Cockatiel (Nymphicus hollandicus)	12	Physical enrichment, substrate (earth, sand, wood shavings, shallow and deep water)	Three periods of 1 w	Preference and behavior	Wood shavings, earth, and sand were preferred as substrates; no bathing behavior was observed	Stevens et al., 2021[42]
Orange-winged Amazon parrot *(A. amazonica)*	34	Foraging devices; toys	25 w	Novel object test	Rotation of devices more effective than enrichment itself to reduce fear	Fox and Millam, 2007[43]
Orange-winged Amazon parrot *(A. amazonica)*	6–12	Foraging enrichment	>4 w	Behavior (foraging), pellet preference	Birds preferred oversized pellets, which naturalized foraging times. Feeding of oversized pellets reduced destruction of wooden cubes (act as foraging substitutes?). Podomandibulation reduced upon feeding regular pellets	Rozek et al., 2010[15]

Orange-winged Amazon parrot *(A. amazonica)*	10	Foraging enrichment	7 m	Motivation for pellet types, destructible cubes	Oversized pellets are highly preferred over regular pellets; chewing/biting of wooden cubes reduced upon provision of larger-sized pellets	Rozek and Millam, 2011[44]
White-eyed conure *(Aratinga leucophthalma)*	10	Foraging enrichment	7 m	Behavior (abnormal behavior)	Reduced abnormal behavior (nonsignificant)	de Andrade and de Azevedo, 2011[5]
Budgerigar *(Melopsittacus undulatus)*	36	Physical and social enrichment	8 m	Behavior (stereotypies)	Stereotypies reduced following interaction with multiple partners	Polverino et al., 2015[45]
Orange-winged Amazon parrot (A. amazonica)	13	Physical, foraging, and social enrichment (handlers)	40 w	Development of abnormal behaviors	Deprivation of enrichment worsened feather condition and increased duration of stereotypies	Cussen and Mench, 2015[46]
White-eyed conure *(Aratinga leucophthalma)*	12	Sensory, foraging and physical enrichment (multiple items)	3 w	Feather-damaging behavior	Enrichment was more effective than drug treatment	Telles et al., 2015[47]
Sulphur-crested cockatoo *(Cacatua galerita)*	2	Cognitive enrichment (training), social enrichment (human contact), foraging enrichment in combination with haloperidol	N/A	Abnormal behavior, feather score, fecal corticosterone	Reduced abnormal behavior and improved feather score; decreased fecal corticosterone concentrations	Peng et al., 2014[48]
Blue-and-gold macaw *(Ara ararauna)*	22	Physical, occupational, and food enrichment	6 m	Behavior analysis, fecal corticosterone	Biting and pacing as well as vocalization, preening, and feather bristling decreased significantly during the enrichment phase, whereas locomotion increased; no differences observed in corticosterone metabolites in the droppings	de Almeida et al., 2018[49]

d, Day; *m*, month; *N/A*, not applicable/not available; *w*, week; *y*, year.

qualified behavior consultant well-versed in training technology based in the science of behavior analysis. Hence, the parrot's previous experiences and rearing history need to be considered when weighing the risks and benefits of the addition of a new bird to the household (see also *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).

Some studies have shown that parent-raised birds that are socialized by people while developing have pet qualities exceeding those of hand-reared birds.[59,61] This can be slightly challenging to accomplish but should be considered the ideal practice. Breeding birds can be trained to station outside of the nest box so that the nest can be inspected, and the young birds handled. Alternately, parent-raised birds can be trained using positive reinforcement techniques after fledging. Minimally, having birds raised with clutch mates or other babies will at least allow them to imprint on both humans and birds. (see Section 9: Embryology, Neonatology and Pediatrics, and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).[61]

Assuming a bird has well-developed social skills, the next concern is providing them with opportunities to socially interact with humans, conspecifics, or other animals. While bird owners like to believe they are providing this for their pets, in most cases, the social contact they provide is inadequate. Socializing a parrot is more than a full-time job. The ideal solution is that birds be kept in a more normal social grouping, especially those that have been reared by their parents and/or with other birds. Compatible birds, housed together, can provide 24-hour socialization for each other. To be compatible, they must have some social skills with other birds. Cohoused birds also should be size and temperament matched (Figure 47.4). Although it can occasionally work, housing large birds with small birds can be a dangerous situation. Larger birds can easily tear the beak or a toe off a smaller one. Likewise, a loud bird may be a source of stress for a nervous or quiet bird. In a study on assessment of personality traits to aid in social pairing of orange-winged Amazon parrots *(Amazona amazonica)*, pairing success was greatest for social-guarded, social-nervous, or nervous-nervous parrot pairs.[62] Another study in white-eyed conures *(Psittacara leucophthalmus)* also indicated effects of temperamental traits on behavior of group-housed individuals. While bold parakeets spent more time on preening, showed more negative social interactions, and tended to spend less time interacting with the environment, vigilant parakeets showed lower levels of positive social interactions and spent less time on locomotion.[63] Both studies therefore indicate that temperament could be useful to determine whether or not individuals could be housed together, thereby avoiding unnecessary disputes and injuries. In general, introductions are easiest with very young birds, and most birds that grow up together remain compatible, provided they do not conflict over a mate or resources. If breeding is not desired, the birds should be the same sex.[20] Although there are exceptions, breeding often will have some undesired effects on the companion characteristics of a parrot during the breeding season. Most breeding pairs will defend the nest territory from all others, resulting in aggressive behavior. If breeding is desired, the pair can be allowed to defend their territory. They should, however, be conditioned to allow nest cavity inspection daily and should be trained to allow normal care procedures (via stationing or other methods) but be left undisturbed otherwise.

The obvious benefit of having birds in pairs or groups is that it corrects for some of the limitations of human companionship.

FIGURE 47.4 Compatible, size-matched birds can be cohoused if the enclosure size permits. These young male blue-and-gold *(Ara ararauna)* and green-winged macaw *(Ara chloropterus)* were hand-raised together. As they mature, greater monitoring for aggressive behavior may be needed. Birds housed in smaller cages may not be able to be cohoused. They can be housed in adjacent cages and allowed play time together when supervised.

Companion birds can be together all the time, reducing the reliance on the owner for companionship and protection. In addition, the benefits of companionship from a conspecific have been well studied, with several studies indicating pair or group housing to increase overall activity and behavioral diversity while lowering the incidence of stereotypic behavior and fear responses.[20,32,45] As such, social housing with a companion may reduce problem behaviors such as nuisance vocalization, stereotypies, or FDB that commonly occur when birds rely too much on the owners' presence and attention.[63] Contact with other birds may vary from limited vocal and/or visual contact (e.g., when birds are placed in the same or an adjacent room or aviary) to more intense contact (e.g., when the cages are placed side by side, the birds are physically housed together or are allowed to interact with each other outside of their cages). Mutual preening is considered important to promote social bonds.

Recently, researchers also developed an approach to allow single-housed parrots to engage in video calling other parrots.[24] During a pilot study with 18 birds, most of the birds showed high motivation and intentionality to use the system, while caretakers all reported benefits from these calls, some arguably life transformative (e.g., learning to forage or fly by watching others). Such options may therefore be worth exploring for highly motivated caretakers with a single-bird household. Alternatively, owners may sometimes provide a "dummy bird," mirror, or mirror-like toy in the cage to serve as a substitute for social interactions, particularly for smaller birds such as budgerigars *(Melopsittacus undulatus)*, cockatiels *(Nymphicus hollandicus)*, and lovebirds (*Agapornis* spp.). Indeed, some studies have shown the beneficial effects in parrots and other birds, where birds

exhibited extensive interaction, more playful behavior, and reduced stress levels upon exposure to a mirror.[64–66] Others, however, have suggested a potential negative effect on behaviors through negatively affecting food intake and nesting activity while increasing occurrence of aggression (to conspecifics or the mirror) or leading to maladaptive behaviors such as pair bonding with the mirror.[67–71] These potential advantages and disadvantages should be discussed with the owner so that an informed decision can be made on the provision of mirrors to any pet bird.

Breeding and sexual behaviors are not desired in singly housed birds. Nevertheless, these behaviors may inadvertently be encouraged by the owner. For most wild birds, breeding occurs during a defined, short season, which is signaled by a changing photoperiod, rainy season, presence of a mate, availability of certain food items, or simply food surplus.[72–75] Many of these key stimuli are present in the captive situation. Pet birds typically are overfed on high-calorie diets. Numerous birds are offered nest boxes, "snuggle" tube perches, or are allowed access to cabinets or other hollow structures that the bird may perceive as a potential nest site. Many owners interact with their birds in ways that signal pair bond formation and reinforcement in parrots. Reproductive instinct is strong in most species and adding in these potent stimuli can suffice to initiate the breeding process. To discourage reproductive behaviors, several strategies can be employed (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 12, Reproduction). Caloric intake should be carefully controlled. This is especially effective for suppressing egg laying since most hens will increase food consumption in preparation for egg laying. Foraging can give the bird the impression that food supply is limited, even if higher amounts of food are offered. Owners should try and restrict physical contact with the bird, specifically the type of contact that simulates courtship or mating behaviors. Alternative activities that stimulate social interaction, such as training, playing, and other active games, should be encouraged to replace much of the "cuddle" time. The petting that is done should be brief, used to reinforce good behaviors, and limited to nonsexual locations of the body. The advice of touching only above the shoulders is appropriate (Figure 47.5). For those species that respond to photoperiod, modifications can be made to regulate the day:night cycle, with a relatively short and consistent day length being most desired. Access to any potential nest sites or nesting material should be restricted. Several of these interventions comprise antecedent arrangement interventions to prevent stimulation of reproductive behavior. However, merely focusing on removal of antecedents for reproductive behavior could create a void for other problem behaviors to occur. Hence, where possible reduction or elimination of reproductive activity should not solely rely on antecedent arrangement but preferably be combined with positive reinforcement of alternative, appropriate behaviors. Aside from foraging and (nonphysical) social interaction, this may include stimulation of exploratory behavior by offering new toys or enrichment, regular replacement of toys, and/or rearrangement of the layout and design of the enclosure and living environment.

Of course, human companionship can be a critical form of enrichment for many birds. A recent study in blue-and-gold macaws (*Ara ararauna*; $n = 5$) used a classical separation-reunion paradigm where birds were temporarily placed in an unfamiliar environment with a familiar caregiver (union; 2 minutes) to then be left alone (separation; 2 minutes) and subsequently be reunited with its caregiver again (reunion; 2 minutes) and found birds to show facial indicators of positive affect (higher crown and nape feather heights; increased redness of the skin; higher frequency of contact-seeking behaviors; eye pinning) during the union and reunion phases compared to the separation phase during which the birds expressed long-distance contact calls.[76] These results indicate that the presence of a human companion can be beneficial to parrot welfare. It should be noted that appropriate interactions can greatly benefit both the bird and the human in this relationship. Noncontact interaction can be a large part of this relationship. Being in the visual and auditory range of human "flock" members appears to be comforting to most human-imprinted birds. The location of cages, play stands, and other living spaces of birds should allow the bird to remain in view of daily household activities. While doing so, the character or temperament of the bird should be carefully considered. For example, an anxious, nervous bird that is known to respond fearfully to novel objects or people may warrant the enclosure to be positioned on the side, near a wall, to provide a sense of security and option to retreat from social activities, whereas a more central location is preferred for a bird that is seemingly curious and "loves" attention. A continuous vocal connection can help reassure a bird that the flock is near. By positively reinforcing the lower-volume vocalizations, and the owner keeping their responses low in volume as well, some of the louder nuisance vocalizations can be minimized. When the owner is away, radios or televisions or other types of background noises may provide the single pet parrot with vocal stimulation. Verbal games seem to be

FIGURE 47.5 Although relished by many birds, excessive petting, cuddling, and close physical contact can simulate pair bonding and lead to a variety of health and behavioral problems. Alternative activities like positive reinforcement training can provide occupational and social enrichment simultaneously.

enjoyed by many birds. Parrots, especially Grey parrots *(Psittacus erithacus)*, have been shown to have considerable skills in language and this can be used to advantage.[77,78] Direct physical contact interactions can serve as social enrichment as well. A human hand or arm can serve as a mode of transportation for birds within a home. This can be coupled with verbal interaction and limited petting, playing, and training activities. Many of these interactions then double as occupational enrichment.

Social interactions with other species in the home also provide enrichment, and literally, any species that can offer the opportunity for birds to interact in a desirable manner for both should be considered as an option that can offer favorable benefits for both. Extreme caution should be taken with predatory species, however, as severe or fatal injury can occur very rapidly. Likewise, a large parrot could severely injure a smaller animal. Careful observation and supervision are critical to make these introductions safe and successful.

OCCUPATIONAL ENRICHMENT

Occupational enrichment is activity based. It involves encouraging either physical or mental activity to the subject animal. This can include any number of activities. Mental stimulation can be provided through cognitive enrichment, which includes activities such as training, playing games, or offering puzzle feeders that the animal must manipulate to obtain food. Moreover, novel objects such as unusual foods, novel toys, and/or unusual scents can be used to stimulate exploration behaviors. Recent studies have also demonstrated the opportunity to teach letter-speech associations (so-called grapheme-phoneme correspondence) to parrots as well as the ability to read and implement computerized technology (e.g., touchscreen devices, tablet-based computer boards, video calling) in parrot enrichment, thereby significantly expanding the available options to engage parrots in activities that align with their higher-cognitive capabilities.[24,79–83]

Physical stimulation, on the other hand, can be promoted by providing the animal with opportunities to exercise (i.e., flying, climbing, swinging, and swaying). While some of these activities can be encouraged by the physical environment and performed independently by the parrot, others are brought about during direct interaction with humans.

Positive Reinforcement Training

Owners will sometimes claim their parrots are seemingly difficult to train. This is perplexing, given their intelligence. Part of the reason is likely to be the typical feeding practices for pet birds. Although words, touch, or attention may be effective at times, at other times, it can be difficult to predict exactly what an individual parrot will find reinforcing. As a consequence, training parrots has long involved less desirable methods that involve coercion and force rather than positive reinforcement. Mostly these techniques were used in good faith, but there is substantial evidence of fallout from coercion.[84] As a result, training using positive reinforcement has nowadays become the standard (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).[85] Positive reinforcement can involve a diversity of primary and secondary reinforcers, which are provided to the bird upon it displaying a desirable behavior. Primary reinforcers, which include resources such as food, water, sleep, and shelter, often work well because of their biological relevance to the animal, especially if the motivation for obtaining these resources is high. For example, a parrot that is hungry (not starving!) becomes infinitely more trainable as food becomes a valuable resource to them. However, secondary reinforcers, such as toys, touch, and attention, which initially begin as neutral stimuli but become conditioned when paired with primary reinforcers, can also make for suitable reinforcers once the bird perceives these as highly desired items and experiences.

Positive reinforcement training provides a means for owners to communicate effectively with their birds and to allow the birds a degree of choice in what behavior they will exhibit. Undesirable behaviors can be replaced with desirable behaviors that are subsequently reinforced (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). In addition, training through positive reinforcement techniques has been shown to reduce abnormal behaviors such as stereotypies and FDB in a limited number of birds, though the effect was highly dependent on the individual.[25,48] Although the process of training is relatively simple, the devil is in the details. The ability to read the body language of the bird, developing timing with delivery of a bridging stimulus and/or reinforcers, and even presenting cues in a manner that does not appear threatening requires practice. Box 47.2 contains a sample instruction sheet for helping clients understand how to train their birds.

Additional training for the owner is strongly recommended. There are many great books, videos, and online resources that can be used to improve training skills (see Chapter 46). One of the most difficult aspects to master is being patient. Pushing a reluctant bird too quickly is likely to hinder learning of the behavior, even if they initially perform the behavior. The fact that they were uncomfortable doing the behavior will make them avoid it in the future. This is particularly difficult when transitioning from traditional training techniques to positive reinforcement behavior.[86]

The behaviors that are trained are far less important than the training itself, as training by itself provides an excellent opportunity for clients to engage their birds without stimulating reproductive behaviors. However, training some husbandry behaviors can greatly reduce stresses that will occasionally occur for any pet bird. If a bird allows the owner to file the nails daily with a fingernail file, then trimming by restraint of the bird will rarely, if ever, be required. Training a bird to defecate in appropriate locations will make it easier to integrate them into normal household routines, while recall is an important behavior to teach to flighted birds to ensure their safe return. Training can also focus on behaviors that are relevant to the veterinary examination, thereby helping to reduce stress from restraint or administering medication (see Chapter 46). For example, training a bird to allow gentle restraint in a towel will facilitate veterinary examinations or other procedures, while training a bird to drink juice or almond milk from a syringe or other device will facilitate delivery of medication if an illness occurs.[87]

Model/Rival Training and Observational Learning

While positive reinforcement training should be used when behaviors need to be taught efficiently, casual interactions can

BOX 47.2 INSTRUCTIONS TO CLIENTS REGARDING TRAINING OF PARROTS

Tips to Create an Eager Student

- Start a foraging program (see Box 47.4).
- Limit a highly favored food item to a small quantity and use it only for training.
- Break up the food to be used as a reward into small morsels (1/4 inch, 0.63 cm or less for a medium- to larger-sized parrot, and even smaller sizes for smaller species).
- Take away all food for about 1–2 hours before training sessions.
- Stop sessions before the bird loses interest in the treats.

Definitions

- Reinforcer: The consequence for presenting behavior. In force-free training, reinforcers tend to be things or activities the animal seeks to acquire or values. This can include items such as preferred food, access to enrichment items, touch, companionship, and, in some cases, verbal responses from caregivers. Desired items should only be considered true reinforcers to a particular bird once it has been demonstrated that they actually increase or maintain behaviors in that bird (and not because an owner, behavior consultant, or trainer perceives it to be one).[86]
  - Food items
  - Food toys
  - Access to a preferred person
- Target: A common tool in animal training is a target. A target can be an item (e.g., stick, light, pen), hand, or spot that the animal needs to touch with a part of its body (e.g., beak, tongue, head, wing, foot). The action of orienting the body part toward a target is called targeting. Once an animal has learned to target, it is possible to use the target to direct the animal where to go or where to place a body part. This allows the trainer to give the animal information and create action that can be reinforced without having to handle or manipulate the animal. For example, another way to train a parrot to lift its foot for nail trimming is to train it to touch a target with its foot.[86]
  - Often the trainer's hand or a colored stick or wand
- Shaping: To train more complex behaviors, it is recommended to break these up into smaller, more easily achievable behaviors or actions that will gradually build toward the more complex behavior. Once these smaller actions or approximations toward the desired behavior are identified, a trainer can start reinforcing these until the behavior is shown fluently. Next, the trainer focuses on building more behavior using targets, showing reinforcers, or careful observation of the animal's action. If the animal makes any action that builds upon the previous action, the trainer reinforces that action. Each approximation that is successfully reinforced brings the animal closer to presenting the desired final behavior.[86]
- Bridging stimulus (bridge or marker): The reinforcer is the tool that communicates to the animal that it has presented behavior desired by the trainer. It is important that delivery of the reinforcer is paired in direct conjunction with the presentation of the desired action. A bridging stimulus is a sound or a signal that can be used to help mark behavior when it is difficult to deliver reinforcers promptly.[86]
  - Clickers
  - Verbal (e.g., "good")
- Cue: Cues are sounds or signals that indicate the opportunity exists to present an action and earn reinforcers. Cues acquire their value by being paired with the action followed by the reinforcer. Sounds and signals are meaningless as cues without this pairing.[86]
  - Verbal (e.g., "step up")
  - Hand signals
- Jackpot: Providing a better (larger amount or more preferred consequence) for performance of a behavior or an approximation that is particularly challenging or novel for the animal. If this is offered during the shaping process, the jackpot should not be so great that it disrupts the flow of the session.

A Brief Overview of How to Train a Behavior Using Shaping

- Find a way to create an action toward your desired goal behavior you can reinforce by showing food, using a target, and/or arranging an inviting environment.
- Gradually build upon this action by reinforcing small approximations toward your desired goal behavior.
- Build reinforcement history for your desired goal behavior.
- Once reinforced behaviors will be repeated and become predictable, insert your cue right before the behavior is offered to create the association with your desired cue.
- Fade out reinforcing for offering and only reinforce when cued.

also be used to teach behaviors. This method, the model/rival method, uses social cues and observational learning to teach the subject.[88–90] In dogs, model/rival training was as effective in teaching object names as positive reinforcement training.[89] In parrots, model/rival training has been used primarily for teaching language skills and involved a teacher and a model/rival doing verbal exchanges in front of the bird. The emphasis is on the name of a particular object. When the model/rival said the name of the object, it was handed to them. Attention is only directed to the bird when it says the name of the object, at which point the object is given to the bird. Therefore the reward is intrinsic to the object rather than any association with a food reward. Using this method, Pepperberg has been able to demonstrate a wide variety of cognitive capabilities of parrots including numeric skills, object permanence, same-different concepts, and other categorical capabilities.[91–94] Similarly, Kleinberger et al. reported birds to learn how to forage or fly from watching other parrots during parrot-parrot video calls.[24] Given the crèche systems often employed in psittacine flocks in the wild, it is highly likely that such social, observational learning is critically important in the learning of survival skills. Hence, observational learning can certainly be employed in companion birds that look to human flock members for cues on behavior. In addition to learning language, responses to various household features can be taught. For instance, a small role-play can be done in front of a stovetop. The model/rival can pretend to burn a finger and act dramatically. The teacher can scold and say, "Yeah, Dangerous!" or "Hot!" This can teach the bird that this is a dangerous place. Similarly, windows and mirrors can be shown to be solid objects. Pictures or objects can be shown to be safe and not to be feared. This method is certainly not mutually exclusive to positive reinforcement training. It just uses intrinsic, social reinforcement. It should be noted that

there may be circumstances when it may not be appropriate. In one experiment, a human-raised gibbon was being taught gestures using this method. Every time the rival performed the task and was rewarded with attention (from the favorite person), the gibbon attacked the rival.[95] It would be easy to believe this could happen with a human-imprinted cockatoo or other parrot as well. Anecdotal reports of "jealousy-based" attacks on perceived rivals for a favored person's attention are all too common in companion bird medicine. While the model/rival improves learning, it may not always be essential to have a second person or bird for observational learning to occur.[96] The mechanisms by which observational learning occurs are not always known, but it certainly can be an additional way to model behaviors in companion birds. The previous example of the stovetop can be done without the model/rival and still achieve the goal. The clinician can recommend a "house tour" game to clients. The bird is carried about the house and introduced to objects, people, and other pets while modeling appropriate responses to these items. Although the goal of these methods is to achieve improved behavior, they inherently engage the bird's mind and stimulate their curiosity. They also provide great alternatives to pair bond–simulating activities like petting and cuddling with birds.

Physical Exercise

The benefits of physical exercise are well documented (Box 47.3).[97–99] Likewise, the negative effects of inactivity are well known. As the number of aging birds increases, the frequency of certain degenerative diseases has grown by an even greater degree.[100–102] While not all these conditions are preventable, many are much less prevalent in animals that receive appropriate diet and exercise. Cardiovascular diseases, such as atherosclerosis and congestive heart failure, can be reduced with appropriate levels of physical activity.[98,99] Obesity, hepatic lipidosis, and arthritis are other conditions that may result from a severe lack of physical activity. The musculature will be stronger with regular exercise. The joints require movement to nourish the articular cartilage. Bone density improves with physical activity as well. Exercise has a great deal of psychological benefit as well.[103] In humans, it can reduce the effects of depression.[104–107] In animals, exercise can help reduce displacement behaviors.[103,104,108,109] The expenditure of energy on healthy physical activity can only help reduce the use of energy on pathologic behaviors.

As in any animal or person, a medical examination should be performed to determine the safety of a new exercise program. Certain conditions may require restriction of exercise, even if it originated because of inactivity. Such conditions may include some orthopedic conditions, atherosclerosis, and heart failure. Carefully planned exercise may still be beneficial in these cases, but they should be tailored to the individual bird and instituted very cautiously and voluntarily as forcing these birds to exercise may cause them to decompensate.

There are many types of exercise. For birds, the simplest and most obvious is flight. The largest mass of muscle in flying species is the pectoral musculature and this is the exercise they are best adapted to. There are complications to having a flighted bird as a pet. These include injuries, escapes, or difficulties with training. Most of these complications result from poor flying skills rather than flying itself and can be managed with appropriate training and flight development. Recall (flight to the handler), flight to a perch, and other such games are easy ways to promote flight activity. An enclosure that is large enough to allow flight will passively encourage this type of exercise. It is much more feasible to provide ample flying space for a budgerigar with a 25- to 30-cm wingspan than for a macaw with a wingspan of over a meter. In some cases, though, an owner may wish to keep the wings trimmed to prevent some of these complications (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 22, Advancements in Management of the Welfare of Avian Species). In these cases, providing ample wing exercise can be more challenging. Wing flapping can be encouraged but should be trained rather than forced. Dropping a hand while a bird is perched upon it will force a bird to flap. However, this can promote biting, sometimes just to hold on. It is also a force-based method and is therefore best avoided. Most birds will flap when the surface they are perched upon moves. Providing swings, flexible branches, ropes, or other movable perching surfaces is a good way to encourage some wing flapping. Often birds on a swing or rope will flap the wings to propel the rope or swing toward another foothold or beak-hold. This motion can be referred to as a flap/swing and is commonly used by parrots when there are numerous flexible perching options in large enclosures. Likewise, many will flap the wings, along with hopping to another perch. This can be referred to as a flap/hop. The flap/swing and flap/hop may be the most beneficial wing exercises for birds that do not have flight capabilities.

More so than any other avian species, parrots are also adapted to climbing. Their hooked beak and zygodactyl feet provide strong holds that allow them to climb vertical heights and grasp perches.[110–113] Parrots can hang from just the beak or from one toe and can flip back on top of a branch with a few flaps of the wings. Even fully flighted parrots will often use their climbing abilities to negotiate a maze of branches rather than fly over them. Tarzan himself would be jealous of the gymnastic capabilities of a fit parrot! To encourage these types of activities, branches, ropes, or ladders can be provided. In fact, nearly all structures or materials that will provide grip to the parrot will be suitable for this purpose.

Many birds are quite vigorous in their bathing activities. They may hop in and out of a spray of water, flap the wings, shake the tail and/or head, and generally have a great time. This can be another means of encouraging exercise.

Beak activity is a relatively low energy form of exercise. It is constant, however. Parrot owners are fully aware of the destructive capability of psittacine beaks. Some birds may initially require encouragement to chew. For this purpose, soft items like paper, cardboard, or softwoods can be provided to the bird. As beak strength improves, harder types of woods can be given. Some parrots may require a small nick or other

BOX 47.3 BENEFITS OF PROVIDING PHYSICAL EXERCISE TO PARROTS

- Increase bone density, joint, and muscle strength.
- Reduce incidence of cardiovascular diseases (atherosclerosis, congestive heart failure).
- Reduce incidence of hepatic lipidosis.
- Prevent and/or treat obesity.
- Reduce displacement and other problematic behaviors.
- Mutual enjoyment of bird and handler.

starting spot to enable the beak to get a grip on the object at first. In addition to stimulating beak activity, enrichment can also be provided to stimulate the parrot to manipulate items dexterously with its feet. This activity, referred to as podomandibulation, is often paired with chewing activity as items are often held up for the beak to engage and is yet another characteristic that is unique to parrots. To stimulate this activity, at least some of the chewing items that are provided should be loose to allow for this kind of manipulation.

Free Flight

Free flight with companion parrots is a growing hobby and has recently even been found to benefit the release of captive birds into the wild.[114–116] Internet videos show spectacular footage of birds flying and landing on their owners' hands. There are also free flight clubs, chat rooms, and other groups that allow enthusiasts to communicate about and practice this activity. Avian veterinarians may encounter individuals who are engaged in, or are planning to engage in, free flight with their birds. A basic knowledge of this activity may be helpful in advising these clients as it is an extremely appealing yet also extremely risky practice.

Benefits: As previously described, exercise for most companion birds is often limited to nonexistent. Clearly, free flight offers the greatest possibility for flight exercise in a companion bird, especially for the larger species for which adequate flight space can be difficult to provide indoors. Along with providing exercise, when expanding a bird's environment to include nearly unlimited space, a much higher degree of enrichment becomes possible. Exposure to fresh air and natural sunlight is an added benefit. Flight also provides a significant amount of mental as well as physical activity. Navigation, wind adjustments, and other fine motor skills are partly mental. Allowing these activities can promote mental development that may not be allowed to develop otherwise. One advantage of free flight is more self-serving. Most people who love birds enjoy watching their antics. Free flight expands the range of available activities to watch. The fear induced by seeing a parrot flying away pales in comparison to the thrill of watching them fly back and make a perfect landing on the hand. Free-flighted birds can be more readily involved in daily life. They can go for hikes, hang out in the yard during a picnic, or other outdoor activities. They can play in a tree that is hundreds of times the size and complexity of a commercial play stand (Figure 47.6).

Risks: There are certainly risks involved with free flight. Of course, there is risk inherent in all activities. Sending a child to school, allowing them to drive, or date, or leave the home at all, will expose them to risks. However, to eliminate all risk is also to eliminate opportunities, enjoyment, and any real semblance of a life. Most people choose to teach their children to live in our world and then trust them to do so. The same process can be applied to pet birds. The first thought most people will get when thinking about free flight is that their bird will escape and fly away. Some people seem to think that pet birds dream of escaping and will do so at the very first opportunity that they get. Certainly, the escape of a bird is devastating. It is also the last thing that most pet owners want to happen. However, most escapes are the result of the bird's inability to return rather than a lack of a desire to return. Recall requires the flying bird to navigate, turn, and land correctly. An unskilled bird can gain altitude but may have difficulty slowing, turning, landing accurately, and performing other fine motor skills. This can result in the bird flying straight away from the owner and landing only from exhaustion in a tree somewhere quite far from where the flight began. This may subsequently result in a parrot getting lost because it is lost and lacks the ability to return. One of the essential components of successful free flight is allowing a bird to learn these skills in an area where they will not get lost. Training for free flight can initially start indoors and then

FIGURE 47.6 (A) In addition to the benefits of actual flight, free-flighted birds can utilize a nearly unlimited array of environmental enrichments. This green-winged macaw *(Ara chloropterus)* is playing on a rope ladder in a large maple tree. (B) The same macaw is foraging in a white mulberry tree. (C) Two free-flighted green-winged macaws and one blue-and-gold macaw *(Ara ararauna)* unable to fly accompany their caregiver on a hike.

continue outdoors in large open expanses where there is little to land on besides the familiar owner or a perch. Further skills can be built from there. In fact, birds that are well trained to this behavior have far less risk of escape than an unskilled, untrained bird that accidentally gets out the door. There is little evidence of a homing capability in parrots as is seen in pigeons, although this may be species variable and even among pigeons may be influenced by multiple factors.[117–119]

The risk of predation is also very real. While this can be true for many pets, the small size of most companion birds makes them susceptible to a wide variety of predators. Aerial predators such as raptors are of particular concern. Raptors can prove to be a risk when a bird is in the air and on the ground or perch. Although they are not necessarily predatory toward parrots, crows, ravens, and other birds can present a risk of injuring or chasing away an otherwise well-trained bird. Predation risk cannot be entirely prevented. However, it can be mitigated by several things. First, flying a very large parrot narrows the range of predators that would attack them. For example, few Cooper's hawks *(Accipiter cooperii)* will try to attack a large macaw that is three times its own weight. Second, the flying skills of a bird will reduce the chances that it will be caught by a raptor. The bird can also learn vigilance, safe perching strategies, flock flying, and other skills that can help it evade predation. Flocking is vital to safe, free flying. Single birds are far more susceptible to predation than multiple birds, and thus flying birds alone is not generally advised. Additionally, the presence of the owner can also serve as a deterrent to predators. Often just walking toward a hawk perched on a telephone pole will cause it to vacate the area.

A fast-flying bird is going to be prone to certain accidental injuries. Indoor flying for some birds carries some of these risks as well. Even wild birds are prone to flight-related trauma (see Section 8: The Trauma Patient, and Chapter 50). Anyone who has worked in a wildlife hospital has seen broken wings, broken legs, concussive head injuries, and other casualties. These cannot always be prevented. The best way to mitigate this risk is to control and carefully select the areas where birds are flown. The complexity of the flying environment can be increased as the flight skill increases. Some environments, such as those with large plate glass windows, wind turbines, transformers, heavy vehicular traffic, and other dangerous structures, are best avoided altogether.

Responsible ways to accommodate free flight: Avian veterinarians should promote responsible pet ownership. The last thing that should be encouraged is anything that could contribute to the establishment of feral populations of nonnative species. Many of the pet bird species would not be able to survive in a cold climate. If they can, it should not be assumed that they would be harmless to the local native species or environment. Displacement of native species, distribution of introduced plant species, and destruction of agricultural and native flora are all distinct potential risks. To prevent this from happening, only well-trained birds should be flown outdoors without restraint. Additionally, these birds should be brought into a safe enclosure whenever they cannot be supervised.

Ideal candidates for free flight are birds that can fly exceptionally well. Flying clumsily across the living room is not an adequate qualification. Free flight will require the ability to turn, slow down, move up and down, and otherwise navigate in three dimensions. Fully functional wings are a prerequisite. Trimming the wings will only hinder the development of the required skills. Injuries could also inhibit adequate flight skills. It is generally recommended to start free flight training when the bird is young. Birds learn flight skills best immediately upon fledging, as this coincides with the time that they master these skills in the wild. At this time, birds will also have an innate need to stay with their perceived parent. This allows them to develop outdoor skills while still having a mental "leash" that keeps them close to the trainer. Birds that are easy to find are also helpful. A large, loud, brightly colored bird is easier to spot in a tree than a small, quiet, green-colored bird. Larger birds present less temptation to hawks, especially when flying in a flock. A group of birds is oddly more difficult for a predator to successfully attack. Flying skills, vigilance in looking for danger, and other skills require practice. These skills can be honed while flying closer to the handler, which will serve as somewhat of a deterrent to some raptors.

Free flight requires a great deal of training of both the handler as well as the bird. Classes are recommended before undertaking free flight. There are few trainers who will encourage this practice for liability reasons. However, they should be sought out and consulted prior to beginning free flight with any bird. In addition to learning how to train the bird, a prospective free flight enthusiast should learn how to retrieve a lost bird and get acquainted with the area resources for doing so. In terms of training flight, there are two phases involved.[114–116] First the bird must learn what is being asked, to then acquire the skills to accomplish the task that is being asked. Since the trainer cannot fly, they cannot teach the bird to do so. Instead, a trainer teaches the bird to come to them for a reinforcer. The bird practices the skills to accomplish this in different circumstances, starting with short hops or flights and eventually culminating in longer flights in more complex environments with air currents, sounds, and other distractions.

PHYSICAL ENRICHMENT

Physical enrichment involves increasing the usable space and complexity of the bird's living environment, including the addition of objects (e.g., toys, chewing materials), substrate, vegetation, or other structural elements (e.g., perches, swings and other climbing structures, hiding places) in the living environment. Offering this type of enrichment will positively affect the animal's behavior by increasing its general activity, locomotory, and exploratory behaviors.

Environmental Complexity

The problem with captivity is, simply put, captivity. Restricting the movements of a bird will limit the extent of exposure to the environment. How restrictive this is largely depends on the environmental complexity available to the bird. A good analogy would be incarceration of prisoners. Placing a prisoner in solitary confinement is far more restrictive than housing one in the general prison population, which is, in turn, far more restrictive than someone confined on "house arrest" with a monitoring anklet. No one likes to think of their birds as prisoners, but many companion birds are given environments far smaller and less complex than an average prisoner is afforded.

Size of the Enclosure

Size of the primary enclosure is one of the factors involved in environmental complexity. Generally, larger spaces will allow a greater diversity of activity than smaller spaces. For example, a crossover study comparing the behavior of budgerigars in

standard-sized (0.65 m^3) and larger-sized (128% and 156% of standard) aviaries demonstrated increased flight distance and more frequent flights following access to additional space, while more wing flapping and tail wagging were observed in the smaller aviaries. Following return to the larger aviaries, flight times increased, suggestive of rebound activity and providing some initial evidence that additional space and flight are beneficial to the welfare of budgerigars.[120] Conversely, extremely small spaces will restrict the available options for activity and lead to the development of locomotor stereotypies and other abnormal behaviors, although this may be affected somewhat by other factors.[45] Nevertheless some birds seem to become bewildered by an extremely large cage. This is likely to be due to early experiences or lack thereof. No parrot has a small cage in the wild, and any aversion to open space should be considered a pathological response, borne from developmental stunting. It is relatively easy to find information about the minimum cage size for birds. However, this may not be the best way to look at the equation. A better way would be to determine the maximum space that *can* be provided by the owner. Once that is determined, then the type of bird to be obtained can be chosen to match the available space. Guidelines stating that a cage should be large enough to allow for the wings to extend without touching the sides and damaging the feathers and tail are grossly inadequate as this size significantly limits the bird's ability to move around. Most birds spend 12 to 22 hours in the cage; it is impossible to allow normal behaviors such as climbing or flying in a space barely large enough to turn around in. Whether or not a bird is flighted, a flight cage, open bird room, or aviary is highly recommended to provide ample opportunity for activity.

Cage Design

In addition to the raw space, the shape and orientation of the cage are also important. Two cages of equivalent volume may have very different amounts of "effective" space. The older cages for small birds with a vertical, narrow, cylindrical shape had no more usable space for the bird than a cage of half the height. Generally rectangular cages oriented horizontally provide the most usable space for birds. As many cages are not appropriately sized, alternative housing may be appropriate for some birds. Rooms can be bird proofed so that a larger area can be available to companion birds for part of the day or even for full-time housing. This can be accomplished by paneling walls with smooth, easily cleaned materials. Steel siding designed for barns can be used for particularly destructive birds (Figure 47.7). Areas around windows, doors, attachment points for perches, toys, or feeders, and electrical outlets should be protected using safe materials. The floor will have to be lined

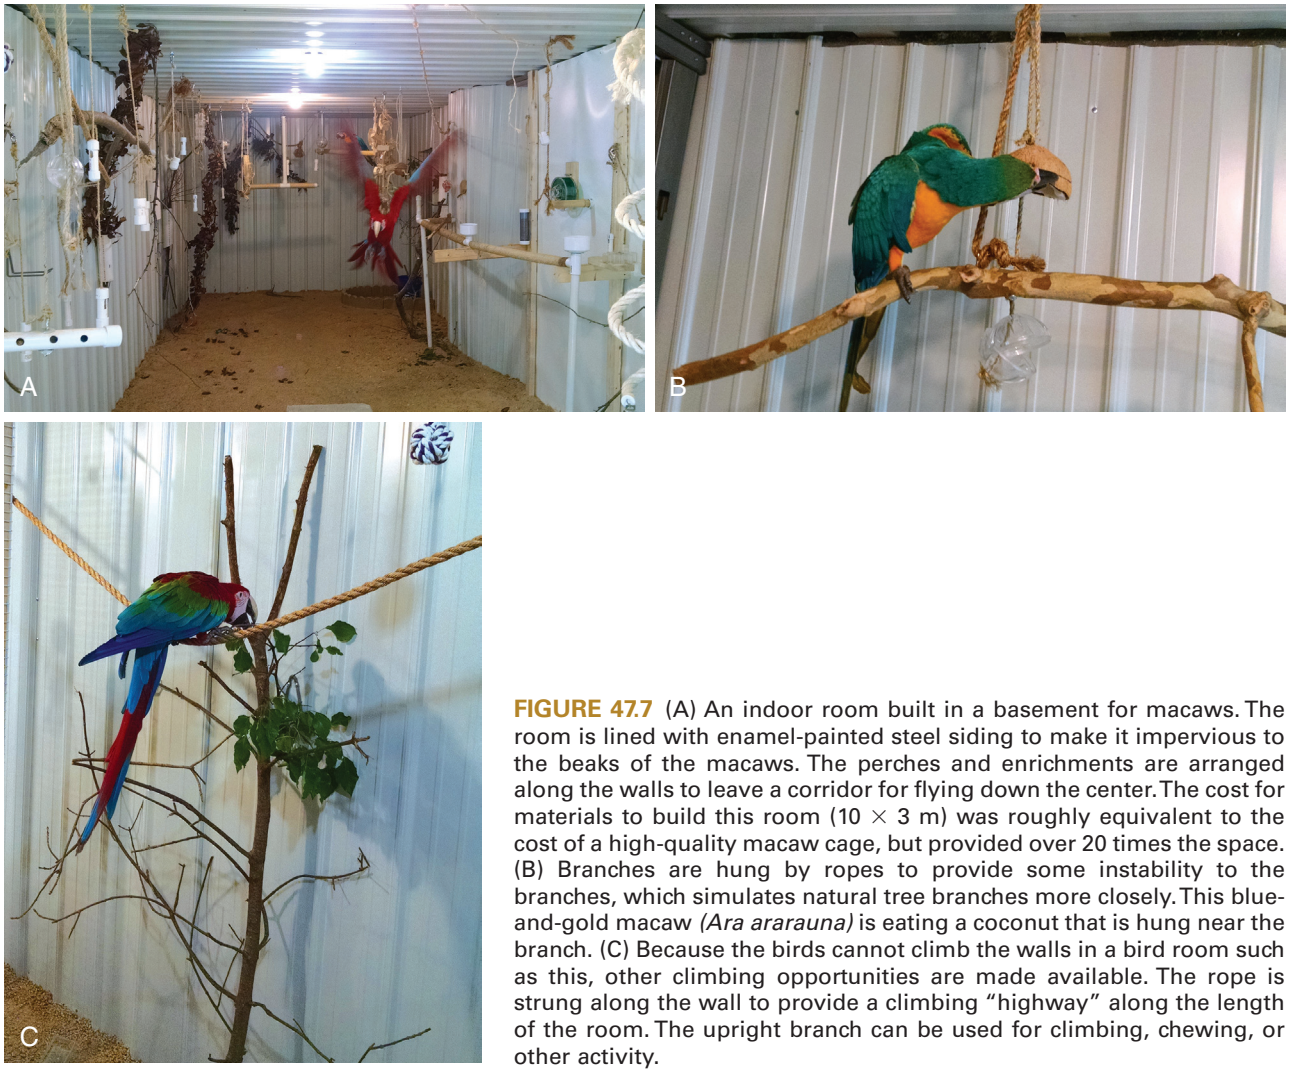

FIGURE 47.7 (A) An indoor room built in a basement for macaws. The room is lined with enamel-painted steel siding to make it impervious to the beaks of the macaws. The perches and enrichments are arranged along the walls to leave a corridor for flying down the center. The cost for materials to build this room (10 × 3 m) was roughly equivalent to the cost of a high-quality macaw cage, but provided over 20 times the space. (B) Branches are hung by ropes to provide some instability to the branches, which simulates natural tree branches more closely. This blue-and-gold macaw *(Ara ararauna)* is eating a coconut that is hung near the branch. (C) Because the birds cannot climb the walls in a bird room such as this, other climbing opportunities are made available. The rope is strung along the wall to provide a climbing "highway" along the length of the room. The upright branch can be used for climbing, chewing, or other activity.

with something easy to clean. While such rooms may require remodeling prior to resale of the home, they will provide a much richer environment for companion birds while in use. Outdoor aviaries are another means of providing additional environmental complexity (Figure 47.8). Size, construction, and furnishing of these aviaries vary substantially as does their purpose. Some provide short-term, supervised outdoor housing, while others are used for full-time housing of the birds. The purpose will dictate the requirements to some extent. Full-time housing will require protection from predators and vermin, a sturdy, beak-resistant design, and protection from the weather. Housing for supervised time can suffice with a simpler construction. Outdoor housing allows the possibility of natural sunshine, fresh air, and a much more diverse array of visual and auditory stimuli. Often, outdoor aviaries are larger than indoor cages. For flighted birds, the transport between indoor and outdoor housing areas should be carefully planned to avoid escapes. Even entry of the caretaker could allow an escape if precautions are not taken. Training a bird to enter a carrier cage for transport would be the safest and least obtrusive way to transport a bird without risk of escapes.

Surroundings

The area surrounding the primary enclosure can be a source of stress or enrichment as well. Well-socialized companion parrots benefit from locating the primary enclosure (cage) in an area of household activity. The area can also be enhanced by placing plants or other interesting items in the vicinity, keeping in mind the propensity for parrots to destroy things they can reach. Ergo, nothing valuable or dangerous should be very close to the cage. Plants can be helpful for shy birds. They can give a sense of visual isolation and security. More on this topic will be discussed under the section on Sensory Enrichment.

Alternative Housing

Play stands are a good alternative site for parrots to spend time. There are numerous arrangements that can be useful. Branches, polyvinyl chloride (PVC) pipe structures, and many

FIGURE 47.8 (A) Outdoor aviaries often provide increased space as well as greater sensory enrichment. The construction is highly dependent on the birds to be housed and the purpose of the aviary. This aviary was constructed from a powder-coated dog kennel. The spacing of the wire is too large for anything other than a very large psittacine bird. It would also not be appropriate for 24-hour daily housing because it would not exclude predators or rodents. However, it provides a pleasant place to spend a few hours outdoors, conditions permitting. Full-time housing would require substantial extra protection and the ability to control climate. A safety vestibule would be essential for flighted birds to avoid escapes as well. Smaller wire spacing is needed for smaller bird species. (B) To extend the season that the aviary can be used, wind blocking materials have been mounted on the exterior of the aviary. These two macaws are acclimated to the weather and enjoy spending time in this aviary when temperatures are as low as 0°C. (C) A smaller outdoor aviary version. This one connects to the indoor bird room in Figure 47.7. The window can be opened and the birds can climb out into the outdoor aviary. Again, this aviary is for short-term supervised activity.

other stands are commercially available or can be readily built to provide a play area for psittacids of varying sizes and activity levels (Figure 47.9). For small- to-medium-sized socialized birds, a basket can be adapted as a portable perch to allow a parrot to follow the activities of the household. Multiple cages can be helpful in some cases, especially in birds that display territorial aggression. A sleep cage will allow the primary cage to be in an area of high activity while providing a dark quiet place to sleep at night. The sleep cage can be smaller and minimally furnished. Alternately, having additional cages in other rooms may just provide a change of scenery. Commuter birds that go to the workplace with the owner have the advantage of staying with their human flock most of the time. The noncontact interaction with various people throughout the day is ideal for well-socialized birds. Travel can be either highly stressful or highly rewarding, depending on the individual

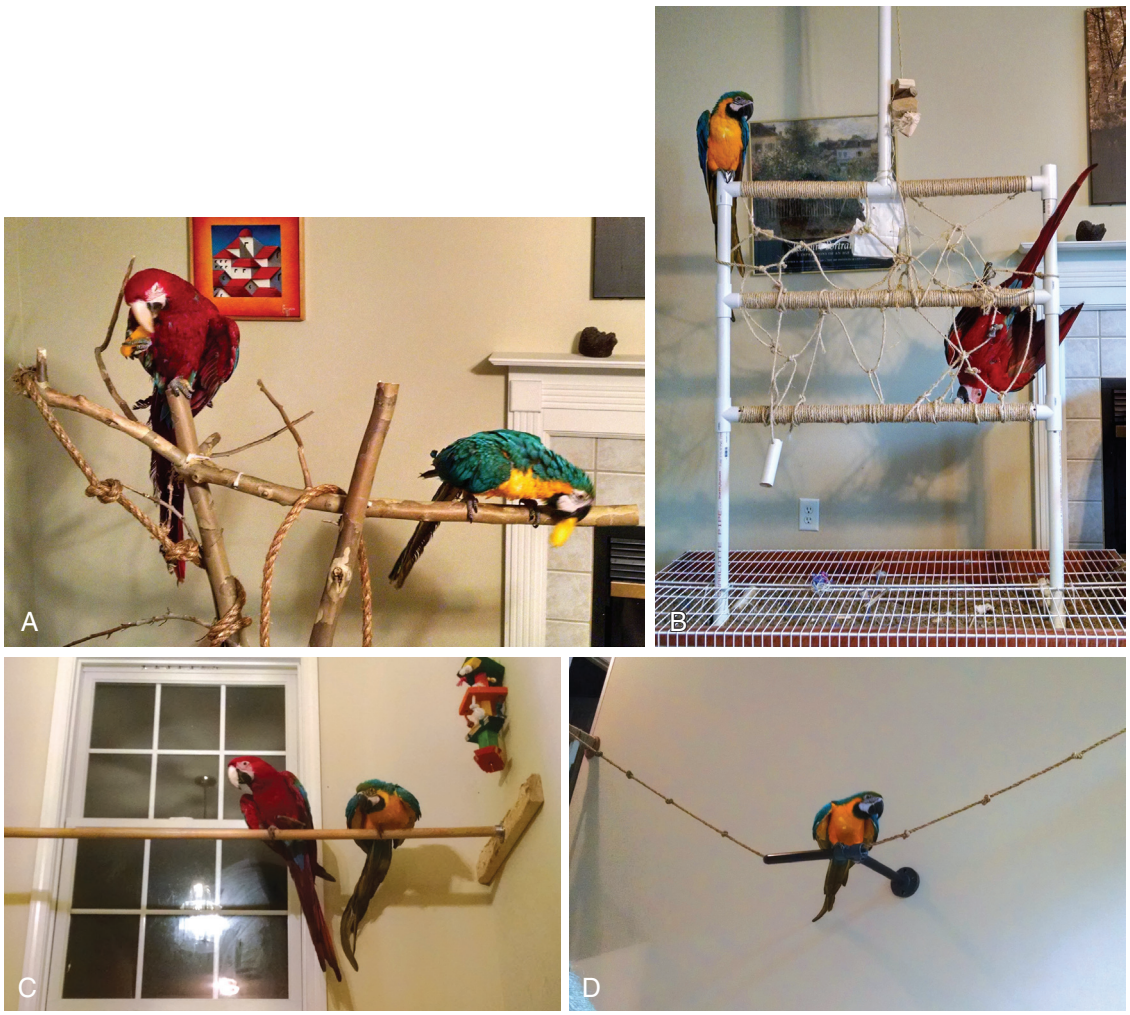

FIGURE 47.9 (A) Play stands allow birds to spend time outside of their primary enclosure. This one is constructed of several natural branches and mounted over a tub to contain messes. Enrichment items can be hung from the branches, and the height is appropriate for training sessions with the birds. (B) A simple play stand constructed of PVC pipe and sisal rope. This stand has multiple levels that allow climbing and a tray base to contain messes. This one has casters to allow it to be moved about easily. (C) This space was above a platform in the foyer of the home. It is largely inaccessible without a tall ladder for people. This was used for flight games with the birds. The birds would fly down to the handler and back up to the perch. There are toys hung at each end of the perch, and the birds could look out the window at the neighborhood. The perch was mounted far enough from the window that the birds did not damage the window frame or ingest anything from the wall. Since the perch is not reachable, this type of play area is only appropriate for birds that are adequately trained to fly to the handler. (D) Additional perches can be mounted in the home. This one has a tightrope walk that provides an additional type of play. Clearly these types of spaces must be carefully applied to prevent injury to the bird, property damage, and other factors. However, they do allow for a greater usage of home space by parrots.

Continued

FIGURE 47.9, cont'd (E) Outdoor play stands can be carefully used with free-flighted birds, harnessed birds, or effectively wing-trimmed birds. Because of the risk of terrestrial and aerial predators, and the ability of parrots to chew through a harness or leash, very close monitoring is needed for this scenario. In this case, a simple play stand is made from an aluminum and fiberglass ladder.

bird and the methods used. Generally, travel will involve more close confinement and sometimes motion sickness, difficulty in delivering water, and other issues. These factors need to be accounted for travel to be a pleasant experience. Certainly, birds that only get into the car to go to the veterinarian will have a more adverse reaction to it than those that go on frequent trips with the owner (Figure 47.10; see Chapter 46). Medical therapies such as metoclopramide or maropitant may be helpful for motion sickness.

FIGURE 47.10 Birds that travel frequently will be less likely to be stressed by it than birds that only travel to veterinary appointments. These macaws are enjoying a camping trip with their caretaker. A screened-in canopy tent provides shade and prevents fly-offs during supervised social time. The perch is a plant hanger that pushes into the ground, wrapped with rope, and hung with simple toys and foragers.

Cage Furnishings

Exploratory opportunities are another feature of avian enclosures that can influence their complexity and positively affect the bird's behavior through increasing behavioral diversity and reducing and preventing abnormal or problem behavior.[21,36,40,42] Parrots have the unique capability among birds to climb using both their feet and beaks. For birds with clipped wings, and those with wing conditions preventing flight, this is the primary mode of locomotion. Provision of cage furnishings that encourage this activity will enhance the ability to explore. Wire cages with horizontal bars provide this opportunity inherently. Additionally, wire cages allow the bird a view of the surrounding area and provide excellent ventilation. However, climbing excessively on the wire of the cage can have deleterious effects on the remiges and rectrices. The feathers often push between bars, bending the barbs back and ultimately breaking them. Alternative climbing opportunities should therefore be available (Figure 47.11). Natural branches are a good addition to most cages. In addition to providing climbing opportunities, they allow for beak activity in the form of stripping bark or chewing the wood. Branches can be oriented horizontally, diagonally, or vertically, depending on the bird's abilities and the configuration of the branches. They can also be hung rigidly between the cage sides or can swing more freely. Very few perches are rigid in nature. If natural branches are unavailable, wooden dowels, cholla cactus spines, rope perches, commercial swings, and PVC pipe can be used. PVC can be roughened with a wire brush to improve grip or can be wrapped in self-adherent bandages or natural twine or rope. Ropes can be used alone as well. The diameter should be appropriate for the size of the bird. The ways the ropes are hung are dependent on the climbing abilities of the bird. Ropes should generally be natural fibers in case the bird chews off fragments and swallows them and to prevent strands from constricting toes. Ladders offer a simple climbing opportunity as well and can be rigid or constructed of rope. Large manila cargo nets are excellent climbing furniture for large birds.

FIGURE 47.11 (A) Climbing opportunities are important for psittacine birds. Perches will be utilized both from the top and the underside by athletic birds. A combination of rigid dowels, rigid branches, springy branches, PVC, bamboo, and ropes can be utilized to provide a means of exploring the environment. Adequate space must be left open for movement of the birds. (B) An outdoor play area for a free-flighted or supervised nonflighted bird. This tree limb mounted in a base has numerous flexible branches suitable for climbing, stripping, and chewing. (C) Sisal rope–wrapped PVC perch. This perch is semiflexible. Rope-wrapped perches should be used cautiously as the fibers can sometimes catch toes. Alternately, PVC can be roughened with a wire brush, wrapped in nonadhesive bandage material, or simply left slippery. (D) This perch is bamboo, hung at a steep angle to provide a sliding option. The same method could be used with PVC pipe. There is also a springy rope perch with a bell in this photo. These are commercially available and appear to be enjoyed by many birds. In the background, numerous branches with foliage are placed to provide chewing opportunities and visual enrichment. (E) Arrangement of this indoor aviary room allows for exploration of the enclosure both by flight and full-length climbing at multiple levels. The window at the end can be connected to a rope to allow the birds to climb out into an outdoor aviary as seen in Figure 47.8C.

One type of item that should be avoided in most situations is a nesting structure. Most species of parrot are quite territorial about their nests and will display aggressive responses to people or even other birds that they would normally tolerate. This is because most species will separate from the flock for breeding. This is the time when the nest structure is usually utilized. Few parrots roost in nests during the nonbreeding seasons. For most parrot species, the nest is a hollow tree cavity. Any hollow item large enough to climb into could be perceived as a nesting structure. The potential nest need not even have an entry hole. Parrots may knock on a cabinet or box and sense the hollow sound. This may be enough to stimulate nesting behavior. Some will chew an entry hole or open a drawer to begin nesting. One possible exception to the seasonal nest usage rule may be Quaker or monk parrots *(Myiopsitta monachus)*. These birds are communal nesters, and nest occupation is not isolated to breeding activity.[121] They also build their nests, which is unique among psittacine birds. Providing these birds with small twigs will allow natural nest-building activity to occur. While this can provide a sort of occupational enrichment, it could create a problem if the bird decides to defend the nest from human caretakers, so the decision to provide nesting materials should be made on an individual basis.

Toys can provide a great deal of activity for parrots (Figure 47.12). There are numerous types of toys that are appropriate for parrots to stimulate different types of activities. Toys should be selected specifically for the species involved and the activity intended to be stimulated. Foot toys simply allow the bird to manipulate the item with the foot. This is usually combined with beak activity or foraging. Birds that would feed in trees in the wild are more likely to use foot toys than ground-feeding species like cockatiels or grass parakeets (*Neophema* spp.). Chew toys are critical for all parrots. These should be constructed of natural, nontoxic materials and should be easy enough to destroy to avoid the bird giving up on the project. Branches with the bark still on them, cardboard, and thin, softwoods are good for birds with low to moderate destructive potential. Harder woods are appropriate for very beaky birds. Long, woven strips of natural materials are available for making toys for parrots. These can be tied or woven into cage bars or other areas. Larger birds can be provided with blocks of untreated lumber, which can be cut into various sizes and presented in a variety of ways, matched to the abilities of the bird. Similarly, natural branches of bird-safe trees can be cut to serve as toys. Wood and branch toys can double as foraging toys by drilling holes in them so that food items can be wedged into them. Puzzles allow the bird to work out a problem to achieve some goal, whether that is a food item, another toy, or just a sound and provide much-needed mental stimulation. Puzzles should be simple at first, gradually increasing the complexity as the bird learns and gains confidence. Some toys provide sensory enrichment and will be discussed in that section. Toys should never crowd the cage to the extent that movement is inhibited. One or just a few of each type of toy can be provided at a given time. Like humans, birds can become bored with continued exposure to the same toys. How many people have home gyms that are collecting dust or serving as a clothing rack? Rotation of the toys will help keep the interest up. However, care must be taken to avoid frightening timid birds with new toys. Some birds will react adversely to new items being placed in the cage. In these cases, toys should be introduced outside of the cage in a nonthreatening way, thereby allowing the bird to approach the toy at its own pace. Bird toys have become somewhat of a cottage industry and costs can range from free or cheap, home-made toys to quite expensive, complex commercial toys. In birds that seem uninterested in toys, teaching or training the bird to use the toy through observational, model/rival methods can be helpful. With some toys, placing small, desirable food items in them can encourage their usage. In addition, parrots can be trained to interact with toys using positive reinforcement and shaping, whereby interactions with the toy are reinforced with food initially. Eventually, the food reinforcer can be faded out, while allowing the reinforcing qualities of engaging with the toy to take over.

Change of Scenery

No matter how interesting a home is, it is always desirable to get away from it occasionally. Even if it seems stressful at first, having exposure to varying environments is critical for pet parrots. The truth is that very few pet parrots will live their entire lives in one home. Their long life expectancy introduces the likelihood of major changes in the home situation. Death or relocation of an owner, rehoming, or other situations necessitate them to be able to adapt to a new environment. When a bird is more accustomed to various locations, this will facilitate transitions to be made smoothly. For well-adjusted parrots, a more variable environment will provide a pleasant stimulation. However, birds that are fearful of new situations may require extra time and behavior modification, including systemic desensitization and counterconditioning, to help them adjust to variations in their environment (see Chapter 46 and *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).[86] If a bird is afraid of leaving the vicinity of the cage, favorite treats can be given as they are carried to the edge of the comfort zone and maybe one step beyond. Close monitoring for fear responses is important and the bird should be returned to the comfort zone immediately if any signs indicating fear are observed. By adequately responding to the bird's behavior and being patient, fear responses may be significantly reduced and eventually overcome.

SENSORY ENRICHMENT

Sensory enrichment involves providing more stimulation to any of the five senses: sight, sound, touch, smell, and taste. Some of these enrichments can double as social, physical, or nutritional enrichment. For parrots, sight, smell, and touch comprise the main senses, thereby emphasizing the need for provision of visual, tactile, and auditory stimulation.

Visual Enrichment

Since avian vision is among the most acute in the animal kingdom, provision of high-quality visual stimulation is considered a critical part of any parrot enrichment program. Visual enrichment can take many forms, including provision of bright-colored toys, moving objects, videos, and mirrors or changing the position of the cage or its furnishings to change

FIGURE 47.12 (A) A sample toy for parrots. This clear plastic sphere can be opened to place food, smaller toys, or other enrichment materials inside. The bird can work these items out through the slots or open the sphere to remove the items. It can be used both as a simple toy or a foraging toy. (B) This toy was constructed using a stainless steel chain, bamboo, driftwood, and scrap, untreated dimensional lumber. Assembly is very simple. After drilling a hole in each item, the chain threads through and the toy can be hung using a stainless steel clip. Because of the tendency for parrots to destroy toys rapidly, the ability to build simple, inexpensive toys is valuable to parrot owners. (C) This bird room has larger PVC pipes mounted to the wall to allow safe fresh foliage and branches to be placed as in a vase. Here, some willow and crab apple branches are provided for chewing. They can be quickly changed when they become depleted. Because this room does not have typical bars, the hanging wire shelves were used to mount commercial toys and perches intended for parrots in cages. (D) This image shows an array of climbing and swinging toys. To the *left* is the bamboo slide and springy rope perch with a bell as shown in Figure 47.11D. There is one branch hanging from a V-shaped section of rope, and then two large branches that are bolted loosely together so that they sway from side to side when the birds move on them. These options provide exercise and build the birds' athletic ability as well as providing entertainment. The birds will flap/swing from one to the next with remarkable agility.

the parrot's line of vision and view. Since parrots are inclined to investigate and subsequently destroy items within their reach, visual stimuli need to be either out of reach, safe enough to be chewed, or both. Both visual and auditory stimulation will be affected by the environmental complexity. The activity and scenery surrounding a bird's cage should be interesting but not stressful to the bird. Cages usually should be in areas with a great deal of household activity. This allows noncontact interaction with people in the household, which provides both visual and social enrichment. In households where no one is home for most of the day, alternative stimuli should be provided. Television, other pet birds, a view of a bird feeder outside, or other interesting stimuli may be useful. As previously mentioned, plants surrounding the cage location can provide visual enrichment and a sense of security. However, care must be taken that these stimuli do not evoke fear responses, at least not on a constant basis. One may think that watching an outdoor bird feeder would be a great stimulus, but seeing birds snatched up by Cooper's hawks may be more like a horror movie to some birds. This is not to say that brief exposure to threatening stimuli is harmful to a psychologically stable bird, but this will depend on prior experience and the individual personality of the bird. Indeed, these stimuli, and the learned response to them, are essential to the survival of birds intended for release or even for those that engage in free flight.

Some toys provide visual enrichment. Mirrors give a visual representation of a bird and many budgerigars and cockatiels will spend hours talking, singing, and interacting with this image. This can sometimes go to undesirable extremes if the bird begins regurgitating to the mirror or loses interest in live avian or human companions. Birds generally have excellent color vision, although their perception is somewhat different from that of humans as they can see in the ultraviolet and fluorescent spectra.[122] Many bird toys are brightly colored, and there is some evidence that certain colors may be preferred for some types of toys. However, this may not be consistent between individuals or even between objects. Orange-winged Amazon parrots preferred wood blocks that were yellow over red, green, blue, violet, or natural colors. The same was not found with rawhide squares or sisal rope.[27] Because this preference was fairly precise for a particular object, and in a single species, it would seem advisable to provide a variety of colors to allow individual selection of preferred colors. For humans, video viewing is a common form of enrichment (or at least entertainment). There is little information about the use of this method in birds, although anecdotally, one of the authors has observed several parrots (e.g., Amazon parrots [*Amazona* spp.], Grey parrots, cockatoos [*Cacatua* spp.], caiques [*Pionites* spp.], cockatiels) favor specific video clips on YouTube. In fact, one bird was even observed to demonstrate attention-seeking behavior toward the owner, which it redirected toward the television, and once the television was turned on by the owner its behavior became calmer and focused on the video clips that would be played. Chimpanzees *(Pan troglodytes)* utilized a television in both single and group housing situations.[123] While similar studies may not exist in parrots, it appears they are able to translate three-dimensional shapes to two-dimensional representations of them.[124] Also, parrots were able to use a touchscreen device, suggesting that two-dimensional viewing is recognized.[29] However, parrots failed to learn language through watching video.[125,126] Many companion bird owners watch television with their birds. Whether this provides enrichment for the bird is a potential avenue for further studies. Pending such studies, the use of video devices for birds can be considered when access can be safely controlled to prevent damage to the device or toxic ingestion or electrical damage to the bird.

Auditory Enrichment

Auditory enrichment, which can be achieved by provision of sound-producing toys, vocalizations of other birds, animals or humans, or radio (music) or television sounds, has particular importance for psittacine birds. Parrots are known for their vocal capabilities as much as for any other reason. The term parroting is used for the mimicry that these birds are famous for. However, they can do far more than mimic. People who live with parrots have long known what science has now demonstrated. Studies in wild parrots show a great deal of vocal variation and even regional dialects.[127–132] Other studies have suggested specific purposes of natural vocalizations.[133–135] While we have only begun to understand avian vocalizations, some parrots have shown the capability to use and understand human speech.[77,94,136] Parrots also have a strong affinity for music.[31,32] They are one of the few groups of animals that have shown the ability to dance in time with music, usually preferring beats that correspond best to their own vocal timing.[137,138] Other studies showed large interindividual differences with no specific preference for specific beats, though continuous beats were preferred over single beats.[138] Provision of auditory stimuli can take many forms. The ideal situation is direct social vocal interaction. Parrots have been shown to learn vocalizations best from social engagement with the teacher.[88] This makes sense given that the purpose of the vocalizations is communication. Whenever possible, birds should be near other birds or their human family, depending on their early socialization. This allows frequent vocal interactions, even when more direct interactions are not possible. When this is not possible, other options can be used. Simple toys like bells can allow birds to make some sound. Birds can either ring the bell or in some cases use it as an echo chamber for their own vocalizations. Years ago, a toy shaped like a hat was marketed for this purpose. It provided the echo chamber for the bird and the amusing image of a bird wearing a hat to the owner. A child's xylophone could be provided to allow the bird to create sounds. Radios or media devices can be used to play a variety of sounds, including talk, bird vocalizations, nature sounds, and music. One study showed a hyacinth macaw *(Anodorhynchus hyacinthinus)* from a zoo use two interactive devices to control its sonic environment,[80] while another demonstrated that Grey parrots learned to use a touchscreen device to select music that would play when they touched an icon.[29] While it would require some setup to protect the device and the bird, and a bit of training, it allows both auditory enrichment and occupational enrichment concurrently. Other technology now allows two-way audio using pet or security cameras. Some pet cameras also allow two-way video and even dispensing of treats to allow simulation of more direct social interaction.

Tactile Enrichment

Touch can be a potent enrichment. While there is little research available on this topic in birds, there is ample evidence

of its benefits in rats.[139] This benefit may be species-specific or associated with social cues, however, and inanimate tactile sources may not be as effective.[140] There are numerous tactile stimuli that appear to be pleasant to birds. Tactile interactions between humans and birds are usually mutually enjoyable. However, care must be taken to avoid simulating the pair bonding activities when preening a bird. Human-imprinted birds can develop a variety of medical and behavioral problems when their reproductive hormones are stimulated. Most touch should be directed to the head and neck. Additionally, this should be applied sparingly with more active interactions, such as training and verbal play, used more extensively. Some birds will provide self-enjoyment by scratching their head feathers slowly with a foot. Others will use a stick or other tool to provide this stimulus. Many of the available toys have the purpose of tactile stimulation of the beak and tongue. Providing a variety of materials in toys allows the tongue and beak to sense a variety of textures. Some toys appear to have a texture that birds enjoy touching with the beak. Many parrots appear to enjoy whittling wood into small fragments, often giving as much time and attention to a piece of wood as they would a favorite food item. Even clean, nontoxic stones can be enjoyed by some parrots. This activity doubles as self-maintenance by providing excellent wear on the beak keratin. Bathing is a natural part of most species' normal grooming, and many appear to enjoy the sensation. Bathing should be provided in a way that is preferable to the bird. Some options to try would be showers, a fine mist, open shallow water, or even wet vegetation.

Olfactory Enrichment

The relatively small olfactory lobe of most avian species has led to the belief that the sense of smell is not important in birds. In truth, various bird species use olfactory signals to communicate, to find food, to navigate, and possibly for other purposes.[141–148] Unfortunately, studies on olfactory sensation in psittacine birds are scarce, with only one study published on olfactory sensitivity in kea *(Nestor notabilis)* and kaka *(Nestor meridionalis)*.[149] Though the sample size was small and responses differed across individuals, both species were able to discern scents and detect novel sense, indicating these species possess functional olfactory abilities. Taking into account that many parrots have specific scents detectable by their human companions, it would seem logical that these serve a purpose as communication chemicals. Applying this to enrichment is somewhat more challenging. Because of their sensitive respiratory system, the use of any volatile materials, candles, or other perfumes is not recommended. Applying the secretions from the uropygial gland of the same or other bird to objects may provide some olfactory stimulation. Care must be taken when collecting this secretion so that the bird does not become overstimulated. Additionally, the purpose of these cues can be associated with reproduction and their use could promote undesirable behavior as well. The use of aromatic foods and herbs can provide other olfactory sensation, although individual preferences may be challenging to identify and meet.

The number of taste buds in birds is small compared to that in mammals. However, there is ample evidence that birds are capable of distinguishing taste and observably have taste preferences. Although some food preferences may involve visual, olfactory, or tactile sensations, some do appear to involve taste. Hispaniolan Amazon parrots *(Amazona ventralis)* were able to distinguish between levels of sodium in diets, and cockatiels can detect plant chemicals in water by taste.[150,151]

Most olfactory enrichment is provided by providing birds with different flavored foods, although it is possible to provide taste or olfactory enrichment without food by rubbing a small amount of spice (e.g., cinnamon, nutmeg) onto chew toys, or exposing birds to nontoxic (natural) scents. Companion parrots observably enjoy certain food items and often vocalize their enjoyment. The challenge with providing taste enrichment is in doing so without disrupting the nutritional balance of the diet. Generally, vegetables are beneficial to the nutritional plane of companion birds. Finding vegetables that are preferred by a particular bird can be challenging sometimes but can provide both micronutrients and enrichment. Fruits are usually preferred by most parrots, but the sugar content dictates that they must be used more sparingly. Parrots do appear to enjoy peppers and while capable of sensing capsaicin, they do not appreciate it as an irritant.[152] Formulated diets have some differences in taste, and some have natural or artificial flavors added to provide some taste enrichment as well. Provision of a variety of formulated diets has some distinct advantages. In addition to the taste differences, most have mild variation in nutrients and almost always have texture, size, and visual appearances. The differences can provide enrichment, but in addition, most avian diets are manufactured by small companies, and a few have become unavailable. Birds accustomed to multiple diets will adapt much easier than those that have only eaten one type.

NUTRITIONAL OR FORAGING ENRICHMENT

Avian veterinarians have always concerned themselves with nutrition. Provision of all required nutrients is critical to the physical health of any animal and the effects of imbalanced diets are all too familiar to the profession. Nutritional balance can be achieved by giving appropriately formulated commercial diets. With extruded or pelleted diets, each bite generally has all the required nutrients. If anything, the amount provided for some nutrients (e.g., vitamin D, vitamin A, calcium) exceeds the amount that is necessary for maintenance in many birds. Other formulated diets take whole seeds and/or pellets and bind them together into a ball or cake with added supplements. Other diets comprise seed mixtures with supplements concentrated in nuggets. With these "fortified seed mixtures," all the components of the diet must be consumed to provide these same nutrients. This rarely happens since most owners feed far more of the diet than the bird will consume. This can lead to the same nutritional deficiencies generally seen with all seed diets. To best provide for nutritional needs of the bird, feeding a primarily pelleted or extruded diet as the base is recommended, with a defined small amount of unsupplemented grains or seeds added to slightly dilute the nutrients. Vegetables and fruits are added to provide vitamin precursors, antioxidants, and other phytonutrients. The total amount of food provided should be calorically appropriate for the bird. It is unnecessary for birds to have unlimited food in front of them 24 hours a day. This common practice has led to obesity, constant reproductive stimulation, and birds that are poorly

responsive to training techniques. The amount of food that a bird is eating should be determined, and if the body weight is appropriate, the food should be trimmed to exactly what is being consumed, with little or none left at the time that the food is refreshed. However, there are times in a bird's life when this amount will not be appropriate. Birds that are growing, raising offspring, or laying eggs may need additional calories or specific nutrients (i.e., calcium for egg laying), as would birds that are molting, ill, or injured, and diets for these birds should be adjusted accordingly.

Food is important for more than nutrition. In humans, food is a part of every culture. Likewise, food for parrots is more than just nutrition. Feeding takes up a large part of the day. Most birds feed socially. To fill a bowl with a uniform nugget does not provide the same opportunities for these birds. To improve the psychological benefits of the diet, several strategies can be employed. Variation of the diet is one method of making it more interesting. Even with a diet composed of 100% formulated nuggets, variation can be offered (Figure 47.13). Using several varieties not only provides some diversity but may also be a good safety precaution. There have been a small number of recalls of formulated diets over the years where a mixing error has caused dangerous excesses of some nutrients in a diet. Using a variety of types would cut the total amount of any one diet that a bird eats. Extruded diets come in many forms and shapes. These may provide the ability of the bird to hold the food in the foot and manipulate it. There are a variety of sizes of most brands of pellets as well. Even the flavors and scents of the diets vary. Some have food coloring added. Vegetables can be given whole or cut into different sized and shaped pieces. Most wild birds will have variable diets depending on the season, so temporal variation of the diet by securing seasonal produce for the birds may be beneficial (Figure 47.14).

FIGURE 47.13 Even when using formulated diets as the main component of the diet, a wide variety of physical forms can be found. Pellets and extruded diets are available in numerous sizes and shapes. Some are colored with food coloring or natural colors. Pressed, supplemented food balls and cakes are also available. This variation allows usage in various foraging devices and larger sizes encourage podomandibulation. Both increase the time spent feeding and provide challenges for a bird.

FIGURE 47.14 Provision of seasonal vegetables allows for some temporal variation in the diet. Many parrots are reluctant to try new foods, especially the first time they are offered. Sometimes with continued offering, the food will be accepted. Often, a different presentation or preparation of the food will encourage consumption. For example, soft, cooked sweet potato may be preferred over crisp, raw sweet potato.

Insectivory appears to be relatively uncommon in psittacids. Those species that do engage in eating insects generally consume larval invertebrates in plant galls or other such areas. Because of this, chasing and capturing are not major components of the process. Species that have been observed engaging in insectivory include blue-headed pionus parrot *(Pionus menstruus)*, peach-fronted conures *(Eupsittula aurea)*, Meyer's parrots *(Poicephalus meyeri)*, and keas.[153–156] Because the process of acquiring the insect prey is very much similar to that of acquiring plant-based foods, and because of the poor nutritional value of many commercially available feeder insects, provision of this food type has not been widely considered for psittacine birds. However, it may be worthwhile considering feeding insects to species for which it matches their natural diet, especially if breeding is desired. If electing to do so, insects should be fed very sparingly, and be selected for appropriate calcium-to-phosphorus ratio, or be supplemented appropriately.

In addition to variation in the types of food offered, nutritional enrichment can also be provided through variation in the way food is presented to the animal (Figure 47.15). Traditionally, parrots have their food presented to them on a silver (stainless steel) platter, with food being provided food in a single bowl situated a few inches away from a water bowl. While this is convenient for the caretaker, this type of feeding eliminates most of the parts of foraging that wild parrots would engage in, and typically results in companion birds fed this way spending only a small fraction of the time consuming food that a wild bird would in seeking, finding, and obtaining food.[73,157–160] This creates an enormous void in time that often is filled with displacement behaviors, including FDB, and oral and locomotory stereotypies. Moreover, the provision of readily available food fails to challenge the intelligent minds of parrots that are accustomed to spending energy to obtain their daily food requirement.

Foraging opportunities appear to be a requirement for healthy behavior in parrots. In fact, parrots will often preferentially consume food that they worked for, even when food is

FIGURE 47.15 (A) A simple forager can utilize two food items. In this case, a dried date is wrapped in a cabbage leaf and held together with a cardboard tube. The wrap can be readily seen and encourages usage. These will become more quickly used once the bird knows about the more desirable inner food. However, the leafy wrap is often wasted. (B) A kabob of fruits or vegetables can provide simple foraging as well. Depending on where it is located, the challenge here is just to get to it and to hold it as the food is eaten from the skewer. (C) This item was a more complex foraging option on purchase. Each chamber had a different mechanism to open it. One had a sliding door; two had hinged doors oriented in different directions and another a rotating door. In typical parrot fashion, this one was quickly broken and only the hinged door remains. It was also originally mounted on a spinning mechanism, which was also quickly broken. However, it was remounted to wood using a bolt and it still serves as a simple forager. (D) This is another simple device. It is a small cup, made from polyvinyl chloride (PVC) pipe and fittings, suspended from a rope. Food is placed inside the cup. The bird must bring the cup up to the perch, and either reach into the cup or tip it to drop the food into their mouth. PVC pipe is a durable material that holds up well to parrot beaks. (E) This forager is a step up in complexity. This one is closed at both ends and only has a single hole for the food to be removed. This one requires the bird to maneuver the pipe just right so that gravity will put the food where it can be reached with the tongue or it drops into the beak. (F) To add an extra step to (E), a small plug of wadded paper can be placed into the hole. It does not add a large challenge, but some birds will spend some time chewing up the paper before proceeding to the food extraction. Another extra step that can be added is to place a smaller-diameter pipe inside the outer pipe. The inner pipe has a similar hole drilled in it. The bird has to align the holes to remove the food. (G) A commercial foraging toy. This one has five chambers that can have food or toys added. The bird must rotate the wheel to open each chamber. (H) This is a two-stage foraging toy. Food is placed in the top. The bird must slide a lever to drop the food into the lower chamber and then must pull a rope on the bottom to release the food into the cup where they can access it. A toy like this may be too challenging for some birds, particularly those that have not had previous foraging opportunities.

readily available in an open dish (i.e., contrafreeloading).[10,19,161,162] By providing foraging opportunities, making collection of food more of a challenge, feeding time can be increased 2- to 4-fold, hence being brought closer to what would occur in the wild.[15,16,33,37,163]

The process of foraging includes numerous activities. Any of these can be manipulated to provide a challenge to a bird, although some are more difficult to manipulate than others. Some parrots travel long distances from their roosting sites to foraging sites. The location of these sites may be culturally known by the flock, or previously discovered by the individual. Upon arrival to the foraging site, the work is not done. The bird must seek and recognize the food among a great deal of inedible material. This may require further flight, climbing, hanging, or even digging or burrowing. Once localized, food can be procured by detaching it from a branch by plucking, pulling it out from in between substrate or inedible materials, or picking it up from the ground with the beak. Some food will be eaten right where it is found, but sometimes it will be transported to a safe perching site for consumption. Often, food is encased in a tough rind or shell that the bird must penetrate to get to the edible portion. Parrots will often use their powerful beaks to crack or puncture the shells or use it to peel off the casing to then extract the food item hidden within. During this process, parrots commonly manipulate the food item simultaneously with their beak, tongue, and feet, a process called podomandibulation (Figure 47.16). As a final act of foraging, the food is broken down into smaller pieces that are then consumed. Table 47.3 lists the phases of psittacine foraging including ways to manipulate these to create challenges for companion birds.

The importance of foraging for captive animals has become more obvious over the past decades.[10,16,33,34,37,44,163–165] The difference in the time budget spent on this activity in free-ranging versus companion birds may be the greatest of any activity. This may be a significant reason for the frequency of displacement behaviors. Some research has shown foraging to reduce stereotypic and FDBs in parrots.[34,44,164] For these reasons, foraging should be considered the most important enrichment activity that can be provided to any captive parrot. It is important that clients be guided on how to institute an effective foraging program. Simply telling owners to supply the bird with foraging toys will not be effective nor suffice. Foraging items should first and foremost be easy for the caretaker to fill, sanitary, safe, and appropriate for the level of the birds' skills. In addition, the various types of foraging activities should be considered (Table 47.3), which then need to be matched to the feeding behavior of the species and the individual. For instance, many popular psittacids (e.g., budgerigars, cockatiels) are primarily ground-feeding birds. They eat a lot of grass seeds and other items they find on the ground. These birds usually do not possess extensive skills in holding food in the feet or opening complicated nuts. However, they do have keen eyes for spotting food particles on the ground. Hence, for these birds, foraging is best provided by offering food in a foraging tray or filling a flat pan with shredded paper or paper litter, in which food can be sprinkled to allow the bird to search, find, and select these food particles. Tree-feeding birds, by contrast, may collect food from the ground but would take it up in the tree, where they will sit down on a branch to eat it. Sometimes they may find food items in the trees themselves, which can be mimicked by hanging food items from the top of the cage or aviary, stimulating the parrots to stretch out while perched or climb or hang on the sides or roof to reach the food. Often, tree-feeding birds will have greater dexterity with the foot and beak. They use these simultaneously to manipulate and open nuts. Several parrot species, especially the more intelligent ones, also exhibit problem-solving abilities to retrieve their food. One of the commonly used tests to investigate an animal's problem-solving abilities is the so-called string-pulling paradigm, which demonstrates the animal comprehends that an out-of-reach food item can be reached by pulling in the string attached to it. Successful completion of this task has been reported in many psittacine species, including keas, green-winged *(Ara chloroptera)*, hyacinth, Lear's macaws *(Anodorhynchus leari)*, blue-fronted Amazon parrots *(Amazona aestiva)*, Grey parrots, Goffin's cockatoos *(Cacatua goffini)*, greater vasa parrots *(Coracopsis vasa)*, yellow-crowned parakeets *(Cyanoramphus auriceps)*, and spectacled parrotlets *(Forpus conspicillatus)*.[166–175] In addition, several species (i.e., hyacinth macaw, palm cockatoo *[Probosciger aterrimus]*, sulphur-crested cockatoo *[Cacatua galerita]*, Goffin's cockatoo, Grey parrot, yellow-crowned Amazon parrot *[Amazona ocrocephala]*, greater vasa parrot, and kea) have been observed to perform even more complex tasks, such as manipulation, manufacturing, and use of sticks, pebbles, or other tools to retrieve food. As such, these birds are more adapted to common commercial foraging toys.[176–184] Regardless of the type of enrichment provided, foraging should always be introduced as a graduated program. A novice forager should not be given a complex foraging toy. Their inability to achieve rapid success may frustrate them and cause them to give up. Further

FIGURE 47.16 Podomandibulation, or the simultaneous use of the beak and the foot, is a unique feeding habit of parrots. Provision of larger food items encourages this activity and effectively increases feeding time.

TABLE 47.3
Different Activities Related to Foraging and Feeding in Psittacine Birds

Foraging Aspect	Definition/Reasoning	Provision in Human-Managed Birds
Commuting	Travel from roosting or nesting site to the site where food can be found. May be cultural or individually learned.	Place foraging opportunities in multiple areas throughout the habitat of the bird. Requires large enclosure or multiple foraging sites. Ability to fly, climb, or walk to the area needed.
Searching	Localization of food or a potential food source. Within a feeding area, multiple foci of food may be present and dispersed among the numerous inedible materials that are present in their vicinity. Some birds may use their digging or burrowing capabilities to uncover food items.	Scatter feeding is one method. Food can be hidden out of sight or mixed in with safe, inedible material such as bedding, shredded paper, wooden beads, small stones, etc. For tree-feeding species, foragers can be interspersed with other types of toys.
Selection	Birds learn to recognize and identify edible from inedible items in the environment, or differentiate between different food items. They often will be able to distinguish between an empty shell, unripe fruits, etc. and ones that are full of appropriate food. This may be identified by weight, sound, color, or other characteristics.	Companion birds can quickly learn to recognize foraging toys. They may be able to tell if there is food in them by sight, shaking them to hear the nugget, or just trying to extract. Wrapping food in paper is a common foraging option. Many birds palpate the paper to find the nugget of food. Providing a mixture of different food items is another possible alternative.
Procurement	Acquisition of a food item, which may include activities such as plucking, pulling, or pecking. Some food items would be in positions where feeding would not be safe or comfortable. The food may be carried to another perching site to consume.	Some foragers should be in challenging sites that require hanging or climbing to reach. In these cases, most birds will carry the food to a perch for consumption. Many birds like to dunk or soak pellets prior to consumption. Separating the water from the foragers will require some movement to allow this behavior.
Extraction	Many psittacine food items are encased in shells or rinds. The beak and tongue are highly skilled at peeling, puncturing and cracking these open and extracting the food items localized inside.	A limited number of shelled nuts or seeds can be provided for this purpose. Alternately, wrapping pellets in paper or other safe materials can substitute for some of this activity. Many puzzle feeders in which food can be hidden attempt to mimic this process as they require the bird to open a lid, drawer, or lock to then extract the food that is placed inside.
Processing	Rather than consuming food in whole, parrots usually break down food particles in smaller bite-sized pieces before consuming them. Larger food items are often held in the foot, while being manipulated with beak, tongue, and foot (podomandibulation). This is especially true in psittacids that feed in trees. Ground feeders are less likely to engage in this.	Provision of large nugget sizes will encourage this behavior, as would provision of whole, larger-sized fruits, vegetables, and whole nuts.

instructions for clients to train their birds how to forage are found in Box 47.4.

Initially, birds may be trained to develop foraging skills using their favorite treats to help increase their motivation to forage, to then expand to regular food items. Once a bird gets proficient with foraging, the original food dish can be eliminated, and all the food can be offered via foraging opportunities. There are unlimited ways to present the food. Sometimes the food can be hidden in other toys, in the bedding, in holes drilled in branches or perches, or in other places that the bird can explore. Some spots will not have any food, others will, which will help to simulate the natural environment and scarcity of food. Some of the foraging sites should be relatively easy, and some should be difficult. Foraging should always continue to challenge the bird. Ideally, finding and consuming the food should take up a larger portion of the day. Although it would be difficult to achieve the 6 to 8 hours of foraging wild birds may get, even 2 to 3 hours would be a huge benefit. Combining several foraging activities in one enrichment and distributing food across multiple items will be helpful to achieve this goal.[163] In addition, enrichments that will only provide access to smaller portions of the food at a time (e.g., pipe feeders with small holes that will only release a few pellets upon rolling or swinging) or those that are made of chewable materials that will require a great deal of time to chew through will be more effective in increasing foraging times in the long term compared to treasure boxes or other items that may initially require a more complex action but are readily performed once the bird knows the trick.[16]

PROMOTING SELF-MAINTENANCE BEHAVIORS

Preening and other self-maintenance behaviors are critical for health and welfare. Preening takes up a large portion of the waking hours of wild birds and helps to maintain feather

BOX 47.4 INSTRUCTIONS TO CLIENTS FOR INITIATING FORAGING ACTIVITIES

Wait until your bird is mastering one step before moving to a more challenging step.

- Step 1: Reduce the total amount of food to just what your bird finishes in a day. Measure the food before putting it in the dish. Then in 24 hours measure what is left. If there is no food after 24 hours, give a little more the next day. If there is some food remaining, further reduce the food.
- Step 2: Divide the food. Get 5–10 smaller dishes (preferably ones that fit in a ring holder). Initially put most in the original dish and just a sprinkle in each of the others. Once your bird is eating from all the dishes, start to divide the food more evenly between them.
- Step 3: Mix in some nonedible materials as distracters. Some choices would be wooden beads, paper litter, or paper scraps. Initially just put a few in each dish. Gradually add more so your bird has to carefully sort through to separate food from debris. Alternatively, you may sprinkle the food on top of the inedible materials.
- Step 4: Cover the dishes. Take a paper towel, put it over the dish, and tuck into the ring holder. If there is no ring, a rubber band or nontoxic paper tape can be used. Now your bird must chew open the dish, then sort through the distracters to find the food. Initially you may motivate your bird by only covering the dish partially with a thin strip of paper, to then gradually increase the portion of the dish that is covered. Once fully covered, a small hole can be made in the paper to help guide the bird. For more experienced birds, thicker pieces of paper or multiple layers can be considered to increase the level of complexity.
- Step 5: Wrap individual food items. Take a few food items and put these in a small piece of paper and twist the ends. Place these in the dish with the other food items and the distracters.

Other ideas:

- Try hiding a few of your bird's favorite foods on or in other toys, cardboard boxes, etc. This can encourage play and a more inquisitive nature.
- Put a food nugget in a paper cup and then roll the top of the cup around a cage bar.
- For a big challenge, hang a food item at the end of a string or rope, so the bird has to pull it up (or bite through the string to let it drop).
- There are lots of "puzzle toys" available for sale. After your bird masters the steps mentioned earlier, try a few of them to see what works best.
- Try a foraging tree. Set up a stand or tree with lots of little spots to hide a food nugget. Put food in some but not all of the spots. This keeps the bird guessing and looking.

quality, which is critical for their survival. Generally, no encouragement is required for birds to preen themselves. If there is sufficient space and the bird is healthy, preening will proceed normally. Birds housed together will allopreen as well. Although most birds like to have their head feathers preened by a conspecific or a human companion, the feathers will develop normally without this assistance. Allopreening should not be forced upon the bird in the name of removing the pin feather sheaths. Premature removal can be uncomfortable and prohibit full development of the feather.

Bathing also is an important component of skin and feather care, not just to soften and remove dirt and debris from feathers and the skin but also because it encourages preening. For many birds, bathing is an excellent and vigorous activity. Generally, the use of plain, cool-to-lukewarm water will suffice, with no need to add soaps, pesticides, or other additives, as these can potentially be harmful. Birds vary tremendously in the method of bathing. Some birds will prefer fine misting or perching in the shower for secondary spray. Some will bathe in wet grass or washed greens; others rather would like to sit in shallow water and splash around. As a result, different bathing methods should be tried until the preferred method is found.[185]

Toenails are maintained by natural wear, but normal wear produces very sharp tips. This is true with the "grooming perches," sandpaper perch covers, as well as other surfaces. Rough surfaces like these can damage the skin of the feet with prolonged exposure and should not make up a large proportion of the available perching space. Although sharp nails are normal for the bird, they are highly uncomfortable for the handler. Unless the owner wants to wear falconry gauntlets, the nails will therefore need to be kept trimmed. As previously discussed, birds can be trained to do this cooperatively (see Chapter 46).

Beaks also can be maintained by normal activity. This requires that some abrasive surfaces be made available. Using a bowl of stones as a foraging site, providing pumice stones, lava stones, and other items may be all that is required. Some birds may even take a stone (small enough to hold, too big to swallow) in the beak and scrape the stone for several minutes.

CREATING ENRICHMENT PROGRAMS

When creating enrichment programs for individual companion birds or groups of birds, a model that is recommended is the SPIDER (Setting goals, Planning, Implementing, Documenting, Evaluating, and Readjustment) model (Box 47.5).[50] The veterinarian can be involved in the goal setting, planning, and in the evaluation and readjustment phases. Some general recommendations that can be helpful for this process can be found in Box 47.6. Proper implementation furthermore relies on adequate implementation of the enrichment plan by the caregiver, who should receive clear (written) instructions on what and how enrichment should be provided to maximize chances of success.

First, the specific goals for the program should be outlined. These goals can be anything from reducing an undesirable behavior, to occupying a given proportion of the day with activities. Goals should be as concrete as possible and readily measurable. Larger, complex goals are ideally broken into smaller, achievable goals that move toward the goal. For instance, a goal of reducing FDB might be broken down into smaller goals that include an increase in foraging time, a reduction of repetitive behaviors, and an increase in bath time.

While planning the enrichment program, the available space, resources, and caretaker time should be considered. Additionally, the species' biology, the individual's temperament, and early life experiences should be carefully considered, as these in part help determine the value of environmental stimuli for the bird *(nature* vs *nurture)*. For example, the value of enrichments will be higher if these are biologically relevant to the species, hence warranting emphasizing the importance of gaining more in-depth knowledge of the species' natural habitat,

BOX 47.5 THE "SPIDER" FRAMEWORK FOR DEVELOPING AND MAINTAINING A SUCCESSFUL ENRICHMENT PLAN[50,186]

S—Setting Goals

Gain in-depth knowledge of the individual (e.g., rearing history, socialization, early life experiences) and natural history (e.g., natural habitat, dietary preferences, social structure, daily activity patterns) of the species involved, which will help determine its biological, social, and cognitive needs. Next, identify clearly which behaviors the enrichment intends to encourage or discourage. Goals should consider the typical time budget, frequency, and variety of behaviors in a given time period.

P—Planning

Create an enrichment plan to achieve the desired goals. A well-thought-out plan addresses the following aspects:

- the type of behaviors that one intends to encourage with the enrichment
- the resources needed to create the enrichment initiative
- the location, time frame, and circumstances during which the enrichment will be offered
- possible safety concerns that warrant additional monitoring

Note that all enrichment initiatives should continue to allow the animal to maintain a choice and exert control over its living environment.

I—Implementation

Actual execution of the enrichment initiative. Scheduling in a calendar-like format will help to ensure that the items are available, enrichment will be provided, and, by planning, opportunities can be created to present items in novel ways and using varied schedules.

D—Documentation

Documentation should include when, how, and what enrichment was presented, and how the animal responded to it (e.g., type, frequency, and duration of interactions).

E—Evaluation

Evaluate periodically whether the enrichment has the effects as originally intended, whether there are any safety or other concerns with its implementation, and whether benefits outweigh the costs (time and money spent on the enrichment).

R—Readjustment

Modify the enrichment plan by adjusting the enrichment or the way it is offered to optimize its effects on the behavior until the achieved goal is reached.

BOX 47.6 PRINCIPLES CRITICAL TO ACHIEVING A SUCCESSFUL AND EFFICIENT ENRICHMENT PLAN

- The enrichment plan should be holistic, that is, each of the five enrichment categories (social, cognitive, physical, sensory, and nutritional) should be represented appropriately in an enrichment plan.
- The enrichment plan should be goal driven, that is, one or more goals should be determined beforehand to direct enrichment strategies and schedules for an animal. Goals may be both general (e.g., increase exploration) and specific (e.g., encourage podomandibulation).
- The enrichment plan should be assessed both at the beginning and throughout time. Method of assessment may vary but needs to be adapted based on the behavioral goal. If the strategy is not satisfactory to meet the anticipated goal, modifications should be explored.
- The use of a planning protocol is highly recommended to ensure that the enrichment plan is goal oriented, tested, and assessed regularly.

dietary preferences, social structure, and daily activity patterns (see Box 47.7 for helpful resources to learn more about the natural history of selected species).[49,187] In addition, the level of novelty offered should be considered as neophobia and exploration have been tightly linked to species' ecology. A study on 61 parrot species with different habitats and diets indicated high and low levels of neophobia to be associated with diets consisting of insects and leaves, respectively. Additionally, species eating nuts or coming from islands showed the longest exploration times, while those eating seeds generally exhibited short exploration bouts.[26] Other studies have shown individual differences in responses to novelty based on their temperament or coping strategy, as well as long-lasting effects of rearing, socialization, and early life exposure to enrichment on novelty-related fear later in life.[11,20,21,43,46,188–190] Hence, a thorough evaluation of the bird's history and responses to enrichment are warranted. Equally important is to ensure that the plan is properly aligned with the capabilities of the individual bird. Offering flight space to a bird without full, functional wings will not be helpful. Likewise, a bird that has eaten from food dishes its entire life should not be challenged with a complex foraging apparatus from one moment to the next, but rather be gradually introduced to the act of foraging. A well-designed enrichment plan furthermore utilizes enrichment of various types and is composed of a mixture of high-, moderate-, and low-energy components, which again are tailored to the abilities, preferences, and needs of the individual bird.

Implementation should be carried out in a logical and gradual way. Too much stimulation and novelty added at once can induce undue stress in some birds. Challenges should be graduated so that each challenge given to a bird is achievable yet allows it to continue to evolve. This is not only important from the bird's perspective (which may become "frustrated" in the process) but also to keep clients engaged as they may otherwise get frustrated or complacent and stop moving the enrichment program forward. Anxious or nervous birds, particularly those that are fearful of novel objects, may require desensitization for even simple enrichments. For these, it is

often best to introduce enrichment items outside of the primary enclosure to prevent accentuating the fear that would arise following immediate placement of the items in the cage.

Documentation can be challenging. Those providing care for a bird should ideally keep a detailed journal on the provided enrichment that was provided, including observations of its usage, and the bird's behavior in general. However, observations can easily be skewed by wishful thinking, available time for observation, and misinterpretation. Additionally, many behaviors of concern occur when birds are left alone. The presence of the caretaker can greatly affect the type, frequency, and intensity of various behaviors. Video recording may be one of the most useful means of documenting the usage of enrichment elements and should be encouraged, whenever possible. Many trail cameras are motion activated and can be very helpful in tracking activity at a particular location (Figure 47.17). Pet cameras and security cameras are also

FIGURE 47.17 Trail cameras like this one can be helpful for documenting enrichment efficacy. Most have motion-activated features and can take short video clips or still photos. These can be used to determine usage and other behavioral changes resulting from the enrichment provided. The camera should be mounted where it cannot be reached by the bird, and the bird should be habituated to its presence.

options. Journals and recordings can be evaluated by the clinician to determine which components of the enrichment program are the most and least useful.

Evaluation of the enrichment plans involves determining what elements are utilized, how much time they occupy, and the range of behaviors that are being displayed, including any increase or decrease in problem behaviors. To accurately assess the value of the enrichment plan, it is essential for the clinician to receive uninterpreted, objective, and accurate observations from the caretaker or to be able to review raw video footage. Comments such as "it made him hormonal" may represent misinterpretation of the root cause of any given response to an enrichment element (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).

Following evaluation, readjustments may be made, including removal or modification of poorly used elements, addition of more of the well-used elements, or addition of new elements of enrichment. Poorly used elements can be revisited later. Sometimes, moving an enrichment item that has been ignored for weeks to a new location will result in substantial interest from a bird. Additionally, most birds will become more accepting of objects after repeated exposure. As such, this method is particularly helpful for fearful birds, who learn to accept the item through the process of habituation. Foraging challenges can be increased in difficulty as the bird progresses. Additionally, an increasing proportion of the daily diet can be provided in this way. Ultimately, healthy, closely monitored birds can have all of their daily food provided via foraging opportunities. Physical exercise can and should progress as the bird develops better physical stamina and condition. Training can begin simple and gradually include more (complex) behaviors. Sensory enrichment can be adjusted to the preferences of the bird. By following this SPIDER method, the enrichment plan can gradually be adjusted to best meet the needs of the individual bird.

USE OF ENRICHMENT FOR TARGETING SPECIFIC BEHAVIOR PROBLEMS

Enrichment is frequently used as a component for the treatment of specific behavioral disorders (Box 47.8). In the

BOX 47.8 RECOMMENDED ENRICHMENT FOR TARGETING SPECIFIC PROBLEM BEHAVIORS

Problem Behavior	Type of Enrichment to be Considered for Behavior Intervention Planning
Feather-damaging behavior	Foraging and nutritional (food acquisition) enrichment
	Occupational enrichment: any type, particularly promoting beak activity
	Physical enrichment: chewing toys, bathing opportunities
	Social enrichment: conspecifics, human contact
	Sensory enrichment—novelty, auditory, sensory, tactile
Stereotypic behavior	Occupational enrichment: cognitive (oral and locomotor stereotypies), physical (flying, movement)
	Foraging and nutritional enrichment
	Physical enrichment: additional space, toys, puzzles, etc.
	Sensory enrichment, high novelty
	Social enrichment (conspecifics)
Aggression	Physical enrichment—(chewing) toys
	Foraging and nutritional enrichment
	Occupational enrichment—training, flight
	Training alternate behaviors and differentially reinforcing these
	Physical enrichment—change of environmental antecedents (territorial-related aggression)
	Social enrichment—positive interaction with multiple members from the household, stimulation flock activity, limit bonding activities (partner-related aggression)
Fear or anxiety	Sensory enrichment—acoustic
	Physical enrichment—toys (gradual introduction, limit novelty and frequency of rotation)
	Concurrent desensitization training and counterconditioning
Excessive vocalization	Social enrichment—soft contact calls
	Sensory enrichment—acoustic
	Occupational enrichment, including foraging enrichment and physical enrichment (chewing toys)
	Negative punishment (walk out of view when bird loudly vocalizes) and time-outs from positive reinforcement
Reproductive behavior	Foraging and nutritional enrichment—mimic "food scarcity"
	Sensory and physical enrichment—high novelty
	Occupational enrichment—training, redirection
	Limit some social enrichment activities (e.g., cuddling)
	Limit physical enrichment (nest boxes, nest materials, mirrors, etc.)

context of behavioral analysis, enrichment can be looked at as an antecedent arrangement or as a form of reinforcement (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). Because the presence of enrichment is not dependent on the behavior of the subject, it is considered *noncontingent* reinforcement. One of the difficulties in treating behavioral disorders is that they can sometimes be inadvertently or unknowingly reinforced. Reinforcement can come extrinsically, as in social reinforcement, or intrinsically, as in neuroendocrine signals. These reinforcers maintain the undesirable behavior and hinder the success of any behavior modification strategy. In humans, a review of 71 publications showed 265 uses of environmental enrichment, either as a standalone treatment or in combination with behavior manipulations used to either prompt or reinforce alternative behaviors or to block or restrain problem behavior.[191] When used alone, environmental enrichment was effective in 41% of the cases, hence indicating the value it can have to treat problem behavior, but when combined with manipulations of alternate or problem behaviors it increased substantially, depending on the manipulation.[191] This suggests that although environmental enrichment can be helpful, a comprehensive plan should be developed to include additional behavior modification methods.

When utilizing enrichment for decreasing problem behavior, it is best to apply the SPIDER model as discussed in the previous section. Frequent consultations will often be required as the process is fluid and necessitates continuous evaluation and readjustment. While planning the enrichment program, priority should be given to the enrichments that are deemed or known to be most effective. If no research is available to determine what would be the most effective enrichment to help treat a particular disorder, enrichments that encourage behaviors that are incompatible with the problem behavior are often going to be most efficient (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior). Clients can get complacent when problem behaviors start to diminish and may subsequently lapse in their enrichment efforts. Hence, a certain amount of encouragement and reminding may be needed at times to maintain any progress that is made.

When looking at specific examples in companion birds, FDB and stereotypies are the best studied.[33,37] Stimulation of foraging activity in particular has been proposed in the treatment of these behaviors as it is often considered that these abnormal repetitive behaviors should be regarded as displacement or redirected foraging in the absence of appropriate stimulation.[192,193] In addition, stimulation of foraging is

considered highly effective as the activity itself is incompatible with the activity of feather destructive behavior. After all, the beak cannot be used for both activities at the same time! In addition, foraging provides a distinct food reinforcement, which can be comparable to or greater than the intrinsic reinforcement received from the feather destruction. Alternative behavior manipulation in this case would be cueing a trained behavior just prior to when feather destruction is anticipated, and strongly reinforcing this behavior. While this can be helpful, most of the FDBs are done in the absence of the caregiver. Blocking or restraint of FDB is occasionally attempted using collars or other restraint devices. Unfortunately, these have significant adverse impacts on the welfare of the bird, often more severe than the feather destructive behavior itself. As such, the use of collars or restraint devices to block access to the feathers and skin should only be considered for birds with self-injurious behaviors that damage the skin or to help prevent the formation of an automatically reinforcing habit. If and when collars are used, caution is advised, and patient welfare should be monitored closely. The least restrictive option should be used to minimize any undue reduction of normal behaviors.

Repetitive behaviors are common in companion birds, particularly in the larger-brained species (e.g., cockatoos).[192] These are sometimes a consequence of antecedents and consequences that promote perpetuation of the behavior. In such cases, the problem may be resolved by rearrangement of the antecedents and by differentially reinforcing alternative behaviors.[194] Other times these movements represent stereotypies. As stereotypies are generally considered displacement behaviors, it stands to reason that provision of more normal activities would both prevent and treat these behaviors. This has proven to be the case in a variety of species, including parrots.[4,5,9,34,195–197] Selection of the enrichment type here is dependent on the form of stereotypy that has developed. It would make the most sense to utilize enrichments that promote behavior that is incompatible with the problem behavior. Additionally, enrichment that promotes high-energy activities can be helpful.

Excess vocalizations are another common complaint among those living with parrots. It is one of the most common reasons for parrots to be rehomed.[198] It should be noted that psittacine birds are inherently loud and that often the "problem behavior" is perfectly normal, just not desired by the owner. Consultation with a qualified behavior consultant can help with problem vocalizations through using applied behavior analysis (ABA) should the clinician see merit in augmenting their behavioral evaluations and action plans for a particular patient (see *Current Therapy in Avian Medicine and Surgery*, Vol 1, Chapter 5, Behavior).

Normal vocalizations should never be suppressed. For example, birds may produce loud vocalizations when they are fearful; hence the vocalizations are functional as an indicator of distress. Rather than suppressing these vocalizations, the fear should be dealt with by removal of the feared object or by desensitization. Similarly, birds that are hungry can produce loud vocalizations. While birds that forage for most of their diet in the wild are more likely to search their foraging sites for food than to vocalize for food, extended deprivation of food or water is likely to bring on justified complaints from the bird. Again, checking if there is food and water and providing these to the bird will in the end be more effective than trying to suppress the vocalization.

One common nuisance vocalization is the contact call. Parrots often use calls to maintain cohesion of the flock as the dense foliage in which they live precludes visual contact. While many owners construe birds making contact calls as spoiled birds "screaming for attention," they should be reminded that these contact calls are natural parts of the social behavior of many species. Bird caregivers can take the initiative of maintaining contact with lower-volume whistles, whispering, humming, or other sounds that reassure the bird that they are still nearby. Often parrots learn these vocalizations and will use them for flock contact rather than their natural loud vocalizations. Conversely, birds that vocalize loudly should not be engaged. All attention and even eye contact should be averted until the bird is quiet or produces a desired, less loud sound, which can be generously reinforced. For other types of excess vocalization, other forms of enrichment may be helpful. Physical, nutritional, and auditory enrichments appear to reduce vocalizations in general.[32,102] Auditory enrichment at low volumes may be incompatible with loud vocalizations because they cannot be heard over loud squawks.

Neophobic fear responses are common in parrots, and use of enrichment can be helpful both in preventing and treating this behavior, whereby novelty appears as important as the type of enrichment provided.[11,21,186] If tolerated by the bird, frequent changes of toys can be helpful to teach that change is normal. However, some birds are so neophobic that the changing of the enrichment item is inherently stressful. A period of habituation may be needed in these cases. New items should be introduced outside of the primary enclosure until accepted by the bird. It can then be placed in the cage and another introduced outside of the cage. The presence of other birds in the same room may also help, as long as the other bird does not evoke a fear response. Large loud birds can be stressful to a smaller or quieter bird. Otherwise, however, the presence of others may increase comfort. Some birds also respond well to having acoustic enrichment as this helps to decrease the startle response following sudden or unavoidable environmental sounds.

Aggression is a common and serious problem in parrots. The hooked beak of parrots is powerful and can inflict painful bites. Aggression can stem from a variety of causes including protection of a territory or nest site, displaced sexual behavior, or fear.[199] When aggression is directed at human handlers, training can be used as both an occupational enrichment and as a means of promoting and reinforcing alternative behaviors, and a more positive human-avian bond. While training can also be used for aggression directed at other animals, training sessions can only occur when the trainer is present. Physical separation of animals may subsequently be needed until these problems can be resolved. For territorial aggression, a change of physical environment can help. Similarly, physical and nutritional enrichment such as toys and foraging opportunities can provide alternative beak and pastime activity, hence stimulating alternative behaviors and alleviating aggression. Social enrichment in the form of positive interactions with multiple household members can reinforce calm behavior in their presence. These interactions can be "hands-off" and include activities such as talking or singing to the

bird, rather than involving interactions that risk biting or force the bird to choose between aggression and cooperation. Additionally, interactions should not simulate pair bonding, especially if the aggression is partner related.

Excess reproductive behaviors are another common behavioral issue for parrots. These frequently cross over into medical problems. Constant stimulation of reproductive hormones predisposes to excessive egg laying, regurgitation, cloacal prolapse, and other health problems. Enrichment can help to regulate some of these issues. Abundance of food is one of the cues used by some species to determine when to nest. A food foraging program reduces the perception of food abundance. If this is insufficient, the quantity of food can be further reduced. Additionally, some types of enrichment may need to be (temporarily) removed. Any enclosed spaces that could be perceived as a nest cavity may warrant removal or blocking of access. Physical contact by touching the bird should be restricted in quantity and limited to the head of the bird. Training activities should be substituted to redirect the bird's attention from reproductive postures or displays.

In conclusion, enrichment is a multidimensional process that can improve the lives of captive animals. Although there are challenges in providing enrichment for parrots, it is both critical and rewarding for the bird and the owner. The benefits can be seen in health, behavior, and overall quality of life. As advocates of avian welfare, it is critical for avian veterinarians to provide strategies for effective enrichment for their patients.
